CHAPTER 20

Immune Dysfunction and Low-Grade Persistent Inflammation in Uremia

Gabriela Cobo, Juan Jesus Carrero, Bengt Lindholm, and Peter Stenvinkel

During the last two decades, the clinical phenomenon of low-grade persistent inflammation—its prevalence, root causes, implications, and possibilities for interventions—in patients with chronic kidney disease (CKD) has been a topic that has attained a great deal of attention in the nephrology community. It is now well established that systemic inflammation is a prominent, perhaps even inherent, feature of advanced CKD. Whereas inflammation is also common in other chronic diseases, such as advanced cardiovascular disease (CVD) that—like CKD—involve premature aging, accelerated vascular alterations, and muscle wasting (1), there are some unique aspects of inflammation in CKD which are mainly related to the decline of renal function that inevitably leads to retention of excess fluid and small- and medium-sized water-soluble molecules. Furthermore, a plethora of larger uremic toxins (including also proinflammatory cytokines that cannot be removed by the failing kidneys) accumulate in patients with advanced CKD and may aggravate immune dysfunction and other abnormalities in patients with CKD.

Inflammation (Latin, *inflammatio*, to set on fire) may be defined as a complex biologic response of vascular tissues to harmful stimuli, such as pathogens, damaged cells, or irritants. Although the inflammatory process should be regarded as a protective attempt by the organism to remove injurious stimuli and to initiate the healing process for the tissue, the problem faced in CKD, as well as in many other chronic debilitating disorders, is that it often leads to a state of persistent inflammation, which can last for months, or even indefinitely.

Chronic inflammation is characterized by the persistent effect of the causative stimulus, leading to destruction of cells and tissues, and provoking deleterious effects at different levels (2,3). Indeed, there is a convincing body of literature demonstrating the association between inflammation and disturbances in nutrition state, CVD and premature death in patients with CKD. The concurrence of all these disturbances has been denoted as the malnutrition-inflammation-atherosclerosis (MIA) syndrome (4) or the malnutrition–inflammation complex syndrome (MICS) (5); however, the International Society of Renal Nutrition and Metabolism (ISRNM) recommended a few years ago that the malnutrition component in

these syndromes should be termed *protein-energy wasting* (PEW) (6). Regardless of the nomenclature, inflammation is a major feature in the uremic milieu (7–12) (**FIGURE 20.1**). In a survey including 663 patients with CKD stage 5 (160 patients evaluated close to the start of dialysis and 503 patients on dialysis) from Sweden, Germany, and Italy, approximately two-thirds of the patients had C-reactive protein (CRP) levels above 3.4 mg/L (8). Similar findings are observed in patients with CKD stages 3 to 5 not yet on dialysis. According to data from the National Health and Nutrition Examination Survey III (NHANES III, n = 15,594), approximately 54% of the patients with glomerular filtration rate (GFR) between 15 and 60 mL/min had some degree of inflammation (CRP greater than 2.1 mg/L). In addition, the age-adjusted probability of having elevated CRP (greater than 2.1 mg/L) rose from 44% to 69% when estimated GFR was 60 and 30 mL/min, respectively (13). The close association between low-grade inflammation, comorbidities, and poor outcome highlights the importance of searching for strategies to ameliorate and avoid such conditions. This chapter describes CKD-associated immune dysregulation as it relates to clinical aspects of inflammation and susceptibility to infection, causes and consequences of inflammation in CKD, and finally, current and novel experimental strategies to avoid and treat the inflammatory burden in this patient group.

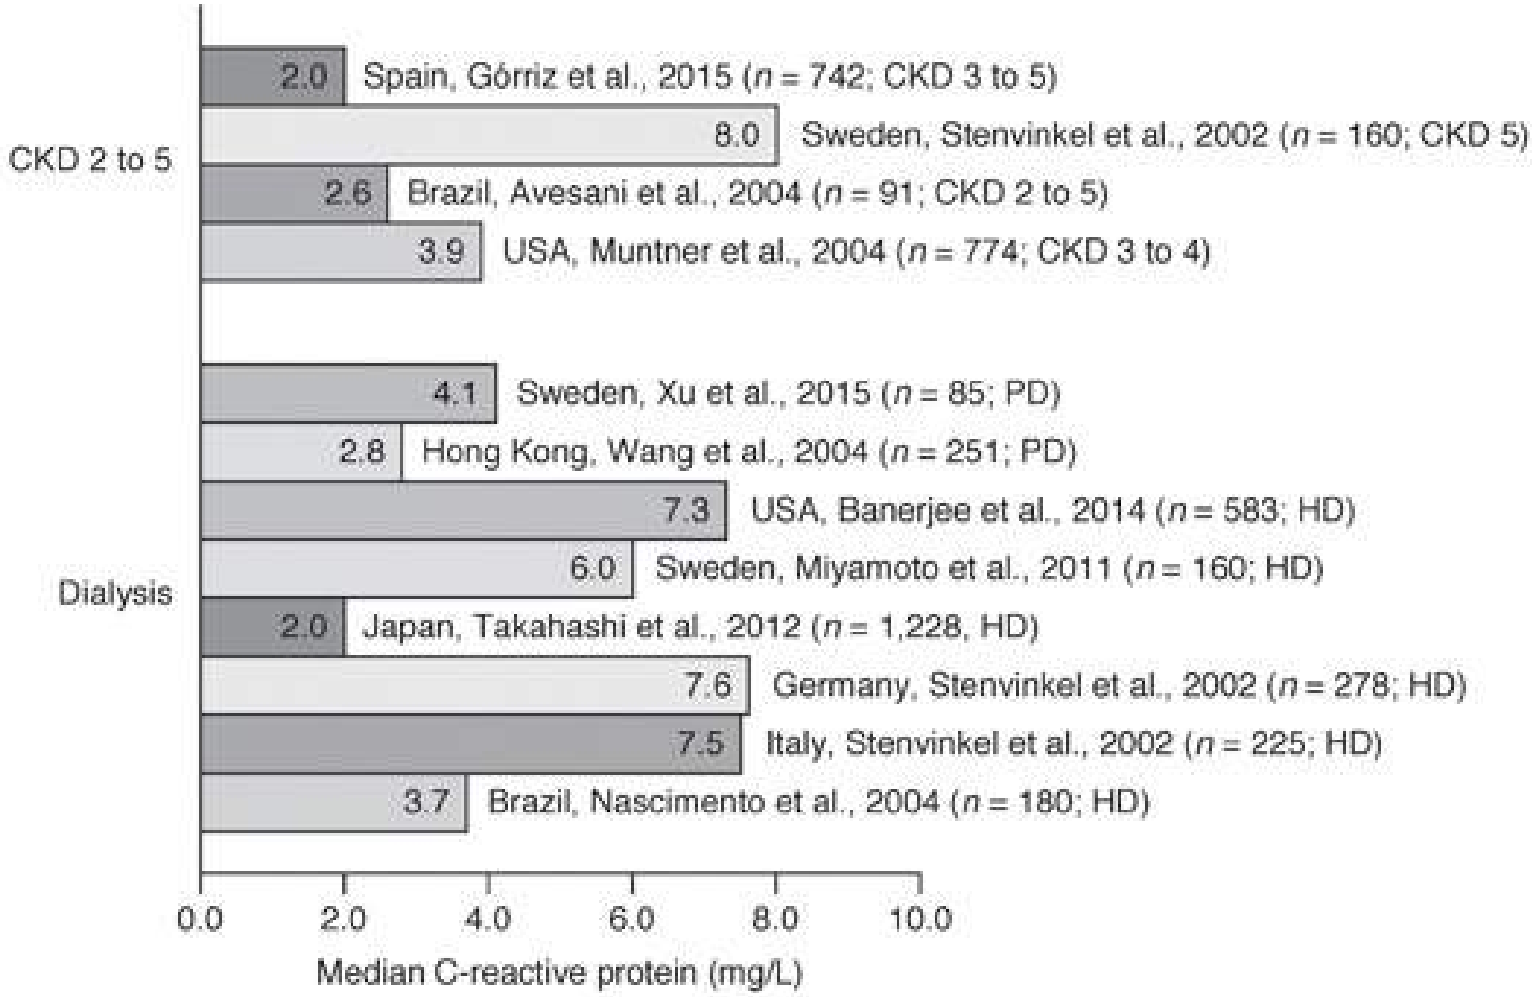

FIGURE 20.1 Median C-reactive protein (CRP) values in reported clinical studies including adult patients on different chronic kidney disease (CKD) stages. As the median CRP in the North American general population is approximately 1 mg/L, even patients with mild to moderate CKD show signs of enhanced inflammatory activity. HD, hemodialysis; PD, peritoneal dialysis.

ALTERED IMMUNITY IN CHRONIC KIDNEY DISEASE

The immune system is a complex orchestration of cells, cytokines, and other molecules that act in a paracrine, autocrine, or endocrine manners to protect the human organism against disease. Uremia is known to be associated with a state of immune dysfunction characterized by both immune depression—that likely contributes to increased incidence and severity of microbial infections and impaired response to vaccination—and immune activation that results in a persistent inflammatory state that might contribute to PEW, atherosclerosis, CVD, and high mortality observed in this group of patients (14).

Within the complex immune system, the two major branches, innate and acquired immunity, are altered in uremic patients. The possible causes responsible for these disturbances in the uremic milieu are linked to the decline of GFR and the noxious effect of uremic toxins that accumulate due to kidney disease; however, numerous other factors such as comorbidities, other superimposed illnesses, genetic predisposition, and therapeutic interventions including the dialysis procedure, to name a few, play important roles in the pathophysiology of these immune disturbances.

With regard to the immune disorders observed in CKD, disturbances in the number and especially the function of basically all immune cells have been described. In general, the functional alterations observed include spontaneous activation, decreased phagocytic capacity, and increased apoptosis, leading to increased generation of cytokines and reactive oxygen species (ROS) and diminished defensive capacity (15). The different immune cells abnormalities observed in uremic patients are summarized in **TABLE 20.1**.

TABLE 20.1 Alterations of Immunocompetent Cells in Chronic Kidney Disease

		Normal Function	Alterations in Chronic Kidney Disease
Monocytes and macrophages		Host defense against microbial infection Tissue healing process Production of cytokines and ROS	General expansion of circulating monocytes (322) Spontaneous activation and decreased phagocyte capacity (323) Overproduction of IL-1β, IL-6, IL-12, and TNF (324)
Polymorphonuclear leukocytes (PMNL)		First line of defense against invading microbes	Spontaneous activation (103) Decreased phagocytic capacity and reduced bactericidal capabilities (325) Altered apoptosis (326)
Lymphocytes B		Production of antigen-specific antibodies	B-cell lymphopenia (327) Impaired differentiation and maturation (327) Increased apoptosis (328)
Lymphocytes T	Helper (CD4+)	Activation of cytotoxic T cells and macrophages Maturation of B-cells and antibody production from these cells Recruitment of PMNL, eosinophil, and basophils Amplification of inflammatory response	Decreased proliferation (329) Depletion of naive and central memory T cells (330) Increased apoptosis (331) Reduced ratio CD4/CD8 (330) Increased Th1/Th2 ratio (332)

Among the mechanisms responsible for the compromised function of the immune cells, those concerning the pattern-recognition receptors, especially the Toll-like receptors (TLR), deserve a special mention. Pattern-recognition receptors play a role in innate immunity by recognizing pathogens through specific pathogen-associated molecular patterns (PAMPs) (16) and triggering effector cells to perform their functions. In uremic patients, disorders in the pattern-recognition receptors system result in impaired function of cells engaged in innate immunity, leading among others, to decreased endocytosis and impaired maturation (17). In the uremic milieu, some of these receptors have been shown to be upregulated, while others are downregulated, leading to different consequences. For instance, upregulation of mannose-binding lecithin (a type of pattern-recognition receptor) is associated with worse patient and graft survival after simultaneous pancreas-kidney transplantation (18), while low levels

associated with increased mortality in infected hemodialysis (HD) patients (19). Toll-like receptors belong also to the family of signaling pattern-recognition receptors that is involved in the maturation of dendritic cells, phagocytic functions, and activation of the complement pathway and production of numerous cytokines, such as interleukin 1β (IL-1β), interleukin 6 (IL-6), and TNF (20). Disorders in this group of receptors are responsible for impaired function of antigen-presenting cells (APCs), leading to more severe illness and increased mortality in case of invading pathogens diseases (14). Interestingly, a study by Kiechl et al. (21) reported that, although subjects with TLR4 polymorphism, which led to TLR4 downregulation, were found to be more susceptible to severe bacterial infections; they had a lower risk of carotid atherosclerosis and reduced intima-media thickness. These results suggest that impaired innate immunity might protect against atherosclerosis, thus resulting in lower cardiovascular mortality because of attenuated receptor signaling and diminished inflammatory response. If a similar situation is present in end-stage kidney disease (ESKD) patients, ESKD patients with impairment of immunity may have a survival advantage in the form of lower risk of CVD. But, again, this alteration may be linked to increased risk of infections and thereby inflammation.

Cytokine Dysregulation in Chronic Kidney Disease

As a consequence of the altered function of the immune cells, a state of hypercytokinemia is characteristic in the uremic milieu, where the delicate equilibrium between proinflammatory cytokines and their inhibitors is clearly dysregulated (22,23). Also, due to the fact that the kidneys are major sites for elimination of many of these cytokines, renal failure contributes notably to the hypercytokinemic state. Additionally, the dialysis procedure *per se* stimulates circulating nuclear cells, inducing cytokine production (24) and making them respond more vigorously after exposure to endotoxin (25).

To properly understand the state of cytokine dysregulation present in CKD patients, a number of considerations involving cytokine measurements should be made (26). First, most of the published studies focus on selected cytokines measured in plasma, culture supernatants, or in association with circulating cells. However, cytokines are “moving targets” counterbalanced by inhibitors or other cytokines with opposite effects. Second, cytokines rarely act alone because they stimulate a variety of cell types to produce and secrete other cytokines in a cascade fashion. Elevation of one cytokine immediately leads to up- or downregulation of several others. As many of the effects of cytokines are local, not systemic, these paracrine effects of cytokines are hard to detect. Third, pro- and anti-inflammatory cytokines bind to specific cytokine carriers (such as α_2-macroglobulin) and these different binding proteins may serve as extracellular cytokine reservoirs and protective shields against degradation. Therefore, it is important to take into account that established immunoassays to detect cytokines usually are not able to distinguish between active proteins and those proteins that are blocked by their specific inhibitors. To understand this complex orchestration, selected cytokines will be reviewed with regard to our current understanding of the uremic cytokine misbalance.

Interleukin 6

Different cells, including T-lymphocytes, macrophages, monocytes, endothelial cells, adipocytes, and fibroblasts, produce IL-6. IL-6 is involved in the production of neutrophils and proliferation of B-lymphocytes as well as in the stimulation of the liver to produce acute-phase proteins. IL-6 also regulates the production of adhesion molecules and induces the secretion of monocyte chemotactic protein, an

important mediator for the release of other cytokines, such as TNF and IL-1β, which subsequently amplify the inflammatory response (27). Notably, IL-6 exhibits both pro- and anti-inflammatory effects and promotes inflammatory events through the activation and proliferation of lymphocytes as well as differentiation of B cells and leukocyte recruitment.

Numerous factors in the uremic *milieu* may stimulate the production of IL-6, and the kidney has been suggested to play an important role in the clearance of IL-6 (28–30). Indeed, Bolton et al. (31) found in a multiple regression analysis that serum creatinine was the sole determinant of plasma IL-6 levels in a group of predialysis and dialysis patients. Other causes responsible for the elevated IL-6 levels in CKD include comorbidities, persistent infections, such as *Chlamydia pneumoniae* (32), fluid overload, sympathetic overactivation, and oxidative stress, conditions that often appear as renal function declines (33).

Elevated concentration of circulating IL-6 is strongly associated with comorbidity and is a powerful predictor of CVD and all-cause mortality in dialysis patients (34,35). This prognostic value might be related to some independent proatherogenic properties showed by IL-6 in the early stages of atherosclerosis (36), in contrast to the putative antiatherogenic effects of CRP (37). Increased expression of IL-6 has been observed at the fibrous plaque stage of the atherosclerotic process (38), and elevated IL-6 levels have been linked to the progression of carotid atherosclerosis in patients with CKD stage 5 (32). The pathways by which IL-6 could contribute to the development of atherosclerosis include diverse metabolic, endothelial, and coagulant mechanisms (39).

Tumor Necrosis Factor

TNF is a pleiotropic inflammatory cytokine that has a pivotal role in regulating both pro- and anti-inflammatory mediators. TNF is an acute-phase protein that initiates the cytokine cascade and thereby increases vascular permeability. TNF is produced mainly by monocytes, macrophages, dendritic cells, and Th1 cells and is in charge of recruiting macrophages and neutrophils to the site of infection. This cytokine holds both growth-stimulating and growth inhibitory properties, and it appears to have self-regulatory properties as well. Deterioration of renal function may be one of the most important factors associated with a significant increase in TNF activity (28,40). TNF is highly multifunctional, affecting insulin resistance (41), coagulation cascade, lipid metabolism, and endothelial dysfunction (42). TNF is also associated with increased catabolism and may promote both atherosclerosis and PEW, and, consequently, higher levels of TNF associate with poor outcomes in patients with CKD (29).

Interleukin 10

Interleukin 10 (IL-10) is an essential anti-inflammatory cytokine produced mainly by immunoactive cells, such as monocytes and lymphocytes, and has been regarded as one of the most important anti-inflammatory immune-regulating cytokines. In fact, IL-10 not only downregulates proinflammatory cytokines, such as IL-1, IL-6, and TNF, but also reduces the production of chemotactic factors, such as IL-8 or CC chemokines, which may attract leukocytes to the location of inflammatory activity (43). Apart from the inhibition of proinflammatory cytokines, several other properties like antiatherogenic and antithrombotic effects have been related to IL-10 (26). IL-10 is capable of preventing the attachment of circulating immune cells to the endothelium (44) by inhibiting the secretion of chemotactic proteins from macrophages; signaling further recruitment of leukocytes to the subendothelial location of inflammation

(43); and reducing the production of matrix metalloproteinases and superoxide anions (45). Additionally, it has been suggested that IL-10 prevent destabilization of the atherogenic plaque (46). As IL-10 is mainly cleared through the kidneys, its half-life is markedly increased and its plasma levels commonly elevated in CKD (47). Furthermore, uremic monocytes produce higher amounts of this cytokine compared to those of healthy individuals (48), probably as a consequence of chronic monocyte activation in patients with uremia. In patients with CKD, the most relevant production of IL-10 seems to occur in monocytes and macrophages, in response to endotoxins and activated complement fragments, agents known to mediate bioincompatibility reactions during renal replacement therapy (RRT). Therefore, dialysis treatment may contribute to the overall level of this long-acting cytokine. Despite the positive features assigned to IL-10, previous studies in CKD have failed to show an association between IL-10 and better outcomes. In fact, higher serum IL-10 levels have also been associated with increased risk of cardiovascular events during follow-up (49), results that can be explain as a consequence of the global proinflammatory uremic milieu that as a compensatory sequel also involves increased release of IL-10.

ENHANCED SUSCEPTIBILITY TO BACTERIAL INFECTIONS IN UREMIA

As mentioned above, CKD is a condition associated with a state of immune dysfunction affecting both innate and acquired immunity and therefore leading to increased susceptibility to infections. Indeed, the incidence of bacterial infections is 50-fold higher in dialysis patients in comparison to the general population (32,50,51). Aside from being a consequence of altered immunity, the high infectious morbidity observed in CKD is multifactorial and the main factors involved are summarized in **TABLE 20.2**. The occurrence of bacterial infections in CKD is commonly related to the dialysis procedure and to the vascular access [especially central dialysis catheters (52)] that represents a continuous portal of entry for pathogens. Additionally, respiratory and urinary tract infections have a high prevalence in CKD patients. Likewise, comorbidity, especially diabetes and peripheral vascular pathology, have an important role in the incidence and prevalence of foot or leg ulcers infection commonly seen in this group of patient.

TABLE 20.2 Risk Factors and Main Pathogens for Bacterial Infections in Chronic Kidney Disease

Risk Factors

- Depressed immunity
- History of bacterial infection (at least one previous episode)
- Vascular access [central venous catheters, use of polytetrafluoroethylene (PTFE) prosthetic devices]
- Dialysis technique (bioincompatible membranes)
- Poor nutritional status
- Comorbidity (diabetes mellitus, peripheral vascular pathology)
- Iron overload (ferritin >500 μg/L)
- Immunosuppressive treatment

Main Pathogens

Gram-positive	Gram-negative
Staphylococcus aureus	*Chlamydia pneumoniae*
Staphylococcus epidermidis	*Escherichia coli*
	Pseudomonas

Among the septicemia episodes in CKD patients, around 40% to 70% of them are caused by gram-positive microorganisms (53–55), being *Staphylococcus aureus* the most commonly encountered gram-

positive agent and mainly associated with vascular access infection (54). The high prevalence of *S. aureus* asymptomatic carriers in nose, throat, and skin, and the required repetitive punctures of the vascular access (55–57) represent important risk factors. In peritoneal dialysis (PD) patients, formation of a bacterial biofilm on the walls of the peritoneal catheter is also a frequent cause of *S. aureus* peritonitis (58). Interestingly, aspirin treatment was recently associated with decreased rate of catheter-associated *S. aureus* bacteremia in HD patients (59). On the other hand, gram-negative bacteria infections are present in approximately 25% of the episodes of bacteremia of CKD patients, and are linked to vascular access infections (53) and gastrointestinal and genitourinary tract infections (57,60), where *Escherichia coli* is the most common gram-negative pathogen isolated (54,55). Moreover, there is a link between the intracellular gram-negative pathogen *C. pneumoniae* and atherosclerotic complications in dialysis patients (51). Although this causative link remains to be demonstrated, ongoing trials using macrolide therapy will allow assessment of whether eradication of this type of infection could result in reduced atherosclerotic morbidity (61).

Furthermore, among other infectious diseases observed in CKD patients, tuberculosis deserves to be mentioned. Due to their particular immune characteristics, patients with CKD are at increased risk of development and reactivation of latent tuberculosis and exhibit a much higher prevalence than the general population (62,63). The presentation of the disease is frequently atypical, with accelerated wasting being one possible consequence of *Mycobacterium tuberculosis* infection. Indeed, in ancient times, tuberculosis was referred to as “phthisis,” which means “consumption.” The diagnosis of tuberculosis infection is specially challenging in CKD due to its frequent extrapulmonary location (64,65) and the scarce sensitivity of tuberculin skin test in dialysis patients, who show anergy in more than 50% of the patients (66). In the last years, new techniques like blood tests determination using stimulation of gamma interferon have been developed with better results (67); however, sometimes, a biopsy of extrapulmonary tissue is required.

Moreover, hidden infectious process, like periodontitis (68) and bowel bacterial overgrowth (69), are prevalent conditions that are usually overlooked, although they are related to deleterious outcomes. In any case, independent of the type of infection, even asymptomatic infections contribute considerably to the persistent inflammatory state observed in CKD patients and result in increased risk of morbidity and mortality (70). Emphasis on the importance of good dialysis care and implementation of routines to avoid infection in this group of susceptible patients are of fundamental importance.

LOW-GRADE PERSISTENT INFLAMMATORY STATE

Systemic inflammation is a common feature in the uremic phenotype (7–12) and is linked to poor outcomes (71). While immune system dysfunction associated to CKD leads to a persistent inflammatory state (72,73) partially due to impaired renal elimination of proinflammatory cytokines and partially due to increased generation of cytokines (29), other factors related to dialysis technique and lifestyle are also important contributors. Moreover, it has recently become apparent that stress-induced premature senescence contributes significantly to the chronic inflammatory state of advanced CKD (74). If persistent, injurious triggers by oxidative stress, hyperphosphatemia, and uremic toxins will prevent DNA damage from being repaired, and cells will undergo senescence and secrete cytokines and growth factors (the so called senescence-associated secretory phenotype; SASP) (75).

Causes of Persistent Inflammatory State

General

A number of factors, both related and unrelated to CKD or dialysis technique, contribute to systemic inflammation in patients with uremia (**FIGURE 20.2**). A reduction of kidney function *per se* is associated with an increased inflammatory response due to the retention of circulating cytokines (26), advanced glycation end products (AGEs) (76), and pro-oxidants (33). Additional mechanisms include sympathetic overactivity (and/or blunted vagal nerve activity) and reduced production of specific cytokine inhibitors [suppressors of cytokine signaling (SOCS)]. As the cholinergic anti-inflammatory pathway is a neural mechanism that inhibits local cytokine release, blunted vagal activity may be a mechanism leading to increased inflammatory activity (77). Overhydration, a frequent complication in CKD, is also an indirect contributor to inflammation. Volume overload, via bacterial or endotoxin translocation in patients with severe gut edema, leads to immune activation and increased inflammatory cytokine production (78). Also, a strong relation between inflammation, residual renal function, and cardiac hypertrophy has been documented (79). Notwithstanding, other inflammatory diseases, such as systemic lupus erythematosus, rheumatoid arthritis and malignancies, are commonly observed in dialysis patients and can contribute to the inflammatory state, like intercurrent clinical events, that not surprisingly seem to be the most important predicting factor of elevation of CRP values in the context of uremia (80).

Causes Related to Dialysis Technique

In addition to the intrinsic inflammation accompanying CKD, patients undergoing RRT are subject to additional potential inflammation-activating factors. Factors associated with the dialysis technique itself include bioincompatible membranes and solutions, dialysate back flow, clotted access grafts, and catheter infections. Other factors, such as failed kidney transplants (81), endotoxemia (71,82), and fluid overload (83) may also influence the inflammatory process in this group of patients.

Additional Causes of Inflammation in Hemodialysis Patients

A number of factors related to HD procedure *per se* promote inflammation. While interestingly, dialysis-related inflammation seems to be associated with a specific genomic pattern (84); several *in vivo* studies imply that the membrane composition, the type and quality of dialysis, and the type of vascular access may contribute to inflammatory processes. In a randomized study, Schindler et al. (85) demonstrated that HD patients treated with polyamide membranes presented lower CRP levels compared to those exposed to cuprophane or polycarbonate membranes (see Chapter 1). In accordance, Memoli et al. (86) showed that a significant relation exists between membrane bioincompatibility and circulating levels of CRP, IL-6, and serum albumin. Likewise, it has been proposed that the amount of convective transport and the frequency of dialysis might influence in the level of inflammation (87). Short daily HD (six sessions per week of 3 hours each) was associated with a reduction in left ventricular hypertrophy and inflammatory mediators compared to conventional HD (three sessions per week of 4 hours each) (88) (see Chapters 8 and 10). Instead, in a multicenter, open-label, randomized controlled trial including 906 chronic HD patients and comparing the benefits of conventional versus high-efficiency postdilution HD, a reduction in all-cause mortality was associated with the latter; however, no difference in predialysis CRP values was found between the groups (89).

As cytokine-inducing substances present in the dialysis fluid may penetrate intact dialyzer membranes, impure dialysate is yet another factor to bear in mind (90). Indeed, Schindler et al. (91) have shown that small bacterial DNA fragments in dialysis fluid can pass through dialyzer membranes. In accordance, Sitter et al. (92) showed that a switch from conventional to online-produced ultrapure dialysate resulted in lower bacterial contamination with a significant decrease in CRP and IL-6 levels. Likewise, Shiffl et al. (93) showed that changing from conventional to ultrapure dialysate reduced the levels of IL-6 and CRP and improved nutritional status. Small studies have demonstrated that ultrapure dialysate is related to a slower loss of residual renal function (94) and a lower cardiovascular morbidity (95) in HD patients. Furthermore, vascular access is fundamental in HD patients, and an appropriate manipulation of it has a major impact on the prevalence of inflammation at the dialysis unit. Both clotted access grafts (96) and catheter infections (97) are significant contributors to the inflammatory process in HD patients. Biofilm formation might be also a cause of inflammation in this patient group (98). In summary, while adequate dialysis treatment to some extent can ameliorate some uremia-related proinflammatory factors, there are many dialysis-related factors that can contribute to the inflammatory state observed in CKD.

Additional Causes of Inflammation in Patients Undergoing Peritoneal Dialysis

The PD procedure *per se* may also induce systemic inflammation. Conventional bioincompatible glucose-based PD solutions, for instance, are thought to be important contributors (99), especially due to their content of glucose degradation products (GDPs) generated during heat sterilization. GDPs have been shown to induce peritoneal inflammation and the formation of AGEs. Additionally, glucose-based solutions lead to a substantial uptake of glucose, which may induce oxidative stress, a potent cause of inflammation (100). Peritoneal transport status is another important factor to consider in PD patients. Several years ago, it was suggested that patients presenting high peritoneal transport rate have worse clinical condition characterized by worse nutritional status and inflammation (101). However, it is now

thought that the worse clinical situation and the high risk of death observed in the group of high transporters may be more closely related to volume overload from inadequate drainage in the exchanges. As volume overload occurs frequently in PD patients (78), this may be another reason for immune activation in this patient group. Additionally, concomitant infections especially peritonitis and percutaneous PD catheter infections are important contributors to inflammation in PD patients.

Activation of Polymorphonuclear Leukocytes

Although polymorphonuclear leukocytes (PMNLs) under noninfectious conditions are quiescent and release little ROS, there are reports that in the uremic milieu, PMNLs are primed long before RRT is initiated (**FIGURE 20.3**) (102). A study by Sela et al. (102) showed that PMNL priming as well as neutrophil counts were directly related to severity of kidney disease. When patients with CKD start dialysis treatment, PMNL priming seems to be further augmented (103). As PMNL priming is believed to be one important contributor to systemic oxidative stress and chronic low-grade inflammation in CKD (102), the characteristics of priming agents in the uremic milieu need to be elucidated. Although most uremic retention molecules have not yet been characterized with regard to their specific pro- and/or anti-inflammatory effects, some interesting observations have recently been reported. Glorieux et al. (104) showed that genuine AGE compounds activate the leukocyte response in the uremic condition. Moreover, the same group recently showed that *p*-cresylsulphate (the main product of the protein-bound uremic retention solute *p*-cresol) activates leukocyte free radical production (105). As *p*-cresol recently was shown to predict mortality in HD patients (106), the potential proinflammatory and proatherogenic effects of *p*-cresylsulphate need further consideration.

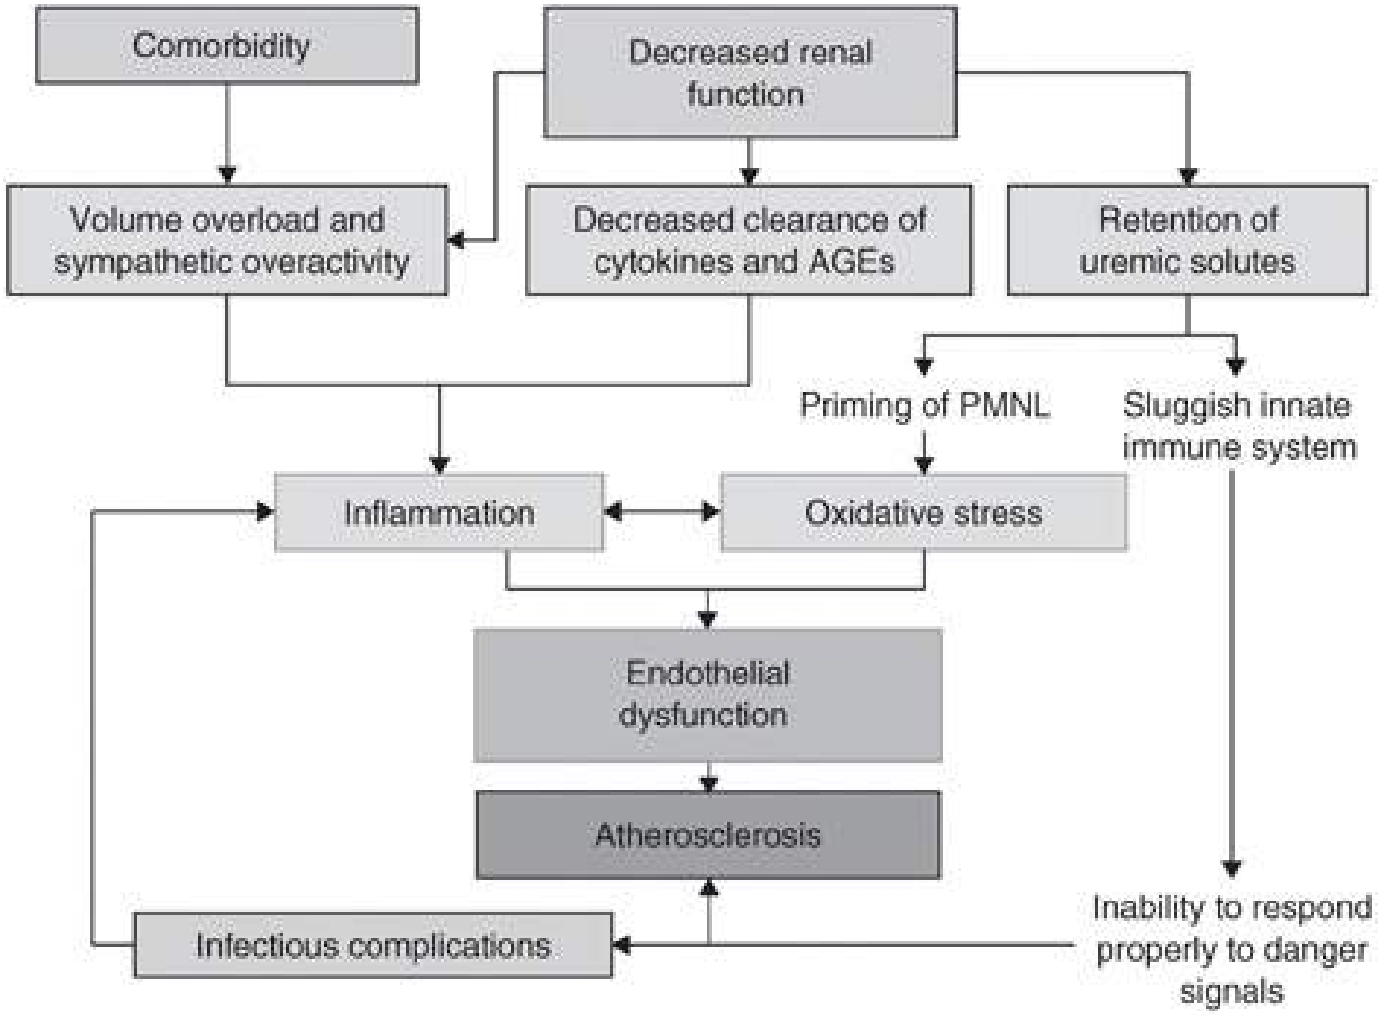

FIGURE 20.3 The interrelations by which inflammation and oxidative stress (through polymorphonuclear leukocyte activation) may lead to accelerated atherosclerosis. AGE, advanced glycation end products; PMNL, polymorphonuclear leukocyte. [Modified from Yilmaz MI, Carrero JJ, Axelsson J, et al. Low-grade inflammation in chronic kidney disease patients before the start of renal replacement therapy: sources and consequences. *Clin Nephrol* 2007;68(1):1–9].

Causes Related to Comorbidity and Lifestyle

Comorbidities and unhealthy lifestyle issues like proinflammatory diets (107) and sedentary behavior (108) can contribute and potentiate the degree of inflammation and deserve special attention.

Oral Health and Periodontal Disease

It is appreciated that oral health is an important aspect in many chronic diseases. In CKD patients, diverse changes in the oral cavity like xerostomia and modifications in the microbial community are seen (109). These conditions together with the impaired immunity, poor oral hygiene, and malnutrition enhance the incidence of periodontitis and other manifestations of poor oral health (110). Although oral cavity health is often overlooked, poor oral health in CKD patients has been associated with systemic consequences as infections, PEW, and atherosclerotic complications (111). Moreover, several studies have shown that patients with periodontitis have elevated levels of CRP, and periodontal disease is thought to be an important contributor to local and chronic systemic inflammation in CKD (112). Given that oral health problems could constitute a permanent source of inflammation, poor dentition and other signs of poor oral health should be an alarm clock also at early stages of CKD. However, it remains to be determined whether more successful management of poor oral health and periodontitis will reduce the risk of inflammation, infections, PEW, and atherosclerotic complications in CKD.

Bowel Bacteria Overgrowth and Altered Gut Microbiota

Uremia results in profound alterations of the gut microbial flora, also called gastrointestinal dysbiosis, and provokes impairment in the structure and function of the intestinal epithelial barrier structure (113). The causes responsible for these derangements are related not only to uremia *per se* but also to other commonly observed conditions like fluid overload, dietary fiber intake, frequent use of antibiotics, slow colonic transit, metabolic acidosis, intestinal wall edema, and oral iron intake. Alterations of the gut microbial flora in CKD are related to systemic inflammation and accumulation of gut-derived uremic toxins. Some of the uremic toxins generated by colonic bacteria include alfa-phenylacetyl-l-glutamine, 5-hydroxyindole, indoxyl glucuronide, *p*-cresol sulfate, and indoxyl sulfate (114). It is thought that they might play a role in the progression of kidney disease and in the pathogenesis of accelerated CVD and numerous other CKD-associated complications (115). In this sense, using pre/probiotics in order to attenuate the imbalance in the microbiota has been proposed as an intervention to minimize inflammation in this group of patients (116). It also has been described that beside the effect of the composition of the intestinal microbiota, uremia leads to an altered function of the intestinal barrier by provoking increased intestinal permeability (117,118). As a consequence of the disrupted intestinal epithelial junctions, an increased translocation of bacterial products across the intestinal barrier is observed, leading to an activation of innate immunity and therefore yielding to systemic inflammation (113).

Obesity and Fat Mass

Obesity, a common feature of CKD, may also contribute to an enhanced inflammatory activity (119). Adipokines and proinflammatory cytokines have a tightly link to fat and muscle tissue (120). Considering the important effect that loss of renal function has on the clearance of these substances (121), the systemic effects of adipokines in patients with CKD appear to be greater than in the general population. It has been estimated that approximately 20% of circulating IL-6 originate from fat tissue, and a significant amount of the circulating TNF comes from macrophages resident in the adipose tissue (122). As visceral fat appears to produce adipokines more actively than subcutaneous adipose tissue, visceral abdominal fat may be a main producer of IL-6. In accordance, in CKD patients evaluated shortly before the start of RRT, a significant association between serum IL-6 and truncal fat, but not between IL-6 and nontruncal fat, was documented (123). This association has also been seen in nondialyzed CKD stage 3 to 5 patients, where increased amount of visceral fat associated with higher inflammatory parameters (124) and increased coronary artery calcification (125). Adding to the importance of fat mass distribution, rather than fat mass as such, in the same cohort, patients with more epicardial adipose tissue presented higher levels of inflammatory parameters as well as higher risk or CVD events (126).

Lifestyle Factors

Many lifestyle factors have been reported to potentiate the inflammatory status in CKD patients. Diet is a source of both anti- and proinflammatory constituents. In a study analyzing two community-based cohorts of elderly individuals, it was demonstrated that a proinflammatory diet is associated with systemic inflammation as well as with reduced kidney function (127). In this regard, dietary habits and food patterns are probably a target of major relevance in modifying systematic inflammatory levels. Moreover, both dialyzed and nondialyzed CKD patients have been reported to have a sedentary lifestyle that associate with higher values of inflammatory markers (108,128). Additionally, the implementation of

programs devoted to increase physical activity in this group of patients has shown improvement in the levels of inflammatory parameters (129).

Obstructive sleep apnea syndrome is a common complication in patients with CKD (130) associated with endothelial damage, inflammation, and oxidative stress, which constitute an independent risk factor for CVD (112). Tobacco is probably the single most significant source of toxic chemical exposure to humans. Smoking is a central factor in many pathologic conditions, and its role in neoplasm, lung, and CVD has been well established for years. In recent years, cigarette smoking was shown to be able to alter both innate and immune systems and augment the production of numerous proinflammatory cytokines such as TNF, IL-1, IL-6, IL-8 GM-CSF, and a decrease in the levels of anti-inflammatory cytokines like IL-10 have been related to this (131,132).

Genetic Predisposition

Phenotypic variation is traditionally divided into a genetic and an environmental component. Undoubtedly, variations in the genome play an important role for the development of specific phenotype in CKD (133,134). Different types of genetic variants, such as insertion/deletions, mini- and microsatellites, or single nucleotide polymorphisms (SNPs), lead to a great variability in human genome, making human beings such unique individuals (134). Our understanding on the genetic predisposition to inflammation in patients with CKD has increased enormously the last decade. Because genetic variations are randomly assorted during gamete formation (independent of environmental factors), this approach, although being an association study, allows distinguishing a cause from an effect. For instance, the IL-6 gene has functional variants that affect inflammation and risk for CVD among dialysis patients, supporting a causal role for IL-6 in CVD (135). Interestingly, the IL-6 gene variants, together with those from the lymphotoxin-α gene, independently predicted risk for CVD in a rather big cohort of dialysis patients (136). Moreover, genetic variations in the IL-6 gene seem to influence inflammatory and peritoneal transport parameters, thereby contributing to the interpatient variability in small solute transport rate at the start of PD (137). Also, genetically determined interindividual differences in TNF (138), IL-10 (139), myeloperoxidase (140), and peroxisome proliferator-activated receptor (PPAR) γ (141) release have been associated with the prevalence of inflammation, CVD, and survival in CKD. Zhang et al. (142) found that although a haplotype consisting of several SNPs in the CRP gene was related to CRP levels measured over time in African American dialysis patients, there was no association between these SNPs and the presence of CVD. This finding is consistent with the growing belief that although CRP is a strong and independent risk marker of cardiovascular death, it is not a risk factor for vascular disease.

External and internal environmental stresses may also affect the phenotype via changes in the epigenome. Aberrant DNA methylation may, in relation to uremic dysmetabolism, have complex interactions for the development of premature CVD. As epigenetic mechanisms regulating the functional properties of the genome are heritable through cell divisions and may be sensitive to an abnormal environment (such as the uremic milieu), they could be potential new targets for interventions. Lastly, shortening of telomeres (nucleoprotein complexes protecting the chromosome ends that are involved in chromosome stability and repair) has been associated with an inflammatory phenotype and increased mortality in HD patients (143). In this context, it is of interest that telomere shortening to a critical length results in loss of histone and DNA methylation at mammalian telomeres, concomitant with increased histone acetylation (144). To conclude, the inflamed uremic phenotype is also the result of genetic factors.

This is supported by the observation that Asian dialysis patients treated in the United States also have a markedly lower adjusted relative risk of mortality than Caucasians (145). Indeed, a substantial heritability (35% to 40%) has been found for CRP and IL-10 production (146,147), and many studies demonstrate a significant impact of genetic variations on the uremic inflammatory response (148,149).

Markers of Inflammation and Implications on Outcome

Prospective studies in patients both on HD (150–152) and PD (153–155) and after kidney transplantation (156) show that even a single measurement of an inflammatory biomarker is an independent predictor of poor outcome in patients with advanced CKD. In addition, results from the Modification of Diet in Renal Disease (MDRD) study showed that elevation of CRP (3 mg/L or more) and hypoalbuminemia predicted outcome in patients with mild to moderate CKD (157). In this regard, based on the large body of evidence available about the association of inflammation and poor outcomes in CKD population, an increased awareness of the importance of regular monitoring of inflammatory status has emerged in the nephrology community. For this purpose, a wide array of measurements are available (158), including among others, CRP, PMNL count, serum albumin, pentraxin-3 (PTX-3), IL-6, and TNF-like weak inducer of apoptosis (TWEAK) to name a few. However, there is poor agreement regarding which is the parameter that best predicts all-cause and cardiovascular mortality in patients with CKD.

In clinical practice, CRP is the most commonly used inflammatory marker. CRP is an acute-phase protein, produced by human hepatocytes in response to proinflammatory cytokines. Its measurement is cheap, reliable, easily obtained, and widely used in many centers around the world, and its interesting profile of features [stability over time (159), unaffected by circadian variation and by food intake] facilitates the use of it in dialysis patients attending different HD schedules. The use of CRP in dialysis units around the world has increased considerably in the last decade according to data from the Dialysis Outcomes and Practice Patterns Study (DOPPS) registry (160), and, interestingly, the dialysis facilities with higher percentage of patients with available CRP measurements reported lower cardiovascular-related mortality. In the uremic *milieu*, CRP levels have shown to be associated with a number of both traditional and nontraditional cardiovascular risk factors, including dyslipidemia, oxidative stress, homocysteine levels, endothelial dysfunction, insulin resistance, and vascular calcification (26). A disadvantage faced with the use of CRP is its intra- and interindividual variability (161) and its variation over time, that in dialysis patients depend mainly on clinical events like transient infections, changes in volume status, or the intermittent stimulus of the dialysis procedure (162). Additionally, there is scarce information regarding the time-dependent predictive value of this measurement in patients with mild to moderate CKD. Moreover, whereas serial CRP measurements predict outcome better than a single CRP measurement in a group of prevalent HD patients (163), no data on serial determinations of inflammatory biomarkers are yet available in mild to moderate CKD. Therefore, prospective studies with careful serial monitoring of inflammatory biomarkers in patients with CKD are needed to evaluate if such an approach will yield more precise information to assess the disease severity.

IL-6 is considered as the key factor in the acute-phase response, and it has been suggested that this proinflammatory cytokine plays a strategic role in the pathogenesis of both PEW and atherosclerosis in the dialysis population (164). Some studies have assessed the predictive value of IL-6 over other inflammatory markers in dialysis patients, finding that IL-6 present the highest predictive value with regard to all-cause and cardiovascular mortality (34,35). Likewise, a comparative study based on ROC

analysis also showed that the prediction power of the combined inflammatory burden of a number of commonly measured cytokines and adhesion molecules was identical to that provided by the sole measurement of IL-6 (165). Notwithstanding this advantage of risk prediction showed by IL-6, in a recent meta-analysis, Zhang et al. (166) found that CRP versus IL-6 had a similar predictive value for cardiovascular and all-cause mortality; CRP [hazard ratio (HR) 1.14 and 1.18, respectively] and IL-6 (HR 1.15 vs. 1.18, respectively). Thus, based on available data, it seems that the prognostic estimation provided by CRP is not much inferior to that by IL-6. Thus, the use of CRP would be sufficient to grade the inflammation status in clinical practice.

Other inflammatory markers that have attained increased interest in recent years are pentraxins. Pentraxins are a superfamily of evolutionarily conserved proteins characterized by a cyclic multimeric structure (167). On the basis of the primary structure of the subunit, the pentraxins are divided into two groups: short pentraxins (e.g., CRP and serum amyloid P) and long pentraxins. The prototype protein of the long pentraxin group is PTX-3. Whereas CRP and serum amyloid P are produced primarily in the liver in response to IL-6 (168), PTX-3 is produced by a variety of tissues and cells, particularly by innate immunity cells in response to proinflammatory signals and endothelial cells (169–171). Because of the extrahepatic synthesis and in contrast to CRP, PTX-3 levels are believed to be a true independent indicator of disease activity, produced at sites of inflammation and intimately linked to endothelial dysfunction (172). PTX-3 is elevated in HD patients as compared to healthy individuals (173) and identified as a novel mortality risk factor in CKD stage 5, independent of traditional risk factors, but most importantly independent of CRP itself (174). This suggests that this protein may have an additional role in the atherogenic process to common inflammatory mediators, perhaps reflecting endothelial damage.

Another novel inflammatory biomarker is TWEAK, (TNFSF12) is a member of the TNF superfamily of structurally related cytokines (175) that can be expressed as a full-length membrane-bound protein or as a soluble protein (sTWEAK) that results from proteolysis of TWEAK (176,177). TWEAK gene is expressed in many tissues, including brain, kidney, heart, arterial wall, monocytes, and macrophages, and it has been found to be involved in different biologic processes, such as induction of cellular growth and proliferation (178,179), osteoclastogenesis (180), angiogenesis (181), and stimulation of apoptosis (182), favoring in that manner an inflammatory microenvironment. Moreover, TWEAK attenuates the transition from innate to adaptive immunity (183), activates nuclear factor-κB (NF-κB) signaling pathway, and induces the expression of different proinflammatory cytokines and cell adhesion molecules (184,185). In CKD, sTWEAK levels are significantly decreased compared to healthy subjects; however, high sTWEAK plasma levels have been reported to have additive effects to the high cardiovascular and all-cause mortality of HD patients with systemic inflammation (186).

CONSEQUENCES OF INFLAMMATION IN THE CLINICAL SETTING OF UREMIA

In the CKD population, persistent inflammation has been associated with several negative outcomes (71), including PEW, atherosclerosis, as well as increased cardiovascular and all-cause mortality (7,187,188). The specific pathways by which this association might be mediated are still not well known; however, it is thought that inflammation, beside its own direct effect, potentiates other known risk factors, like

oxidative stress (189), insulin resistance (190), endothelial dysfunction (191), vascular calcification (192), bone mineral disorders (193), and depression (194). Additionally, inflammation may magnify the risk for poor outcomes via mechanisms related to self-enhancement of the inflammatory cascade and exacerbation of both the wasting and the vascular calcification processes (195).

Protein-Energy Wasting

The term *protein-energy wasting* describes the loss of muscle mass and fuel reserves of the body (6). PEW is observed in as many as 18% to 75% of patients with CKD (196,197), and inflammation appears to be an important contributor of this complex syndrome, both by direct and indirect mechanisms of muscle proteolysis and by impinging upon and magnifying other causes of PEW in a vicious circle. In several studies, inflammatory markers have continuously been related to markers of muscle mass (198), indicating an important role of cytokines in the development of PEW and muscle catabolism (199). Muscle mass was inversely correlated to both IL-6 and CRP in HD patients, even after adjustments for age and gender (10). Also, markers of decreasing muscle mass during a 1-year period on HD were associated with higher IL-1β concentrations (200). Besides that skeletal muscle–derived IL-6 may contribute to the production of IL-6 and oxidative stress during the HD session (201,202), IL-6 *per se* may stimulate muscle protein breakdown and promote cancer-related wasting (203,204) and wasting observed in uremic patients (198). On the other hand, while IL-6 inhibits the secretion of insulin-like growth factor 1 (IGF-1), decreased IGF-1 signaling may also be involved in the sarcopenia process (205). Some of the known related mechanisms between PEW and inflammation are described below (**FIGURE 20.4**).

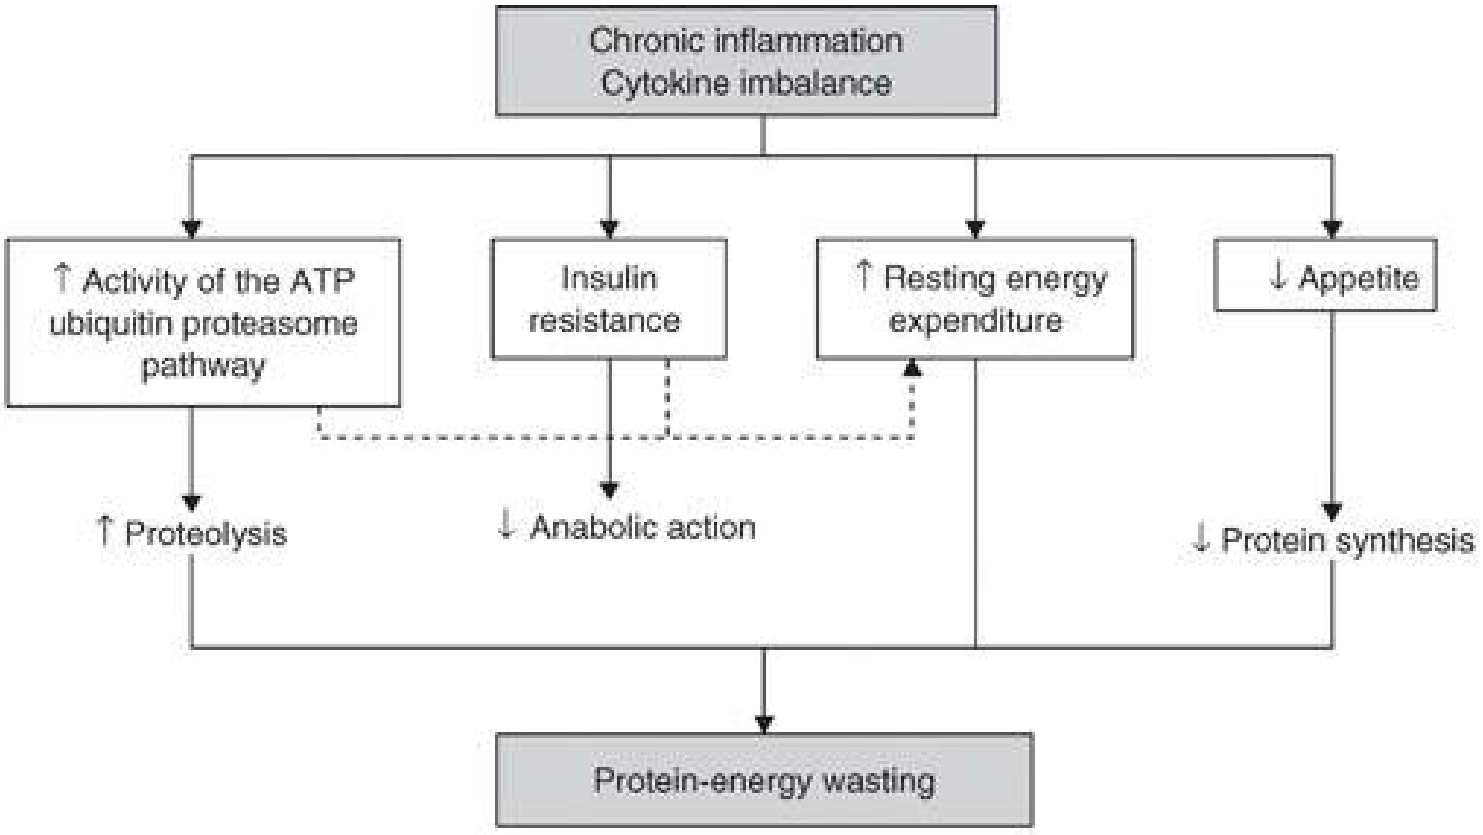

FIGURE 20.4 Potential mechanisms by which chronic inflammation may lead to protein-energy wasting. ATP, adenosine triphosphate, ↑, increase; ↓, decrease. (Modified from Avesani CM, Carrero JJ, Axelson J, et al. Inflammation and wasting in chronic kidney disease: partners in crime. *Kidney Int* 2006;70:S8–S13.)

Anorexia

Anorexia represents a complex and multifactorial disorder with a high prevalence among CKD patients (206). Although anorexia is a typical consequence of CKD, other metabolic abnormalities that are not fully corrected by dialysis therapy are also involved. In these derangements, given that some inflammatory markers like CRP, IL-6, and TNF have been described as related to uremic anorexia (207,208), systemic inflammation is likely to play an integrative role in the physiopathology of anorexia in CKD. Inflammatory cytokines have the capacity to regulate the appetite through disturbing specific brain areas related to appetite regulation (209). Specific cytokines access the brain and act directly on hypothalamic neurons and/or generate mediators targeting both peripheral and/or brain target sites (209,210); thus, inflammation may influence the size, duration, and frequency of meals.

A difference in the relation between inflammation and anorexia among genders needs to be pointed out. A recent study showed that among CKD patients, anorectic women exhibited a more favorable inflammatory and nutritional status than anorectic men (155). This difference where apparently uremic men are more prone to inflammation-induced anorexia might be explained by a possible protective role of sex hormones against the burden of inflammation. Indeed, gender is physiologically associated with feeding behavior (158) and inflammatory status (159), and men with inflammation on dialysis seem to have a worse survival as compared to women with the same conditions (5). Although the role of sex-specific regulation of feeding is unclear, increased anorectic signals and earlier satiety have been reported in men suffering from chronic illnesses (160,161), perhaps contributing to a different response pattern to anorexigenic diseases (such as heart failure and cancer) among men and women (162). An indirect support of this hypothesis is that novel anorexigenic agents, such as megestrol acetate or nandrolone decanoate, have a chemical structure similar to sex hormones.

Increased Insulin Resistance

An increased insulin resistance predisposes to a loss of muscle mass by decreasing the anabolic action of insulin. Type 2 diabetic HD patients have significantly increased skeletal muscle protein breakdown (211). Thus, dialysis patients and patients with diabetes mellitus had significantly accelerated loss of lean body mass (LBM) during the first year of RRT (212). The link between inflammation and insulin resistance occurs mainly through (a) a defect in insulin intracellular signaling pathways during inflammation, (b) induction of lipolysis by TNF, and (c) a decrease in the secretion of adiponectin caused by TNF (213). Additionally, the administration of recombinant TNF to cultured cells or to animals impairs insulin action, and obese mice lacking functional TNF or TNF receptors have improved insulin sensitivity compared with wild-type counterparts (214).

Activation of the Adenosine Triphosphate Ubiquitin-Proteolytic System

Metabolic acidosis is a common phenomenon in progressive CKD that may lead to stimulation of protein breakdown and subsequent muscle wasting through stimulation of the ATP-ubiquitin-proteolytic pathway (215). Because TNF increases ubiquitin gene expression in skeletal muscle, it is possible that it causes muscle wasting by stimulating protein catabolism through the ubiquitin proteosome pathway (215,216).

Increased Resting Energy Expenditure

The diverse metabolic abnormalities present during the inflammatory response, like fever, elevated oxygen consumption, enhanced lipolysis and fat utilization, increased concentration of catabolic hormones, and extensive protein catabolism, consume high quantities of energy that account for as much as 15% of the daily energy expenditure (217). Studies in predialysis and dialysis patients have consistently shown that inflammatory markers are associated with increased resting energy expenditure (10,218,219) and an increased mortality risk (10).

Depression

Depressive symptoms are related to poor outcomes and higher mortality in CKD and in other patient groups, and they are seen more frequently with the gradual reduction in renal function (220–222). Cytokines are thought to be important mediators of brain immune connections and may play an important role in the pathogenesis of depression due to their effect on neurotransmitters and neurohormones (220,223). In dialysis patients, depressive symptoms seemed to worsen in the presence of increased IL-6 levels (222–226), and 8 weeks of fluoxetine treatment in depressed HD patients decreased serum IL-1β levels (227). Depression may undeniably link to fatigue (228) and unwillingness to eat (206), contributing in a vicious circle to anorexia, physical inactivity, PEW, and worse outcome, all of which have also been attributed, in part, to the effects of systemic inflammation.

Vascular Calcification

Although vascular calcification (or rather ossification) can be observed in the general population (229), CKD is a condition associated with a markedly increased prevalence of both intima and media arterial calcification (230). Indeed, several studies indicate that large artery calcification (assessed by computer tomography or chest x-ray) is present in 30% to 70% of patients with CKD (231,232), and even in approximately 15% of uremic pediatric patients (233).The presence of arterial ossification is associated with functional estimates of arterial dysfunction, such as NO-dependent vasodilation in dialysis patients (234) and pulse wave velocity (235), both of which have been associated with adverse outcome in patients with CKD (236,237). Indeed, vascular ossification is associated with increased risk of CVD (231,238,239) and mortality (238). Currently, there are a wealth of data evidencing intimate links between vascular calcification and systemic inflammation (**TABLE 20.3**). TNF can induce mineralization of calcifying vascular cells *in vitro* (240), and coculture of these cells with monocyte/macrophages (the source of most cytokines) can accelerate this process (241). Receptor activator of NF-κB ligand (RANKL) is a membrane-bound or soluble cytokine essential for osteoclast differentiation, whereas the decoy receptor osteoprotegerin (OPG) masks RANKL activity. Although both seem to influence the inflammatory component of atherosclerosis (242), it is of interest that OPG upregulates endothelial cell adhesion molecule in response to TNF (243). These findings suggest a mechanism by which OPG may stimulate inflammation in atheroma and thereby promote the progression and complications of atherosclerosis, which would agree with the observed detrimental effects on survival of both increased inflammation and OPG levels in HD patients (244). On the other hand, vascular calcification, as part of the atherosclerotic process, is due to the deposition in the arterial intima of basic calcium phosphate (BCP) crystals, similar to those that mineralize bone. It was recently shown that BCP crystals could interact with human monocyte-derived macrophages, inducing a proinflammatory state through protein kinase C and mitogen-activated protein (MAP) kinase pathways (245). This implies a vicious circle of

inflammation and arterial calcification that could explain the associations between inflammation and outcome in CKD.

TABLE 20.3 Factors Related with Vascular Calcification through Inflammation in the Uremic Milieu

Factors	Association with Inflammation
Inhibiting calcification	
Osteoprotegerin	+
Osteopontin	+
Bone morphogenic protein-7	+
Fetuin-A	++
HDL-cholesterol	+
Matrix gla protein	unknown
Promoting calcification	
Leptin	+
TNF	++
Genetic factors	+
Diabetes mellitus	+

HDL, high-density lipoprotein; TNF, tumor necrosis factor; +, association; ++, strong association.

Among the inhibitor factors of ossification, fetuin-A is the most studied. Mice lacking the gene encoding for fetuin-A rapidly develop ectopic soft tissue ossification and die at an early age (246). In CKD, low levels of circulating fetuin-A are associated with increased cardiovascular burden and mortality (247–249). Inflammation and PEW may be important causes of a decrease in serum fetuin-A level in patients with CKD, as increased proinflammatory molecules and the presence of wasting downregulate its plasma levels (250,251). Also, fetuin-A was associated with cardiac valve calcification and inflammation in PD patients (252). Taken together, these data suggest the existence of an active interplay between vascular calcification and atherosclerosis through inflammation, against a background of severe calcium-phosphorus disturbances. If the above mentioned theory is further supported by forthcoming studies, then the treatment of all three entities (atherosclerosis, calcium-phosphorus disturbances, and inflammation) have to be instituted early, concomitantly, and intensively in these patients.

Endocrine Disorders

The kidney is a key modulator of the endocrine function and an important target for hormonal action. As a direct consequence, the uremic state is associated with abnormalities in the synthesis or action of many hormones (253). Evidence suggests that this hormonal dysmetabolism may be aggravated by persistent inflammation.

Thyroid Hormones

CKD *per se* causes alterations in thyroid hormones in the absence of an underlying intrinsic thyroid disorder (254,255) characterized by a decrease in total (T_3) and free (fT_3) triiodothyronine plasma concentration, whereas thyroid-stimulating hormone (TSH) levels are usually normal. Indeed, the so-called low T_3 condition is present in approximately one-fourth of patients with CKD (256). Traditionally, decreases in plasma T_3 concentration have been interpreted as an attempt to conserve body energy stores

by reducing metabolic rate. However, recent data suggest that low T_3 levels may not just be an innocent bystander and could be involved in the increased mortality risk in CKD. Low T_3 levels are independent predictors of all-cause mortality in HD (257) and PD patients (258) and even in patients with clinical and biochemical euthyroid CKD stage 5 (259). Although the reasons for this observation are as yet unknown, they may connect a state of subclinical hypothyroidism with low-grade persistent inflammation (260). Indeed, IL-6 signaling has been reported to downregulate the peripheral conversion of total thyroxine (T_4) into T_3 in both experimental (261) and clinical (262) studies. Low T_3 levels specifically predicted cardiovascular mortality (**FIGURE 20.5**) in patients with CKD stage 5 (259), whereas in a PD cohort, these levels were associated with left ventricular hypertrophy (257). This working hypothesis merits further consideration.

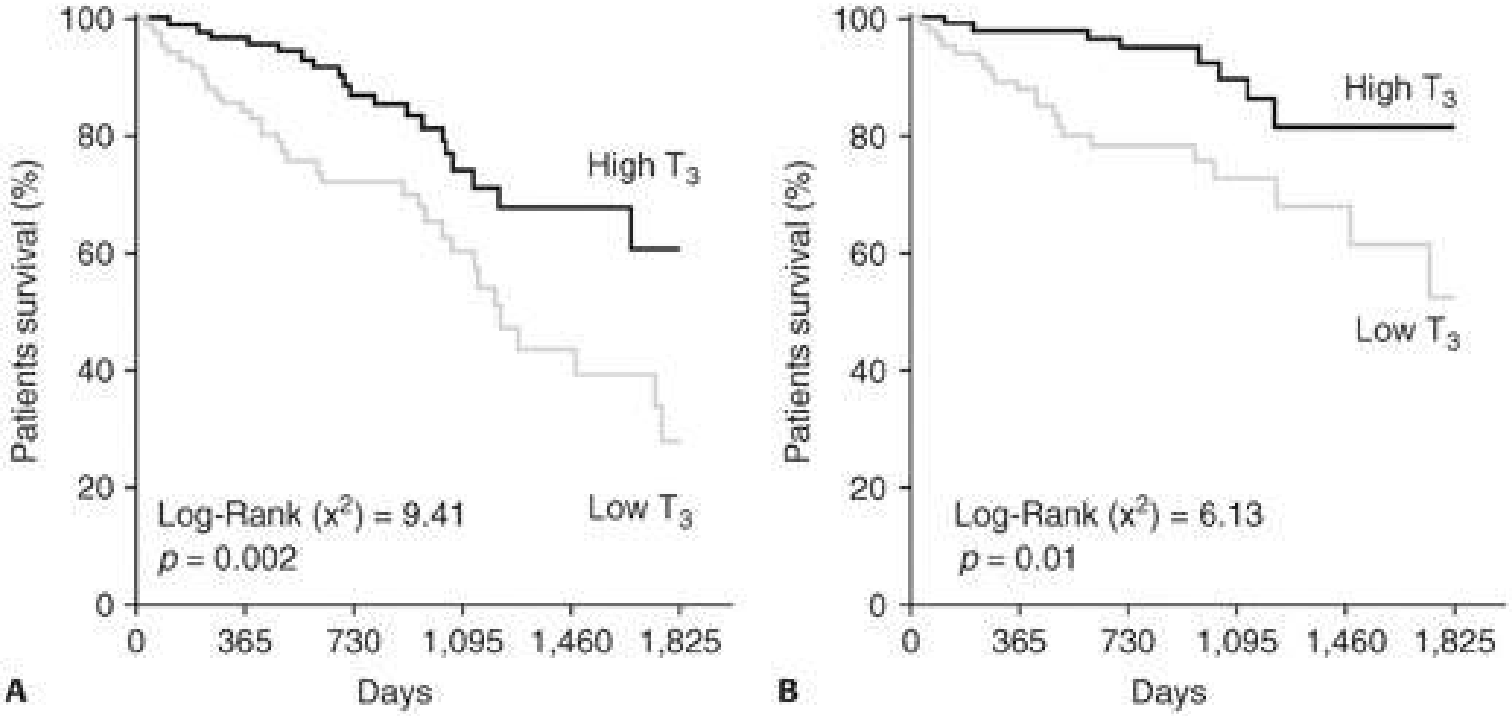

FIGURE 20.5 Association of low triiodothyronine levels with all-cause **(A)** and cardiovascular **(B)** mortality in 187 patients with clinical and biochemical euthyroid stage 5 CKD. [Modified from Carrero JJ, Qureshi AR, Axelsson J, et al. Clinical and biochemical implications of low thyroid hormone levels (total and free forms) in euthyroid patients with chronic kidney disease. *J Intern Med* 2007;262(6):690–701.]

Sex Hormones

Testosterone deficiency or hypogonadism is common in men with CKD, with a prevalence ranging from 35% to 50% of men undergoing RRT (263,264). Although the high prevalence of hypogonadism observed in this group of patients to a large extent may be a consequence of the failing kidney *per se* (265), inflammation is thought to have an important contributory role in the physiopathology of hypogonadism. Thus, the hypothalamic–pituitary–testicular axis is suppressed by different inflammatory cytokines (266,267), and therefore, an inflammatory state may induce testosterone deficiency. In support of this, studies depict a strong inverse association between endogenous testosterone and surrogate markers of inflammation in CKD populations (268–271). However, it is also possible that testosterone has immune-modulatory actions *per se*, as suggested by the suppression of cytokine production in hypogonadal men with diabetes, coronary heart disease, and metabolic syndrome after supplementation with testosterone

(272–274).

Other Hormones

The inflammatory response inhibits growth hormone (GH) action (275), and GH forearm perfusion demonstrated that a resistance to pharmacologic doses of GH is not related to uremia *per se* but rather to an increased inflammatory state (276).

PREVENTION AND TREATMENT OF INFLAMMATION

Because persistent inflammation may be a silent reflection of various pathophysiologic alterations in CKD, and as its presence is associated with many deleterious outcomes, it is essential that inflammatory markers are regularly monitored and therapeutic attempts be made to target inflammation (**FIGURE 20.6**). While a heightened attentiveness to the presence of inflammation will lead first of all to treatment of comorbidities (especially infections), other interventions are valuable in the clinical management of "uremic inflammation" (277) (**TABLE 20.4**). These include improvements in dialysis therapy (278) and fluid status (279) as well as implementation of healthy lifestyle habits, including diet modifications (280,281) and an increase in physical activity (129). As the use of central venous catheters is a common source of inflammation in HD patients (282), their use should be limited and as short as possible. Some of the possible interventions are described more in detail below.

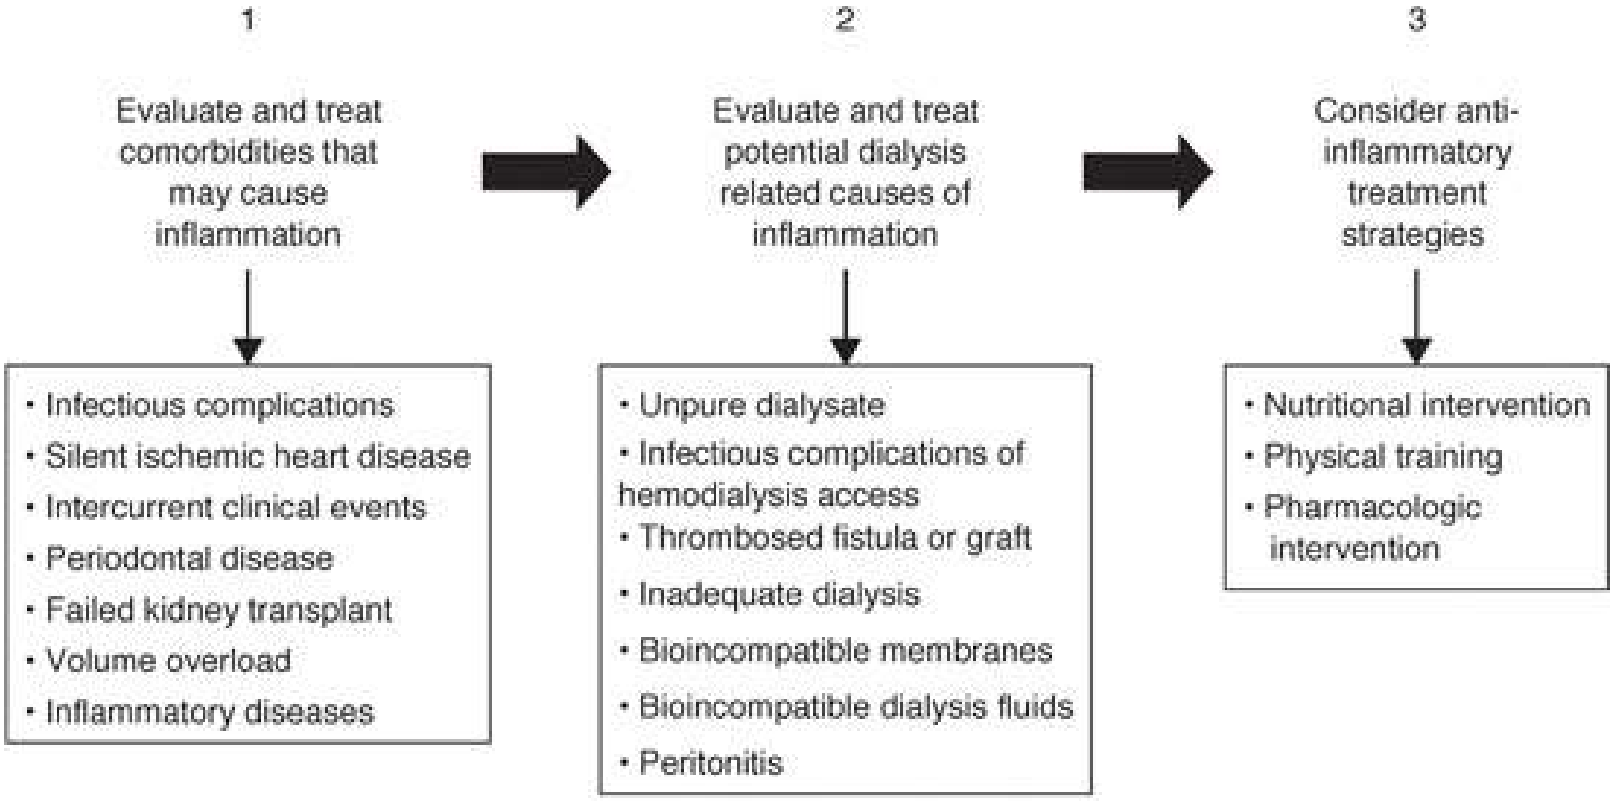

FIGURE 20.6 Suggested steps to target persistent inflammation in dialysis patients.

TABLE 20.4 Currently Available Anti-Inflammatory Treatment Strategies in Patients with Chronic Kidney Disease

	I. Associated with Dialysis Treatment *Per se*
Ultrapure dialysate	Repeatedly shown to reduce CRP (90–93)
Biocompatible membranes	The inflammatory reaction is affected by choice of dialyzer (85).
Hemodiafiltration (HDF)	On-line HDF did not provoke an inflammatory response (334).
Daily dialysis	Dramatic positive effect on CRP in one study (88)
Vascular access in HD	Central venous catheters are a common source of inflammation in HD patients (282) and their use should therefore be limited and as short as possible.
	II. Nutritional and Lifestyle Interventions
Physical training	Both aerobic and resistance training enhance immune function and exert anti-inflammatory effects (129,284).
Cognitive-behavioral therapy for sleep disorders	Improves sleep quality and decreases inflammatory parameters in HD and PD patients (335,336)
Smoking cessation	Active smokers present higher levels of inflammatory markers. Inflammatory markers in former smokers approach levels among nonsmokers over time, suggesting that cessation may result in a reversal of smoking-associated alterations in immunity and inflammation (337).
Salt restriction	Dietary sodium restriction is associated with the attenuation of the inflammatory state depicted by a reduction in levels of CRP, IL-6, and TNF (338).
Omega-3 fatty acids	12-week fish oil supplementation decreased CRP in HD patients (288)
Gamma-tocopherol	Small RCT in HD patients shows effect on IL-6 (299).
Pomegranate juice	One year of pomegranate juice intake yielded a significant time response reduction in PMNL priming, protein oxidation, lipid oxidation, and levels of inflammation biomarkers (339).
Probiotics	After 6 months of treatment, there was a decrease of TNF, IL-5, and IL-6 levels and an increase of IL-10 (340).
High fiber intake	High dietary total fiber intake is associated with lower risk of inflammation and mortality (341).
Low-fructose diet	Changing to a low-fructose diet decreased values of hsCRP and sICAM. hsCRP values returned to baseline with resumption of regular diet (300).
Green tea	Reduces HD-induced production of hydrogen peroxide, hypochlorous acid, atherosclerotic disease risk factors, and proinflammatory cytokines (342)
Soy	Lower prevalence of inflammation and better outcome in Asian HD patients might be due to soy intake; soy supplementation decreases CRP in HD patients (290).
	III. Commonly Used Pharmacologic Interventions
Statins	Inhibit cholesterol synthesis but also showed anti-inflammatory (303,304) and anti-oxidative properties (305) in HD patients; no effect on survival in 4D (306)
ACE inhibitors	Reduction in IL-6 response to coronary artery graft surgery (308); lower inflammatory (309) and adhesion molecules (310) in CKD patients using ACE inhibitors
Sevelamer	A small RCT shows decrease in CRP and increase in fetuin-A with sevelamer treatment (314).
Antidepressant	Sertraline treatment for depression significantly decreased serum IL-6, independent of its efficacy for depression treatment (343).
Allopurinol	Decreases CRP, slows down progression of kidney disease, and reduces cardiovascular and hospitalization (344)
D-vitamin	Reduction of inflammation biomarkers in patients with congestive heart failure (312)
Cholecalciferol	Reduction of inflammatory markers and left ventricular hypertrophy (345)
Paricalcitol	Significant decrease in hsCRP, TNF, and IL-6 (346)
Linagliptin	Significant decreases of IL-6 levels after 6 months treatment (347)
Heparin	Low molecular weight heparin reduces inflammation in HD patients (348).
	IV. Potential Novel Anti-Inflammatory Interventions
N-Acetylcysteine	Small show effect on outcome in HD (297).
Pentoxifylline	Significantly decreased serum concentrations of TNF, IL-6, and CRP (349)
Bardoxolone	Inhibits inflammation by activating the Nrf2 pathway (350), improving of glomerular filtration rate observed in DM-2 CKD patients (351). An RCT including CKD-4 diabetic patients observed a higher rate of cardiovascular events with bardoxolone methyl than with placebo prompted termination of the trial (352).
Anticytokine drugs	Tocilizumab (353), Canakinumab (354), Anakinra (355), and Etanercept (356) have shown promising results in chronic inflammatory diseases. Lack of data regarding the safety and concrete benefits of some of these medications in dialysis patients.

CRP, C-reactive protein; HD, hemodialysis; PD, peritoneal dialysis; IL-6, interleukin 6; TNF, tumor necrosis factor; RCT, randomized controlled trial; PMNL, polymorphonuclear leukocyte; IL-5, interleukin 5; IL-10, interleukin 10; hsCRP, high-sensitivity C-reactive protein; sICAM, soluble intercellular adhesion molecule; 4D, Die Deutsche Diabetes-Dialyse; CKD, chronic kidney disease; ACE, angiotensin-converting enzyme; DM-2, type 2 diabetes mellitus; CKD-4, stage 4 chronic kidney disease.

Lifestyle and Nutritional Measures

At first, given the documented associations between proinflammatory cytokines and lifestyle factors (283), appropriate lifestyle modifications, such as weight loss or exercise training (284), may be an important component in normalizing deregulated cytokine system activity in CKD (284). Dietary interventions could also play an important role that has been, up to now, underestimated. According to *in vitro* and animal studies, different bioactive food components exert a positive effect on oxidative stress and inflammation (285); however, whether these effects can be extrapolated to humans will require further studies. HD patients who are fish eaters have been reported to have lower mortality (286), and small studies in HD patients suggest that omega-3 fatty acids have beneficial effects in different clinical conditions related to CKD (287); however, the potential beneficial effects of fish oil or omega-3 fatty acids consumption on inflammation needs to be confirmed by further investigation. Of interest, a small randomized controlled trial with fish oil in HD patients found significant reductions in CRP concomitant with rise in blood omega-3 levels (288). Flavonoid compounds like genistein (present in soy) are also of potential interest due to their similarity with sexual hormones and protective impact on cardiovascular functions, that it is thought to be mediated by their ability to interfere with cytokine production by repression of IL-6 mRNA (289). A small interventional study using isoflavone soy in HD patients showed inverse correlations between changes in serum isoflavone levels and CRP levels (290).

Resveratrol, a phenolic compound found in various plants, including grapes, berries, and peanuts, has also anti-inflammatory properties by antagonizing the activity of NF-κB (291). Although it is conceivable that resveratrol supplementation in CKD patients could be beneficial, there are yet no studies documenting the effect on uremic inflammation. In mice, however, it has been shown that that resveratrol treatment inhibits oxidative stress and renal interstitial fibrosis (292). Other natural antioxidants like vitamin E and *N*-acetylcysteine may inhibit proinflammatory cytokine release (293,294) and improve endothelial dysfunction (295,296). They have been shown to reduce cardiovascular events in rather small cohorts of dialysis patients (297,298). Recent results from a randomized controlled trial with γ-tocopherol and docosahexaenoic acid in HD patients showed a significant reduction in selected biomarkers of inflammation (299). Increased fructose intake has recently been implicated as a potential contributor to hypertension, inflammation, and CKD, potentially via generation of uric acid. The reduction in inflammatory markers observed in 28 CKD patients on a low-fructose diet (300) indicates the need for further studies on the putative long-term anti-inflammatory effects of such a diet. Finally, a number of other nutritional interventions, such as fiber-rich food, nuts, probiotics, and diets with low content of AGEs, may have anti-inflammatory properties and should be evaluated in CKD (301,302).

Nonspecific Anti-Inflammatory Pharmacologic Interventions

The role of unspecific anti-inflammatory pharmacologic treatment strategies either alone or combined as a preventive therapy needs further evaluation. It is notable that several commonly used drugs may possess significant anti-inflammatory effects. Statins not only inhibit cholesterol synthesis but also show anti-inflammatory actions (303,304) and anti-oxidative properties (305) in HD patients. However, no effect on survival was demonstrated in the Die Deutsche Diabetes-Dialyse (4D) randomized controlled trial (306). In another study, IL-8, IL-6, and TNF levels were reduced during aspirin consumption in HD patients (307). Angiotensin-converting enzyme inhibitor (ACEI) treatment is associated with a reduction in IL-6

response to coronary artery graft surgery (308). In accordance, we have found lower plasma levels of TNF, CRP (309), and adhesion molecules (310) in patients with CKD treated with ACEI. Of interest, ACEI has also been shown to prevent wasting in patients with heart failure (311). Other interesting approaches may include D-vitamin, which effectively reduced the inflammatory milieu in a randomized controlled trial performed in patients with chronic heart failure (312). Sevelamer has also been suggested to exert favorable impact on lipids and inflammatory markers with potentially useful antiatherogenic effects in HD patients (313). In addition, short-term sevelamer intake significantly increased fetuin-A levels and improved flow-mediated dilation in patients with nondiabetic CKD stage 4 (314). *N*-Acetylcysteine could also be an interesting option to test considering its effect on reducing atheroma progression (probably through a decrease in oxidative stress) in an animal model of uremia-enhanced atherosclerosis (315). Finally, PPAR-γ activators, such as rosiglitazone, may be another interesting strategy to explore given their anti-inflammatory effects in PD patients (316). However, as the myocardial ischemic risk associated with rosiglitazone treatment may be increased in patients with type 2 diabetes (317), these drugs should be used with caution in dialysis patients.

Targeted Anticytokine Interventions

As targeted anticytokine treatment strategies have shown interesting results in other patient groups with inflammation, these drugs may also be of interest to study in dialysis patients. Thalidomide, a drug with immunomodulatory, anti-inflammatory, and antiangiogenic properties, exerts its therapeutic effects through the modulation of TNF. As thalidomide induces a Th2 response and has been associated with weight gain in other wasted patient groups, such as those with HIV or tuberculosis (318), it would be of interest to test the effects of this drug in dialysis patients. Pentoxifylline has been shown to reduce TNF expression by more than 50% and to improve hemoglobin levels in a small group of HD patients with erythropoietin-resistant anemia (319). Finally, as promising results in patients with type 2 diabetes (320) and in patients with acute gout (321) with IL-1-receptor antagonists have been reported, this may be another future treatment of uremic inflammation. Although specific anti-inflammatory drugs (tocilizumab, canakinumab, pentoxifylline) have been found to be of value in other inflammatory diseases (281), there is still lack of data regarding the safety and concrete benefits of these medications in dialysis patients.

CHAPTER 21

Hepatitis and Human Immunodeficiency Virus Infections in End-Stage Kidney Disease Patients

Ruth Berggren

Despite widespread implementation of universal precautions, chronic dialysis patients remain at risk for parenterally transmitted infections including with hepatitis B virus (HBV), hepatitis C virus (HCV), or human immunodeficiency virus (HIV) from blood product transfusions or nosocomial transmission in hemodialysis units (1–4). Adverse outcomes, including increased mortality rates, are noted among dialysis patients with chronic viral hepatitis (5). Yet not all dialysis patients are appropriately screened or considered for hepatitis treatment nor are they consistently vaccinated appropriately against HBV. In this chapter, the epidemiologic significance, morbidity, and mortality of HIV, HBV, and HCV infections in the chronic hemodialysis population are examined. Methods for preventing transmission and management recommendations for dialysis patients with chronic viral hepatitis or HIV infection are reviewed. Of these three parenterally transmissible viruses, HBV is the most likely to be transmitted in the setting of hemodialysis, and infection control guidelines reflect this difference (6). As of 2008, U.S. hemodialysis facilities must follow Centers for Disease Control and Prevention (CDC) guidelines in order to receive Medicare reimbursement for outpatient hemodialysis (7). This chapter reviews guidelines for immunization of the hemodialysis population against HBV, which differ from those for the general population, and summarizes postexposure prophylaxis (PEP) guidelines for personnel and/or patients accidentally exposed to HIV. GB virus C (GBV/HGV) is not addressed because although recent evidence reveals HGV can be transmitted in hemodialysis units, this is a relatively nonpathogenic virus with no known long-term sequelae for dialysis patients (8).

EPIDEMIOLOGY OF HEPATITIS B VIRUS, HEPATITIS C VIRUS, AND HUMAN IMMUNODEFICIENCY VIRUS INFECTIONS IN HEMODIALYSIS PATIENTS

National surveillance of dialysis-associated diseases in the United States in 2002 demonstrated the

prevalence of hepatitis B surface antigen (HBsAg), anti-HCV antibody, and HIV infection at 1.0%, 7.8%, and 1.5%, respectively (9). In 2002, a minority of hemodialysis centers were routinely screening for HIV, so the 1.5% HIV prevalence in dialysis centers may be an underestimate. These data are the result of surveillance questionnaires administered by the CDC to all chronic hemodialysis centers licensed by the Centers for Medicare and Medicaid Services (CMS). The 4,035 centers representing 263,820 patients and 58,043 staff were surveyed regarding hemodialysis practices, disposable dialyzer reuse, cleaning and disinfection procedures for dialysis equipment, HIV prevalence, HBV vaccination coverage, and the results of testing patients for HBsAg and anti-HCV antibody (10). The study found that the incidence of viral hepatitis did not differ substantially according to infection control practices.

In 2002, 27.3% of U.S. centers reported at least one patient with chronic HBV and 2.8% of centers reported at least one newly acquired HBV infection. Patients still acquire HBV infection in hemodialysis centers due to inadequate infection control or breaches of technique (9). The risk of seroconversion for patients with untreated percutaneous exposure to HBV is as high as 30% (11). In 2002, HBV incidence was 0.12% overall but higher in centers where injectable medications were prepared on medication carts in treatment areas compared to centers with a separate medication room. According to a cross-sectional study of 8,615 adult hemodialysis patients in Western Europe and the United States, the prevalence of HBV infection in this population ranges between 0% and 7% (4,12). In developing countries, rates of chronic HBsAg carriers range from 2% to 20% (4). Higher rates in developing countries are attributed to the higher background prevalence of HBV and difficulties following infection control strategies against HBV in the setting of lack of infrastructure and financial resources (4).

Although HCV seroprevalence among U.S. dialysis patients is 5 times higher than in the general population (7.8% vs. 1.6%), HCV incidence has been declining (13). In 2002, HCV incidence at U.S. dialysis centers was 0.34%, representing a significant decline from the previous decade (6). Centers using disposable containers for priming dialyzers demonstrated significantly lower HCV incidence (9). HCV transmission may occur in centers having opportunities for cross-contamination among dialysis patients, including failure to disinfect contaminated equipment or shared environmental surfaces. The duration of time on dialysis is the most important risk factor independently associated with HCV infection (6). Employment of nurses with at least 2 years of formal dialysis training is associated with lower seroconversion risk (14).

The proportion of U.S. hemodialysis patients with HIV increased from 0.3% to 1.4% from 1985 to 1999 (6); more recent estimates show stability with about 1.5% since 2002 (9). Patient-to-patient transmission of HIV infection has not been reported in American hemodialysis centers. In other countries, however, HIV transmission has been attributed to mixing of reused access needles and inadequate equipment disinfection procedures (15).

MORBIDITY AND MORTALITY OF HUMAN IMMUNODEFICIENCY VIRUS, HEPATITIS C VIRUS, AND HEPATITIS B VIRUS INFECTION IN HEMODIALYSIS PATIENTS

With the advent of highly active antiretroviral therapy (HAART), survival of HIV-infected patients on hemodialysis has vastly improved. A 2-year prospective French study followed all HIV-infected patients on hemodialysis in France through 2003. Survival was compared with that of 584 hemodialysis patients who did not have HIV infection in the same period. The 2-year survival rate was statistically indistinguishable from the survival of the control cohort. However, there were some significant mortality risk factors including low CD4+ T cell count (hazard ratio [HR] 1.4/100 CD4+ T cells per mm^3 lower), high viral load (HR 2.5/1 log10 per mL), absence of HAART (HR 2.7), and a history of opportunistic infection (HR 3.7) (16). Nevertheless, HIV-infected patients who are taking appropriate HAART and getting proper follow-up are comparable to non–HIV-infected end-stage kidney disease (ESKD) patients with regard to morbidity and mortality.

Among maintenance hemodialysis patients, HCV is associated with higher all-cause and cardiovascular mortality across almost all clinical and demographic groups (17,18). A database of 13,664 dialysis patients who underwent HCV testing during a 3-year interval (through June 2004) was analyzed. In logistic regression models, HCV infection was linked to younger age, male gender, black race, Hispanic ethnicity, Medicaid insurance, longer dialysis duration, unmarried status, HIV infection, and smoking. The mortality HR associated with HCV infection was 1.25 (95% confidence interval 1.12 to 1.39; p <0.001) (5). A longitudinal study showed a mortality rate of 33% for HCV-infected dialysis patients, compared with 23.2% mortality for the HCV-uninfected dialysis group over a 6-year follow-up (18).

In contrast to HCV, HBV-related liver disease in the hemodialysis population has a relatively benign course (19). Although HBV infection in hemodialysis patients more often results in a chronic carrier state compared to patients without kidney disease, the risk of death from liver disease is low (11,20). No significant difference in mortality between dialysis patients according to HBsAg status has been consistently shown (4,21,22). There are contradictory data from a small study in India, which indicates that HBsAg-positive hemodialysis patients had a higher mortality rate (72.7% vs. 21.4%) than HBsAg-negative hemodialysis patients due to fulminating hepatic failure in these individuals (4,23).

SCREENING AND PREVENTION RECOMMENDATIONS FOR HUMAN IMMUNODEFICIENCY VIRUS, HEPATITIS B VIRUS, AND HEPATITIS C VIRUS IN HEMODIALYSIS PATIENTS

In 2006, the CDC issued revised guidelines for HIV screening in the general population as follows: “HIV screening is recommended for patients in all health-care settings after the patient is notified that testing will be performed unless the patient declines (opt-out screening). Persons at high risk for HIV infection should be screened for HIV at least annually (**TABLE 21.1**). Separate written consent for HIV testing should not be required; general consent for medical care should be considered sufficient to encompass consent for HIV testing” (24). These guidelines apply equally to the population receiving chronic hemodialysis. Therefore, all individuals should be screened before the initiation of hemodialysis (**FIGURE 21.1**) and annually thereafter if they are at high risk. The definition of individuals at high risk for HIV

infection includes injection drug users, men who have sex with men and persons with multiple sexual partners including those who exchange drugs or money for sex, and heterosexual partners of HIV-infected persons. There is no recommendation to segregate HIV-positive from HIV-negative dialysis patients or to dedicate dialysis machines solely to HIV-positive patients. As of 2015, there is no effective vaccine for the prevention of HIV, and prevention of infection requires education of patients and staff to minimize risk (25).

TABLE 21.1 Screening Schedule for Hemodialysis Patients: Hepatitis B (HBV), Hepatitis C (HCV), and Human Immunodeficiency Virus (HIV)

Patient	Admission	Monthly	Twice Yearly	Yearly
All	HBsAg	—	—	—
	Total anti-HBc	—	—	—
	Anti-HBs	—	—	—
	Anti-HCV, ALT	—	—	—
	Anti-HIV	—	—	—
		—	—	—
HBV nonimmune[a]	—	HBsAg	—	—
HBV-immune[b] but HBc negative	—	—	—	Anti-HBs[c]
Anti-HBs+ and anti-HBc+[d]	—	—	—	No additional testing
Anti-HCV–	—	ALT	Anti-HCV	—
Anti-HIV–	—	—	—	Anti-HIV if high risk

[a]All nonimmune persons should be immunized against HBV.
[b]A patient is HBV-immune if anti-HBs is greater than or equal to 10 mIU/mL.
[c]Boost HBV vaccine if anti-HBs declines to less than 10 mIU/mL.
[d]A patient who is both anti-HBc+ and anti-HBs+ demonstrates immunity due to prior infection does not need annual screening.
HBsAg, hepatitis B surface antigen; ALT, alanine aminotransferase.
From Centers for Disease Control and Prevention. Recommendations for preventing transmission of infections among chronic hemodialysis patients. *MMWR Recomm Rep* 2001;50(RR-5):1–43.

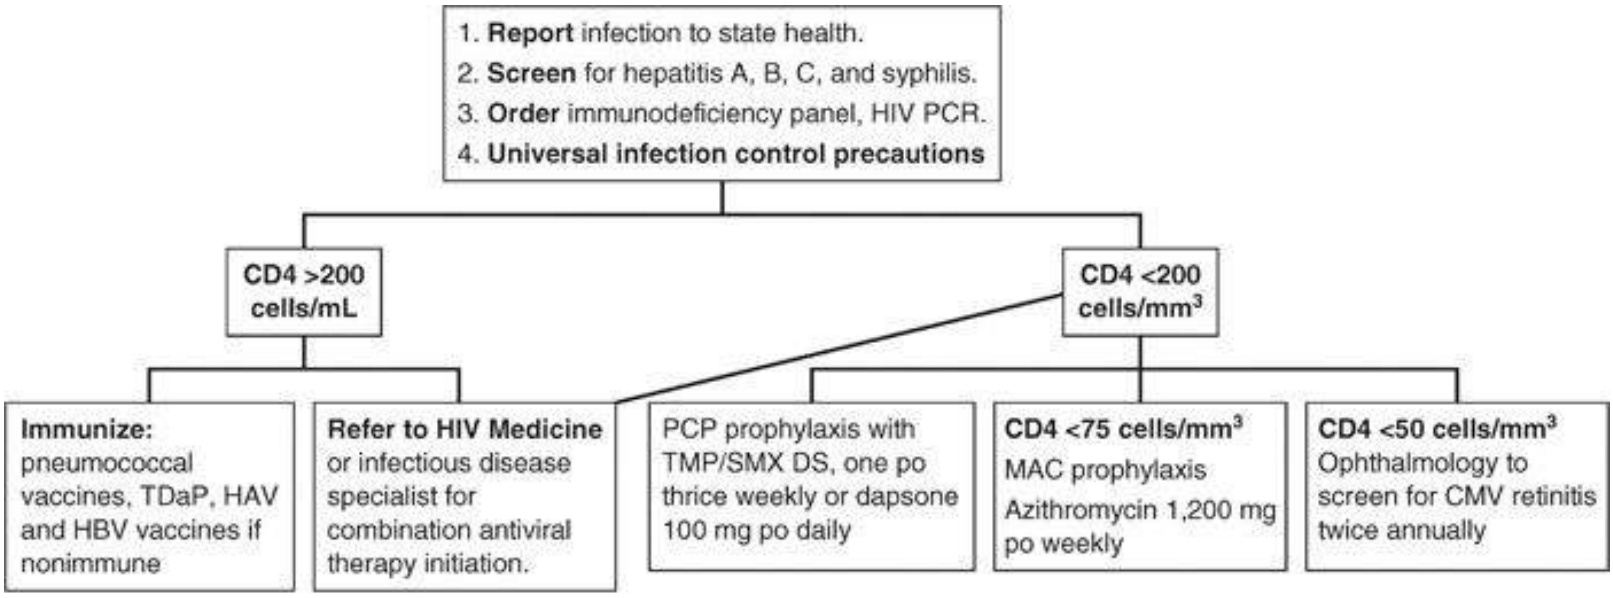

FIGURE 21.1 Incidentally discovered HIV in a dialysis patient. CD4: absolute CD4 + T lymphocyte count measured by immunodeficiency panel. All HIV infections must be reported to state health department to permit contact tracing. All newly diagnosed HIV-infected patients should have an immunodeficiency panel ordered right away to determine need for potentially life-saving prophylaxis against opportunistic infections, which can be initiated prior to seeing a specialist. Antiviral therapy is now recommended for all HIV-infected patients regardless of CD4 cell count; do not wait for CD4 cell count to drop below a certain threshold to make referral for therapy. If specialist cannot see new HIV patient right away, initiate standard vaccines noted as appropriate. HBV or HCV coinfected patients have special management considerations in selecting antiviral therapy for HIV. Unlike the case for hepatitis B infection, hemodialysis patients with HIV infection do not require segregation or use of a dedicated hemodialysis machine. HIV, human immunodeficiency virus; PCR, polymerase chain reaction; TDaP, tetanus, diphtheria, and pertussis; HAV, hepatitis A virus; HBV, hepatitis B virus; PCP, pneumocystis pneumonia; TMP/SMX, trimethoprim/sulfamethoxazole; DS, double strength; MAC, *Mycobacterium* avium complex; CMV, cytomegalovirus. (From Guidelines for the prevention and treatment of opportunistic infections in HIV-infected adults and adolescents. http://aidsinfo.nih.gov/guidelines. Accessed July 9, 2016.)

Hepatitis B Virus Screening and Immunization

Hepatitis B screening is especially critical in hemodialysis units because HBV-infected patients need to be isolated in a separate room and assigned dialysis equipment, instruments, supplies, and staff members that are not shared by HBV-susceptible patients (6). Several tests for which serologic assays are commercially available may be used to diagnose HBV infection. These include HBsAg and anti-HBs, anti-HBc, hepatitis B envelope antigen (HBeAg), and antibody to HBeAg (anti-HBe) (**TABLE 21.2**). One or more of these markers are detectable during phases of HBV infection (6).

TABLE 21.2 Hepatitis B Serologic Profile Interpretation for End-Stage Kidney Disease (ESKD) Patients

Serologic Test Profile	Results	Interpretation	ESKD Differences
HBsAg Total anti-HBc Anti-HBs	Negative Negative Negative	Susceptible	
HBsAg Total anti-HBc Anti HBs Anti-HBc IgM	Negative Positive Positive Negative	Immune due to natural infection	
HBsAg Total anti-HBc Anti-HBs	Negative Negative Positive	Immune due to hepatitis B vaccination	Vaccine induced transient HBsAg positivity can be seen in HD populations[a]
HBsAg Total anti-HBc IgM anti-HBc Anti-HBs	Positive Positive Positive Negative	Acutely infected	
HBsAg Anti-HBc IgM anti-HBc Anti-HBs	Positive Positive Negative Negative	Chronically infected	ESKD patients may be anti-HBc core alone positive and have +HBV DNA.
HBsAg Anti-HBc Anti-HBs	Negative Positive Negative	Four possible interpretations: 1. Resolved infection 2. False-positive anti-HBc, susceptible 3. Low-level chronic infection 4. Resolving acute infection[b]	ESKD patients with this pattern should be immunized but also have HBV DNA PCR, and if positive, evaluate for treatment criteria (see algorithm).

[a]Because of the possibility of transient vaccine-induced HBV antigenemia, defer HBsAg testing for at least 4 weeks after vaccination to avoid false positives.
[b]The pattern noted in the table, with the designation of possible "resolving acute infection" may be seen during the window period between disappearance of HBsAg and appearance of anti-HBs.
HBsAg, hepatitis B surface antigen; IgM, immunoglobulin M; HD, hemodialysis; PCR, polymerase chain reaction.

HBsAg indicates ongoing HBV infection and the potential for transmission to others. Among newly infected patients (**FIGURE 21.2**), serum HBsAg is found 30 to 60 days after exposure to HBV and persists for variable periods. Anti-HBc antibody develops in all HBV infections, appearing at onset of liver enzyme elevations in acute infection and persisting for life. Acute infection can be detected by immunoglobulin M (IgM) anti-HBc antibody, which persists for up to 6 months (6).

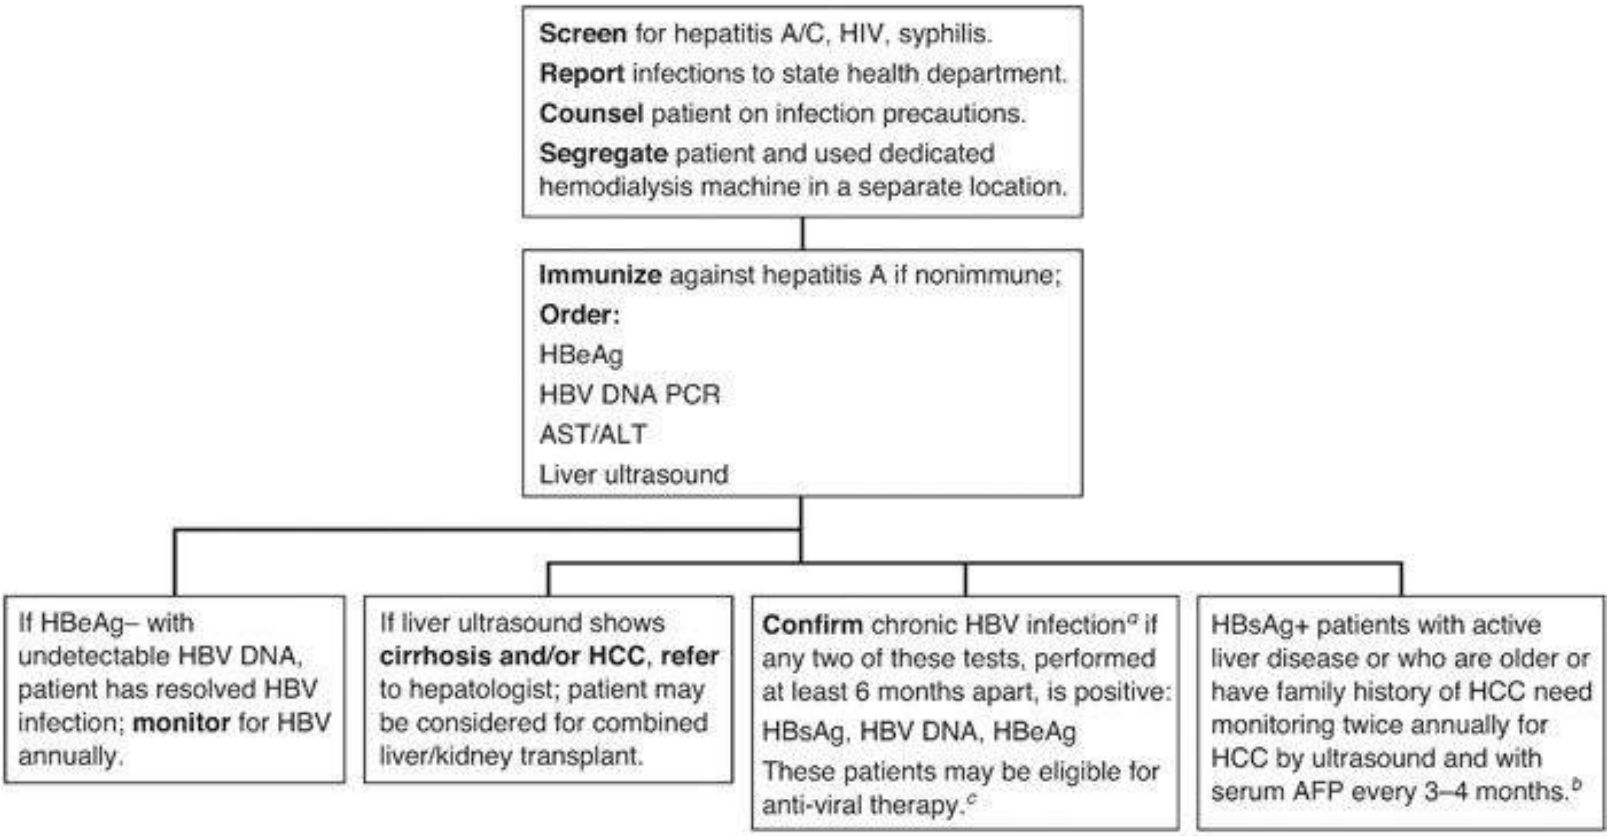

FIGURE 21.2 Incidentally discovered HBV (HBsAg+) in a dialysis patient. [a]For confirmation of chronic HBV infection, a positive result any two of these tests, performed at least 6 months apart is acceptable: HBsAg, HBV DNA, HBeAg. From Completeness of reporting of chronic hepatitis B and C virus infections–Michigan 1995–2008. *MMWR* 2013;62(06);99–102. [b]From Di Bisceglie AM. Hepatitis B and hepatocellular carcinoma. *Hepatology* 2009;49(5S)S56–S60; Chan TM. Hepatitis B virus and dialysis patients. UpToDate. Updated August 14, 2015. Accessed July 9, 2016. [c]Treat chronic HBV when abnormal ALT levels suggest liver inflammation and HBV DNA levels are greater than or equal to 4 to 5 log10 copies/mL. Optimal therapy for chronic HBV infection in dialysis patients is being studied. Clinical data support using interferon-alfa or nucleotide or nucleoside analogs for these patients (see **TABLE 21.4**). HCC, hepatocellular carcinoma; AFP, serum alpha fetoprotein, tumor marker for HCC; HBV, hepatitis B virus; PCR, polymerase chain reaction; AST, aspartate aminotransferase; ALT, alanine aminotransferase.

For those who recover from HBV (>85% of adults), HBsAg is eliminated from blood in 2 to 3 months, followed by the development of anti-HBs antibody. Anti-HBs antibody indicates immunity from HBV infection. After infection, most people are positive for anti-HBs and anti-HBc antibodies. In contrast, only anti-HBs antibody develops in persons who have been vaccinated against hepatitis B. Those who do not recover from HBV become chronically infected and remain positive for HBsAg (and anti-HBc). A small number (0.3% per year) eventually clear HBsAg and develop anti-HBs antibody (2,6).

Some individuals have anti-HBc antibody as the only HBV serologic marker. Isolated anti-HBc antibody can occur after HBV infection among persons who have recovered but whose anti-HBs antibody levels have waned or among persons who failed to develop anti-HBs antibody. HBV DNA is detected in <10% of persons with isolated anti-HBc antibody, and these persons are unlikely to be infectious to others. For most people with isolated anti-HBc antibody, the result appears to be a false positive. A primary anti-HBs antibody response develops in most of these individuals after a three-dose hepatitis B vaccine series. We have no data on response to vaccination for hemodialysis patients with this serologic pattern (2,6).

HBeAg can be detected in serum of those with acute or chronic HBV infection, usually appearing shortly after the appearance of anti-HBc. The presence of HBeAg correlates with viral replication, whereas anti-HBe correlates with the loss of replicating virus. All HBsAg-positive people should be

considered infectious, regardless of HBeAg or anti-HBe status. HBV infection can also be detected using tests for HBV DNA. These tests are most commonly used for persons being treated with antivirals (2,6).

All hemodialysis patients should be screened for hepatitis B [HBsAg, anti-HBc total, anti-HBs, and alanine aminotransferase (ALT)] upon admission to the dialysis unit. It is important to note that in chronic uremia, the serum aminotransferases are spuriously low in chronic HBV infections and must not be relied upon to indicate which patients need hepatitis screening (4). Nonimmune individuals should be immunized and screening for HBsAg repeated monthly until seroconversion from vaccination has been documented. Individuals who are anti-HBs and anti-HBc positive require no additional HBV testing because they are immune. After vaccine-induced seroconversion to anti-HBs positive (≥10 mIU/mL) dialysis, patients should be screened annually for anti-HBs. A booster dose of vaccine should be given if anti-HBs declines to <10 mIU/mL, and annual testing should continue thereafter.

Since 1977, the recommendation has been that HBsAg-positive persons should be isolated in a separate room, using separate machines, equipment, instruments, and supplies. Staff members assigned to HBsAg-positive patients should not be assigned to HBV-susceptible patients during the same shift. Dialysis equipment assigned to HBsAg-positive patients must not be shared by HBV-susceptible patients, and the routine cleaning and disinfection of equipment and environmental surfaces is of paramount importance. HBV is viable for up to 7 days on environmental surfaces and has been detected in dialysis centers on clamps, scissors, dialysis machine controls, and doorknobs. Blood-contaminated surfaces are a reservoir for HBV transmission, and dialysis staff members must take great care not to transfer virus to patients from these contaminated surfaces by their hands or gloves or through contaminated supplies (6).

Hepatitis B Virus Vaccine Recommendations

HBV vaccination recommendations for susceptible hemodialysis patients and staff include documentation of baseline serologies followed by three intramuscular doses of vaccine, with the second and third doses given at 1 month and 6 months after the first dose. Because immunocompromised persons have lower vaccine response rates, both the Recombivax HB and Engerix-B vaccine formulations have separate, U.S. Food and Drug Administration (FDA)-approved, recommendations for predialysis versus dialysis-dependent persons. With Recombivax HB, dialysis-dependent patients should receive 40 µg in 1 mL at 0, 2, and 6 months, whereas the recommended Engerix schedule for dialysis patients is for 40 µg at 0, 1, 2, and 6 months. All doses should be administered in the deltoid by the intramuscular route. Since hepatitis B vaccine became available, no HBV infections have been reported among vaccinated hemodialysis patients if they maintained protective levels of antibody to HBV. Fifty percent to 70% of nonresponders will respond to three additional doses. For nonresponders after six doses of vaccine, no data support additional doses. Among successfully immunized hemodialysis patients whose antibody titers subsequently declined below protection, data show that most respond to a booster dose. Periodic hepatitis B antibody screening of vaccine responders in the hemodialysis unit should permit identification of individuals in need of a booster dose to maintain immunity (6,11).

HEPATITIS C VIRUS SCREENING

Because morbidity and mortality rates are higher in HCV-infected hemodialysis patients, these individuals should be screened at initial entry to hemodialysis, and annually thereafter if they engage in high risk

behaviors, including injection drug use, intranasal cocaine use, or are men who have sex with men. Screening should use both ALT and an enzyme immunoassay (EIA) or the supplemental recombinant immunoassay (RIBA) that detects anti-HCV antibodies. The CDC has recommended monthly ALT screening for HCV-negative persons, regardless of risk factors, as early detection of an infection would permit consideration of therapy (**FIGURE 21.3**) (6). The EIA is at least 97% sensitive, but it does not distinguish between acute, chronic, or resolved HCV infection, and therefore, a positive antibody test should be followed by a reverse transcriptase polymerase chain reaction (RT-PCR) assay for HCV, which is commonly used in clinical practice and commercially available. Persistent viremia with HCV defines chronicity, which is seen in some 85% of infections. After treatment, or after spontaneous viral clearance (which may occur in 15% to 45% of infected persons), a sustained virologic response (SVR) is defined by finding undetectable HCV by RT-PCR after a 12- (SVR12) or 24-week (SVR24) interval (26). Regardless of whether a hemodialysis patient with HCV is a candidate for specific HCV therapy, knowledge of this comorbidity allows the clinician to counsel the patient about prognosis and about basic health maintenance measures that may improve outcomes. HCV-infected persons should abstain from alcohol because it accelerates fibrosis progression; avoid excessive acetaminophen use; avoid behaviors such as sharing of needles, razor blades, or toothbrushes which may result in transmission of viral infection to others; and they should be immunized against both hepatitis A and B to prevent fulminant hepatitis superinfection (27). There is no vaccine available for prevention of HCV in 2015.

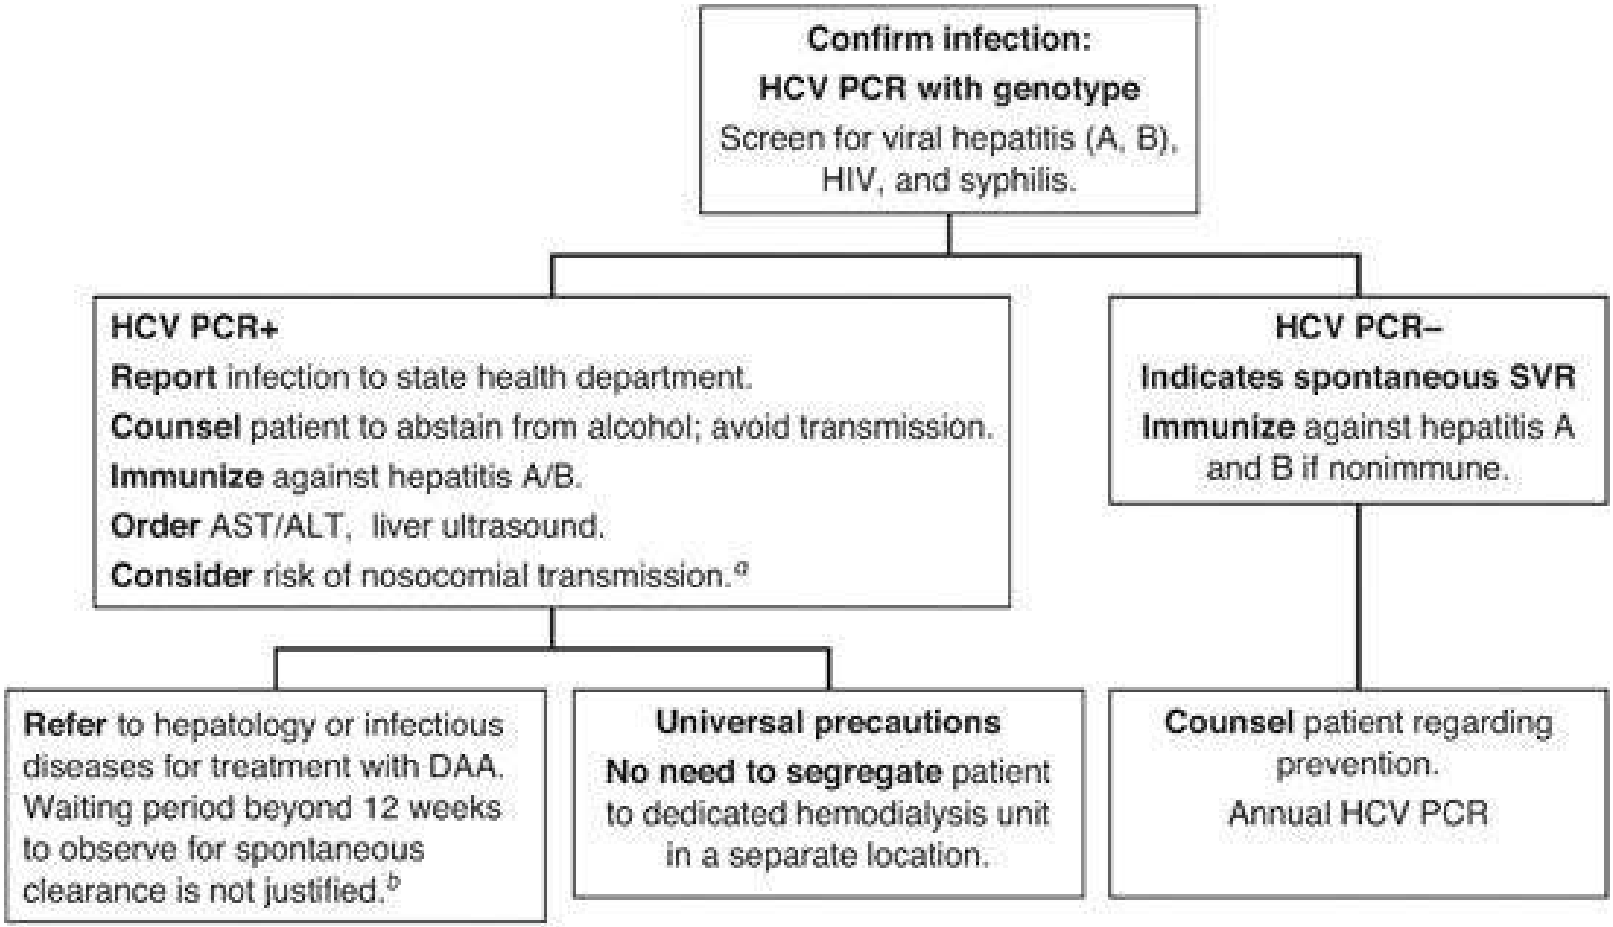

FIGURE 21.3 Incidentally discovered HCV (Aby+) in a dialysis patient. All oral regimens available depending on HCV genotype. [a]If nosocomial HCV transmission is suspected, HCV PCR should be performed and repeated in 2 to 12 weeks for each potentially exposed patient. There is a risk of false-negative PCR early after infection. [b]https://www.kidney.org/professionals/kdoqi/12-10-1601. HCV, hepatitis C virus; PCR, polymerase chain reaction; AST, aspartate aminotransferase; alanine aminotransferase; DAA, directly acting antiviral therapy; SVR, sustained virologic response.

TREATMENT OF HEPATITIS C, HEPATITIS B, AND HUMAN IMMUNODEFICIENCY VIRUS IN HEMODIALYSIS PATIENTS

Treatment of Hepatitis C in Hemodialysis Patients

The higher mortality rate of HCV-infected hemodialysis patients creates a significant motivation to consider HCV treatment in these individuals, especially if kidney transplantation is being considered. HCV infection results in worse survival of both patients and organ grafts after transplantation. Posttransplant diabetes mellitus is also more common in patients with HCV infection. Because organ transplant is associated with accelerated fibrosis progression (28), it is advisable to consider treating HCV before kidney transplant. Direct-acting, all oral antiviral drugs for hepatitis C have simplified therapy and improved SVR rates to over 90% for many patient populations. Still, treatment of HCV during hemodialysis requires ongoing study due to limited information about safety and efficacy of anti-HCV drugs in this setting. Current guidelines continue to recommend pegylated interferon and dose-adjusted ribavirin for patients with HCV genotype 2,3,5, or 6 infections and creatinine clearance (CrCl) below 30 mL/min (rating: class IIb level B) (**TABLE 21.3**). For genotypes 1a, 1b, and 4, patients with CrCl below 30 mL/min, who do not have cirrhosis, can be treated with daily fixed dose combination oral combination therapies (in 2015, these included paritaprevir, ritonavir, ombitasvir, and dasabuvir with or without ribavirin at reduced doses) (28). Some of these oral combinations have been used successfully during hemodialysis; however, anemia and other side effects (liver enzyme elevations) may be severe, and these patients must be managed in consultation with hepatology or infectious disease specialists.

TABLE 21.3 Dosing of Hepatitis C Medications in Dialysis

HCV Genotype	Drug	Normal Dose	Hemodialysis Adjustment
	Ribavirin (RBV)[a]	1,000–1,200 mg daily (weight based)	200 mg daily or thrice weekly; after dialysis
1a or 1b	Ombitasvir/ paritaprevir/ritonavir (part of dose pack)[b]	12.5 mg/75 mg/50 mg 2 tablets po daily × 12–24 wk	Not defined; limited clinical data, no adjustment
1a or 1b	Dasabuvir (part of dose pack)[b]	250 mg 2 tablets po daily × 12–24 wk	Limited clinical data exist, no adjustment
1a or 1b	Four-drug dose pack +/− RBV	RBV added for HCV genotype 1a; not needed for genotype 1b	A recommended regimen for HCV genotype 1b
1a, 1b, 4	Elbasvir/grazoprevir	50 mg/100 mg po daily for 12–16 wk	Limited clinical data no adjustment
2,3,5, or 6	Pegylated interferon 2a	180 μg sc weekly with daily RBV	135μg sc weekly with daily RBV

[a]RBV should be discontinued if hemoglobin level declines by more than 2 g/dL despite erythropoietin.
HCV, hepatitis C virus; po, by mouth; sc, subcutaneous.
From Recommendations for Testing, managing, and treating hepatitis C. http://hcvguidelines.org/sites/default/files/HCV-Guidance_April_2016_d1.pdf. Accessed July 9, 2016.

Because studies of all oral direct-acting antiviral drugs for HCV during hemodialysis are ongoing, we continue to rely on interferon-based regimens for non-genotype 1 or 4 patients in 2015 (28). Studies of interferon α (IFN-α) monotherapy in hemodialysis patients demonstrate SVR rates of 33% to 40%, which are generally higher than for those without kidney disease. High adverse event rates are reported for these studies as well, leading to caution in making generalized recommendations for the HCV-infected dialysis patient. Pegylated interferon is still used in combination with oral antivirals in certain patients with HCV

genotypes 3, 4, 5, and 6 (28). Because ribavirin is cleared by the kidney and causes a dose-related hemolysis, HCV-infected hemodialysis patients who need this drug must be carefully monitored for hemolysis and require significant dose reduction. Treatment should be individualized, focused primarily on patients who are renal transplant candidates, and undertaken only by experienced clinicians who can inform patients about potential benefits and risks. Proactive screening for HCV in chronic kidney disease (CKD) patients should lead to HCV treatment during earlier stages of CKD, allowing better tolerability of the best antiviral regimens and avoiding some of the toxicities that cause concern during hemodialysis (13). Publication of data for specifically targeted antiviral therapy for hepatitis C will be a welcome development for the HCV infected patient on chronic hemodialysis (29).

Treatment of Hepatitis B in Hemodialysis Patients

Recommendations for the treatment of HBV infection, including for hemodialysis patients, have been published in the guidelines of the American Association for the Study of Liver Diseases (AASLD) (30). Antiviral therapy should be provided to patients with established chronic infection (HBsAg+ for more than 6 months) who have evidence of viral replication (HBV DNA >20,000 IU/mL if HBeAg positive; HBV DNA >2,000 IU/mL if HBeAg negative) and evidence of liver disease (ALT greater than 2 times normal or moderate/severe hepatitis on biopsy) (30,31). The goal of therapy is viral suppression and prevention of viral complications such as cirrhosis or hepatocellular carcinoma. In patients with HBV-associated kidney diseases, including polyarteritis nodosa or immune complex glomerulonephropathy, HBV treatment before the patient requires dialysis is important and can facilitate remission of proteinuria and preservation of renal function (31). Treatment should be with one of six approved antiviral medications. While pegylated IFN-α adefovir or entecavir is the preferred initial antiviral for the general population with chronic HBV, interferon is poorly tolerated. Entecavir is favored in patients with kidney disease because of a high genetic barrier to resistance and favorable renal safety profile (31). Although lamivudine has the longest track record in hemodialysis, it engenders high rates of viral resistance and is considered suboptimal as a first-line treatment option (31). Prior treatment with lamivudine leads to resistance mutations for entecavir; such patients may be treated with tenofovir or adefovir in hemodialysis (30,31). Adjustments of adult dosage of nucleoside/nucleotide analogues should be in accordance with CrCl (**TABLE 21.4**). In hemodialysis patients, adefovir dose is only 10 mg weekly following dialysis; entecavir dose is .05 mg (nucleoside analogue naive) to 0.1 mg daily in lamivudine refractory patients, or 0.5 mg every 7 days (32). Telbivudine is dosed at 600 mg every 96 hours, with no supplement following dialysis. Tenofovir is given at 300 mg every 7 days after dialysis. Patients who fail to respond to IFN-α may be re-treated with nucleoside analogues. Those who fail to achieve a primary response as evidenced by <2 log10 decrease in serum HBV DNA level after 6 months of nucleic acid therapy may be switched to an alternative treatment (30). A test for HBV resistance mutations should be performed to differentiate primary nonresponse from breakthrough infection and to guide subsequent therapeutic choices. The recommended treatment duration for HBeAg-positive HBV is 48 weeks for peg IFN-α. Duration of nucleoside analogue treatment depends on HBeAg status. Most patients will require very long-term suppressive therapy. All patients with cirrhosis require life-long treatment with nucleoside/nucleotide analogues (32). However, for noncirrhotic, HBeAg-positive chronic HBV, treatment may be discontinued if the patient has achieved HBeAg seroconversion and completed at least 12 months of additional

treatment after appearance of anti-HBe, with persistently normal ALT and undetectable HBV DNA. If HBV DNA testing is not available, treatment should be continued until 12 months after the patient has achieved HBsAg clearance, regardless of prior HBeAg status (32). Patients with compensated cirrhosis should receive long-term treatment (2,4).

TABLE 21.4 Dosing of Hepatitis B Medications in Dialysis

Drug	Normal Dose	Hemodialysis Adjustment
Adefovir	10 mg po q24 h	10 mg po weekly (dose after dialysis)
Entecavir	0.5 mg po daily	0.05 mg q24 h or 0.5 mg po q7 d
Entecavir	For lamivudine refractory or decompensated liver disease	0.1 mg q24 h or 1 mg q7 d
Lamivudine	300 mg po daily	50 mg po once, and then 25 mg q24 h (dose after dialysis on dialysis day)
Telbivudine	600 mg po daily	Tablets: 600 mg po q96 h Solution: 120 mg po q24 h (after dialysis on dialysis day)
Tenofovir	300 mg po daily	300 mg po once weekly dose after dialysis; consider alternative for treatment of HBV and/or HIV

po, by mouth; HBV, hepatitis B virus; HIV, human immunodeficiency virus.

Treatment of Human Immunodeficiency Virus in Hemodialysis Patients

With the advent of HAART, survival of HIV-infected dialysis patients has significantly improved in the United States. Using the United States Renal Data System database, 6,166 HIV-infected patients with ESKD who received dialysis in the United States were evaluated. The majority of the patients were black (89%), 7.4% white, and 3% other. From 1990 to 1999, the annual death rates in HIV-infected dialysis patients declined from 458 to 240 deaths per 1,000 patient-years, reflecting the introduction of HAART in 1995 to 1996 (33). Detailed information exists regarding the metabolism and pharmacokinetics of HIV therapeutics in renal insufficiency (34), and quite a few of these medications (including abacavir, efavirenz, etravirine, rilpivirine, nevirapine, most protease inhibitors, enfuvirtide, dolutegravir, elvitegravir, and raltegravir) require no dosage adjustment in renal insufficiency. Thus, HIV-infected patients on chronic hemodialysis may continue with HAART, so long as their regimen has been reviewed for drugs which require dose adjustment in kidney disease (**TABLE 21.5**). Regularly updated guidelines regarding HIV therapy and dose adjustment for renal insufficiency may be found at https://aidsinfo.nih.gov/guidelines. HIV patients require no additional management considerations in the hemodialysis setting other than universal precautions and patient education regarding preventing transmission to others.

TABLE 21.5 Dosing of Human Immunodeficiency Virus Medications in Dialysis

Drug	Normal Dose	Hemodialysis Adjustment
Abacavir	300 mg po bid	None
Didanosine	250 mg (<60 kg)/400 mg (>60 kg) po qd	75 mg (solution) to 125 mg po qd (weight based)
Emtricitabine	200 mg tablet po qd	200 mg tablet po q96 h or 60 mg po q24 h (solution)
Lamivudine	300 mg po qd or 150 mg po bid	1 × 50 mg, then 25 mg po q24 h
Tenofovir	300 mg po qd	300 mg po q7 d
Zidovudine	300 mg po bid	300 mg po qd
Efavirenz	600 mg po qd	None
Etravirine	200 mg po bid	None
Nevirapine	200 mg po bid	Limited data
Rilpivirine	25 mg po qd	None
Atazanavir	400 mg po qd	300 mg qd with 100 mg ritonavir qd if treatment naive
Darunavir/ritonavir	800 mg/100 mg po qd	None
Darunavir/cobicistat	1 tablet po qd	None
Fosamprenavir	1,400 mg po bid	None
Indinavir	800 mg po qd	None
Lopinavir/ritonavir	400 mg/100 mg po bid	None
Nelfinavir	1,250 mg po bid	None
Ritonavir (rtv) (booster)	100–400 mg po qd	None
Saquinavir/rtv	1,000 mg/100 mg po bid	None
Tipranavir/rtv	500 mg/200 mg po bid	None
Dolutegravir	50 mg po qd–bid	None
Elvitegravir	85–50 mg po qd	None
Raltegravir	400 mg po bid	None
Enfuvirtide (T-20)	90 mg sc bid	None
Maraviroc	Dose differs based on concomitant medications or potential drug–drug interactions.	Without CYP 3A inhibitors; 300 mg po bid; for orthostasis reduce to 150 mg po bid

Coformulated HIV drugs are to be avoided in hemodialysis.
From Panel on Antiretroviral Guidelines for Adults and Adolescents. Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents. Washington, DC: U.S. Department of Health and Human Services. http://aidsinfo.nih.gov/contentfiles/lvguidelines/AdultandAdolescentGL.pdf. Accessed July 9, 2016; Appendix B, Table 7.

INFECTION CONTROL MEASURES IN THE DIALYSIS UNIT

In 2001, the CDC issued recommendations for preventing transmission of infections among chronic hemodialysis patients. These recommendations were updated and clarified in 2008 and also incorporated by reference into the CMS conditions for coverage for ESKD facilities. As a result, since October 2008, all ESKD facilities must follow CDC recommendations in order to receive Medicare reimbursement for outpatient dialysis (7). Knowledge of guidelines for prevention of HBV and HCV in the dialysis setting and infection control practices were assessed in a CDC national survey. In 2002, 63% of these centers reported reuse of disposable dialyzers, most of whom reprocessed them at their own facilities. Most centers reported using per acetic acid (72%), while 20% used formaldehyde, and 4% used heat or glutaraldehyde for disinfection. The practice of dialyzer reuse is considered safe if performed according to recognized protocols (10).

General infection control precautions for all patients include wearing disposable gloves during patient care, with removal of gloves and hand washing between patients. Nondisposable items that are not disinfectable (such as cloth covered blood pressure cuffs) should be dedicated for use on a single patient (6).

Multiple-dose vials containing medications or diluents taken to a patient station should be used only for the designated patient. This guideline was updated and clarified by CDC in August 2008 to specify that all single-use injectables must be dedicated for use on a single patient and be entered one time only to prevent transmission of both bacteria and blood-borne viruses. When multiple-dose medication vials are used, they should be assigned to a single patient whenever possible; patient doses should be individually prepared in a centralized area away from the dialysis stations. Multiple-dose medication vials should not be carried from station to station. Medication vials, syringes, or supplies should not be carried in pockets. All units need clean areas that are clearly designated for preparation and storage of medications and unused equipment (6). In addition, dialysis centers are required to report clusters of infections and adverse events to local public health authorities (7).

External venous and arterial pressure transducer filters/protectors should be used for each patient treatment to prevent contamination of dialyzer pressure monitors. Filters and protectors should be changed between each patient and not reused. However, internal transducer filters are not changed routinely between patients. Dialysis stations must be disinfected between patients, with special attention to cleaning control panels and frequently touched surfaces. All fluid should be properly discarded; used dialyzers and tubing must be placed in leak-proof containers during transport to disposal or reprocessing areas (6).

The HBsAg-positive patient must be dialyzed in a separate room using separate equipment, machines, and supplies. Staff taking care of HBsAg-positive patients may not care for HBV-susceptible patients during the same shift (6). Neither HIV- nor HCV-infected patients require dialysis in separate rooms.

POSTEXPOSURE PROPHYLAXIS GUIDELINES FOR PATIENTS AND STAFF

Human Immunodeficiency Virus

Recommendations from the U.S. Public Health Service were updated in 2013 and reflect better safety and tolerability of new antiviral medications (35,36). PEP with a three-drug antiviral regimen (emtricitabine, tenofovir, and raltegravir) is recommended whenever occupational exposure to HIV has occurred. It is important to document the HIV status of the source patient to determine management (36). Rapid HIV tests for source patients of unknown serostatus can expedite decisions regarding HIV PEP after occupational exposures. If PEP is offered, and the source patient is later determined to be uninfected, the PEP should be discontinued. Most HIV exposures do not result in the transmission of infection. The average risk for acquisition of HIV, after exposure to a known HIV-infected patient, is 0.3% per needle stick exposure and only .09% per mucous membrane blood splash. Therefore, the potential toxicity of antiretroviral drugs must be carefully considered before making a decision about PEP (35). After an exposure, the injured site or splashed mucous membrane should be immediately and thoroughly washed for 10 minutes with soap and water. The injury report should be made as soon as possible after the exposure to facilitate the institution of PEP within a few hours and no longer than 24 to 36 hours. Guidelines no longer recommend a two-drug regimen for lower risk exposures (i.e., those that did not involve large-bore hollow needles, deep punctures, visible blood on device, or needle used in patient artery or vein). Now, all occupational

exposures require greater than or equal to three-drug PEP (e.g., emtricitabine, tenofovir, and raltegravir). If the patient is known or suspected to have drug-resistant HIV infection, expert consultation should be sought to customize the regimen; however, PEP administration should not be delayed (36). The duration of PEP for a confirmed exposure is 28 days, during which time the exposed health care worker should be counseled to abstain from unprotected sex, blood or tissue donation, or breastfeeding. PEP should be discontinued if the source patient is later determined to be HIV negative. Further details regarding risk assessment and PEP may be found at https://aidsinfo.nih.gov.

Expert Consultation Is Advised in the Following Situations

A report of an occupational exposure should be done no later than 72 hours after the incident and should include whether it is an unknown source, known or suspected pregnancy in the exposed person, breastfeeding in the exposed person, suspected resistance of the source virus to antiretroviral agents, toxicity of the initial PEP regimen, or serious medical illness in the exposed person (36). For all of these situations, local experts may be consulted and/or the National Clinician's Postexposure Prophylaxis hotline (PEP line; 1-888-448-4911) should be contacted. Whether or not expert consultation is sought, PEP should be initiated within hours of the exposure, not days later.

Serologic Follow-up after Exposure to Human Immunodeficiency Virus

Follow-up for the HIV-exposed health care worker should start with a baseline HIV antibody test by EIA and a follow-up appointment within 72 hours of exposure. HIV testing is repeated at 6 weeks, 12 weeks, and 6 months after the exposure. If a newer, fourth-generation combination HIVp24 antigen–antibody test is utilized, then HIV testing may be concluded after the 12-week test (36). In the particular circumstance where the exposure source is coinfected with HIV and HCV and the exposed person becomes HCV infected, an additional 12-month serologic follow-up to exclude HIV infection is recommended (35,36).

Hepatitis B Virus

The risk of HBV infection from a needle stick contaminated by HBV-infected blood ranges from 6% to 30% depending on the HBeAg status of the source. Patients who are both HBsAg and HBeAg positive are more likely to transmit HBV (37). In contrast, the risk of developing clinical hepatitis from a needle carrying HBsAg-positive, HBeAg-negative blood is 1% to 6%, and the risk of developing serologic evidence of HBV infection in this instance is 23% to 37% (6).

Percutaneous injuries actually account for the minority of HBV infections among health care providers. In fact, most infected health workers do not recall an overt needle stick, but up to a third of infected providers do recall caring for an HBsAg-positive patient. It is important to remember that HBV can survive at room temperature in dried blood on environmental surfaces for at least 7 days. Thus, HBV infections in health providers with no history of occupational injury come from blood or body fluid exposures that inoculated virus into scratches or abrasions, or on mucosal surfaces. HBV transmission via contact with contaminated surfaces has been repeatedly demonstrated in hemodialysis units (6).

PEP for an occupational exposure to hepatitis B in a nonimmune person should include both hepatitis B immune globulin (HBIG) and the hepatitis B vaccine series. Regimens consisting of multiple doses of HBIG alone or hepatitis B vaccine series are 70% to 75% effective in preventing HBV infection. After a percutaneous exposure to HBsAg-positive blood, multiple doses of HBIG should be initiated within 1

week. Although the efficacy of combining HBIG and the vaccine has not been formally evaluated for occupational settings, the superior efficacy of this protocol after perinatal exposure, compared with HBIG alone, is extrapolated to the occupational setting. As individuals requiring PEP at their work are continually at risk for HBV infection, they should receive the hepatitis B vaccine series.

Hepatitis C Virus

HCV is not efficiently transmitted via occupational blood exposures. The incidence of HCV seroconversion after a needle stick from an HCV-positive source is 1.8%. Transmission seldom results from mucous membrane exposures to infected blood, and no transmission in health workers has been documented from skin exposures. Unlike HBV, environmental contamination with blood containing HCV is not a meaningful risk for transmission in the health care setting (with the exception of hemodialysis units where HCV transmission has been associated with poor infection control practices). The risk of transmission from exposure to fluids other than HCV-infected blood is probably quite low (6).

After a percutaneous exposure to HCV, the exposed person should have baseline HCV antibody and RNA testing within 48 hours. If negative, follow-up HCV RNA and ALT testing every 4 to 6 weeks for 6 months is recommended to permit identification and treatment of acute infection (28). HCV clearance after acute infection is most likely to occur within 12 weeks of the onset of symptoms and is more likely in patients with symptomatic hepatitis. Safety and efficacy data for IFN-sparing oral therapy for HCV are not yet available, *but* current guidelines advise at 4 to 6 months of monitoring for spontaneous virologic clearance before initiating treatment. If the decision is made to initiate treatment after 6 months, treatment as described for chronic hepatitis C is recommended (28).

CHAPTER 22

Endocrine Disorders in Dialysis Patients

Yin Oo, Naim Maalouf, and R. Tyler Miller

Patients with renal insufficiency or who are receiving dialysis may develop the same endocrine disorders that are found in the general population including thyroid, adrenal, gonadal, and pituitary diseases, the areas addressed in this chapter. The symptoms of diseases of these hormone systems may overlap and be confused with the symptoms of kidney disease. Patients with kidney disease are also subject to endocrine disorders that arise as a consequence of their kidney disease. These disorders include infertility, impotence, growth hormone (GH) resistance, and disorders of mineral and bone metabolism. Additionally, uremia, metabolic acidosis, and chronic inflammation, which frequently accompany chronic kidney disease and end-stage kidney disease (ESKD), cause a generalized hormone insensitivity syndrome, a situation that contributes to illness in dialysis patients and complicates the diagnosis of many endocrine disorders. In this chapter, thyroid, adrenal, and pituitary diseases are discussed because they occur in patients with kidney disease, may not be suspected, and may be difficult to diagnose because many tests of endocrine function are altered, or are not possible to carry out in kidney disease. Fertility and impotence will also be considered because these are important problems for many patients. In each section, the physiology of the endocrine system, the most common diseases that affect it, and the diagnosis and therapy if they differ from diagnosis and therapy in the normal patient population are reviewed. Disorders of vitamin D, parathyroid hormone (PTH), bone metabolism, and lipids are considered elsewhere.

THYROID DISORDERS

Introduction

An appropriate supply of thyroid hormone is essential for normal metabolism, cardiovascular function, mental status, and muscle strength. Diagnosis of thyroid disease in patients on dialysis is complicated by the fact that kidney disease can produce many of the same findings as thyroid disease and is often caused or accompanied by diseases such as diabetes, connective tissue diseases, and liver disease. These conditions can confound physical findings or alter standard tests used to evaluate thyroid function.

Thyroid physiology, the effects of kidney disease, the most common thyroid disorders, and their evaluation, and management are described in this section.

Thyroid Physiology

Thyroid function is regulated at multiple levels to ensure that only minimal variation in circulating thyroid hormone levels occurs. The complexity of regulation of thyroid hormone reflects its importance as a regulator of development as well as metabolism and essential systemic functions. The synthesis and secretion of thyroid hormone are primarily controlled by the hypothalamus and pituitary. Although T_4 is the predominant circulating form of thyroid hormone, T_3 is the biologically active form and is responsible for negative feedback at the levels of the hypothalamus and pituitary that can reduce thyrotropin-releasing hormone (TRH) and thyroid-stimulating hormone (TSH) secretion, respectively. The hypothalamus produces TRH, and TRH stimulates TSH production and release by the thyrotrophic cells in the anteromedial region of the pituitary. TRH production and secretion increase in response to reduced circulating levels of T_3. TSH is the primary trophic hormone for the thyroid gland and is responsible for its size, vascularity, and the level of thyroid hormone production as well as the release of thyroid hormone.

Iodine, an essential substrate of thyroid hormone synthesis that is concentrated in the thyroid by an active transport mechanism, contributes to control of thyroid hormone synthesis and release. Excess iodine inhibits iodine uptake and thyroid hormone synthesis by the thyroid. High levels or acute high doses (such as given with Lugol's solution or with iodinated contrast dye) reduce thyroid hormone synthesis and secretion. The primary route of iodine excretion is the kidney, and as renal insufficiency progresses, one would expect iodine to be retained. Dialysis patients have increased serum inorganic iodine and thyroid iodine content as well as an increased incidence of enlarged thyroid glands, but the full physiologic implications of this situation are not understood (1).

Both T_4 and T_3 are produced in the thyroid, but T_4 is the predominant secreted form. T_3 levels in the systemic circulation primarily reflect peripheral conversion of T_4 to T_3 by a monodeiodinase, a metabolic step that is also subject to regulation. Several proteins in the blood bind and transport thyroid hormone, including thyroid-binding globulin (TBG), prealbumin, and albumin. Except in rare circumstances, the effects of the other proteins are negligible compared to that of TBG. Loss of thyroid hormone through hemo- or peritoneal dialysis is negligible under normal circumstances (1). Finally, the sensitivity of tissues to thyroid hormone can be altered through changes in thyroid hormone receptor expression (2).

Serum thyroid hormone levels vary with changes in the concentration of serum thyroid hormone–binding proteins. In states such as liver disease (acute and chronic hepatitis, primary biliary cirrhosis), HIV infection, use of estrogen, tamoxifen, or pregnancy, TBG levels are increased, which will be reflected in increased total thyroid hormone. In the nephrotic syndrome, following administration of androgens, or high-dose glucocorticoids, and in major systemic illnesses or acromegaly, TBG levels are decreased, and total serum thyroid hormone levels are reduced. In the absence of other complicating factors, serum free T_3 (fT_3) and free T_4 (fT_4) levels, the biologically important parameters, are normal.

Peripheral conversion of T_4 to T_3 is controlled by at least three enzymes, types 1 (5′), 2 (5′), and 3 (5′) deiodinases. Type 1 deiodinase is expressed in liver, kidney, thyroid, the central nervous system (CNS), and the pituitary and is responsible for conversion of T_4 to T_3 in these tissues. This enzyme is

primarily responsible for systemic T_3 levels but may also produce reverse T_3 (rT_3), a metabolically inactive form of T_3. The peripheral conversion of T_4 to T_3 (presumably through inhibition of this enzyme) is reduced in a number of conditions that are important in nephrology including renal failure, malnutrition, liver disease, other systemic illnesses, and following trauma or surgery (euthyroid sick syndrome, nonthyroidal illness syndrome, or NTIS). Drugs that impair conversion of T_4 to T_3 include glucocorticoids, propranolol (>200 mg/d), amiodarone, and oral cholecystographic agents. The type 2 deiodinase is expressed in the CNS, pituitary, brown fat, and placenta. In states (see subsequent text) where peripheral conversion of T_4 to T_3 is reduced, type 2 deiodinase may maintain the CNS, pituitary, brown fat, and placenta in a relatively euthyroid state through *in situ* production of T_3. Type 3 deiodinase is expressed in the CNS, placenta, and skin and is the primary source of rT_3. rT_3 is an inactive metabolite of T_4 that increases in some conditions including burns, trauma, and uremia. The fact that local concentrations of T_3 may differ because of differential regulation of the deiodinases can make it difficult to determine if a hypothyroid state truly exists.

Measurement of Thyroid Function

The suspicion of thyroid disease is raised by the patient's history and physical findings and confirmed with laboratory measurement of thyroid hormone levels. Described below are the most commonly used assays with an emphasis on the laboratory characterization of the euthyroid-sick, NTISs because renal failure produces this pattern of laboratory values in up to 65% of dialysis patients (**FIGURE 22.1** and **TABLE 22.1**) (3–5). Sensitive assays are available for measuring fT_4, fT_3, rT_3, and TSH, and these measurements are the clinical tests used most commonly to establish the diagnosis of thyroid hormone excess or deficiency. Total serum T_4, T_3, and rT_3 are measured by radioimmunoassay (RIA for rT_3 is measured in special circumstances). Its level increases with alterations in peripheral deiodinase activity in systemic illnesses. T_4 is tightly bound by serum proteins (primarily TBG), and the level of total T_4 changes substantially with changes in the level of TBG. TBG may change markedly with disease or nutritional state so that a high or low total T_4 level may not be meaningful if the level of the thyroid hormone–binding protein is also high or low. Renal failure and dialysis do not directly affect TBG levels, although its levels may be reduced with persistent nephrotic range proteinuria, high rates of peritoneal protein loss, or following androgen administration for anemia in patients who might not also be receiving erythropoietin.

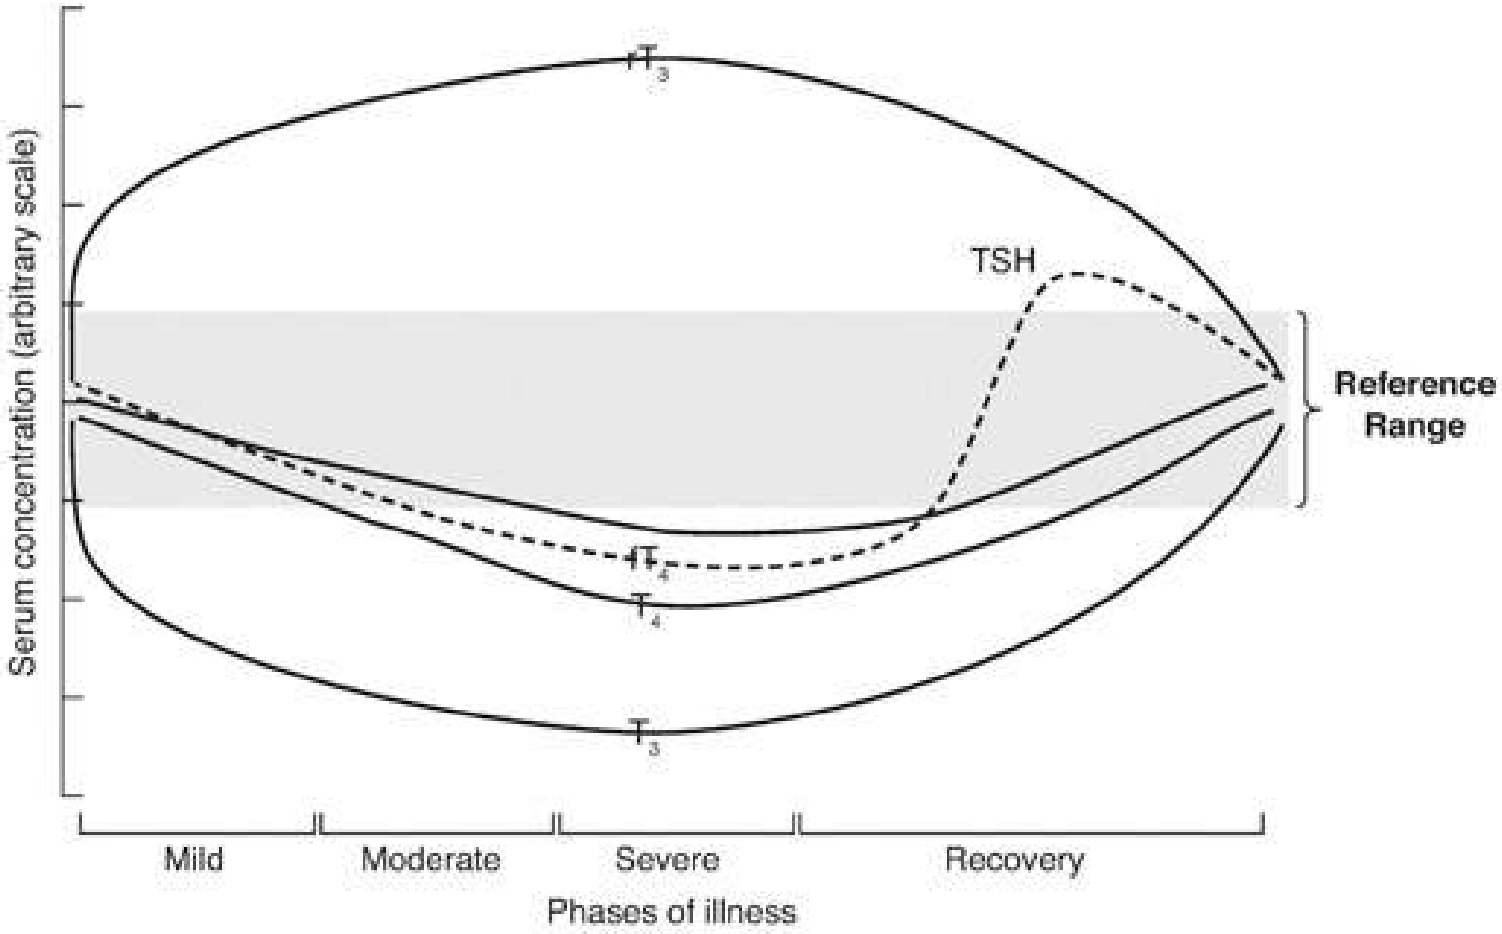

FIGURE 22.1 The varying levels of thyroid hormones, thyroid-stimulating hormone (TSH), and free T_4 (fT_4) in the "euthyroid-sick syndrome." Patients with kidney disease and receiving dialysis treatment may have thyroid function test values that correspond to any severity of illness shown on the graph when they do not have intrinsic thyroid, pituitary, or hypothalamic pathology. (Adapted from Meuwese CL, Dekkers OM, Stenvenkel P, et al. Nonthyroidal illness and the cardiorenal syndrome. *Nat Rev Nephrol* 2013;9:599–609.)

TABLE 22.1 Changes in Thyroid Function Tests in Euthyroid/Sick, Hypothyroid, and Thyrotoxic States

	Normal	Euthyroid/Sick	Hypothyroid	Thyrotoxic
TSH	0.5–5 mIU/L	Normal to slightly decreased early; increased during recovery	Increased	Decreased
Free T_3	2.0–3.5 pg/mL	Decreased	Decreased	Increased
Free T_4	0.9–1.7 ng/dL	Decreased	Decreased	Increased
rT_3	10–24 ng/dL	Increased	Decreased to normal	Normal

Reference values for TSH (0.5 to 5 mU/L or 0.5 to 5 μU/mL), free T_3 (2.0 to 3.5 pg/mL) or free T_4 (0.9–1.7 ng/dL), and reverse T_3 (10–24 ng/dL) are given as the normal values. The direction of the change in the serum value is shown under the heading for each condition. In many situations, not all values will be abnormal but may be at the upper or lower limits of the normal range.

TSH, thyroid-stimulating hormone; rT_3, reverse T_3.

From Larsen PR, Davies TF, Hay ID. The thyroid gland. In: Wilson JD, Foster DW, Kronenberg HM, et al., eds. *Williams Textbook of Endocrinology*. 9th ed. Philadelphia, PA: WB Saunders, 1998:389–515.

The biologically active form of the hormone is that which is "free" in the serum and not protein bound. In the past two decades, improved assays have allowed for more accurate measurement of true free thyroid hormone levels. Thus, in states of "pure" thyroid disease, the lack of specificity for total T_4 or T_3 is no longer a diagnostic problem because the level of fT_3 is a function of the level of fT_4. However, in conditions such as kidney disease, malnutrition, or other systemic diseases (euthyroid sick or NTISs), the activity of the peripheral deiodinases is altered, and conversion of T_4 to T_3 is not regulated normally (5,6). In these situations, serum fT_4 and fT_3 measurement are essential to fully characterize thyroid function.

Sensitive assays exist that allow direct measurement of TSH, the trophic hormone from the pituitary that participates in feedback regulation of thyroid function. TSH levels are a function of T_3 biologic activity in the hypothalamus where TRH production and release respond to T_3 levels and T_3 biologic activity in the pituitary. In primary thyroid disease, if T_3 levels are reduced, TSH levels rise. If T_3 levels are elevated, TSH levels are suppressed. However, hypothyroidism can occur as a result of a failure of the hypothalamopituitary axis resulting in low or inappropriately normal TSH levels, and thyrotoxicosis can result from increased secretion of TSH such as from a pituitary tumor. The normal range for TSH is 0.5 to 5 mU/mL. Patients who are thyrotoxic have serum TSH levels below 0.5 mU/mL, and patients who have hypothyroid have serum levels above 5 mU/mL. If pituitary failure is suspected, a TRH stimulation test can be performed.

Dialysis patients have at least one systemic illness, chronic kidney disease, and frequently others such as malnutrition and diabetes. These chronic illnesses (and others) alter the activity of peripheral deiodinases and cause an abnormal pattern of thyroid function tests, termed the *euthyroid-sick syndrome* (3,5). This patient population is also characterized by increased levels of circulating cytokines such as interleukin 6 (IL-6) that may also contribute to biochemical abnormalities including the euthyroid sick state (6). The euthyroid sick syndrome is characterized by reduced total and free serum T_3 and increased serum rT_3 as a result of increased peripheral deiodination of T_4 to rT_3. The degree of reduction of the serum T_3 level corresponds to the severity of the systemic illness (**FIGURE 22.1**). In mild to moderately severe illnesses, fT_3 is reduced, rT_3 is increased, but T_4, fT_4, and TSH levels are normal. With severe illness, the fT_4 levels may fall in the subnormal range. During recovery from a severe illness, the TSH level may rise to levels slightly above normal before normalizing. Consequently, thyroid hormone levels in dialysis patients must be interpreted using a euthyroid-sick pattern as normal.

Whether patients with the NTIS are in fact physiologically hypothyroid is not known. fT_4, fT_3, and rT_3 levels reflect systemic metabolism of T_4, while TSH levels reflect hypothalamic and pituitary levels of T_3. In the presence of illness where peripheral conversion of T_4 to T_3 is reduced, TSH levels may not reflect low T_3 levels because the conversion of T_4 to T_3 in the tissue responsible for sensing T_3 activity (hypothalamus and pituitary) is mediated by a deiodinase whose activity does not appear to change with systemic illness. In contrast, systemic measurement of thyroid hormones reflects metabolism by different deiodinases whose activity may change with systemic illness. Consequently, the CNS and pituitary may appear euthyroid, while the remainder of the body is hypothyroid. Administration of L-T_4 to severely ill patients has been studied but does not alter their outcomes (7,8). Survivors could be identified by their

high baseline T_3:T_4 ratios. Low serum T_3 levels in dialysis patients are associated with reduced survival (4). Preliminary studies in dialysis patients suggest that treatment of dialysis patients with low doses of T_3 results in a less favorable nitrogen balance and increased protein degradation (1).

Thyroid Diseases

Thyroid diseases can be separated into those that cause increased hormone levels (thyrotoxicosis), decreased hormone levels (hypothyroidism), those that produce nonfunctional nodules, and the inflammatory diseases of the thyroid.

Thyrotoxicosis

Thyrotoxicosis is a pathophysiologic condition that results from excess thyroid hormone. The precise manifestations of thyrotoxicosis depend on the magnitude of hormone excess, the age of the patient, and the presence of other illnesses such as cardiovascular disease and diabetes. In general, the effects of thyroid hormone excess represent an exaggeration of its normal physiologic response and are usually most prominent on metabolism and on the cardiovascular and nervous systems.

Elevated thyroid hormone levels cause an increase in metabolic rate that is reflected in increased calorie utilization, oxygen consumption, heat generation, and increased basal body temperature. Protein synthesis and breakdown are increased, but degradation exceeds synthesis, leading to weight loss and decreased body mass. Many such patients have an abnormal glucose tolerance that may simulate diabetes mellitus. Lipid metabolism is also altered with both increased synthesis and degradation of lipids, but with degradation exceeding synthesis, leading to increased serum free fatty acid levels, while triglyceride and cholesterol levels are decreased. The metabolic manifestations of thyrotoxicosis may be difficult to detect in patients with renal disease and those who are on dialysis because they overlap with those of renal failure or with chronic diseases such as diabetes mellitus that are commonly found in the dialysis population. Although kidney disease patients rarely are hyperthermic, they commonly are catabolic and glucose intolerant.

Thyroid hormone has a direct cardiostimulatory activity that leads to increased cardiac output through resting tachycardia (heart rate greater than 100 bpm), increased stroke volume, and decreased peripheral resistance. The increased cardiac output is a response to supply the increased oxygen demands and the requirement to dissipate heat. Patients with hyperthyroidism may also have increased blood pressure and a widened pulse pressure. Because of the high frequency of hypertension and alterations in total body volume in dialysis patients, these findings may not be valuable in identifying patients with thyrotoxicosis. However, arrhythmias, congestive heart failure, and a change in pattern of angina may provide excellent clues to the presence of thyrotoxicosis. Supraventricular arrhythmias, especially atrial fibrillation, are common and may be the presenting complaint in patients with thyrotoxicosis. In the absence of preexisting heart disease, congestive heart failure is an uncommon presentation of thyrotoxicosis. Patients with thyrotoxicosis and atrial fibrillation are commonly resistant to heart rate control with digitalis. The frequency, pattern, or severity of angina is frequently increased in thyrotoxic patients with coronary artery disease. Patients may complain of shortness of breath in the absence of congestive heart failure. This sensation may be due to reduced lung compliance and muscle weakness in some circumstances.

Thyrotoxicosis usually produces prominent effects in the nervous system. Patients complain of nervousness that is characterized by a short attention span, restlessness, and compulsion to move despite fatigue. These patients often have fast jerky movements and a fine rhythmic tremor of hands and tongue. They are emotionally labile and often complain of insomnia. Psychiatric disorders occur including manic-depressive, schizoid, and paranoid states. In patients with seizure disorders, the seizure threshold is lowered resulting in an increased frequency of seizures. The hyperkinetic state described is uncommon in dialysis patients, but fatigue, restlessness, inattention, psychiatric and emotional disturbances, and changes in seizure frequency occur frequently. Consequently, the existence of any one of this constellation of findings in a patient may not be helpful in suggesting thyrotoxicosis, but their appearance in a patient who was previously stable may be of diagnostic value.

Common gastrointestinal (GI) symptoms include increased motility (faster gastric and intestinal emptying and transit times) with less well-formed stools, and increased stool frequency. Overt diarrhea is rare. Appetite is generally increased in hyperthyroid patients, although it may be decreased in severe cases or in the elderly. Patients with kidney disease usually have decreased bowel motility, so apparent normalization of bowel function may be a clue to thyrotoxicosis. Hepatic dysfunction with elevated transaminases has been reported in thyrotoxicosis, possibly due in part to increased O_2 extraction in the splanchnic bed (9).

Increased levels of thyroid hormone alter the structure and function of muscle and bone. Patients complain of proximal muscle weakness and fatigability. These symptoms are usually partly due to wasting and loss of muscle mass but are also due to primary changes in the muscles. Myopathy is more common in men than women. In patients with normal kidney function, thyrotoxicosis leads to loss of bone mass with increased bone turnover, greater urinary excretion of Ca and PO_4, and turnover markers such as deoxypyridinoline, with reduced levels of serum PTH and vitamin D. In dialysis patients, the effects of excess thyroid hormone on bone mass presumably are similar, but they have not been reported.

Causes of Thyrotoxicosis

Dialysis patients develop thyrotoxicosis for the same reasons as patients with normal kidney function. The causes include Graves' disease or toxic diffuse goiter, toxic thyroid nodule, toxic multinodular goiter, thyroiditis, and rarely due to increased secretion of TSH due to a pituitary adenoma, increased secretion of TRH, or resistance of either the hypothalamus or pituitary to T_3. Graves' disease is the most common cause of thyrotoxicosis and is an autoimmune disease that results from circulating autoantibodies (thyroid-stimulating immunoglobulins or TSIs) that appear to be directed against the TSH receptor on the thyroid cell membrane. The disease is characterized not only by thyrotoxicosis but also by an infiltrative ophthalmopathy producing exophthalmos and dermopathy. Toxic multinodular goiter usually arises in a multinodular thyroid gland. The thyrotoxicosis is usually less severe than in Graves' disease, but it occurs in an older population so cardiovascular symptoms may be more prominent (2). Thyroid nodules may be more common in patients receiving chronic dialysis (10). Thyroiditis may be triggered by a viral infection, exposure to iodinated contrast material, or medications such as amiodarone.

Diagnosis of Thyrotoxicosis

Thyrotoxicosis may not be suspected in dialysis patients because the symptoms of thyrotoxicosis may be ascribed to other underlying illnesses such as cardiovascular disease, hypertension, and volume overload.

Many of the symptoms may be masked by medications such as β-blockers or other blood pressure medications. Weight loss may be masked by retained fluid or ascribed to gastroparesis. Nevertheless, new symptoms that are consistent with thyrotoxicosis, particularly cardiovascular symptoms, should suggest the possibility of thyrotoxicosis (**TABLE 22.1** and **FIGURE 22.2**). The complaint or finding of increasing neck size or a lump in the anterior neck is particularly valuable in identifying patients who may be thyrotoxic. Thyrotoxicosis is caused by elevated T_3, and a diagnosis of thyrotoxicosis requires elevated levels of fT_3 and/or fT_4, so these hormones should be measured. If thyrotoxicosis is caused by primary overproduction of thyroid hormone by the entire gland (Graves' disease) or by nodules (95% of cases), the TSH level will be suppressed. If thyrotoxicosis is caused by overproduction of TSH (pituitary tumor, hypothalamic lesion or ectopic production, <5% of cases), the TSH level will be elevated.

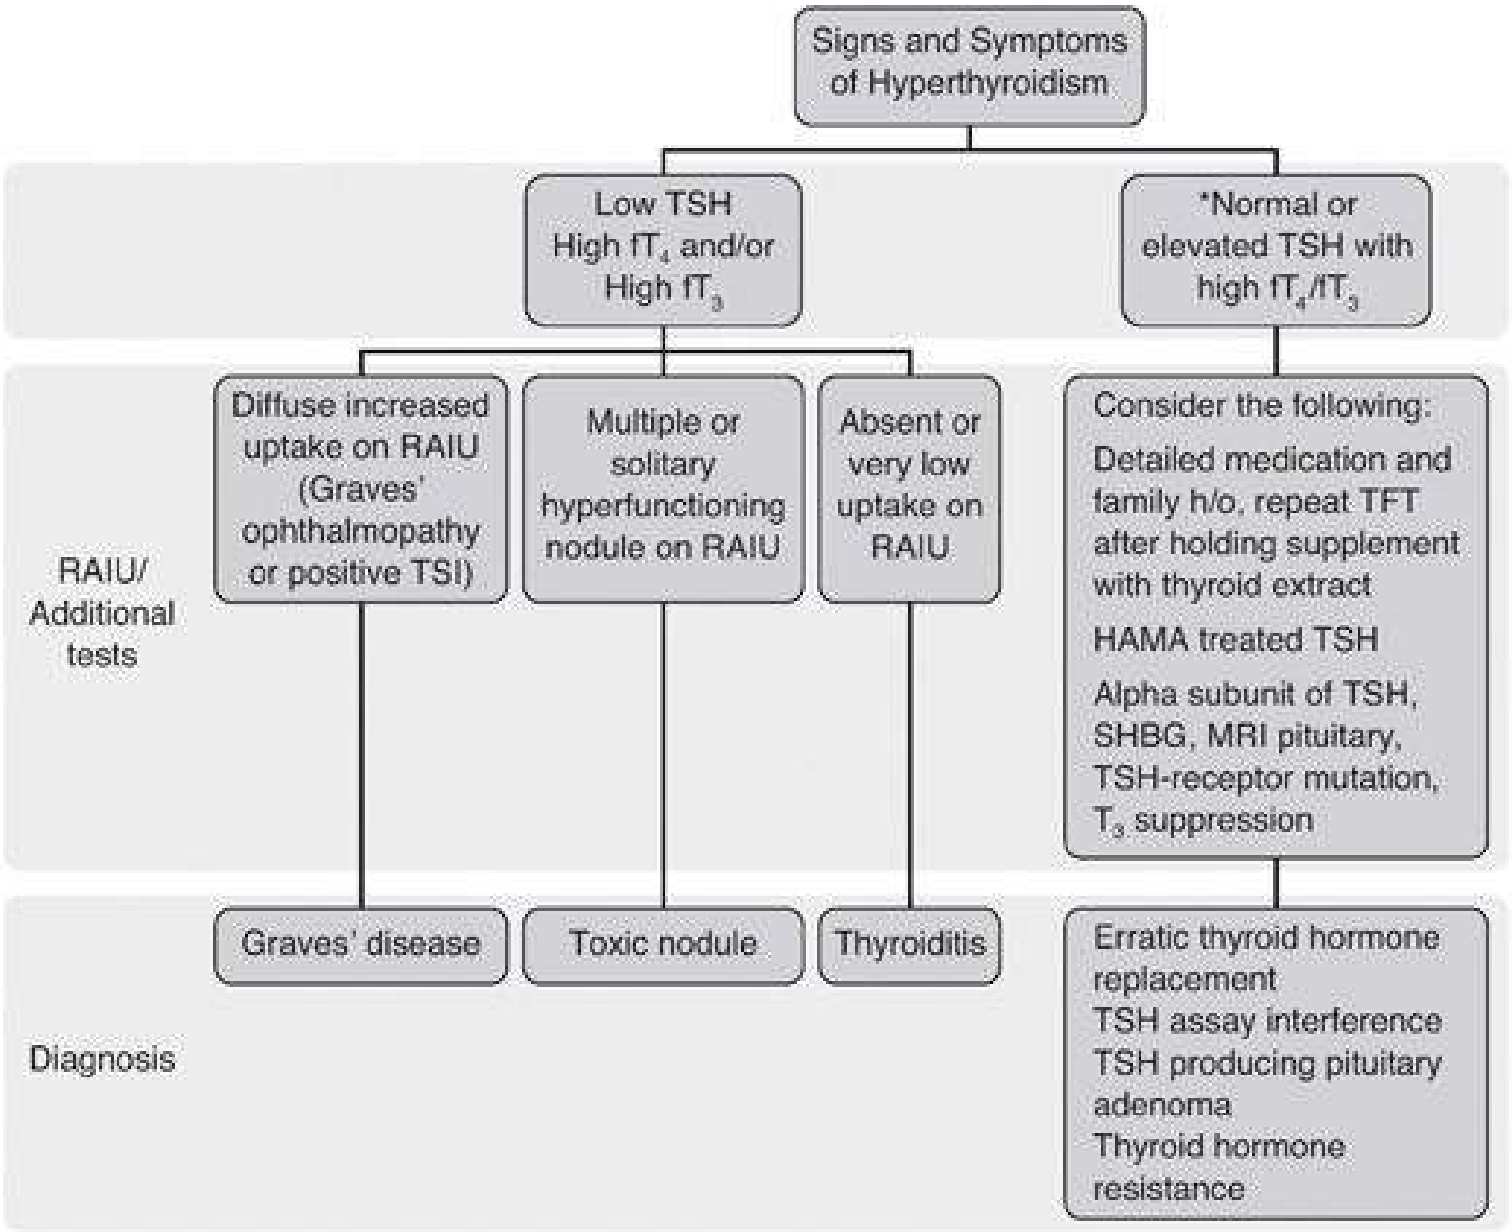

FIGURE 22.2 The detail diagnostic workup of this category is beyond the scope of this review. RAIU, radioactive iodine uptake scan; TSI, thyroid-stimulating immunoglobulin; TFT, thyroid function tests; HAMA, human anti-mouse monoclonal antibody; SHBG, sex hormone–binding globulin.

Treatment of Thyrotoxicosis

The immediate treatment of thyrotoxicosis in patients with kidney disease is the same as other patients and

includes the use of β-blockers, dexamethasone, and agents that block thyroid hormone synthesis and release (propylthiouracil and methimazole). In patients with renal failure, propylthiouracil can cause granulocytopenia, agranulocytosis, rheumatic syndromes, and hepatitis. However, the doses of both propylthiouracil and methimazole are not changed in dialysis patients. Radioactive ^{131}iodine (^{131}I) ablation may also be used, although it is cleared by both peritoneal and hemodialysis (11). Disposal of the radioactive effluent can be a problem for which guidelines do not exist.

Hypothyroid States

Hypothyroidism occurs for three general reasons: (a) most commonly, loss of functional thyroid tissue; (b) loss of trophic activity by TSH; and (c) defective hormone synthesis (as with iodine deficiency). Loss of trophic activity in pituitary or hypothalamic lesions represents approximately 5% of all cases of hypothyroidism. The symptoms of hypothyroidism are generally the opposite of those of thyrotoxicosis. They are even more difficult to identify in kidney disease and dialysis because like kidney disease, hypothyroidism results in generalized constitutional symptoms and gradual loss of function. Reduced glomerular filtration rate (GFR) is associated with hypothyroidism, and a GFR of <30 mL/min confers a risk of hypothyroidism that is increased approximately twofold over the normal population (GFR >90 mL/min) (12).

In hypothyroidism, the metabolic rate slows, resulting in decreased oxygen consumption; heat generation decreases; appetite decreases; and the rate of protein synthesis is reduced. The latter may be due to decreased effectiveness of GH and insulin-like growth factor 1 (also known as *somatomedin C*). The oral glucose tolerance test is flat, and the peak insulin response is delayed. The rate of degradation of insulin is decreased leading to an increased sensitivity to exogenous insulin. Patients also have increased capillary permeability which leads to peripheral edema. Cholesterol and triglyceride circulating concentration levels are elevated as a consequence of their decreased clearance, and high-density lipoprotein (HDL) levels are reduced. Superficially, none of these findings are specific for hypothyroidism and are seen frequently in dialysis patients.

Hypothyroidism reduces heart rate and myocardial contractility, diminishing pulse pressure and reducing cardiac output. The heart is enlarged, and a pericardial effusion frequently develops. Pleural effusions are also common. Electrocardiogram (ECG) abnormalities include sinus bradycardia, prolonged PR interval, reduced amplitude of the P wave and QRS complex, and nonspecific ST-segment and T-wave changes. These changes may contribute to congestive heart failure. Other than the bradycardia, these findings are commonly seen to progress slowly over months and are commonly seen on dialysis services in patients with normal thyroid function.

In hypothyroidism, GI motility is decreased and constipation is a frequent complaint. The mucosa of the GI tract is atrophic causing reduced absorption, but the decreased transit time partially compensates for the decreased absorption rate. Ascites consisting of mucopolysaccharide- and protein-rich fluid is common. Superficially, these findings are not pathognomonic for hypothyroidism and can occur for a variety of reasons in the dialysis population.

The most prominent symptoms in hypothyroidism are frequently found in the nervous system. They include reduced cognitive function, deterioration of memory, slow speech, syncope, and coma. Psychiatric symptoms may include paranoia or depression. Speech is thick and slurred as a consequence

of infiltration of the larynx and tongue by mucopolysaccharides. Movements are slow and appear uncoordinated and may be further compromised by compression of peripheral nerves by myxedematous deposits. Reflexes are slow due to altered nerve responses including delayed relaxation time. Myxedematous patients complain of stiff, sore muscles, but muscle strength usually remains intact.

Causes of Hypothyroidism

Loss of functional thyroid tissue occurs following ablation of hyperactive thyroid tissue (such as following ablative therapy for Graves' disease with ^{131}I), idiopathic hypothyroidism, or in the late stages of Hashimoto's thyroiditis (autoimmune thyroiditis). Excess iodine inhibits thyroid function by inhibiting thyroid uptake of iodine and thyroid hormone synthesis and release. As the primary route of excretion of iodine is the urine, one might expect high levels of iodine to accumulate in patients with renal failure. Regulation of iodine metabolism in kidney disease and dialysis patients has not been studied systematically, but ^{131}I is removed by hemodialysis and peritoneal dialysis (11). One report of three cases exists of hypothyroidism due to iodine accumulation in dialysis patients eating a high-iodine diet (13). Iodinated contrast agents may also represent an iodine load for dialysis patients that could affect thyroid function. Another group of patients who may be at risk for hypothyroidism are patients with iron overload syndromes (14). Metabolic acidosis causes reduced T_3, and T_4, levels and increased TSH levels with an increased sensitivity of TSH secretion to TRH stimulation (15). In dialysis patients, correction of metabolic acidosis increases TSH levels so the metabolic acidosis associated with kidney disease is a treatable cause of hypothyroidism (16).

Diagnosis of Hypothyroidism

Many of the symptoms of hypothyroidism are nonspecific and overlap with those of chronic kidney disease (17). Consequently, hypothyroidism may not be suspected and may go undiagnosed. Patients who are at particular risk for hypothyroidism are those who have a history of previous ablative treatment of thyroid disease, possibly those with other autoimmune endocrine diseases, or those whose general condition deteriorates for unexplained reasons. The physical signs of hypothyroidism such as delayed reflexes may be undetectable in a diabetic patient with neuropathy, or a slow pulse may be masked in a patient taking β-blockers, and may also be difficult to identify in dialysis patients who have many comorbid conditions and take many medications. Nevertheless, if present, delayed reflexes are valuable in making the diagnosis of hypothyroidism as long as other neurologic disorders are not present. If a patient is not taking medications that could slow the heart rate, then heart rate is also valuable in screening patients for hypothyroidism. Measurement of circulating thyroid hormone levels will usually reveal a "sick-euthyroid" pattern with a variable (low or normal) fT_4, low rT_3U, low fT_3, and normal or mildly elevated TSH. However, dialysis patients who are truly hypothyroid will have elevations of TSH with normal hypothalamopituitary function, so primary hypothyroidism can be diagnosed with a serum TSH in most situations. Whether mild elevations of TSH represent subclinical hypothyroidism, or whether this state represents a euthyroid CNS and pituitary with a hypothyroid periphery is not clear (2). Normal patients with minimal elevations of their TSH levels (<10 to 15 mU/mL) are usually not symptomatic. Isolated hypothyroidism is unusual in pituitary or hypothalamic lesions (see subsequent text), but if hypothyroidism is due to pituitary or hypothalamic failure (tumors, following radiation therapy, trauma), the TSH level may be extremely low (less than 0.5 mU/mL). In these situations,

evaluation of the pituitary and hypothalamus structure with either computed tomography (CT) or magnetic resonance imaging (MRI) scans and function with TSH and TRH stimulation tests is indicated. Corroborative evidence of hypothalamic or pituitary disease with reduced follicle-stimulating hormone (FSH), luteinizing hormone (LH), GH, and cortisol levels should also be sought.

Treatment of Hypothyroidism

Thyroid replacement therapy in hypothyroid patients on chronic dialysis is the same as that in other populations. In general, patients with kidney disease are at risk for cardiovascular disease if they have not already been diagnosed with it. Consequently, their thyroid hormone should be replaced slowly to avoid precipitating angina or congestive heart failure, unless the patient is comatose or severely ill with another diagnosis. The usual replacement dose of levothyroxine (T_4) is around 1.6 µg per kilogram body weight per day. Some physicians use thyroid extract (120 mg/d) or T_3 (liothyronine or cytomel, replacement dose 50 to 100 µg/d), but levothyroxine (T_4) has the advantage that the body can regulate its conversion to T3 and the serum half-life is longer (18). A role for T_3 in euthyroid-sick patients has not been established (2). The effectiveness and dosing of thyroid replacement therapy is usually followed by measuring serum TSH because no other physiologic or symptomatic parameter is sufficiently sensitive.

ANTERIOR PITUITARY DISORDERS

Introduction

The anterior pituitary gland integrates information from the brain (hypothalamus) and feedback from peripheral hormones to control production of its trophic hormones (19,20). The hormones produced by the anterior pituitary, adrenocorticotropic hormone (ACTH), GH, prolactin, TSH, FSH, and LH, all have specific effects on different tissues in the body, and their excess production as well as loss of their production produces specific syndromes. In general, syndromes of pituitary hormone excess can be related to individual hormones because they are individually controlled and produced in distinct cell types. In contrast, deficiency syndromes involve multiple or all of the hormones secreted because they are caused by processes that destroy the hypothalamus and/or pituitary. Prolactin is the exception because its synthesis and release are under tonic inhibitory control by the hypothalamus. Chronic kidney disease alters the regulation and response to GH, prolactin, FSH, and LH. The biology of these hormones is complex and not fully understood in normal conditions, and their biology remains only partially characterized in dialysis patients. TSH is discussed earlier in the section “Thyroid Diseases.”

Physiology

The anterior pituitary contains cells that produce several hormones including ACTH, GH, prolactin, TSH, FSH, and LH. Each hormone is produced by an individual cell type. Functioning tumors of the pituitary are usually clonal and produce one hormone of the anterior pituitary. The venous system that drains the hypothalamus forms a plexus in the anterior pituitary so that peptide-releasing factors descending from the hypothalamus control the activity of the pituitary cells and the release of ACTH, GH, prolactin, TSH, FSH, and LH. The six peptide-releasing factors are corticotrophin-releasing factor (CRF) that stimulates ACTH release, TRH that stimulates TSH release, gonadotropin-releasing hormone (GnRH) that simulates

FSH and LH release, growth hormone–releasing hormone (GHRH) that stimulate GH release, somatostatin that inhibits secretion of all of the pituitary hormones but is most potent in inhibiting GH release, and prolactin inhibitory activity (PRIH) that tonically inhibits prolactin release. PRIH may be several factors including dopamine. These hormones are also subject to regulation at the level of the pituitary by direct feedback mechanisms.

Growth Hormone

GH has a variety of growth-promoting and metabolic effects (19,20). GH is produced in the somatotrophs of the pituitary and is secreted under the dual control of GHRH (stimulatory) and somatostatin (inhibitory), which results in a pulsatile pattern of release. GHRH secretion is increased by dopamine, serotonin, α-adrenergic agonists, hypoglycemia, exercise, protein-rich food, and emotional stress and is inhibited by β-adrenergic agonists, free fatty acids, insulin-like growth factor 1, and GH. GH is carried in the serum primarily by a binding protein, growth hormone–binding protein (GHBP), which is derived from the GH receptor. Although GH has direct differentiating effects on some cell types, most of its effects are through stimulation of production of somatomedins or insulin-like growth factors 1 and 2 (IGF-1 and IGF-2). IGF-1 appears to replicate many of the biologic effects of GH, but the function of IGF-2 is less well defined. IGF-1 is produced locally in small quantities in response to GH, but the liver appears to be the main site of production. IGF is carried in the serum by a six-member family of binding proteins (IGFBP 1–6) and is so tightly bound that only approximately 1% of the hormone is free.

The growth-promoting effects of GH are primarily to increase cell number and produce a positive nitrogen balance, with accumulation of Ca, Mg, K, Na, and PO_4. Before puberty and the closure or epiphyses, GH increases bone length and thickness and produces a proportional increase in the size of other organs and tissues except the CNS. In adulthood (after the closure of epiphyses), bones cannot grow in length and only become thicker while other organs increase in size. Like insulin, GH is an anabolic hormone, but in contrast to insulin, it leads to carbohydrate intolerance, inhibits lipogenesis, increases mobilization of fat, and promotes ketosis. In nondiabetic patients with even low amounts of insulin present, these effects of GH are anabolic, but in diabetic patients, its effects are diabetogenic. In the absence of insulin, GH does not have anabolic activity. GH levels increase with exercise, hypoglycemia, and sleep.

GH excess causes gigantism if it occurs before puberty, and acromegaly if it occurs after epiphyseal closure. The most common cause of GH excess is a microadenoma of the pituitary. GH deficiency may occur as a consequence of hypothalamic disease or as a result of loss of GH receptors (Laron dwarfism). If it occurs in infancy or childhood, growth failure results. In adults who are fully grown at the time GH deficiency develops, the consequences appear to be minimal and may involve mild loss of muscle mass and impaired nutrient utilization, but the condition has not been studied well.

Chronic kidney disease and dialysis alter the GHRH-GH-IGF-1 system such that uremic patients appear to be insensitive to GH and IGF-1 and have higher GH levels due to increased secretory bursts and an increased half-life of GH with reduced IGF-1 levels (16,21–25). This resistance to GH and IGF-1 may explain why acromegaly is so rare in dialysis patients. This field is complicated because the nutritional and metabolic status (metabolic acidosis) of the patient and chronic illnesses alter the GH/IGF axis (16). Consequently, the relative importance of malnutrition, acidosis, uremic toxins, and decreased

clearance of peptides by the kidney are difficult to determine. This remains an area of intense investigation in both clinical and basic science. Most of the recent information is from the pediatric literature because of interest in the growth retardation found in pediatric renal failure and dialysis patients. In the adult population, insensitivity to GH and IGF-1 may contribute to the catabolism and wasting that commonly occur. Information on the mechanisms of resistance to GH and IGF-1 has not been completely established in humans. Some information is available from human studies and more can be inferred from animal disease models.

In kidney disease, GH levels are increased due to reduced clearance of GH by the kidney and an increased number of secretory bursts. In one study, the circulating concentrations in controls were 0.7 μg/mL versus 1.22 μg/mL in dialysis patients (21). In prepubertal patients, secretion is increased, but in pubertal patients and presumably adults, it is decreased (23,26). The level of GHBP (which reflects hepatic GH receptor expression levels) is reduced, providing a possible mechanism for GH insensitivity. Studies in humans and experimental animals indicate that metabolic acidosis is sufficient to confer resistance to GH (16,24,27,28). Dialysis patients are resistant to the short-term metabolic effects of IGF-1, IGF-1-stimulated reductions in plasma insulin, cortisol, C-peptide, and amino acid levels (29). Although the levels of IGF-1 are normal to slightly reduced, the levels of IGFBP (particularly IGFBP-2, 3, and 5) are increased (30). Because these IGFBPs bind IGF-1 tightly, the bioavailability of IGF-1 is reduced (23). The levels of the IGFBPs appear to be increased because of their reduced clearance by the kidney. In experimental systems, excess IGFBP is sufficient to inhibit the growth-promoting effects of IGF-1 (23). The half-life ($t_{1/2}$) and volume of distribution of recombinant human IGF-1 are reduced in dialysis patients (31). Low molecular weight substances in uremic serum also appear to inhibit the action of IGF-1 (23,32).

The biologic effects of GH and IGF-1 are inhibited at many levels in uremia, and tissue resistance to these hormones may contribute to morbidity and mortality in this patient population. The benefits of human growth hormone (hGH) therapy are most clear in the pediatric population, and recombinant human growth hormone (rhGH) treatment is now established therapy for children with growth failure due to ESKD and renal insufficiency once nutritional and metabolic deficiencies (including acidosis, PO_4 levels, and PTH levels) have been corrected or optimized (33). Long-term (4 to 8 years) administration of recombinant hGH (achieving supranormal levels and increasing IGF-1 levels) to children with chronic renal insufficiency and failure can restore linear growth and result in catch-up growth so that they achieve normal height (34,35). rhGH treatment may also improve muscle mass and bone density. This therapy does not have adverse effects on Ca, PO_4, bone metabolism, glucose tolerance (although insulin levels may be elevated), the incidence of malignancy, or benign intracranial hypertension, and for patients with kidney insufficiency, the rate of progression of kidney disease was not accelerated (33–35). The dose of rhGH is higher than for patients with GH deficiency, on the order of 0.35 mg/kg/wk (28 IU/m^2/wk), and may be higher during puberty. Nutritional requirements may increase in patients treated with rhGH. Methods for following dosing of the drug (e.g., serum IGF-1 levels) have not been established. Factors that contribute to a favorable response to hGH are increased height at the initiation of therapy, young age at the start of therapy, and shorter duration of dialysis treatment (33,35).

The role for recombinant hGH in the treatment of adults on dialysis is less clear because long-term, large-scale studies have not been performed. Patients treated with rhGH for 6 months show an increase in

muscle mass, hand grip strength, albumin levels, and increased bone turnover with a decrease in bone density and total body mineral content (36–40). Shorter term metabolic studies demonstrate that rhGH treatment leads to a positive nitrogen balance (40). Although these studies support an anabolic effect of rhGH in dialysis patients and do not report complications of therapy, they are of relatively short duration, so the risk of potential complications of elevated levels of GH and IGF-1 that include insulin resistance and glucose intolerance, hypertension, cardiomyopathy, abnormal bone growth, and an increased incidence of colonic polyps cannot be determined. Optimal treatment of acidosis may restore the sensitivity of patients to GH and IGF-1, so improvements in the GH-IGF-1 system may be effected without administration of rhGH (41,42). Erythropoietin may sensitize the pituitary to the effects of GHRH, so optimal therapy with this agent may also have anabolic effects (43,44). The leptin system does not appear to play a major role in the catabolic state of dialysis patients (45,46).

Prolactin

Prolactin is produced by the lactotrophs in the pituitary, and it is secreted in a pulsatile fashion. In contrast to other pituitary hormones, prolactin is under tonic negative control by inhibitory factors from the hypothalamus. Its normal function in women is to promote lactation in cooperation with estrogen and progesterone, but its function in men is not established. Increased prolactin levels are caused by dopamine antagonists, oral contraceptives, diseases of the hypothalamus or pituitary that interfere with tonic suppression of prolactin secretion, and tumors. Up to 30% of pituitary tumors secrete prolactin. Prolactin is a stress response hormone, and its blood levels may rise with stress or pain. Normal prolactin levels are 2 to 15 μg/mL, levels in dialysis patients are often in the range of 15 to 50 μg/mL, and levels greater than 250 μg/mL are suggestive of first trimester pregnancy or a prolactin-secreting tumor (20,21). In women, excess production of prolactin results in galactorrhea, suppression of menstrual cycles, and infertility, and in men, infertility (47).

In dialysis patients, prolactin levels are elevated because of increased secretion and decreased clearance (21,47). Elevated prolactin levels may be responsible for some of the gonadal abnormalities found in kidney disease. Recent reports indicate that erythropoietin reduces prolactin levels by mechanisms that may be independent of the improvement in anemia (48). Hypothyroidism, pregnancy, and medication-induced hyperprolactinemia should be excluded by careful history, physical exam, TSH, and human chorionic gonadotropin (hCG) measurements. Prolactinomas can be effectively treated with dopamine agonist that suppresses prolactin production. Sexual function in dialysis patients has improved in response to bromocriptine, a dopamine agonist that suppresses prolactin production (49). Cabergoline is more effective than bromocriptine because cabergoline is better tolerated and has higher affinity for dopamine receptor binding sites (50,51). However, about 10% to 15% of patients with prolactinomas are resistant to dopamine agonist therapy and may require additional therapy such as transsphenoidal surgery or radiotherapy (52).

Follicle-Stimulating Hormone, Luteinizing Hormone, and Gonadal Function

FSH and LH are secreted by the same pituitary cell, the gonadotrope. Their secretion is controlled by the integration of signals from luteinizing hormone–releasing hormone (LHRH) and feedback signals from estrogen, progesterone, and androgens, and gonadal peptides such as inhibin (20). Pulsatile, rather than continuously elevated, levels of LHRH are required for normal gonadal function. The frequency and

amplitude of the pulses is controlled by the hypothalamus through hypothalamic function and feedback mechanisms from the periphery. LH controls production of estrogen and progesterone in the ovary and testosterone in the testis. FSH stimulates sertoli cells to produce sperm and expression of LH receptors by Leydig cell. In women, FSH stimulates follicle development. These systems are abnormal in both men and women with kidney disease or who are on dialysis. Although psychological factors may contribute to sexual dysfunction, abnormalities at the levels of the hypothalamus and gonads are probably the predominant cause.

Reproduction in Women

Female dialysis patients frequently exhibit amenorrhea, dysmenorrhea, dysfunctional uterine bleeding, and cystic ovarian disease. These disorders occur because of disruption of normal menstrual cycles at the level of the hypothalamus and ovary (47,53). LH levels are tonically elevated due to increased release, the estrogen-induced LH surge does not occur, and FSH levels are normal or slightly elevated (53). Suppression of pulsatile LHRH secretion by prolactin may contribute to this problem. Additionally, the ovaries have a subnormal steroidogenic response to LH. The frequency of menstruation has risen from 10% to 20% 20 years ago to approximately 40% at this time which may reflect improved dialysis quality or care, but these cycles are generally thought to be anovulatory (54).

Conception occurs with a frequency of approximately 0.3% to 2.2% per year in Western countries, although these numbers represent estimates because accurate records are not kept (54–58). The frequency of conception on dialysis appears to be increasing, which may reflect improved dialysis techniques, beneficial effects of erythropoietin, and in some cases the effects of frequent dialysis regimens. Of the patients who conceive and progress to the first trimester, approximately 50% deliver viable infants. In two studies of patients who were treated with dialysis when they were pregnant, those who conceived before starting dialysis delivered viable infants in 75% to 80% of the cases, and those who conceived on dialysis delivered viable infants in 40% to 50% of cases (55,58,59). Pregnancies are complicated by intrauterine death, hypertension, intrauterine growth retardation, premature labor, premature birth of babies with low birth weights for gestational age, and an increased frequency of congenital malformations (60). Neonatal care is an important factor in the survival of these infants (55–58). Deliveries of viable infants occur at approximately 32 weeks, and the outcome improves with longer gestation. The infants weigh on the order of 1,200 to 1,550 g at birth. An increased dose of dialysis appears to be beneficial with reports of weekly Kt/V values of 6 to 8, or dialysis 5 to 6 days per week (55–57,61,62). Increased doses of erythropoietin are required to maintain hemoglobin levels in an acceptable range, and transfusions are sometimes required in addition (55,58). In many cases, patients are hospitalized around week 20 of gestation for management of blood pressure, dialysis fluid balance, nutrition, and anemia (63). Transplantation provides the best outcomes in fertility and pregnancy for patients with ESKD.

Evaluation for amenorrhea, dysmenorrhea, or dysfunctional uterine bleeding in women receiving dialysis should be carried out in consultation with a gynecologist. The evaluation should include a thorough pelvic examination, Pap smear, and may also include measurement of serum prolactin, LH and FSH levels, a pelvic ultrasound, and endometrial biopsy.

Reproduction in Men

In men, erectile dysfunction, impotence, decreased libido, and decreased sperm count are manifestations

of uremia. LH is elevated due to increased secretion and decreased clearance. The increased LH production may be caused by low levels of testosterone synthesis by the testes. FSH levels are usually normal but may be high with severe testicular dysfunction. Presumably, increased prolactin levels would interfere with normal regulation of LHRH secretion. Evaluation of men for impotence should include measurement of serum prolactin, testosterone, FSH, and LH levels. Correction of anemia with erythropoietin may improve the function of the hypothalamo–pituitary–testicular axis in dialysis patients (64). Patients should also be evaluated for autonomic neuropathy and peripheral vascular disease since these two entities are relatively common in dialysis patients, especially those with hypertension and diabetes. Following kidney transplantation in young men, testicular size, sperm counts, and fertility commonly remain abnormal. These findings may reflect effects of antirejection regimens but nevertheless are a consequence of ESKD (65).

In contrast to women whose primary reproductive endocrinologic defect appears to be hypothalamic, hypogonadism is more prominent in men (66). These men, who have reduced testosterone levels, may respond to replacement testosterone. Erectile dysfunction is common in dialysis patients, affecting 70% to 80% of men (67). The incidence is higher in men with diabetes and who have been on dialysis for long periods, and these men tend to have reduced testosterone levels and reduced penile blood flow. Approximately 80% of men with erectile dysfunction respond to sildenafil (Viagra) (68). The level of penile blood flow is the most important parameter for predicting a response to sildenafil.

Adrenocorticotropic Hormone

ACTH stimulates steroidogenesis in the glomerulosa and fasciculata layers of the adrenal glands. ACTH is derived from proopiomelanocortin (POMC), a peptide that is produced by the corticotrope cells of the anterior pituitary and cleaved to ACTH and β-lipotropin (LPH). ACTH is further cleaved into α-melanocyte-stimulating hormone (α-MSH or ACTH 1-13) and ACTH-like peptide (ACTH 18-39). β-Lipotropin is processed to lipotropin (LPH) and β-endorphin. Secretion of ACTH is stimulated by corticotropin-releasing hormone (CRH) and vasopressin. Negative feedback control is provided by suppression of CRH, vasopressin, and ACTH secretion by cortisol, and inhibition of CRH secretion by ACTH. ACTH is secreted in a pulsatile fashion in a diurnal pattern that is maximal in the early morning and minimal in the evening.

In dialysis patients, ACTH levels are normal or slightly increased compared to normal controls, and its metabolism does not appear to be altered. Normal and abnormal responses to dexamethasone and metyrapone suppression tests have been reported. The circadian rhythms and levels of cortisol are normal, and the response of the adrenals to ACTH stimulation is normal. Consequently, a number of the tests of pituitary–adrenal function used in normal patients are applicable to dialysis patients.

DISORDERS OF THE ADRENAL CORTEX

Introduction

The adrenal cortex produces two physiologically important steroid hormones, cortisol and aldosterone. The primary physiologic effect of aldosterone is on the kidneys, where it acts on the distal nephron to promote Na reabsorption and K and H excretion. Aldosterone also affects transport in the colon, but this appears to be a minor effect, and disorders of aldosterone metabolism in dialysis patients have not been

reported. Consequently, this section deals with glucocorticoid excess or insufficiency.

Glucocorticoids are essential for life and affect glucose and lipid metabolism, the immune system, and bone and mineral metabolism. No tissue or organ system including the cardiovascular, GI, or CNS functions normally in the absence of glucocorticoids. Glucocorticoid activity is required for glycogen synthesis and maintenance of glycogen stores, gluconeogenesis, and has a permissive effect on lipolysis. The effects of glucocorticoids on the immune system under normal physiologic conditions are not fully understood, but pharmacologic concentrations decrease the number of peripheral lymphocytes, inhibit T-cell activation, macrophage proliferation, and inhibit the actions of a number of mediators of inflammation including chemokines, prostaglandins, and histamine. Glucocorticoids affect bone formation by reducing osteoblast numbers, decreasing intestinal Ca reabsorption, and increasing serum PTH levels.

Adrenal Insufficiency

In the general population, primary adrenal insufficiency usually presents as adrenal crisis following some form of stress such as surgery or an acute illness. Patients complain of anorexia, nausea, vomiting, and weakness with a history of weight loss. The findings may include volume depletion, hypotension and shock, hypoglycemia, fever, and possibly hyperpigmentation. This constellation of findings is caused by loss of both cortisol and aldosterone. The loss of aldosterone is largely responsible for the symptoms and findings related to volume depletion. Patients who are receiving renal replacement therapy but who encounter a physiologic stress can also develop adrenal crisis (25,69).

Dialysis patients have minimal renal function and therefore do not develop the salt-losing nephropathy associated with adrenal insufficiency. Presumably, if dialysis patients develop adrenal insufficiency, they present more like patients with secondary adrenal insufficiency (pituitary lesions with loss of ACTH production) or tertiary (hypothalamic lesions with loss of CRF production). In these patients, adrenal crisis is rare, and they present with insidious onset of generalized symptoms of malaise and signs and symptoms of hypoglycemia.

Primary adrenal insufficiency is caused by tuberculosis, fungal diseases, metastases from tumors, and autoimmune disease. As dialysis patients are at increased risk for tuberculosis, they are also presumably at increased risk for adrenal insufficiency due to tuberculosis. Autoimmune adrenalitis is associated with polyglandular autoimmune syndromes I and II which are associated with mucocutaneous candidiasis and hypoparathyroidism, and thyroid disorders and insulin-dependent diabetes, respectively. Primary autoimmune polyglandular syndrome type II is more common than the autosomal recessive type I syndrome. Patients with HIV infections and with cytomegalovirus, mycobacterium avium intracellulare, cryptococcus, or Kaposi’s sarcoma may manifest partial adrenal insufficiency. Adrenal insufficiency can be precipitated by ketoconazole because it inhibits cortisol synthesis, or rifampin because it increases cortisol metabolism (69). Secondary or tertiary adrenal insufficiency is associated with destructive lesions of the pituitary or hypothalamus such as tumors, postradiation therapy, trauma, or use of anticoagulants. In these situations, other pituitary hormones are usually lost in addition to ACTH. Adrenal insufficiency is also caused by long-term use of glucocorticoids for immune suppression as in patients with systemic lupus erythematosus, other glomerular diseases, or following renal transplantation.

Diagnosis of Adrenal Insufficiency

Renal failure and dialysis do not alter the diurnal variation of cortisol or the adrenal response to ACTH

(25). Consequently, AM and PM cortisol levels and the ACTH stimulation test can be used to demonstrate adrenal or hypothalamic–pituitary–adrenal function (**TABLE 22.2** and **FIGURE 22.3**). As serum cortisol concentrations are normally highest in the early morning hours ranging between 10 and 20 µg/dL (275 to 555 nmol/L), inappropriately low cortisol less than 3.6 µg/dL (100 nmol/L) strongly suggest adrenal insufficiency (70). Values below 10 µg/dL (275 nmol/L) make the diagnosis likely but require additional standard or low-dose ACTH stimulation test (cosyntropin test). In the standard ACTH stimulation test, plasma cortisol is measured before, 30 minutes after, and 60 minutes after intravenous injection of 250 µg of synthetic ACTH (ACTH 1-24). A cortisol value ≥18 to 20 µg/dL (500 to 550 nmol/L) at any of the time points in the test indicates normal adrenal function. The low-dose ACTH stimulation test is preferred and has improved sensitivity in cases of secondary adrenal insufficiency of recent onset or partial adrenal insufficiency. The prolonged ACTH stimulation test or an insulin-induced hypoglycemia test helps differentiate between primary and secondary or tertiary adrenal insufficiency (71–73). The overnight, single-dose metyrapone suppression test with measurement of serum cortisol, 11-deoxycortisol, and ACTH is useful for making a diagnosis of complete or partial pituitary-adrenal insufficiency and is the most sensitive test of pituitary-adrenal reserve (69). Patients may have a normal response of ACTH and cortisol to hypoglycemia but have an abnormal response to metyrapone suppression. Metyrapone blocks conversion of 11-deoxycortisol, a compound with no glucocorticoid activity and that does not participate in feedback to cortisol. As cortisol production decreases, ACTH rises and stimulates the production of cortisol precursors which can be measured as 11-deoxycortisol. Metyrapone (30 mg/kg body weight) is given orally at midnight, and 8 AM cortisol, 11-deoxycortisol, and ACTH levels are measured. A normal response is a rise in 11-deoxycortisol from 210 to 660 nmol and a level of ACTH greater than 17 pmol/L. If the cortisol level is normal or greater than 210 nmol/L in the 8-AM sample, the dose of metyrapone was inadequate to block cortisol synthesis. A normal response to the metyrapone suppression test excludes abnormalities of the hypothalamo–pituitary–adrenal axis. ACTH release can also be measured in response to CRF to document intact pituitary function (69). Patients who are addisonian may become symptomatic with the metyrapone suppression test, so it should be supervised. If primary adrenal insufficiency is suspected, a CT scan of the abdomen to evaluate the size of the adrenal glands is warranted.

TABLE 22.2 Tests for Primary or Secondary Adrenal Insufficiency

	Normal	Primary Adrenal Insufficiency	Pituitary/Hypothalamic Insufficiency
ACTH (8 AM)	4.5–12 pmol/L (20–52 pg/mL)	Increased	Low or normal range
Cortisol (8 AM)	10–20 µg/dL (275–550 nmol/L)	<275 nmol/L	Low or normal range
Cosyntropin stimulation	Peak cortisol ≥18–20 µg/dL (500–550 nmol/L) after 30–60 min	<18 µg/dL (500 nmol/L) after 30–60 min	Normal or low if adrenals are atrophic
Metyrapone	8 AM ACTH ≥17 pmol/L, 11-deoxycortisol 210–660 nmol/L	8 AM ACTH ≥17 pmol/L, 11-deoxycortisol <210 nmol/L	8 AM ACTH ≤17 pmol/L, 11-deoxycortisol <210 nmol/L

Reference values or normal responses are shown for normal patients.

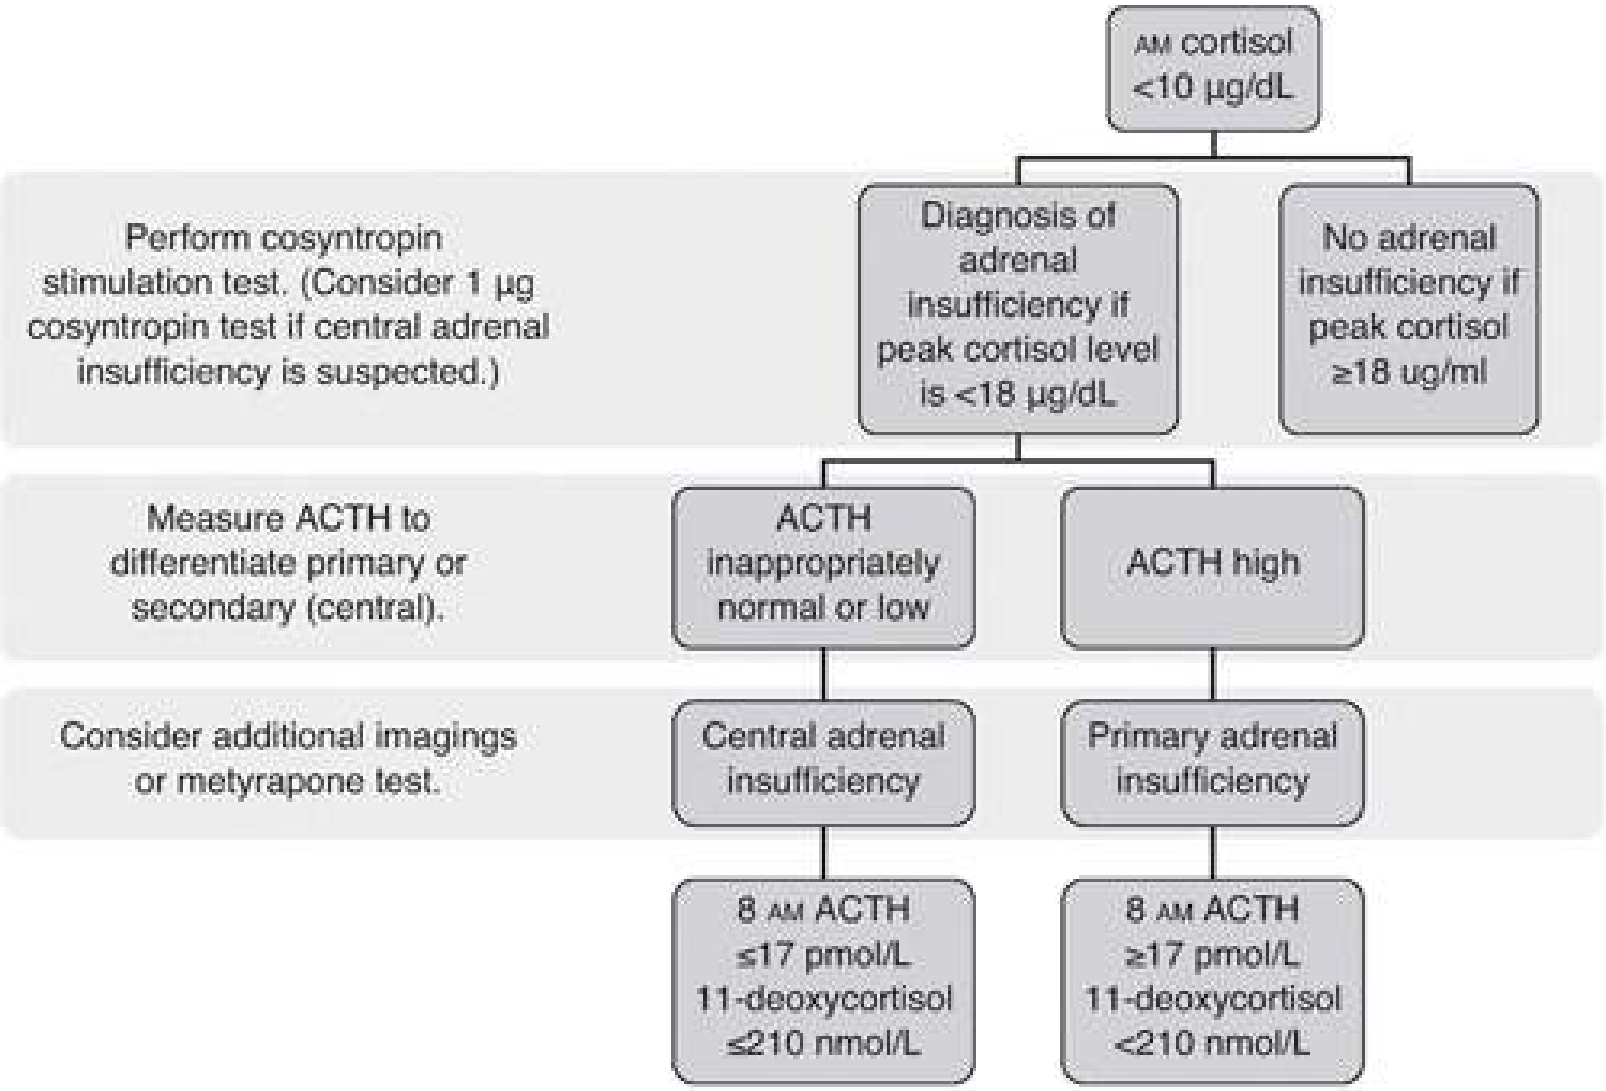

FIGURE 22.3 Diagnostic algorithm for adrenal insufficiency. ACTH, adrenocorticotropic hormone.

Adrenal Hyperfunction

The adrenal glands may overproduce aldosterone or cortisol. Overproduction of aldosterone is caused by adrenal adenomas of the glomerulosa layer (either single or multiple). In patients with kidney disease who are on dialysis, it is not clear if aldosterone excess causes clinical abnormalities. Consequently, this section deals with glucocorticoid excess or Cushing's syndrome. Cushing's syndrome may be caused by excess ACTH (usually due to a pituitary adenoma, see preceding text), adrenal hyperplasia, or exogenous glucocorticoids for inflammatory diseases or antirejection therapy. Cushing's syndrome is characterized by centripetal obesity, glucose intolerance, weakness (due to proximal myopathy), hypertension, psychological changes (depression or mania), bruisability, striae, osteopenia, menstrual irregularities or impotence, acne or oily skin, hypertension, edema, and hirsutism. None of these findings is diagnostic of cortisol excess, but the occurrence of several of them in the same patient is suggestive of Cushing's syndrome. In dialysis patients, hypertension and edema and menstrual irregularities or impotence may not be valuable because they are so common in the dialysis population.

Diagnosis of Hypercortisolism

The diagnosis of Cushing's syndrome in dialysis patients can be based on most of the same criteria as the general population (**TABLE 22.3** and **FIGURE 22.4**). Glucocorticoid use for inflammatory diseases of the

kidney or as part of an antirejection regimen are probably the most common causes of Cushing's syndrome in the dialysis population. In the absence of such a history, glucocorticoid excess may be either primary or secondary. Renal failure and dialysis do not alter the diurnal variation of cortisol or the adrenal response to ACTH, so AM and PM cortisol levels can be used to demonstrate abnormal diurnal variation (loss of the PM fall) in cortisol.

TABLE 22.3 Serum Assays and Provocative Tests for Hypercortisolism

	Normal	Primary Adrenal Overproduction	Pituitary or Hypothalamic or Ectopic Adrenocorticotropic Hormone
ACTH	4.5–12 pmol/L (20–52 pg/mL)	Reduced (usually <2 pmol/L)	Normal or modestly increased in Cushing's disease Elevated, usually >20 pmol/L (>90 pg/mL) in ectopic ACTH syndrome
Serum cortisol	Normal diurnal variation Highest at 8 AM 220–660 nmol/L Lowest at midnight <50 nmol/L (<2 μg/dL)	Loss of diurnal variation with midnight elevation >200 nmol/L (>7.5 μg/dL)	Loss of diurnal variation with midnight elevation >200 nmol/L (>7.5 μg/dL)
Low-dose dexamethasone suppression	8 AM cortisol ≤140 nmol/L (<5 μg/dL),[a] 8 AM ACTH ≤4.4 pmol/L	8 AM cortisol ≥220 nmol/L, low ACTH	8 AM cortisol ≥220 nmol/L, elevated ACTH
High-dose dexamethasone suppression	8 AM cortisol ≤140 nmol/L	No suppression on AM cortisol	>50% suppression of plasma or urinary cortisol from baseline value in Cushing's disease Cortisol is not suppressible in ectopic ACTH syndrome.
Metyrapone test	8 AM ACTH ≥17 pmol/L, 11-deoxycortisol 210–660 nmol/L	8 AM ACTH no change to increased, 11-deoxycortisol no change to decreased	Cushing's disease 8 AM ACTH ≥17 pmol/L, 11-deoxycortisol 210–660 nmol/L(typically, >1,000 nmol/L) Ectopic ACTH syndrome No change or increased

Reference values and normal responses are shown in the normal column.

[a]Endocrine society suggests cortisol cut-off point of <50 nmol/L (1.8 μg/dL) to improve the sensitivity of diagnosis of hypercortisolism.

ACTH, adrenocorticotropic hormone.

From Melmed S, Casanueva FF, Hoofman AR, et al. Diagnosis and treatment of hyperprolactinemia: an Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab* 2011;96:273–288; and Fiad TM, Kirby JM, Cunningham SK, et al. The overnight single-dose metyrapone test is a simple and reliable index of the hypothalamic-pituitary-adrenal axis. *Clin Endocrinol (Oxf)* 1994;40:603–609.

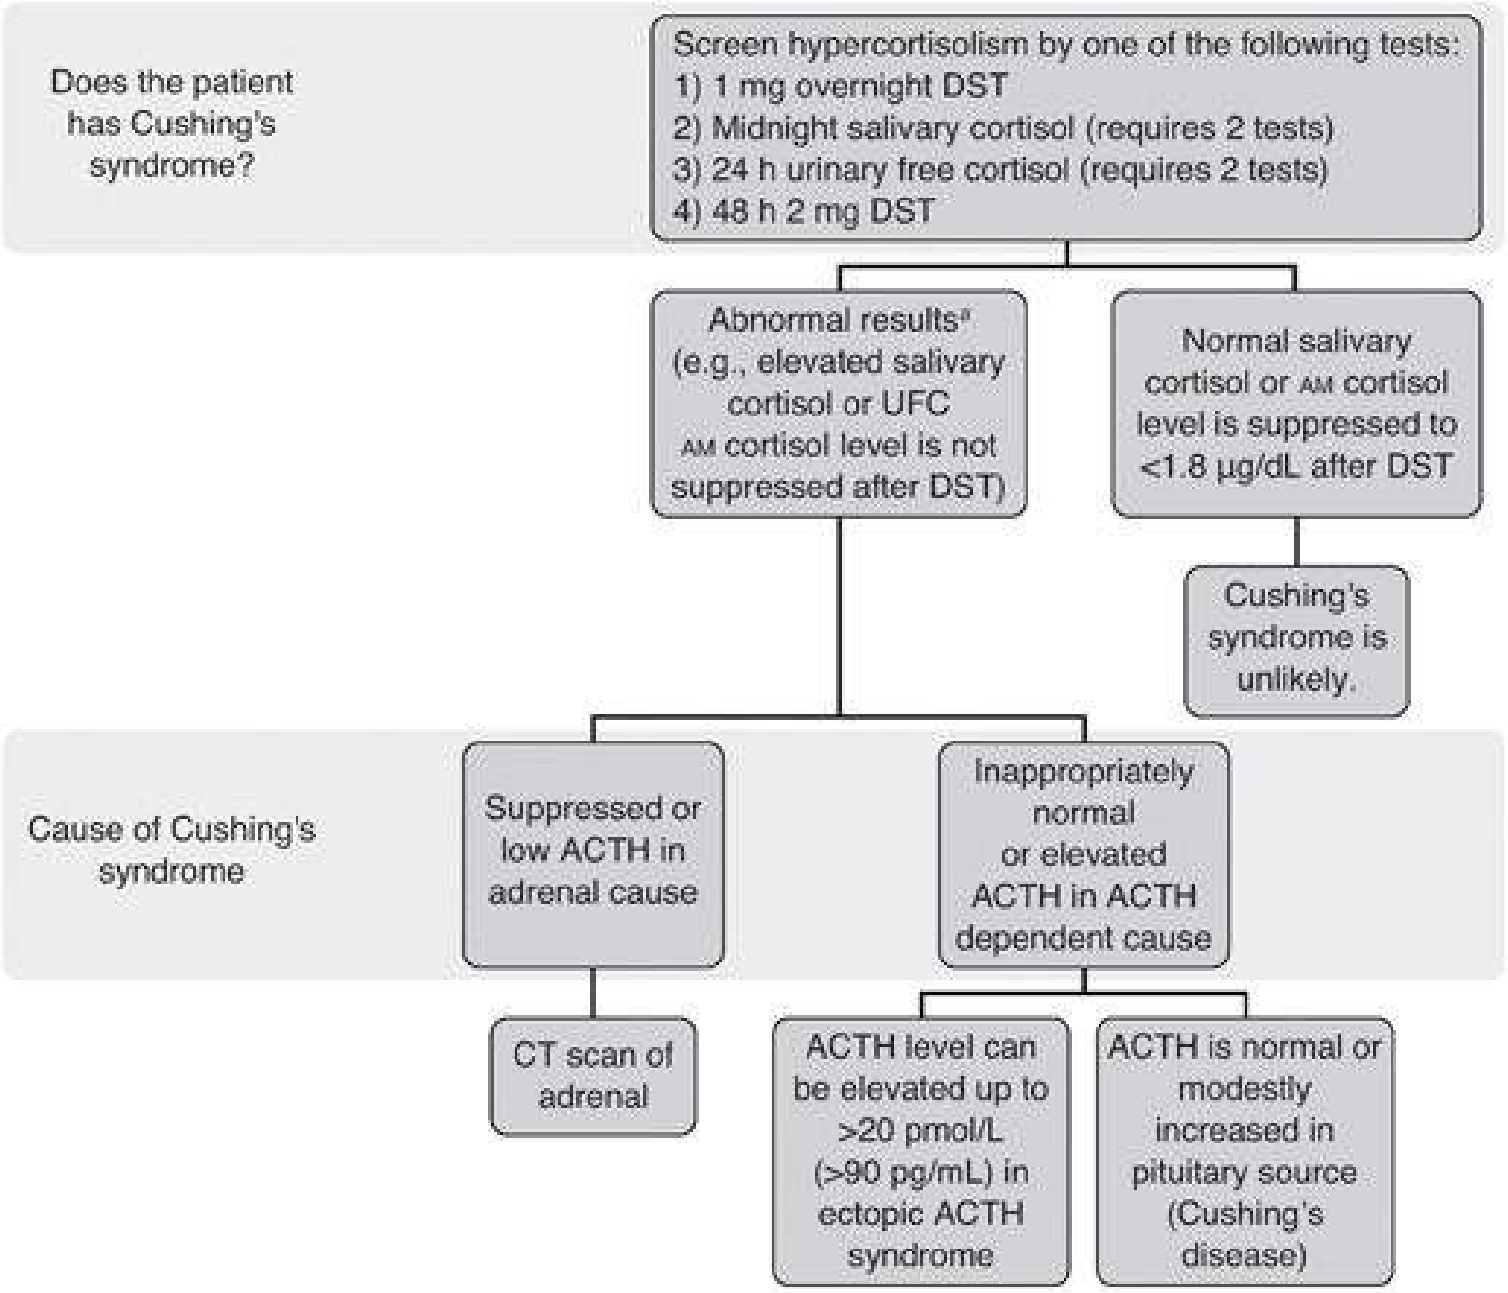

FIGURE 22.4 Diagnostic algorithm for Cushing's syndrome. DST, dexamethasone suppression test; ACTH, adrenocorticotropic hormone; UFC, urinary free cortisol; CT, computed tomography. [a]Abnormal results should be confirmed with one of other additional screening tests.

Screening for hypercortisolism can be achieved using 8-AM cortisol measurement after a low-dose overnight dexamethasone (1 mg DST), the 2-mg/48-h dexamethasone suppression test, midnight salivary cortisol (requires two measurements on separate days), or urinary free cortisol (UFC) (requires two measurements on separate days). Biochemical excess of cortisol in an initial screening test should be confirmed by performing different provocative tests before looking for the source of the excess cortisol or cause of Cushing's syndrome (74). The sensitivity of UFC is diminished in chronic kidney disease patients when creatinine clearance falls below 60 mL/min as kidney filtration of cortisol fall linearly with more severe kidney disease (75).

Dexamethasone suppresses ACTH secretion through negative feedback at the levels of the pituitary and hypothalamus. The low-dose dexamethasone suppression test (1 mg PO between 11 PM and midnight with measurement of 8-AM cortisol and ACTH) is designed to distinguish patients with glucocorticoid excess for any reason from patients with normal hypothalamo–pituitary–adrenal function. If the patient is

normal, the low dose of dexamethasone will suppress cortisol production, and the 8-AM plasma cortisol level should be less than 140 nmol/L (5 µg/dL) and the ACTH should be less than 4.4 pmol/L (20 pg/mL). Most experts advocate usage of lower cortisol cut-off point below 50 nmol/L (1.8 µg/dL) to improve diagnostic sensitivity to over 95% (74,76). Initial screening tests for hypercortisolism are 1 mg dexamethasone suppression test, UFC, or midnight salivary cortisol. In some cases, the 2-day low-dose dexamethasone suppression test is used. The high-dose dexamethasone suppression test and metyrapone are used to identify the source of cortisol after two different screening tests confirm cortisol excess. As UFC is not reliable in chronic kidney disease, if 1 mg dexamethasone suppression test is positive, the midnight salivary cortisol level should be measured to confirm cortisol excess.

The midnight salivary cortisol value measured by RIA greater than 2.0 ng/mL (5.5 nmol/L) on two separate days has 100% sensitivity and 96% specificity for diagnosis of Cushing's syndrome (77).

The distinction between primary and secondary or tertiary hypercortisolism can be made measuring ACTH level (**FIGURE 22.4**), using high-dose dexamethasone suppression test (**FIGURE 22.5**) or the single-dose metyrapone test with measurement of serum 11-deoxycortisol and cortisol (59,62).The morning plasma ACTH measured by two-site immunoradiometric assay helps in differentiating ACTH-dependent from ACTH-independent causes. ACTH is undetectable (<1 pmol/L) in patients with adrenal tumors; normal at 2 to 11 pmol/L (9 to 52 pg/mL) or modestly elevated in Cushing's disease and elevated up to >20 pmol/L (>90 pg/mL) in ectopic ACTH syndrome (51).

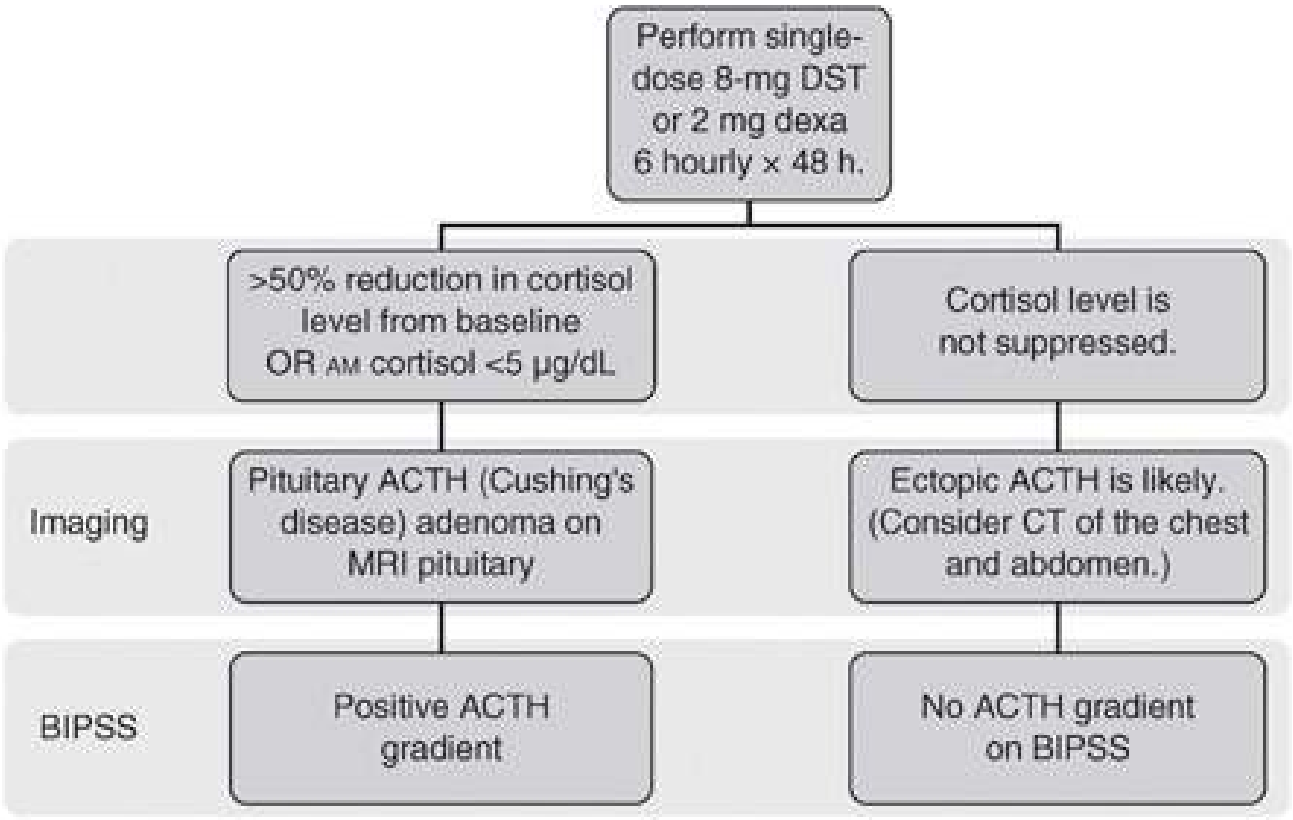

FIGURE 22.5 Further diagnostic workup for ACTH dependent Cushing's syndrome. DST, dexamethasone suppression test; ACTH, adrenocorticotropic hormone; MRI, magnetic resonance imaging; CT, computed tomography; BIPSS, bilateral inferior petrosal sinus sampling.

In patients with pituitary adenomas or increased hypothalamic activity, ACTH can be undetectable and 8-AM cortisol levels can be suppressed to less than 140 nmol/l (5 µg/dL) on high doses of dexamethasone (8 mg of dexamethasone given between 11 PM and midnight). If the hypercortisolism is

due to ectopic ACTH, ACTH and cortisol will not typically suppress with either high or low dose of dexamethasone. However, there are some exceptions as approximately 50% of patients with ectopic ACTH syndrome due to indolent bronchial carcinoid tumors may show some suppression after high-dose dexamethasone. The “gold standard” test for distinguishing between Cushing’s disease and an ectopic source of ACTH is bilateral inferior petrosal sinus sampling with CRH. The finding of central (inferior petrosal) to peripheral plasma ACTH gradient greater than 2:1 or 3:1 after CRH administration is consistent with Cushing’s disease (51).

The metyrapone suppression test can also be used to distinguish primary adrenal overproduction of cortisol from excess ACTH secretion due to pituitary or hypothalamic disease. Metyrapone blocks conversion of 11-deoxycortisol, a compound with no glucocorticoid activity and that does not participate in feedback, to cortisol. The reduced cortisol levels stimulate ACTH production which in turn stimulate the cortisol synthetic pathway. A pituitary adenoma responds to reduced cortisol with increased ACTH production resulting in an increase in 11-deoxycortisol production. In contrast, in the presence of an adrenal adenoma, the hypothalamopituitary axis is atrophic, the increase in ACTH is minimal, and 11-deoxycortisol levels fall or do not change. Approximately half of adrenal adenomas and most adrenal carcinomas do not respond to ACTH. The uninvolved contralateral adrenal gland may be atrophic and unable to respond to ACTH (69). If a pituitary or hypothalamic lesion is suspected, structural evaluation of the pituitary and hypothalamus with CT or MRI scans is indicated (**FIGURES 22.4** and **22.5**). The metyrapone test is no longer widely used to differentiate patients with Cushing’s disease from those with a primary adrenal cause as these conditions can be more reliably distinguished by measurement of plasma ACTH followed by CT scanning of the adrenals (51).

CHAPTER 23

Gastrointestinal Complications in End-Stage Kidney Disease

George T. Fantry, Seema Patil, and Donna S. Hanes

Gastrointestinal symptoms are very common in patients with end-stage kidney disease (ESKD) (1), occurring in 77% to 79% of patients undergoing hemodialysis (2,3). Before the widespread use of dialysis, gastrointestinal complications accounted for a large part of the uremic syndrome. Uremia causes pathologic and physiologic changes throughout the gastrointestinal tract, which results in gastrointestinal disturbances involving both the upper and lower gastrointestinal tract (4,5) as well as the pancreas, leading to a broad spectrum of gastrointestinal complaints (**TABLE 23.1**) (2). There is an increased frequency of gastroesophageal reflux disease (GERD), gastritis, gastrointestinal bleeding, pancreatitis, ascites, and constipation. These gastrointestinal complications of ESKD have a negative impact on quality of life (1), increase morbidity, and may contribute to death. This chapter reviews the pathophysiology, diagnosis, and management of these common gastrointestinal disorders in dialysis patients.

TABLE 23.1 Prevalence of Gastrointestinal Symptoms in Patients on Hemodialysis

Symptoms	Percentage
Nausea	74
Vomiting	68
Anorexia	64
Constipation	59
Heartburn	52
Abdominal distension	51
Abdominal pain	49
Diarrhea	25
Dysphagia	16

ESOPHAGUS

Upper gastrointestinal symptoms, including nausea, vomiting, heartburn, and epigastric pain are common

in patients with chronic kidney disease. In addition to dialysis-related nausea and vomiting, potential esophageal causes of these symptoms include GERD or reflux esophagitis and esophageal motility disorders.

Multiple studies have found an increased prevalence of GERD-related symptoms in chronic kidney disease and hemodialysis patients (6–8). Additionally, the prevalence of GERD, as assessed by endoscopy and 24-hour pH monitoring in patients with GERD-related symptoms and ESKD, has been demonstrated to be very high (81%), suggesting that upper gastrointestinal symptoms in patients with chronic kidney disease are important in predicting the presence of GERD (9). Furthermore, continuous ambulatory peritoneal dialysis (CAPD) was a risk factor for the development of GERD (9,10). This association is likely due to increased intra-abdominal pressure when the abdominal cavity is filled with dialysate fluid and its effect on lower esophageal sphincter pressure.

A potential relationship between kidney disease and GERD-associated esophagitis was suggested in an autopsy series of patients with ESKD revealing a high prevalence of mild to severe esophagitis (36%) (11). However, in prospective studies of patients with chronic kidney disease on hemodialysis, the prevalence of esophagitis was much lower, ranging from 5.8% to 13% (12–14). The prevalence rate of endoscopic esophagitis in these studies is similar to or slightly greater than that in the general population. In a case-controlled study showing that the prevalence of GERD symptoms and esophagitis was increased in chronic kidney disease patients, multifactorial logistic regression analysis revealed a negative relationship between the presence *Helicobacter pylori* infection in the stomach and reflux esophagitis (8). This finding suggests that *H. pylori* infection may protect against the development reflux esophagitis which has been previously proposed by others (15,16).

A high prevalence of hiatal hernia has been reported in patients with ESKD (2,17,18). Hiatal hernias are known to play a role in the pathophysiology of GERD by altering the antireflux barrier and by acting as a reservoir for potential acid refluxate. Nonspecific esophageal motility disorders have been identified in chronic hemodialysis patients (19–21); however, the clinical significance of these findings is uncertain.

A presumptive diagnosis of GERD can be made when esophageal symptoms such as heartburn and regurgitation are present, and empiric therapy with acid-suppressive therapy with a proton pump inhibitor should be instituted. Symptom response to therapy confirms the diagnosis. Endoscopy should be performed in patients with persistent symptoms. Early endoscopy is indicated for unexplained nausea and vomiting or when alarm symptoms such as dysphagia are present.

STOMACH/DUODENUM

Dyspeptic symptoms are very common in patients with chronic kidney disease leading to investigation for possible gastroduodenal pathology, such as gastritis, duodenitis, and peptic ulcer disease. Many decades ago, a high prevalence of diffuse hemorrhagic gastritis and duodenitis was described in patients with fatal acute uremia (22,23). A subsequent autopsy study of chronic hemodialysis patients revealed a similar frequency of gastritis, which was less extensive and severe (11). More recent radiologic and endoscopic studies have confirmed a high prevalence of gastroduodenal lesions—such as gastritis, gastric erosions, duodenitis, and duodenal erosions—in patients with chronic kidney disease with endoscopic or histologic evidence of peptic disease found in up to 60% to 74% of the patients (12,14,24–27). There is a strong association between *H. pylori* infection and gastritis; however, poor correlation between endoscopic and

histologic findings was seen (24).

Physiologic abnormalities in the presence of ESKD—such as decreases in pancreatic and duodenal bicarbonate secretion and elevated serum gastrin levels—led to speculation of an association between chronic kidney disease and peptic ulcer disease. Early clinical studies of small numbers of patients utilizing diagnostic radiology techniques suggested that chronic kidney disease was a risk factor for the development of peptic ulcers, but more recent endoscopic studies in patients on chronic hemodialysis have found a prevalence of peptic ulcers similar to that of the general population (12,14,28). Identified risk factors for the development of peptic ulcers include age, peritoneal dialysis, diabetes mellitus, congestive heart failure, and low serum albumin (29). There is a difference in the clinical presentation and endoscopic features of peptic ulcers in uremic patients compared with patients with normal kidney function. Uremic patients are more likely to be asymptomatic (13) or have low symptom scores (27) and to present with hemorrhage (30,31). In addition, uremic patients are more likely to have giant and multiple ulcers as well as *H. pylori*–negative and postbulbar duodenal ulcers (30,32).

Given the frequency of dyspepsia in patients with chronic kidney disease and the known role of *H. pylori* as a pathogen in the development of gastritis and peptic ulcer disease, a number of studies have addressed the prevalence of *H. pylori* in ESKD. Most studies have demonstrated that the prevalence of *H. pylori* infection in patients with ESKD is similar to or possibly less than that of the general population (33–40), and there appears to be an inverse association between the duration of dialysis treatments and the presence *of H. pylori* infection (38,39). Dyspepsia is not associated with *H. pylori* infection in patients with chronic kidney disease (26,41), a finding that is similar to the lack of a clear association between *H. pylori* infection and functional dyspepsia in the general population. These findings suggest that other factors likely contribute to the development of gastritis and dyspepsia.

Multiple diagnostic tests are available to detect *H. pylori* infection including histology, rapid urease test (RUT), *H. pylori* stool-specific antigen (HpSA), and [13] C-urea breath test ([13] C-UBT). Using histology as the gold standard, the diagnostic accuracy of RUT is decreased in patients on hemodialysis compared to patients with chronic kidney disease and patients with normal kidney function (27). However, the diagnostic accuracy of the noninvasive tests, [13] C-UBT and HpSA, remains high in hemodialysis patients (27,42). Standard treatment of *H. pylori* infection with proton pump inhibitor–based triple therapy (i.e., omeprazole, amoxicillin, clarithromycin) twice daily for 2 weeks is as effective in patients with chronic kidney disease on hemodialysis or CAPD as in those individuals with normal kidney function (43,44).

Another potential cause of frequent dyspeptic symptoms—such as nausea, vomiting, abdominal bloating, early satiety, and anorexia—in dialysis patients with chronic kidney disease is abnormal or delayed gastric emptying (41,45–48). Gastroparesis is a common complication of diabetes mellitus, the most common cause of chronic kidney disease requiring dialysis, particularly in the presence of other end-organ damage such as chronic kidney disease. In addition to diabetic gastroparesis, gastric emptying can be significantly delayed in nondiabetic dialysis patients as well (48–51). Potential causes of abnormal gastric emptying in these patients include neuropathy directly related to the uremia and alterations in gastrointestinal hormones that can affect gastric emptying. The prevalence of dysmotility-like dyspepsia has been shown to be higher in CAPD patients than in hemodialysis patients (41). In CAPD patients, studies showing delayed gastric emptying when the abdominal cavity is filled with

dialysate and absent when the abdominal cavity is empty suggest that increased intra-abdominal pressure may play an important role (52); however, this remains controversial (53). Delayed gastric emptying in patients with chronic kidney disease is not associated with *H. pylori* infection (41,51,54).

Upper gastrointestinal symptoms due to gastroparesis may have an adverse effect on nutritional status and may be one of the important factors that lead to malnutrition in dialysis patients. Delayed gastric emptying in chronic hemodialysis patients is associated with changes in biochemical indicators of nutritional status such as albumin and prealbumin (49). Furthermore, treatment of gastroparesis in nondiabetic dialysis patients with promotility agents such as erythromycin or metoclopramide can significantly improve gastric emptying and short-term nutritional status as measured by serum albumin (50).

There are several therapeutic options for the management of patients with dyspepsia. An empiric trial of a proton pump inhibitor can be considered. Alternatively, a serum *H. pylori* antibody can be obtained. If the *H. pylori* antibody is positive, appropriate treatment with a 2-week course of proton pump inhibitor–based triple therapy should be instituted. In patients with persistent dyspepsia, endoscopy is warranted. Early endoscopy should be pursued in older patients and in those with associated vomiting, anorexia, and unexplained weight loss. When empiric therapy fails and a diagnostic esophagogastroduodenoscopy (EGD) is unrevealing, it may be useful to obtain a gastric emptying study to assess for gastroparesis that can be treated with a promotility agent such as metoclopramide.

GASTROINTESTINAL BLEEDING

Gastrointestinal bleeding is a common complication of ESKD, accounting for up to 8% to 12% of cases of upper gastrointestinal bleeding (55,56). The frequency of bleeding in patients with chronic kidney disease with underlying gastrointestinal pathology may be partially explained by a high occurrence of clotting abnormalities in this patient population (56). These are primarily due to multifactorial platelet dysfunction, but abnormalities in clearance of anticoagulant medications in ESKD can contribute to increased risk of bleeding (57). Treatment options to restore platelet function in patients with ESKD and active bleeding include correction of anemia (58), administration of desmopressin [1-deamino-8-D-arginine vasopressin (DDAVP)] (59), and cryoprecipitate infusion (60). Most studies have found that peptic ulcer disease (gastric or duodenal ulcers) is the most common cause of upper gastrointestinal bleeding in patients with chronic kidney disease, accounting for 30% to 60% of bleeding episodes (55,56,61). Risk factors for upper gastrointestinal bleeding among patients with ESKD include cardiovascular disease, current smoking, and inability to ambulate independently (62).

The association of chronic kidney disease with bleeding upper gastrointestinal angiodysplasias is controversial. A few studies have shown that angiodysplasias of the stomach and duodenum are a significantly more common source of upper gastrointestinal bleeding in patients with chronic kidney disease (55,56,63,64), with angiodysplasias identified as the cause of bleeding in 13% to 23% of patients (55,56). However, this has not been a universal finding (61,65,66). In one study, the prevalence of angiodysplasias as a cause of upper gastrointestinal bleeding was related to the duration of kidney disease and the need for dialysis (55). The lesions are often multiple and can also be found in the small bowel and colon (56,63,67,68). Recurrent bleeding is frequent and more common in patients with chronic kidney disease (56,64). In addition to acute gastrointestinal hemorrhage, patients with bleeding

angiodysplasias often present with chronic gastrointestinal blood loss manifested by chronic anemia and hemoccult-positive stool (65). Erosive esophagitis and erosive gastritis may also be more common causes of upper gastrointestinal bleeding in chronic kidney disease patients (56,61).

The diagnosis of angiodysplasias in the appropriate clinical setting is usually made by endoscopy with upper endoscopy and/or colonoscopy. The diagnosis of angiodysplasia can sometimes be difficult to make, as the lesions may be very small and hidden between or behind folds. A high index of suspicion for the possibility of angiodysplasias should be maintained in patients with recurrent acute bleeding episodes, which are undiagnosed after conventional endoscopy with upper endoscopy and colonoscopy, and in patients with unexplained chronic iron deficiency anemia and hemoccult-positive stool. In this subset of patients, small bowel angiodysplasia is the most common cause of bleeding, and further endoscopic evaluation of the small bowel with enteroscopy and/or wireless capsule endoscopy is warranted. Chronic kidney disease is a predictive factor for positive findings on enteroscopy and wireless capsule endoscopy (69,70). When identified endoscopically, the lesions can be successfully treated with thermal therapy using contact probes (71) or argon plasma coagulation (72).

Endoscopic intervention for gastrointestinal angiodysplasias is ineffective when the vascular lesions are diffuse, inaccessible, or escape identification. Additionally, rebleeding is an important clinical issue after endoscopic therapy. Estrogen and progesterone therapy has been proposed for the prevention of recurrent bleeding from angiodysplasias. Potential mechanisms for the beneficial effect of estrogen on bleeding gastrointestinal telangiectasias include improvement in coagulation status with decreased bleeding time and improvement in the integrity of the vascular endothelial lining. Studies of hormonal therapy have had mixed results with two small studies showing cessation of bleeding and decreased transfusion requirement (68,73), but a more recent larger trial finding no significant benefit with hormonal therapy (74). Other therapies for recurrent bleeding from angiodysplasias have been studied. Treatment with thalidomide, an angiogenesis inhibitor, improved outcomes in a small study as compared to iron supplementation (75). Octreotide has been shown to benefit patients in small studies, and a decrease in transfusion requirement with octreotide treatment was confirmed in a meta-analysis (76). However, a recent systematic review found low quality or insufficient evidence to support treatment of angiodysplasia with hormonal therapy, thalidomide, or octreotide (77).

PANCREAS

Abnormal glandular morphology and pancreatic exocrine function are very common in ESKD. Pancreatic endocrine function as measured by beta-cell response has been consistently shown to produce normal glucose and insulin levels which do not differ between groups of patients with ESKD regardless of dialysis modality. In contrast, C-peptide concentrations are markedly increased over controls, and the return of insulin to basal levels is delayed with ESKD (78). Several mechanisms have been postulated to explain this finding. Iron deposition from chronic administration and elevated levels of islet amyloid polypeptide may contribute to beta-cell dysfunction (79,80). Aggressive iron depletion with phlebotomy and recombinant human erythropoietin reverses some of these defects, and recently, deferoxamine therapy has shown substantial promise in reducing insulin resistance and improving B-cell function (81). L-carnitine nutritional supplements may provide additional benefit by improving some of the beta-cell responsiveness, but the clinical benefit remains to be proven (82).

Approximately 70% of patients have abnormal pancreatic exocrine function (83). Investigators have demonstrated reduced duodenal amylase, lipase, bicarbonate, and protein levels in response to secretory stimulation tests (84,85). In addition, fecal chymotrypsin levels are significantly reduced in chronic kidney disease (86). These changes in excretory pancreatic function are infrequently associated with ultrasonographic changes within the pancreas. Autopsy studies reveal a correlation between pancreatic disease and elevated intact parathyroid hormone (PTH) levels (87). Whether these abnormalities are part of the clinical spectrum of chronic pancreatitis or represent a distinct uremic pancreatopathy is unclear. Other possible causes of pancreatic disease in dialysis patients include hypercalcemia, hypertriglyceridemia, vascular insufficiency, and drug toxicity [such as long-standing diuretic use, antibiotics, and nonsteroidal anti-inflammatory drugs (NSAIDs)] (**TABLE 23.2**). The clinical result of these changes may lead to steatorrhea, which may contribute to the malnutrition seen commonly in dialysis patients (88).

TABLE 23.2 Potential Causes of Pancreatic Disease in Dialysis Patients

Alcoholism
Gallstones
Hyperparathyroidism
Hypercalcemia
Hypertriglyceridemia
Vascular insufficiency
Drug toxicity
Diuretics
Antibiotics
Nonsteroidal anti-inflammatory agents
Heparin (transient)
Dialysate
Systemic lupus erythematosus
Polycystic kidney disease

Patients with chronic kidney disease frequently have elevated serum amylase and lipase levels in the absence of clinical pancreatitis, probably related to diminished kidney clearance. The kidney is responsible for 20% of the clearance of these enzymes. Serum amylase, lipase, and trypsin values remain normal until the creatinine clearance is less than 50 mL/min (89). The levels then rise to approximately two to three times normal, which may correlate with the duration of chronic kidney disease (90). Total serum amylase, pancreatic amylase, and salivary amylase isoenzymes are elevated, but isoenzymes are not routinely measured in clinical practice (86,91). Serum amylase in asymptomatic patients rarely exceeds 500 IU/L and is unaffected by dialysis (89,92). The predialysis serum lipase activity is also increased in patients with ESKD and rises further after hemodialysis. This effect is related to the lipolytic effect of intradialytic heparin and dose. Patients on CAPD and with peritonitis also have mild elevations in serum and peritoneal amylase (up to 100 IU/L); however, marked elevations, as seen in patients with pancreatitis or cholecystitis, are not found (93,94).

Acute pancreatitis has been reported to be more common in ESKD than in the general population. Several series report an incidence of 2.3% to 6.4% in patients with kidney disease (95,96). Pancreatitis is significantly more common in those with alcohol abuse, systemic lupus erythematosus, and polycystic kidney disease. It is not significantly associated with biliary tract disease, hyperlipidemia, or hypercalcemia. The mortality is 20% to 50%. Acute pancreatitis is equally common in patients on CAPD

and on hemodialysis (96–98). The dialysate may be clear, hemorrhagic, or cloudy. It has been suggested that metabolic abnormalities related to absorption of glucose and buffer from dialysate, hypertriglyceridemia, or absorption of a toxic substance in the dialysate, bags, or tubing may increase the risk of pancreatitis in dialysis patients (99).

Chronic pancreatitis can interfere with absorption and may result in malnutrition, vitamin deficiencies, and chronic wasting in dialysis patients (88). Histologic evidence of pancreatitis can be seen in greater than 50% of patients with ESKD, 85% of which is chronic (100). Pathologic changes include calcifications, fibrosis, abscess formation, and deposition of hemosiderin. However, despite the frequency of chronic morphologic findings and functional abnormalities of the pancreas associated with ESKD, clinically significant chronic pancreatitis is rare. Most patients are asymptomatic; rarely, symptoms suggestive of malabsorption, such as steatorrhea, develop (101).

Diagnosing pancreatitis in dialysis patients can be very difficult. Dialysis patients frequently experience abdominal discomfort, nausea, and vomiting as a result of uremia or dialysis treatments. Nonspecific elevations of serum amylase and lipase are common. Therefore, interpretation of hyperamylasemia must be approached with caution. Clinicians should maintain a high level of suspicion if values exceed three times the normal limit. Abdominal computed tomography (CT) can be useful to confirm pancreatic inflammation and peripancreatic abnormalities suspicious for pancreatitis. Early diagnosis and therapy may reduce the progression or severity of disease. Acute pancreatitis is more likely to be severe and is associated with a worse prognosis in dialysis patients than in the general population (102). Using Ranson's criteria, the mortality for patients with three or more (including kidney insufficiency) criteria approaches 70%, compared to 11% for patients without kidney disease. Complications such as pancreatic abscesses, pseudocysts, and necrosis occur with the same frequency as in the general population. However, dialysis patients develop twice as many systemic complications, such as cardiovascular and pulmonary complications, and sepsis (103). Treatment should be similar to that for nondialysis patients, including bowel rest, volume resuscitation as needed with frequent dialysis to maintain euvolemia, and pain control. Pain management strategies should avoid the use of meperidine (Demerol), which may lower the threshold for seizures in ESKD.

NEPHROGENIC ASCITES

Nephrogenic ascites (NA) or idiopathic dialysis ascites (IDA) is an uncommon but important cause of morbidity in dialysis patients. By definition, it is a disorder that manifests as massive, refractory ascites in chronic hemodialysis patients where all other causes of ascites have been excluded (104). The incidence appears to be decreasing with improved volumetrically controlled dialysis and nutrition and is center-dependent (104,105). Most patients present with sustained volume overload, arterial hypertension, large interdialytic weight gains, minimal extremity edema, cachexia, and a history of dialysis-associated hypotension (104–107). NA is frequently associated with hyperparathyroidism, hypoalbuminemia, and uremia; has a male predominance; and is unrelated to age or race (108). It is associated with a grave prognosis, with a 1-year mortality rate of more than 30% (106) (**TABLE 23.3**).

TABLE 23.3 Causes and Characteristics of Nephrogenic Ascites

Possible causes
Sustained volume overload
Impaired lymphatic drainage
Elevated hepatic venous hydrostatic pressure
Increased peritoneal membrane permeability resulting from
Dialysate solutions
Uremic toxins
Hyperparathyroidism
Hypoalbuminemia
Circulating immune complexes
Hemosiderosis
Activation of the renin-angiotensin system
Celiac disease
Clinical characteristics
Refractory ascites in the absence of hepatic, neoplastic, or infectious disease
Arterial hypertension
Minimal extremity edema
Cachexia
History of intradialytic hypotension
Exudative ascites

Adapted from Hammond TC, Takiyyuddin MA. Nephrogenic ascites: a poorly understood syndrome. *J Am Soc Nephrol* 1994;5:1173–1177.

The pathophysiology of NA is complex, probably multifactorial, and incompletely understood. Many patients have a history of previous CAPD, suggesting persisting abnormalities of the peritoneal membrane. However, the syndrome also occurs in patients even before the initiation of dialysis (106). The accumulation of ascites may occur up to 18 months preceding dialysis to as late as 5 years after initiation of dialysis. The characteristics of the ascitic fluid indicate that the underlying pathogenesis is an alteration of the balance between peritoneal membrane permeability and impaired resorption due to peritoneal lymphatic obstruction, without a significantly elevated hepatic vein hydrostatic pressure (107,109). The ascitic fluid is straw colored and exudative, with a total protein of more than 3 g/dL; ratio of serum albumin to ascites albumin of less than 0.9 g/dL; and a low ascites total protein/serum total protein of more than 0.72. Therefore, NA must be differentiated from pancreatitis, malignancy, and tuberculous peritonitis (110). Changes in membrane permeability as a result of dialysis membranes and fluid, circulating immune complexes, iron deposition, abnormal sodium transport, or activation of the renin-angiotensin system have been proposed (104,107,111–113). Celiac disease has also been described as a rare cause (114). Histologic examination of the peritoneum typically demonstrates chronic inflammation, fibrosis, and mesothelial cell proliferation (105).

The diagnosis of NA is one of exclusion. Examination of the ascitic fluid is critical to establish an exudative pattern. Diagnostic paracentesis is central to establish the protein content and rule out infectious or neoplastic causes. Ultrasonography or CT may help delineate hepatic structure, but peritoneoscopy with biopsy is generally more definitive.

The treatment of NA is multimodal and includes strict volume control, daily hemodialysis for several weeks, frequent paracentesis, and optimization of protein nutrition. Other strategies have been employed with varying and unsatisfactory success. Ascites may respond to ascitic fluid reinfusion, peritoneal venous shunts, CAPD, bilateral nephrectomy, intraperitoneal corticosteroids, and possibly angiotensin-

converting enzyme (ACE) inhibitor therapy (105,109,115–119) and iron depletion (120). However, kidney transplantation remains the definitive treatment for NA and offers the best hope for cure. Patients experience complete resolution of ascites within 6 weeks of graft functioning but may have a recurrence after graft failure (121,122). Such measures can reverse the progressive course of cachexia and malnutrition, improve the quality of life, and improve survival.

CONSTIPATION

Functional constipation consists of decreased bowel frequency with fewer than three stools per week or frequent straining, incomplete evacuation, hard or lumpy stools, and the need for manual maneuvers. In the general population, the prevalence of constipation rises with age, affecting more than 25% of patients older than 65 years (123,124). Approximately 63% of hemodialysis patients experience constipation, possibly as a result of associated comorbidities, poor nutritional status, and increased colonic transit time or medications (**TABLE 23.4**) (125). Among CAPD patients, the prevalence of constipation is 29% and is age-related (126). The lower rate of constipation in CAPD has been attributed to better metabolic and potassium control and increased dietary fiber intake. In most patients, constipation is bothersome and may interfere with the quality of life; however, in rare instances, severe obstipation can be associated with colonic perforation and death.

TABLE 23.4 Factors Commonly Associated with Constipation in Dialysis Patients

Drugs
Analgesics
Anticholinergics
Antidepressants
Anticholinergics
Serotonin antagonists
Antipsychotics
Antihypertensives
Calcium channel antagonists
Calcium-containing drugs
Iron supplements
Aluminum binders
Calcium acetate binders
Calcium carbonate
Opiates
Neurogenic disorders
Autonomic neuropathy
Diabetic enteropathy
Intestinal pseudoobstruction
Metabolic problems
Hypercalcemia
Hypocalcemia
Hypothyroidism
Nutritional factors
Malnutrition
Dehydration
Low dietary fiber
Hyperkalemia
Inactivity

Uremic patients having chronic constipation, abdominal pain, and distension should be evaluated for

colonic pseudoobstruction. This is associated with colonic perforation in up to 50% of cases, particularly if the bowel wall diameter exceeds 12 cm (127). Neostigmine can be considered in the absence of contraindications unrelated to ESKD but may require dose adjustment. Early endoscopic or surgical decompression may result in complete recovery. Aluminum hydroxide binders have been associated with 78% of these cases as well as drugs and autonomic neuropathy (128). Plain abdominal films can be helpful to confirm the diagnosis, and CT scan or colonoscopy can rule out potential causes of mechanical obstruction. Antacid impactions should be considered in patients with ESKD, as they can ingest a large volume of antacids for dyspepsia and control of phosphorus absorption. Complications of antacid impactions such as stercoral ulceration and perforation are not uncommon (129).

The initial evaluation of a patient with constipation should include a careful history and physical examination, with emphasis on recent changes in bowel movements, and medications. If no cause is identified, imaging studies to rule out mass lesions, megacolon, and strictures may be useful. If these studies are normal, studies to assess for prolonged fecal transit time and pelvic floor dysfunction should be considered, in conjunction with consultation with a gastroenterologist.

Early and aggressive measures to reduce constipation are important, as uremic patients have a greater risk of developing diverticula and perforation than the general population (130). This is particularly true in patients with polycystic kidney disease, approximately 80% of whom have diverticuli, compared with 49% of patients with other causes of chronic kidney disease (131). Medical management of constipation in dialysis patients can begin with increasing dietary fiber and activity and avoiding volume depletion. Medications should be tailored to reduce the number of drugs associated with constipation (**TABLE 23.4**). Hyperosmolar, magnesium-containing compounds can cause hypermagnesemia in kidney disease and are contraindicated. Phosphate-containing enemas are also contraindicated. Stool softeners with docusate sodium may improve the ability of water to enter the stool but are not very effective. Chronic use of aluminum binders may worsen constipation, renal osteodystrophy, and encephalopathy. Chronic use of intestinal wall stimulants such as bisacodyl may induce hypokalemia and protein malnutrition; their use should be restricted to short-term management only. Lactulose, sorbitol, and polyethylene glycol are helpful in dialysis patients and can be used occasionally for refractory constipation (132). Lubiprostone and linaclotide are newer agents that can be employed for treatment of chronic constipation. For severe incapacitating constipation, surgical measures may be necessary.

CHAPTER 24

Chronic Kidney Disease-Mineral Bone Disorder in Patients with End-Stage Kidney Disease

Wajeh Y. Qunibi

Chronic kidney disease (CKD) is a global epidemic affecting 5% to 10% of the world population (1). Historically, nephrologists have been primarily concerned about of CKD progression to end-stage kidney disease (ESKD). However, we now realize that CKD is associated with a number of other comorbidities that contribute to the high risk of death. Among these comorbidities, three interrelated disorders have recently been the subject of intense interest and debate. First, disorders of mineral metabolism including those of calcium, phosphorus, parathyroid hormone (PTH), fibroblast growth factor-23 (FGF-23), and vitamin D metabolism. These disorders are very prevalent in CKD patients (2), usually become manifest when the glomerular filtration rate (GFR) falls below 60 mL/min, and worsen with progressive loss of kidney function. Some mineral disorders, such as the increase in FGF-23 and the decrease in klotho and calcitriol, may be observed early in the course of CKD and precede the onset of clinically detectable abnormalities in serum phosphorus, calcium, and PTH. The nature and degree of the changes in mineral metabolism may be influenced by various therapeutic interventions, such as phosphate binders, vitamin D, or calcimimetic agents. Second, bone disease, previously called renal osteodystrophy, which is also common in patients with CKD and universally present in patients with ESKD. Bone disease can be a consequence and/or a cause of abnormal mineral metabolism. Third and more serious component of CKD comorbidities is the accelerated cardiovascular disease (CVD), particularly cardiovascular calcification, which is now established as the leading cause of morbidity and mortality in patients with CKD (3,4). Age, gender, and race-adjusted cardiovascular mortality rate has been found to be 30- to more than 100-fold greater in dialysis patients than that in age- and race-matched individuals from the general population (3).

Increasing evidence has shown that the aforementioned abnormalities, singly and in combination, contribute to adverse outcomes of patients with CKD. For example, disturbances in mineral metabolism are known to be associated with bone disorders, cardiovascular calcification, and arterial stiffness but more importantly associated with all-cause and cardiovascular mortality in CKD patients (2,5,6). Indeed,

abnormalities in mineral metabolism are among the most important factors that contribute to the high cardiovascular mortality in these patients. Similarly, bone disease may lead to abnormalities in mineral metabolism and predispose to cardiovascular calcification and increases the risk of cardiovascular mortality. Because these disorders are deemed causally interrelated, the Work Group of the Kidney Disease: Improving Global Outcomes (KDIGO) (7) recommend using the term *chronic kidney disease-mineral and bone disorder* (CKD-MBD) to describe such a systemic disorder that occurs as a result of CKD (**FIGURE 24.1**). The new definition of CKD-MBD has now replaced the traditional term *renal osteodystrophy* since the latter does not incorporate the broad clinical spectrum described above. Indeed, the KDIGO Work Group recommends to restrict the use of the term *renal osteodystrophy* to describe the bone pathology associated with CKD, as seen on bone biopsy, using an expanded classification system based on parameters of bone turnover, mineralization, and volume (8).

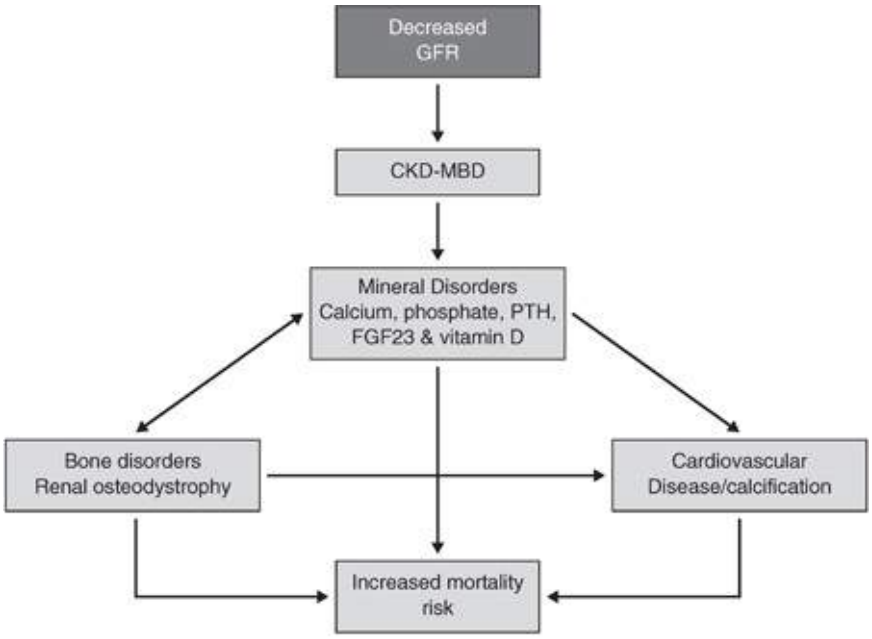

FIGURE 24.1 Chronic kidney disease-mineral bone disorder (CKD-MBD).

BIOCHEMICAL ABNORMALITIES IN PATIENTS WITH CHRONIC KIDNEY DISEASE-MINERAL AND BONE DISORDER

The first component of CKD-MBD is abnormal mineral metabolism including that of serum calcium, phosphate, PTH, vitamin D, and FGF-23. The pathophysiology of CKD-MBD comprises a number of feedback loops involving the kidney, bone, intestine, heart, and the vasculature, with the aim of maintaining the calcium and phosphate balance, often at the expense of abnormalities in other components of the system. The kidney plays a central role in regulating mineral metabolism, and as such, disturbances in mineral metabolism may occur early in the course of CKD because of the inability of the failing kidneys to maintain the levels of serum phosphate and calcium in the normal range. Bone disease develops as early as CKD stage 2 and becomes almost universal in patients with CKD stage 5 (9,10). Vascular calcifications also develop early, and its prevalence increases as the GFR declines such that approximately 80% of incident dialysis patients have evidence of coronary artery calcification (11–13). Given that these abnormalities are interrelated, and that they worsen with progressive loss of GFR, a

clear understanding of the central role of the kidney in calcium and phosphate homeostasis will certainly help in understanding the pathophysiology of CKD-MBD.

In order to document the various abnormalities relevant to CKD-MBD, laboratory evaluation of serum phosphate, calcium, PTH, alkaline phosphatase, as well as selective imaging for soft-tissue calcification should be done. In this regard, several studies have shown that serum calcium and phosphate values do not become abnormal until the GFR falls below 40 mL/min/1.73 m^2 and are relatively stable until GFR falls below 20 mL/min/1.73 m^2 (14,15). However, 12% of patients with GFR >80 mL/min/1.73 m^2 had a high PTH (defined as >65 pg/mL, the upper limit of normal of the assay used), and almost 60% of patients with GFR <60 mL/min/1.73 m^2 had elevated PTH levels (14). In incident dialysis patients, serum levels of calcium and phosphate at the start of dialysis were 9.35 mg/dL and 5.23 mg/dL, respectively, but increase over the initial 6 months of renal replacement therapy (16). High levels of serum alkaline phosphatase greater than 120 U/L were reported in almost 30% of prevalent dialysis patients and found to be associated with mortality (17). In this chapter, these abnormalities are discussed, and current therapeutic options are summarized.

The Role of Phosphorus in Chronic Kidney Disease-Mineral and Bone Disorder

Phosphate is an inorganic molecule with a central phosphorus atom and four oxygen atoms. Although the terms *phosphorus* and *phosphate* are often used interchangeably, the term *phosphate* refers to the sum of the two physiologically occurring inorganic ions, hydrogen phosphate (HPO_4^{2-}) and dihydrogen phosphate ($H_2PO_4^-$), but most laboratories report this measurable, inorganic component as phosphorus. Inorganic phosphorus is critically important for a number of physiologic functions including cell membrane phospholipid content and function, cell signaling, energy transfer through mitochondrial metabolism, platelet aggregation, mineral metabolism, and skeletal development. As a result, the body has developed homeostatic mechanisms to maintain serum phosphate in the range of 2.5 to 4.5 mg/dL.

Phosphorus is the sixth most abundant element in the human body. The adult human body contains between 700 and 1,000 g of phosphorus, of which 85% is in bone, 14% is in the intracellular compartment, and the remaining 1% is in the extracellular fluids (**FIGURE 24.2**) (18). Normal daily dietary intake varies from 800 to 1,500 mg. Absorption of dietary phosphate occurs along the entire length of the small intestine, but absorption occurs mainly in the small intestine (19,20). Intestinal phosphate absorption occurs through two well-defined mechanisms (21). Most of the phosphate absorption occurs by a passive, concentration-dependent diffusion process. It is still unclear whether this passive absorption takes place by a paracellular or transcellular transport pathway. Of note, this pathway for sodium-independent phosphate transport is unregulated (22). Even in patients with severe hyperphosphatemia, phosphate absorption from the diet is only slightly lower than that in normal subjects. A smaller fraction of phosphorus is absorbed through a saturable, active transport pathway through the intestinal epithelial brush border sodium phosphate cotransporter 2b (Npt2b) which is regulated by dietary phosphate and 1,25 dihydroxyvitamin D [$1,25(OH)_2\ D_3$] (21,22). These transporters are expressed in the small intestine and are upregulated under conditions of dietary phosphate deprivation. It is this active phosphate transport mechanism that becomes important under conditions of low phosphate intake. For example, during dietary phosphate restriction, 80% to 90% of phosphorus is absorbed. Approximately 150 mg of phosphorus is secreted daily into the gastrointestinal (GI) tract.

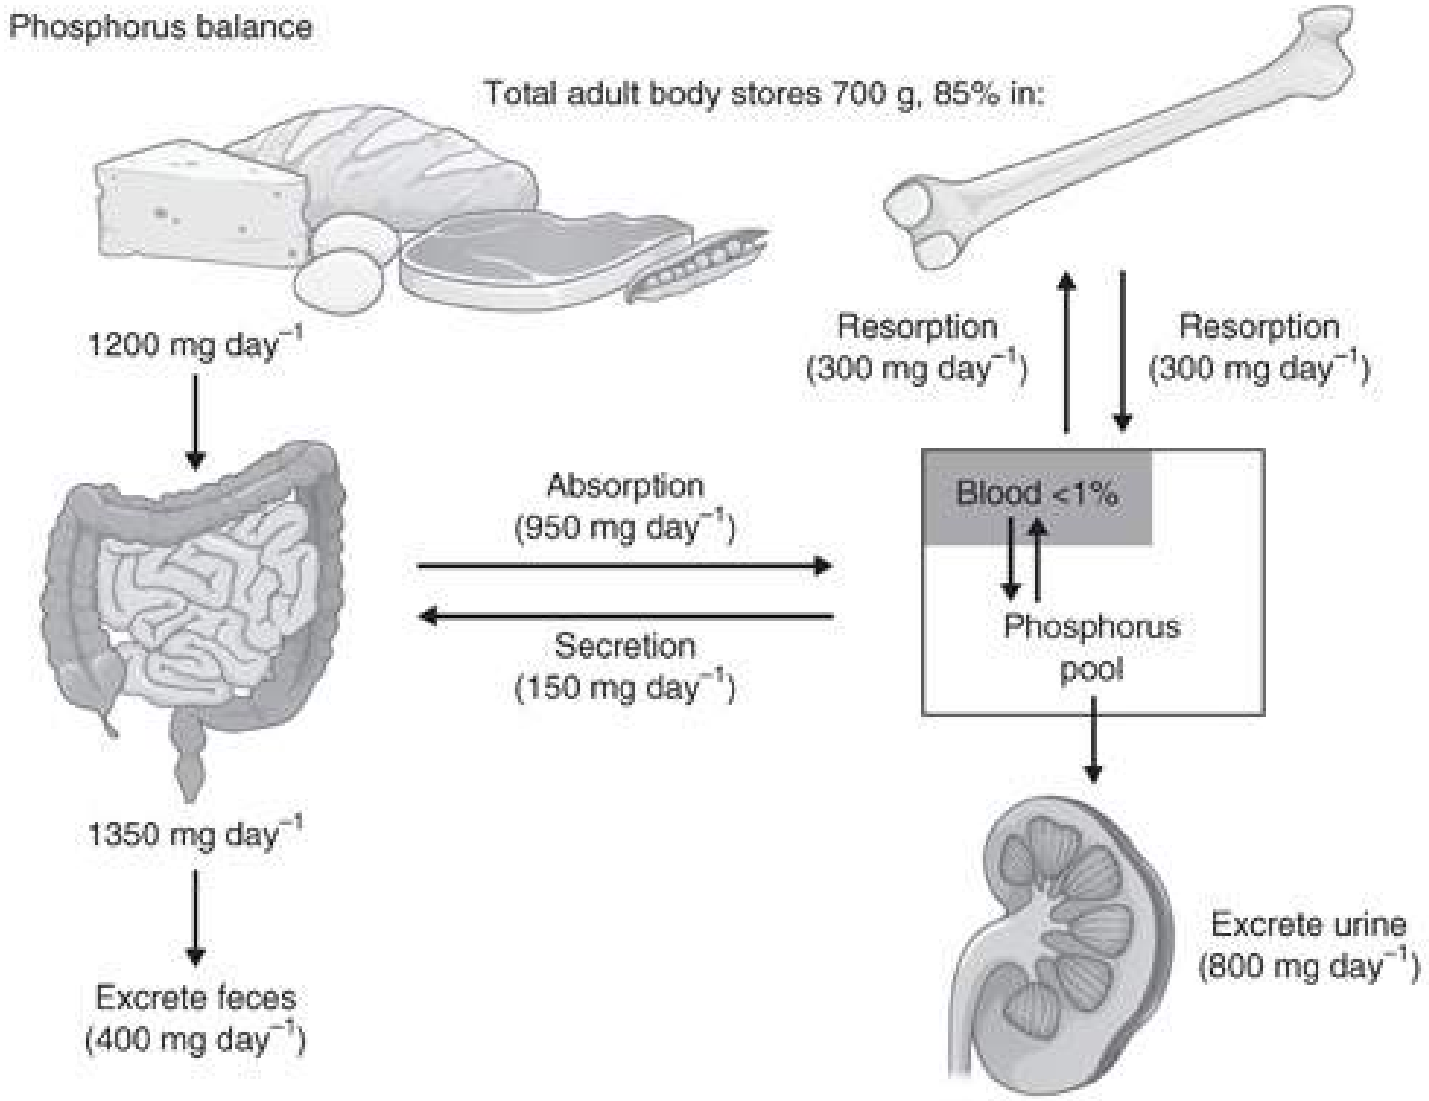

FIGURE 24.2 Normal phosphorus homeostasis. (Reprinted from Hruska KA, Mathew S, Lund R, et al. Hyperphosphatemia of chronic kidney disease. *Kidney Int* 2008;74:148–157.)

To maintain phosphate balance, the kidneys are responsible for excreting an amount of phosphorus equals to that absorbed from the intestine. The main factors that regulate proximal tubular phosphate excretion are the serum phosphate concentration itself, PTH, as well as FGF-23. These factors act on the proximal tubular epithelial brush border sodium phosphate cotransporters (Npt2a and Npt2c). Thus, serum phosphate concentration is primarily determined by the ability of the kidneys to excrete dietary phosphate. Interestingly, there is a diurnal variation in both serum phosphate levels and urinary phosphate excretion. Serum phosphate levels reach a nadir in the early hours of the morning, increasing to a plateau at 4 PM, and further increasing to a peak from 1 to 3 AM (23,24). A similar circadian pattern of serum phosphate was reported in CKD with lowest concentrations at 8 AM and highest at 4 PM and 4 AM (25). However, no diurnal variation was found in patients on dialysis when studied on a nondialysis day (26).

Phosphorus is present in most food products, particularly those with high protein content (27,28). In general, the higher the protein intake, the higher the phosphorus load, particularly in foods with a high phosphate-to-protein ratio as well as those with food additives and preservatives (27,20). In the steady state, serum phosphate concentration is primarily determined by the ability of the kidneys to excrete dietary phosphate (29). However, a tendency toward phosphate retention due to decreased phosphate filtration and excretion occurs as the GFR declines, but hyperphosphatemia is not commonly seen until the

GFR drops to <25 to 40 mL/min/1.73 m^2. This is due to the actions of PTH, FGF-23, and klotho on the proximal tubular phosphate reabsorption. In patients with advanced kidney disease, hyperphosphatemia results from a decrease in functioning nephrons, a decrease in the amount of filtered phosphate, and a subsequent decrease in excreted phosphate. Thus, in patients with CKD stage 4 or 5, the dietary intake of phosphate will likely exceed urinary excretion which leads to a positive phosphate balance. Hyperphosphatemia occurs almost universally in patients undergoing dialysis despite an apparent dietary phosphate restriction. Initially, excess phosphate will be buffered by bone, but once bone buffering is saturated, soft tissue phosphate deposition, usually in combination with calcium, ensues.

Consequences of Hyperphosphatemia

High serum phosphate is not a benign biochemical abnormality as it has been shown to be associated with a number of adverse clinical consequences (**FIGURE 24.3**). In this review, I will focus on the effects that hyperphosphatemia exerts in CKD-MBD. In the parathyroid gland (PTG), hyperphosphatemia directly stimulates parathyroid cells leading to increased PTH secretion. Also, it suppresses the 1-α-hydroxylase activity in the kidney which contributes to calcitriol deficiency. Finally, hyperphosphatemia stimulates the secretion of FGF-23 from osteocytes as will be discussed later.

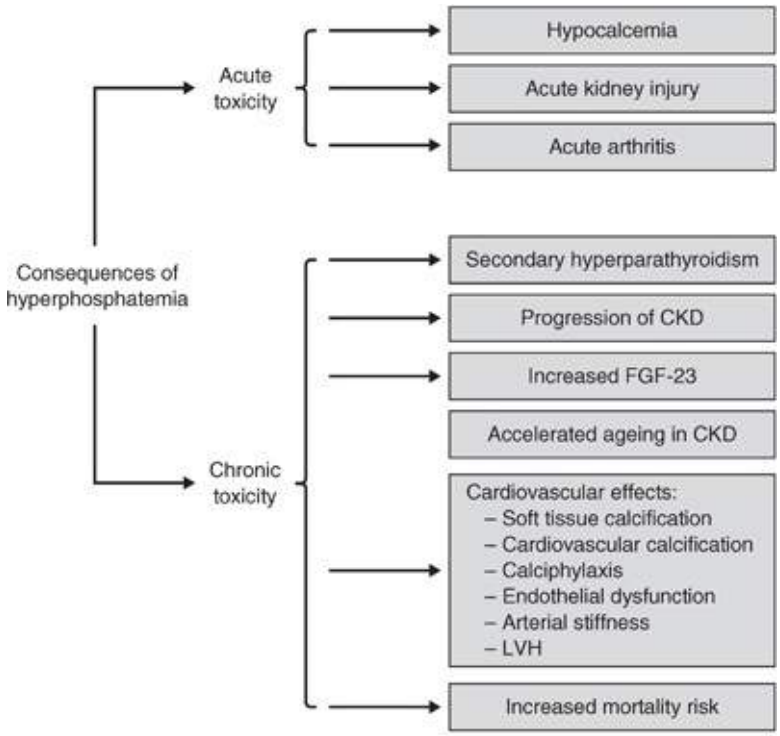

FIGURE 24.3 Clinical consequences of hyperphosphatemia.

Perhaps, the most important consequence of hyperphosphatemia is on the cardiovascular system where it stimulates osteoblastic transformation of the vascular smooth muscle cell (VSMC) in the vasculature and directly contributes to extraskeletal calcification. This was supported by finding an association of high serum phosphate with increased mortality risk was demonstrated in patients with CKD, particularly those on maintenance dialysis. Epidemiologic studies in the last two decades have consistently identified serum phosphate as an independent predictor of cardiovascular mortality in dialysis patients (2,30,31). In 25,588 patients on hemodialysis from Dialysis Outcomes and Practice Patterns Study (DOPPS), serum phosphate level of 3.6 to 5 mg/dL was associated with the lowest risk of cardiovascular mortality, while serum phosphate level greater than 7 mg/dL was associated with the

greatest risk of mortality (32). Serum phosphate levels are also associated with cardiovascular outcomes in non-CKD individuals. Higher serum phosphate, even within the normal range, was found to be associated with a greater risk of carotid atherosclerosis, coronary calcification, and cardiovascular mortality in patients with CKD (33,34). Moreover, in 15,732 patients from the Atherosclerosis Risk in Communities (ARIC) Study followed for 12.6 years, serum phosphate adjusted for GFR was associated with coronary events, stroke, and cardiovascular death (35). Higher serum phosphate is also associated with arterial stiffness, a marker of cardiovascular risk that may be related to vascular calcification (36). A recent meta-analysis of 47 cohort studies in 327,644 patients with CKD found an 18% increased risk of death for every 1-mg/dL increase in serum phosphate, while there was no significant association between all-cause mortality and serum PTH or calcium (6). Even in individuals with GFR >70 mL/min, higher serum phosphate levels were associated with a greater risk of cardiovascular events in a 15-year follow-up (37). However, these epidemiologic studies suffer from a number of limitations such as the level of serum phosphate above which there is increased risk of mortality in dialysis and CKD patients and the circadian variability in serum phosphate levels, which can be as high as 1 mg/dL, making interpretation of serum phosphate levels in the aforementioned studies difficult (24). Also, no clinical trial has shown that lowering serum phosphate to any specific level is associated with improvement in patients' outcomes. Nonetheless, a number of pathophysiologic mechanisms underlie the association between higher serum phosphate and CVD. These include cardiovascular calcification, endothelial dysfunction, and left ventricular hypertrophy (LVH) (see below).

The Role of Phosphate in Secondary Hyperparathyroidism

It has been recognized for decades that persistent hyperphosphatemia plays a key role in the pathogenesis of secondary hyperparathyroidism (SHPT). The mechanism by which phosphate plays such a role are both indirect and direct. Elevations in serum PTH levels may become evident usually when the GFR falls below 60 mL/min/1.73 m^2 before hyperphosphatemia or hypocalcemia are detectable by routine laboratory measurements. To explain this phenomenon, it was initially proposed that reduced GFR leads to retention of phosphate, transiently increasing serum phosphate level which in turn leads to a reduction in the level of serum ionized calcium in the blood, which then triggers an increase in the secretion of PTH. The goal for the increase in PTH level is to restore the serum calcium back to normal. Thus, PTH increases renal phosphate excretion by decreasing proximal tubular resorption of phosphate, mobilizing calcium from bone, and by stimulating the production of calcitriol by the kidney, which in turn increases intestinal absorption of calcium. As a result, a new steady state is reached where serum phosphate and calcium are normal at the expense of a higher level of PTH. This "trade-off" continues as the GFR declines further until severe SHPT develops (38). In this regard, several studies have shown that high-phosphate diet results in parathyroid hyperplasia (39,40). Moreover, dietary phosphate restriction in proportion to the reduction in GFR was effective in preventing the initial rise in PTH secretion and the development of hyperparathyroidism (41,42). Beside the reciprocal decline in serum ionized calcium due to transient hyperphosphatemia, phosphate retention may also inhibit the 1-α-hydroxylase enzyme in the kidney and thus may decrease the production of calcitriol. Moreover, it is now clear that high serum phosphate may directly stimulate the production and secretion of PTH, independent of its effects on serum ionized calcium and calcitriol (42–45). This effect is posttranscriptional and suggests that the stability of PTH mRNA may be regulated by phosphate and that this effect is mediated by proteins within the PTG

that bind to the 3′ untranslated region of the PTH gene transcript (46–49). Furthermore, phosphate retention seems to reduce the production of arachidonic acid by parathyroid tissue; this signaling mechanism may be due to the effect of changes in cytosolic calcium on the phospholipase A2–arachidonic acid pathway (50). On the other hand, the effect of a low-phosphate diet in preventing parathyroid growth seems to be mediated by an increase in the cell cycle regulator p21 (51). Therefore, there are both indirect and direct mechanisms by which serum phosphate initially promotes PTH secretion (**FIGURE 24.3**). However, as will be discussed later, the recent discovery of FGF-23 has changed our understanding of the pathogenesis of SHPT.

The Role of Serum Calcium in Chronic Kidney Disease-Mineral Bone Disorder

Dietary calcium is also absorbed by two different mechanisms. First is an active, transcellular pathway via the transient receptor potential vanilloid 6 (TRPV6) channel on the apical membrane of the duodenum and proximal jejunum, and second by a paracellular pathway that occurs throughout the length of the intestine (52,53). Of the average 1,000-mg calcium ingested by a normal adult per day, 800 to 900 mg of these appear in the feces. Of the ingested calcium, 400 to 500 mg may be absorbed and 300 mg is secreted via the intestinal secretions, thus leaving a net calcium absorption of only 100 to 200 mg per day (54). In healthy adults who are in calcium balance, this net amount of absorbed calcium is excreted in the urine. The adult human body contains approximately 1,200 g of calcium, 99% of which is stored in bone as calcium–phosphate complexes, primarily as hydroxyapatite. Skeletal mineralization is one of the most important functions of calcium as it provides skeletal strength and a dynamic store to maintain the intra- and extracellular calcium pools. Less than 1% of the total body calcium is present in the serum, and its concentration is tightly regulated within a narrow physiologic range that is optimal for its functions. This range is between 8.5 and 10.5 mg/dL, but serum calcium is not a good indicator of the total body calcium. Moreover, it should be realized that the ionized component, which represents 40% of the total serum calcium, is the fraction of serum calcium that is closely regulated. In persons with healthy kidneys, normal serum level of calcium is maintained through the interaction of PTH and $1,25(OH)_2$ D_3 (calcitriol), the active metabolite of vitamin D. Decreased ionized calcium level stimulates secretion of PTH which in turn acts to increase serum calcium (55).

The kidneys play a critical role in the regulation of normal serum calcium concentration which is maintained in the normal range until very late in CKD when it may decrease slightly. Although calcium balance in CKD is poorly understood, two recent balance studies in patients with CKD not yet on dialysis have shed some light on this subject. In the first study, Spiegel and Brady (56) found that subjects with late stage 3 and stage 4 CKD were in slightly negative to neutral calcium balance on a daily calcium intake of 800 mg but were in markedly positive balance on 2,000 mg calcium intake per day. In the second study, Hill et al. (57) studied eight patients with stage 3 or 4 CKD who received a controlled diet with or without 1,500 mg/d calcium carbonate supplement during two 3-week balance periods in a randomized placebo-controlled crossover design. The study found that patients were in neutral calcium balance while consuming a diet containing 957 mg calcium per day. However, increasing calcium intake with 500 mg calcium from calcium carbonate taken three times daily with meals produced positive calcium balance. The authors attributed this positive calcium balance to increased intestinal calcium absorption and net retention in the face of the kidneys' failure to increase urine calcium excretion. As will be discussed later,

the adverse consequences of positive calcium balance on mortality and cardiovascular calcification continue to be hotly debated.

Effects of Calcium on the Parathyroid Hormone

Since calcium plays a critical role in a wide range of biologic functions, its serum concentration is maintained within a very narrow range by a number of hormones including PTH, vitamin D, FGF-23, calcitonin, and estrogen. Among these, PTH is the primary regulator of serum calcium. On the other hand, ionized calcium is the primary regulator of PTH secretion (**FIGURE 24.4**). This bidirectional relationship has been described by an inverse sigmoidal curve (58). The midpoint or set point of this curve is the calcium-stimulated PTH, which is a key determinant of the serum ionized calcium concentration *in vivo*. In normal subjects, a small decrease in serum ionized calcium results in a sharp increase in serum PTH level within minutes. Also, an equally small increase in serum ionized calcium results in rapid decrease in the serum PTH level. Decreased serum ionized calcium triggers a sharp increase in PTH secretion which in turn acts to increase the plasma calcium by activating the 1-α-hydroxylase enzyme in the kidney and increasing the synthesis of calcitriol [$1,25(OH)_2$ D_3], which in turn enhances intestinal calcium absorption. PTH also mobilizes calcium from the readily available bone calcium stores and activates bone resorption indirectly by binding to PTH receptors on osteoblasts, which in turn increase osteoclast number and activity but also directly by binding and stimulating osteoclasts which lead to bone resorption (59). Finally, PTH increases calcium reabsorption in the distal nephron by activating adenylyl cyclase, which increases cyclic AMP levels and protein kinase A. The latter then phosphorylates and activates the transient receptor potential vanilloid 5 (TRPV5) which leads to increased transcellular calcium transport. Moreover, PTH increases the expression of several calcium transport proteins such as TRPV5, calbindin-D28k, and other transport proteins in the distal nephron, which also enhance renal calcium reabsorption (60). As a result, free serum calcium concentration is maintained in the normal range.

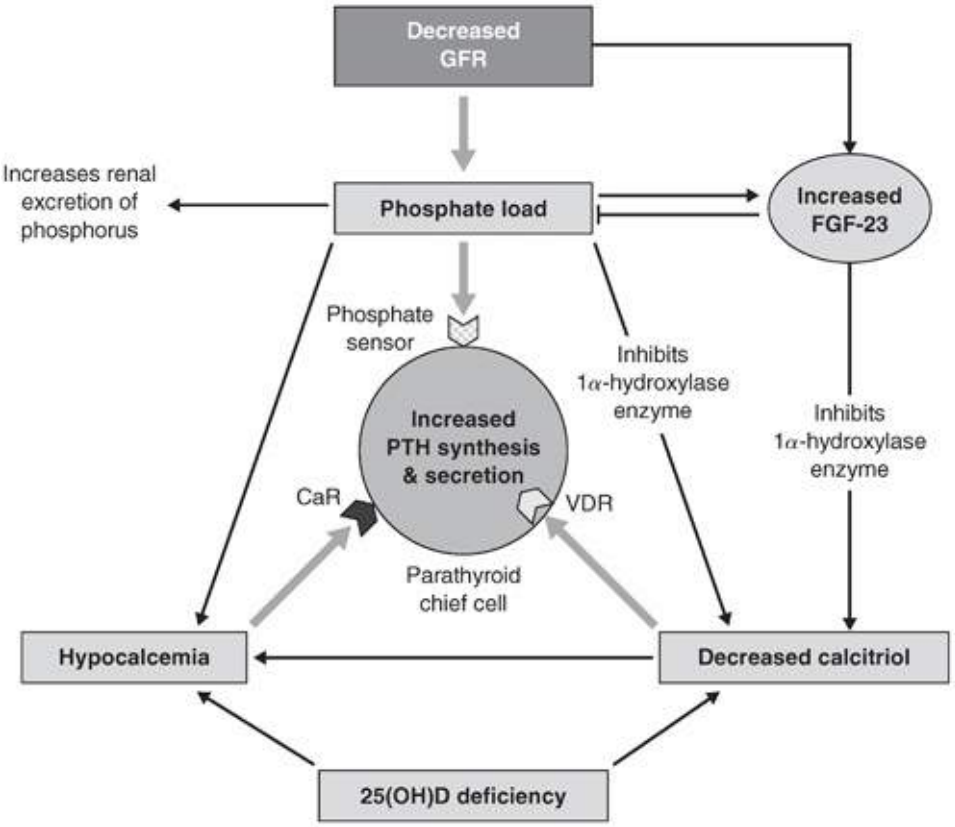

FIGURE 24.4 Pathogenesis of secondary hyperparathyroidism in chronic kidney disease (CKD).

Total serum calcium usually decreases during the course of CKD. This is due to several factors including phosphate retention, decreased calcitriol [1,25$(OH)_2$ D_3] level, and resistance to the calcemic actions of PTH on bone. Phosphate retention may cause calcium precipitation in soft tissues, decreases calcium efflux from bone by increasing resistance of bone to PTH action, and inhibits the 1-α-hydroxylase enzyme, leading to further reduction in the already decreased level of calcitriol and decreased intestinal absorption of calcium (61). However, hypocalcemia is relatively uncommon in CKD patients and may not be critical in the development of SHPT (62). Moreover, the increase in PTH level first become evident when the GFR drops below 60 mL/min/1.73 m^2, despite normal serum calcium and phosphate concentrations (15). On the other hand, circulating calcitriol concentrations begin to fall much earlier when the GFR is even above 60 mL/min/1.73 m^2 and are markedly decreased in subjects with ESKD (63). The primary reason for the decline in calcitriol concentration is increased FGF-23 concentration, rather than the loss of functioning renal tissue (64). Hyperphosphatemia may also contribute to the decline in calcitriol synthesis late in the course of CKD by suppressing the 1-α-hydroxylase enzyme. Thus, the primary stimulus for PTH secretion in CKD is the low calcitriol level. However, when hypocalcemia is present and persistent, it directly increases PTH mRNA concentrations via posttranscriptional actions and stimulates the proliferation of parathyroid cells over days or weeks leading to the development of PTG hyperplasia (65).

Changes in serum ionized calcium are sensed by the calcium-sensing receptor (CaSR) on parathyroid cells. More than two decades ago, it was shown that the secretion of PTH is mainly regulated by the CaSR, a membrane receptor that responds to small changes in serum ionized calcium (66). This receptor, a member of the G-protein-coupled membrane receptors on the parathyroid chief cells, enables the parathyroid cells to act as calcium electrodes and thus sense and respond rapidly to very small changes in the level of extracellular calcium. Hypocalcemia stimulates PTH secretion by inactivating the CaSR

while hypercalcemia activates the CaSR and inhibits the secretion of PTH. Also, CaSR inhibits PTH gene expression at the transcriptional and/or posttranscriptional level, and thus, it can inhibit parathyroid cellular proliferation. The discovery and cloning of the CaSR in the PTG has increased our awareness of the importance of calcium ion in regulating PTH secretion. Kovacs et al. (67) have shown that CaSR knockout mice develop severe parathyroid hyperplasia and hyperparathyroidism despite significantly increased $1,25(OH)_2 D_3$ levels. By contrast, studies in vitamin D receptor (VDR) knockout mice show that these VDR-deficient animals develop hyperparathyroidism that can be reversed by the administration of calcium and normalizing serum calcium levels (68). Therefore, it was not surprising that CaSR became a rational target for therapeutic intervention by agents that either mimic the actions of calcium ion on PTH secretion (type I calcimimetics) or induce changes in the structural conformation of the CaSR and thus increase the sensitivity of the receptor to extracellular ionized calcium (type II calcimimetics) and can lower PTH secretion from the PTG. In CKD, the number of CaSRs may be reduced in hypertrophied PTGs, particularly in areas of nodular hypertrophy (69–71). Decreased expression of the CaSR appears to be related to the proliferation of parathyroid tissue, and both may be related to increased serum phosphate (70,72). Such decrease in CaSR number can lead to inadequate suppression of PTH secretion by calcium, resulting in inappropriately high PTH concentrations in the setting of normal or even high calcium concentrations. However, experimental studies suggest that calcimimetic agents may even suppress PTH secretion in human parathyroid cells with pathologically reduced CaSR levels (73) and attenuate parathyroid hyperplasia (74).

Role of Vitamin D in Chronic Kidney Disease-Mineral Bone Disorder

Calcitriol [$1,25(OH)_2 D_3$] is a key hormone in the regulation of mineral metabolism. It acts by binding to a nuclear VDR, which is ubiquitously distributed in most tissues, leading to transcriptional regulation of target genes. Calcitriol is a critical factor in the regulation of serum calcium, phosphate, PTH, and FGF-23. It enhances the absorption of phosphate from the small intestinal cells by upregulating the apical membrane sodium-dependent phosphate cotransporter 2b (Npt2b), the rate-limiting step in intestinal phosphate absorption. It also helps to maintain the plasma calcium concentration through actions on the intestine, bone, and the kidney. In the intestine, it acts by increasing the expression of TRPV6 while in the kidney, it enhances calcium reabsorption by increasing the expression of the transporter protein TRPV5 in the distal renal tubular and connecting tubular cells (75). However, its effect on bone with regard to regulating serum calcium is not entirely clear but may involve increasing calcium release from bone by binding to osteoblasts and osteocytes and suppressing bone matrix mineralization during negative calcium balance (76).

CKD is both a state of calcitriol deficiency and resistance. Nutritional vitamin D deficiency (25-hydroxyvitamin D), which is very common in CKD, is an important contributor to calcitriol deficiency (64,77). In general, 25-hydroxyvitamin D is not biologically active, and thus, it must be metabolized in the kidney to its active form, the $1,25(OH)_2 D_3$ or calcitriol, by the enzyme 1-α-hydroxylase in the renal proximal tubular cells and several other extrarenal cells. There are a number of factors that regulate the activity of this enzyme, the most important of which is PTH, serum phosphate, serum calcium, and various hormones (**FIGURE 24.4**). More recently, FGF-23 and secreted frizzled related protein 4 (sFRP4) have been shown to inhibit the 1-α-hydroxylase enzyme activity (78,79). In fact, it has been shown that the

primary cause of the low calcitriol level in patients with CKD is increased FGF-23 concentration rather than the loss of functioning renal tissue (64). Also, hyperphosphatemia may contribute to the decline in calcitriol synthesis late in the course of CKD by suppressing the 1-α-hydroxylase enzyme. Given that calcitriol exerts a potent negative feedback on the PTG, thereby decreasing PTH production and release, its low level in CKD is now believed to trigger the initial increase in PTH secretion. However, when hypocalcemia is present and persistent, it directly increases PTH mRNA concentrations via posttranscriptional actions and stimulates the proliferation of parathyroid cells over days or weeks leading to the development of PTG hyperplasia (65).

Role of Parathyroid Hormone

PTH (1-84) is a single-chain polypeptide of 84 amino acids that is cleaved from pre-pro-PTH, where it is stored along with its fragments in secretary granules in the PTG. PTH is synthesized as a pre-pro-PTH and then is proteolytically processed to pro-PTH in the endoplasmic reticulum and then to PTH in the Golgi and secretory vesicles. All intracellular pro-PTH is normally converted to PTH before secretion. Once released, PTH has a short half-life of 2 to 4 minutes as it is cleaved after secretion into N-terminal, carboxy C-terminal, and midregion fragments. These fragments are usually metabolized by the liver and in the kidney (80). In patients with reduced GFR, the renal excretion of the C-fragment is reduced, resulting in marked elevation of PTH levels. PTH 1-84 is the biologically active hormone that exerts its effects through the interaction of its first 34 amino acids with the type 1 parathyroid hormone receptor (PTHR1). Some of PTH fragments lacking residues at the extreme N-terminus such as PTH (7-84) is believed to interact with its own distinct receptors and may have antagonistic effects to the calcemic action of PTH (1-84) and PTH (1-34) (81,82).

The serum concentrations of PTH depend on its release from stores in secretory granules within the PTG and also by synthesis of new PTH. The primary stimulus for PTH secretion is reduction in serum ionized calcium concentration. Hypocalcemia, acting through the CaSR, induces a rapid release of stored PTH in secretory granules and retards its degradation within the PTG. Moreover, it increases division of the parathyroid cells in the PTG likely through the action of the CaSR (55). In addition to calcium, high serum phosphate levels also increase PTH secretion independently of changes in serum calcium or serum levels $1,25(OH)_2$ D_3. However, it is not clear how the parathyroid cell senses changes in the serum phosphate level. Also, vitamin D alters the transcription of PTH and may indirectly inhibit its release by increasing the expression of CaSR in the PTG (**FIGURE 24.4**). Low vitamin D level removes the inhibitory effect of vitamin D on transcription and thus stimulates PTH synthesis and secretion. On the other hand, hypercalcemia, administration of the active vitamin D analogs, as well as high FGF-23 level inhibit PTH synthesis or release (55,83,84).

PTH is considered a systemic toxin that has been implicated in the pathogenesis of various uremic complications including CKD-MBD (85). It acts by binding to its receptor, the PTHR1, which is widely expressed in many tissues including bone, kidney, and the vasculature. As discussed above, PTH increases extracellular fluid calcium by mobilizing calcium from its readily available stores in bone and also by increasing osteoclastic bone resorption. Moreover, it increases calcium reabsorption in the distal nephron by upregulating the TRPV5 and TRPV6, calbindin-D28K, and other transport proteins in the distal nephron (60). Another important function of PTH is its phosphaturic effect which is mediated by

rapid internalization and subsequent degradation of Npt2a and Npt2c proteins in the apical membrane of the proximal tubule. PTH also stimulates the 1-α-hydroxylase enzyme in the kidney which in turn converts 25OHD into its active form, the $1,25(OH)_2 D_3$. Lastly, PTH enhances the synthesis and secretion of FGF-23 from bone cells. Studies have shown that continuous infusion of (1-34) PTH for 24 to 46 hours increased serum FGF-23 levels in healthy volunteers and in patients with ESKD (86,87). By contrast, parathyroidectomy decreased serum FGF-23 levels (88,89). However, since PTH stimulates the production of $1,25(OH)_2 D_3$, it is difficult to determine whether its effect on FGF-23 is the result of a direct stimulatory effect on osteocytes or to an indirect effect of elevated $1,25(OH)_2 D_3$ levels (90). Finally, because of its effect on bone, both high and low PTH levels may increase the risk of vascular calcification (91). The systemic toxic effects of PTH are many and include cardiomyopathy, hyperlipidemia, carbohydrate intolerance, bone marrow fibrosis, and anemia resistant to erythropoietin, pruritus, peripheral neuropathy, and encephalopathy (85,92,93). Moreover, high PTH serum levels have been shown to be associated with higher mortality rates in dialysis patients (2,31,94). In a recent study from DOPPS, the mortality risk in dialysis patients was higher for PTH level of 301 to 450 pg/mL and >600 pg/mL compared with the group with PTH of 150 to 300 pg/mL. Also, cardiovascular mortality and the risk of hospitalization were higher for PTH >600 pg/mL. On the other hand, PTH level <50 pg/mL was also associated with mortality, particularly among patients with diabetes and those with lower body mass index (95).

Accurate measurement of the serum PTH concentration is essential for the proper evaluation and management of patients with CKD-MBD. Measurements and interpretation of PTH values in patients with CKD, particularly those on chronic dialysis, remain challenging with wide variations among various assays in current use (96). What constitutes an appropriate assay for PTH measurement remains unclear. PTH level was initially measured by radioimmunoassay (RIA) (first-generation assays) using various polyclonal antibodies directed against epitopes that are located within the mid- or C-terminal portion of the PTH molecule. However, these assays proved to be inaccurate and have been replaced by two-site immunometric assay (IMAs) (second- and third-generation assays). The second-generation assays, so-called “intact PTH” assays, not only measure the full-length PTH molecule (1-84) but also detect the PTH (7-84) fragment (97,98). On the other hand, the more recent third-generation assay measures only PTH (1-84) and is referred to as the whole, bioactive or biointact PTH assay. However, the role of this assay in the diagnosis of renal osteodystrophy remains to be established.

The difficulty in interpreting PTH values led some authors to suggest that measurements of PTH levels in CKD and dialysis patients are not even necessary because there is inadequate evidence to link PTH to skeletal and cardiovascular end points in CKD (80). However, others believe that there is sufficient evidence that links PTH with adverse outcomes, especially when levels are toward the extremes of the KDIGO recommendations, and thus, PTH measurements are helpful in evaluating CKD-MBD in such patients (99). In our opinion, a single value of PTH measured at a single time point is unlikely to precisely reflect the underlying bone disease in patients with CKD, but the trend of serial measurements of PTH, using the same PTH assay, would be more informative. Another important but difficult issue is what represents an appropriate target range for PTH level. The 2009 KDIGO clinical practice guidelines suggest a broad range of PTH values, ranging from 2 to 9 times the upper limit of normal (7). Although very high or very low PTH values can predict with some certainty the nature of the

underlying bone disease, we believe that the higher end of the KDIGO recommended value for PTH is bound to increase the prevalence of osteitis fibrosa (100). Indeed, a recent study from DOPPS showed that SHPT is on the rise since the KDIGO guidelines were released (95). Moreover, data from the Control of Renal Osteodystrophy in South America study and the Analyzing Data, Recognizing Excellence, and Optimizing Outcomes study from Europe showed that PTH values as recommended by the 2003 KDOQI guidelines may be associated with the best clinical outcomes (101,102). Thus, as we previously suggested, a PTH level in the 100 to 400 range may minimize both low turnover bone disease and osteitis fibrosa (100). This range is also supported by recent data from the Japanese Society for Dialysis Therapy (JSDT) which showed that patients with PTH levels outside their recommend target range of intact PTH between 60 and 240 pg/mL have increased mortality risk (100,103). The adverse consequences of high PTH levels was recently reported from the Cardiovascular Health Study which showed that serum PTH levels >65 pg/mL were associated with greater N-terminal pro-B-type natriuretic peptide, cardiac troponin T, and left ventricular mass, particularly in patients with CKD (104).

Role of Fibroblast Growth Factor-23 in Chronic Kidney Disease-Mineral Bone Disorder

FGF-23 is a circulating peptide that plays a key role in the control of serum phosphate concentrations (105,106). FGF-23 is produced by bone osteocytes and osteoblasts in response to calcitriol, increased dietary phosphate load, PTH, and calcium (106,107). The primary function of FGF-23 is to maintain normal serum phosphate concentration by reducing renal phosphate reabsorption and by reducing intestinal phosphate absorption through decreased calcitriol production (**FIGURE 24.4**). In the renal proximal tubular cells, FGF-23 binds to the fibroblast growth factor receptor (FGFR) and its coreceptor, klotho, causing inhibition of the expression of the Npt2a and possibly Npt2c (108). As discussed earlier, FGF-23 also inhibits expression of 1-α-hydroxylase enzyme, leading to decreased calcitriol synthesis by the kidney (109).

FGF-23 and PTH mutually regulate each other in a negative feedback loop (110). Studies have shown that PTH stimulates synthesis and secretion of FGF-23 by activation of PTH/PTHrP receptor on osteocytes and osteoblasts (88,90,111). On the other hand, other studies showed that FGF-23 suppresses PTH synthesis (112,113). However, among CKD patients, the presence of high PTH concentrations, despite high FGF-23 concentrations, suggests that the PTG is relatively resistant to the elevated concentrations of FGF-23 in uremia. This may be related to the markedly decreased expression of FGFR 1 and klotho protein in the hyperplastic PTG (114,115). Klotho is a transmembrane protein that is produced by osteocytes and is essential for FGF-23 receptor activation (116). Klotho is expressed in the kidney and the PTGs, making these organs the target for FGF-23. Unlike FGFRs which are quite ubiquitously distributed, klotho expression is restricted, and thus, its presence may control whether a cell is an FGF-23 target. Its expression in the kidney and PTGs decreases during CKD progression in mice and humans (113,114,117). Klotho itself is a target gene of calcitriol (118,119). Moreover, klotho extracellular domain does not directly bind to FGF-23 but enhances FGF-23 binding to its receptor complex with a much higher affinity than to the FGFR alone (120). Decreases in klotho induce resistance to FGF-23 in these target organs, which further increases blood FGF-23 levels (113,114,117). It has been shown that a 50% decrease in klotho expression results in approximately 300% increase in blood FGF-23

levels in mice (121).

Patients with CKD have increased FGF-23 concentrations due to increased secretion by osteocytes and decreased catabolism by the diseased kidney (122,123). Klotho expression declines early in the course of CKD and then progressively with decreasing GFR (124). The reduction in klotho temporally coincides with the rise in FGF-23, suggesting that this decline may be partially responsible for the progressive rise in FGF-23 concentration. Moreover, the decrease in klotho expression on hyperplastic PTGs may contribute to the resistance and impaired parathyroid suppression by FGF-23 (114). On the other hand, FGF-23 may be a regulator of klotho expression in the kidney (121). Klotho deficiency is bound to decrease its regulation of FGF-23 production and thus allows hyperphosphatemia to become the principal regulator of FGF-23 secretion in CKD. Moreover, the decrease in membrane-bound klotho expression curbs FGF-23 actions on FGFR/klotho complexes leading to loss of negative feedback to FGF-23 secretion and continued production of FGF-23 by the osteocyte. Interestingly, in the absence of klotho expression as in the heart, the very high levels of FGF-23 in advanced stages of CKD enable FGF receptor activation in the heart, independent of klotho, leading to direct pathologic effects such as left ventricular hypertrophy (125).

FGF-23 level increases prior to changes in calcium, phosphorus, calcitriol, or PTH levels and therefore is now recognized as one of the earliest detectable biomarkers of the CKD-MBD (**FIGURE 24.5**) (126). Patients with advanced CKD have increased FGF-23 and PTH levels but decreased calcitriol levels. This constellation of compensatory changes initially result in normal serum calcium and phosphate levels, but eventually, such mechanisms become overwhelmed in patients with ESKD resulting in the full expression of the syndrome of CKD-MBD. One component of CKD-MBD that FGF-23 and/or klotho may play a role is vascular calcification. Some studies reported an independent association between circulating FGF-23 level with the progression of coronary calcifications (127,128), but more recent data indicate that FGF-23 is not involved in vascular calcification (129), while klotho deficiency is a recognized factor in that process (129). However, robust data are currently available to implicate the high levels of FGF-23 in dialysis and CKD patients with left ventricular mass, heart failure, and mortality but not with ischemic heart disease (125,130–132).

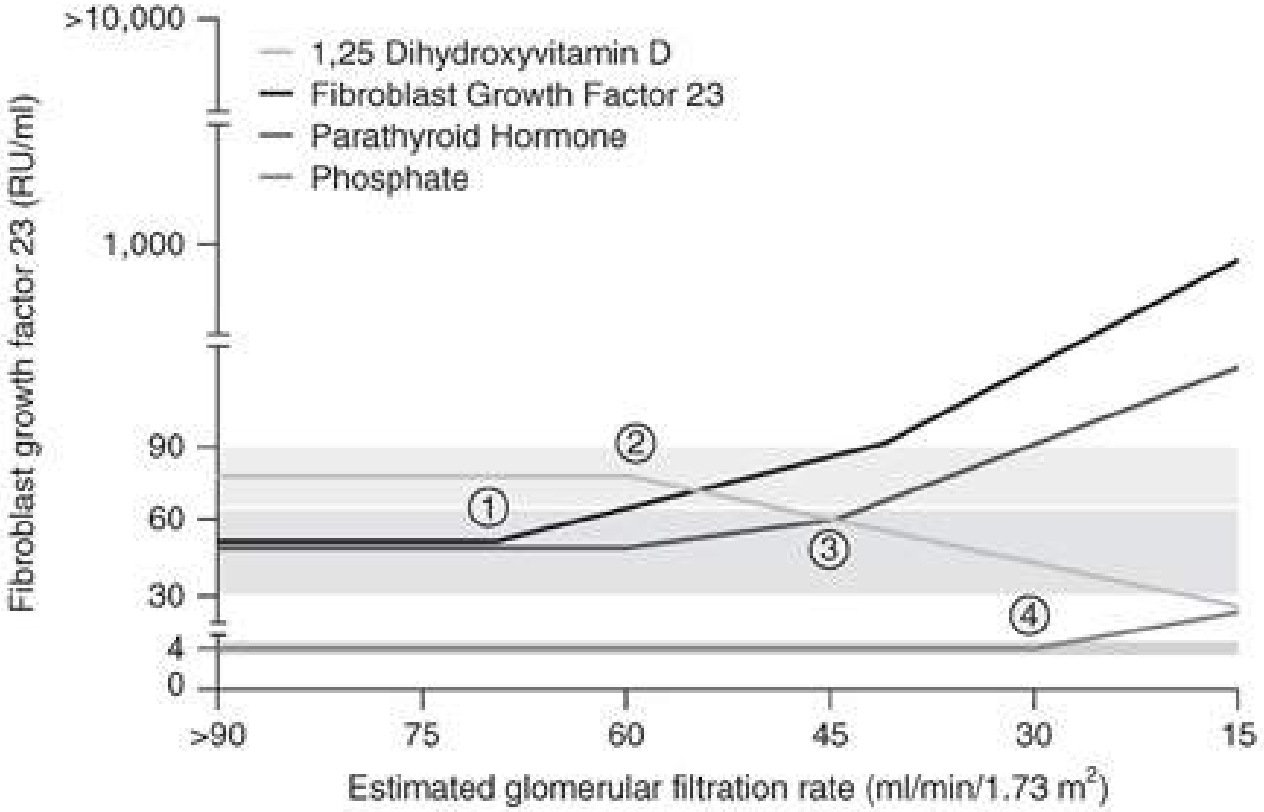

FIGURE 24.5 Biochemical phenotype of disordered mineral metabolism in CKD. The graph summarizes evolution of abnormal mineral metabolism along the spectrum of CKD. Depicted values are based on published literature. (Reproduced with permission from Isakova T, Ix JH, Sprague SM, et al. Rationale and approaches to phosphate and fibroblast growth factor 23 reduction in CKD. *J Am Soc Nephrol* 2015;26:2328–2339.). The *x*-axis represents glomerular filtration. The *y*-axis represents circulating levels of individual analytes with temporal changes in and normal ranges of fibroblast growth factor-23 (FGF-23), 1,25 dihydroxyvitamin D (1,25D), parathyroid hormone (PTH), and phosphate. Elevated FGF-23 is the earliest alteration in mineral metabolism in CKD (**1**). Elevations in FGF-23 levels cause the early decline in 1,25D levels (**2**) that leads to secondary hyperparathyroidism (**3**). All of these changes occur prior to elevations in serum phosphate levels (**4**).

CARDIOVASCULAR CALCIFICATION

The second important component of CKD-MBD is vascular calcification. This type of calcification results from abnormal deposition of calcium phosphate salts into the vascular wall as well as in other cardiac structures including the aorta, coronary arteries, cardiac valves, as well as peripheral vessels. Vessels from healthy control subjects do not calcify even after long-term exposure to supraphysiologic levels of phosphate and/or calcium *in vitro*, whereas vessels from CKD and dialysis patients calcify (133). Calcification starts as early as CKD stage 2, as shown in an animal model of CKD equivalent to human CKD stage 2 (134) but becomes accelerated with progressive loss of GFR particularly in patients with ESKD who are receiving dialysis. Several studies have documented that patients with ESKD on dialysis have a higher prevalence and severity of cardiovascular calcification than age- and gender-matched healthy subjects. Vascular calcification in patients with CKD can be either atherosclerotic affecting the intima, or medial calcification with calcium phosphate deposition in the media of the vessel wall. It has been argued that medial calcification is a manifestation of accelerated atherosclerosis in patients with CKD (135), but others believe that atherosclerotic and medial calcification are two distinct entities, with the latter developing more commonly in patients with CKD particularly those with diabetes

mellitus (136). Clearly, both forms of calcification can occur concomitantly in patients with CKD.

The cause of accelerated calcification in patients with ESKD is multifactorial and include both the traditional CVD risk factors and uremia-related risk factors (12,137). Vascular calcification in patients with CKD was initially thought to be a passive, physicochemical process in which serum phosphate and calcium are deposited in the arterial wall. However, we now know that vascular calcification is more complex and involves an active, cell-mediated, and highly regulated process similar to bone formation with VSMC playing a critical role. Just as in bone formation, vascular calcification results from either an imbalance between factors that promote calcification and those regulatory molecules that act to inhibit calcification (12,137,138). Incubation of human aortic smooth muscle (SM) cells in high phosphate medium similar to those regularly seen in dialysis patients directly enhanced extracellular calcification in these cells via a sodium-dependent phosphate cotransporter-sensitive mechanism (139). In this scenario, serum phosphate induces transformation of VSMC to an osteoblast-like cell by simultaneously downregulating the production of SM genes such as α-actin and SM22 and upregulating Runx2 (Cbfa1), osterix, osteopontin, osteocalcin, and alkaline phosphatase. Similarly, high calcium in the medium also induces transformation of VSMC to an osteoblast-like cell (133). It is likely that calcium and phosphate have synergistic procalcification effects in mediating VSMC cell apoptosis, osteochondrocytic differentiation, and matrix vesicle release (140). However, recent *in vitro* studies have found calcium to be a stronger procalcification factor than phosphate. Experimental studies utilizing human VSMC explant cultures or aortic ring cultures clearly document a role for calcium in the pathogenesis of vascular calcification in CKD and dialysis patients. In one study, when arterial rings obtained during abdominal surgery from children with normal renal function, those with impaired renal function, and from those on dialysis were exposed to high phosphate and calcium media, calcium-induced calcification more potently than phosphate, but only in rings from patients with CKD or those on dialysis (133). This suggests that VSMCs from healthy vessels have effective inhibitory mechanisms that prevent calcification, while those with CKD, particularly dialysis patients, become susceptible to calcification.

The now phenotypically transformed VSMCs lose their contractile function and behave like bone-forming cells that lay down a collagen-1 rich extracellular matrix and pinch-off matrix vesicles that are rich in calcium and phosphate. These vesicles are capable of initiating mineralization of the vascular wall just as they do so in bone (138). The key transcription factor here is Runx2 without which no such transformation of VSMCs or mineralization of the vessel wall can occur. Increased calcium levels promote calcification further by inducing apoptosis of VSMCs (133,141,142). Both matrix vesicles and apoptotic bodies serve as nucleation sites for hydroxyapatite, particularly in the presence of low calcification inhibitors such as matrix-Gla protein (MGP) and fetuin-A. Thus, unlike vessels from healthy individuals, vessels from predialysis and, to a much greater extent, dialysis patients have been primed to calcify (133). Susceptibility to calcification in CKD may be related to a decrease in matrix vesicles calcification inhibitors such as fetuin-A and MGP and to degradation of the elastin by matrix metalloproteases (MMP), such as MMP-2 and MMP-9, which are upregulated in the arterial wall in CKD (138). The degradation of elastin leads to overexpression of transforming growth factor (TGF)-β, which is thought to be involved in osteoblast differentiation and in enhancing VSMC calcification and arterial stiffness (138). From the above, it can be deduced that vascular calcification is the result of interaction between factors that promote calcification and those that normally inhibit calcification in the

microenvironment of the vessel wall and not simply by spontaneous deposition of calcium phosphate.

One of the factors that was suspected of enhancing vascular calcification in dialysis and CKD patients is the calcium load provided from use of calcium-based phosphate binders (CBPBs). While a number of clinical trials (143–145), epidemiologic studies (146), and meta-analysis (147) have shown increased risk of all-cause mortality or progression of cardiovascular calcification in CKD patients treated with CBPB, other clinical trials (148,149), epidemiologic studies (150), and meta-analysis (151) did not show a difference between calcium-based and non–calcium-based phosphate binders. In fact, a recent randomized placebo-controlled pilot clinical trial by Block et al. (152) showed that therapy with both non–calcium- and calcium-based phosphate binders resulted in progression of vascular calcification, albeit to a smaller degree in noncalcium phosphate binders. Thus, the effects of calcium load from use of CBPB on progression of cardiovascular calcification, while plausible, remain controversial (153). An important issue that needs to be investigated is whether slowing vascular calcification by any means, including phosphate binders, would translate into improvements in clinical outcomes. Two epidemiologic studies have in fact reported that use of any type of phosphate binder, possibly with the exception of aluminum-based binders, is independently associated with improved survival in dialysis patients compared with no use of binder at all (154,155). A third study in an incident United States Renal Data System (USRDS) cohort that started dialysis in 1996 to 1997, when only CBPBs were used in the United States, found no association between the use of these agents and mortality (156). As a result, the KDIGO Work Group stated that “there were inconclusive data to indicate that any one binder has beneficial effects on mortality or other patient-centered outcomes when compared with any other binder” (7). However, 16 of 17 members of the KDIGO Work Group felt that the weight of evidence is in favor of the non-CBPBs. In patients with CKD stages 3 to 5D, the Work Group recommend restricting the dose of CBPBs and/or the dose of calcitriol or vitamin D analog in the presence of persistent or recurrent hypercalcemia, arterial calcification, or adynamic bone disease (ABD).

The clinical consequences of vascular calcification in patients with CKD are serious. Cardiovascular calcification increases the risk of cardiovascular events including myocardial infarction, fatal arrhythmia, congestive heart failure, and valvular heart disease (4,157). Hyperphosphatemia may be associated with increased cardiac stroke index, increased systolic and decreased diastolic blood pressure, increased pulse pressure, and increased pulse wave velocity (4,157). Moreover, these patients had higher common carotid artery diameter and lower wall-to-lumen ratios. The authors speculated that these changes were due to medial calcification of the arterial wall, which leads to arterial stiffness. These hemodynamic disturbances may result in LVH and compromise coronary artery blood flow during diastole. It is noteworthy that in the Framingham Heart Study, abdominal aortic calcification identified by plain radiographs was independently predictive of subsequent vascular morbidity and mortality (158).

RENAL OSTEODYSTROPHY

The third component of CKD-MBD is renal bone disease. Abnormal bone lesions are common in patients with CKD and usually start early when most biochemical measures of mineral metabolism are still normal. Most patients with early stages of CKD (stages 1 to 3) have age-related osteoporosis, while those with the more advanced stages of CKD (stages 3 to 5D), particularly those who have abnormalities of mineral metabolism, usually have renal osteodystrophy (159). Abnormal bone quality and quantity can

lead to increased bone fragility, resulting in fracture. Both osteoporosis and renal osteodystrophy may coexist and can lead to increased bone fragility and fractures in all stages of CKD.

In patients with CKD, progressive bone lesions may result in bone pain, fractures, and deformities in growing children, reduced growth velocity, and abnormal height, particularly in those on maintenance dialysis. The prevalence of fractures among the dialysis population is between 10% and 40% (7). Such complication is often associated with serious consequences. As an example, hip fractures may be associated with bleeding, infection, and increased risk of mortality. Osteoporosis is traditionally diagnosed by finding low bone mineral density (BMD). By contrast, CKD-MBD can lead to an abnormal bone quality even in the setting of a normal or high bone mineral content in patients with CKD stages 3 to 5D. Thus, measurement of BMD by dual-energy x-ray absorptiometry (DXA) scan may not distinguish between the various types of renal osteodystrophy as seen with bone histology (7). A more accurate but also more expensive is the use of quantitative computed tomography (QCT), which was recently shown to prospectively identify more bone loss at the hip than DXA (160). However, bone biopsy is the gold standard as it provides information on the three variables suggested by KDIGO: bone turnover, mineralization, and volume (TMV). Turnover refers to a spectrum of bone formation rates from abnormally low to very high. Mineralization reflects the amount of unmineralized osteoid. Bone volume, which is the end result of changes in bone formation and resorption rates, contributes to bone fragility. In a recent review of studies dating from 1969 to 2007, the KDIGO group reported that bone volume/trabecular volume (BV/TV) is generally lower in dialysis patients compared with that in nondialysis CKD patients across all renal osteodystrophy categories (7).

Renal osteodystrophy encompasses four different types of bone lesions including osteitis fibrosa cystica, ABD, osteomalacia, and mixed lesions (**TABLE 24.1**). The prevalence of these types of bone diseases, as determined by bone biopsy carried out in adult dialysis patients between 1983 and 2006, showed that osteitis fibrosa was present in 34% of patients, ABD in 19%, osteomalacia in 10%, and mixed lesions in 32%. Only 2% of bone biopsies in dialysis patients were reported as normal (7). However, the prevalence of these bone lesions have changed over the last two to three decades, largely due to changes in patients' demographics and in therapeutic strategies. In the early dialysis era, aluminum-based phosphate binders were the predominant phosphate binders, vitamin D therapy was not routinely used, dialysis patients were younger, diabetes was not as prevalent, and multiple renal transplantations were not frequently done. Also, clinical studies of the relationship between plasma PTH levels and bone histology among dialysis patients during the 1980s and early 1990s reflected the impact of the changes in therapeutic strategies and the demographics of the dialysis population during that period. Of note, nearly all studies during this period used a first-generation RIA for PTH from Nichols Institute Diagnostics. In the present era, more than half of patients receiving dialysis are 65 years of age or older, and nearly 50% of them have diabetes, and one-third of diabetic patients are African Americans. Moreover, aluminum-based phosphate binders were replaced by CBPB and more recently with non–calcium-containing binders such as sevelamer hydrochloride and lanthanum carbonate. Also, large intermittent intravenous doses of vitamin D analogs as well as cinacalcet are being used to treat the bone lesion associated with SHPT. Consequently, aluminum-induced bone disease has decreased from 40% of biopsies carried out before 1995 to 20% in patients biopsied after 1995 (7).

TABLE 24.1 Histopathologic Classification of Renal Bone Disease "Renal Osteodystrophy"

- High turnover bone disease
  - Mild secondary hyperparathyroidism
  - Osteitis fibrosa
  - Mixed bone lesions
- Low turnover bone disease
  - Aluminum-induced osteomalacia
  - Osteomalacia
  - Adynamic bone disease
- Others
  - Dialysis-related amyloidosis

Unfortunately, few studies have assessed the impact of these demographic and therapeutic changes on bone histology among patients with CKD. However, in a seminal paper, Sherrard et al. (161) reported the results of their bone biopsy study in 259 patients from their dialysis program. Their results showed an increased incidence of the so-called aplastic bone lesion, particularly in patients treated with peritoneal dialysis. Sixty-six percent of these patients had low turnover bone lesions, whereas 62% of those treated with hemodialysis had the high turnover bone lesion of SHPT. Aluminum-associated osteomalacia was noted less frequently than before, largely due to the substantial decline in the use of aluminum-based phosphate binders. This spectrum of bone lesions is considerably different from that previously reported. Indeed, in hemodialysis patients, the frequency of osteitis fibrosa and ABD are currently similar, but ABD is the predominant lesion in peritoneal dialysis patients. Yet, the increasing use of non–calcium-containing phosphate binders and cinacalcet may result in a change in the histologic bone lesions in the future. Moreover, the higher target for PTH level recommended by the KDIGO clinical practice guidelines may also result in resurgence of predominant lesions of osteitis fibrosa (7).

PATHOPHYSIOLOGY OF RENAL BONE DISEASE

High Bone Turnover Bone Disease

Osteitis Fibrosa and Secondary Hyperparathyroidism

Bone is the main reservoir for both calcium and phosphate, and its turnover is regulated by PTH and vitamin D. Thus, disturbances in these mineral metabolism are expected to result in bone disease. Normal bone histology is illustrated in **FIGURE 24.6A**. The classical histopathologic form of renal bone disease is osteitis fibrosa, an entity caused mainly by SHPT (**TABLE 24.1** and **FIGURE 24.6B**). The disease begins quite early in the course of CKD when the GFR declines to less than 60 mL/min/1.73 m^2, in response to a series of abnormalities that initiate and maintain increased PTH secretion (162,163). The hallmark of osteitis fibrosa is marrow fibrosis and increased bone remodeling (164). There is increased bone formation rate, which is characterized by increased amount of osteoid, and increase in the number of osteoblasts. Concomitantly, there is increased resorption of bone caused by increased number and activity of osteoclasts. Many of the histologic features occur in response to the high PTH level with contributions from local cytokines and low level of calcitriol. The degree to which these features develop is generally proportional to the PTH level and the duration of exposure to such levels. In the aforementioned study, Sherrard et al. (161) noted that 45 of their 259 unselected patients had mild and 57 had severe hyperparathyroidism. Those with more severe disease had a longer duration of renal failure. As discussed

above, a number of factors play a role in triggering increased synthesis and secretion of PTH by the PTGs in patients with CKD. These include decreased serum ionized calcium, phosphate retention, decreased plasma levels of $1,25(OH)_2 D_3$ (calcitriol), the active form of vitamin D, and skeletal resistance to the calcemic actions of PTH.

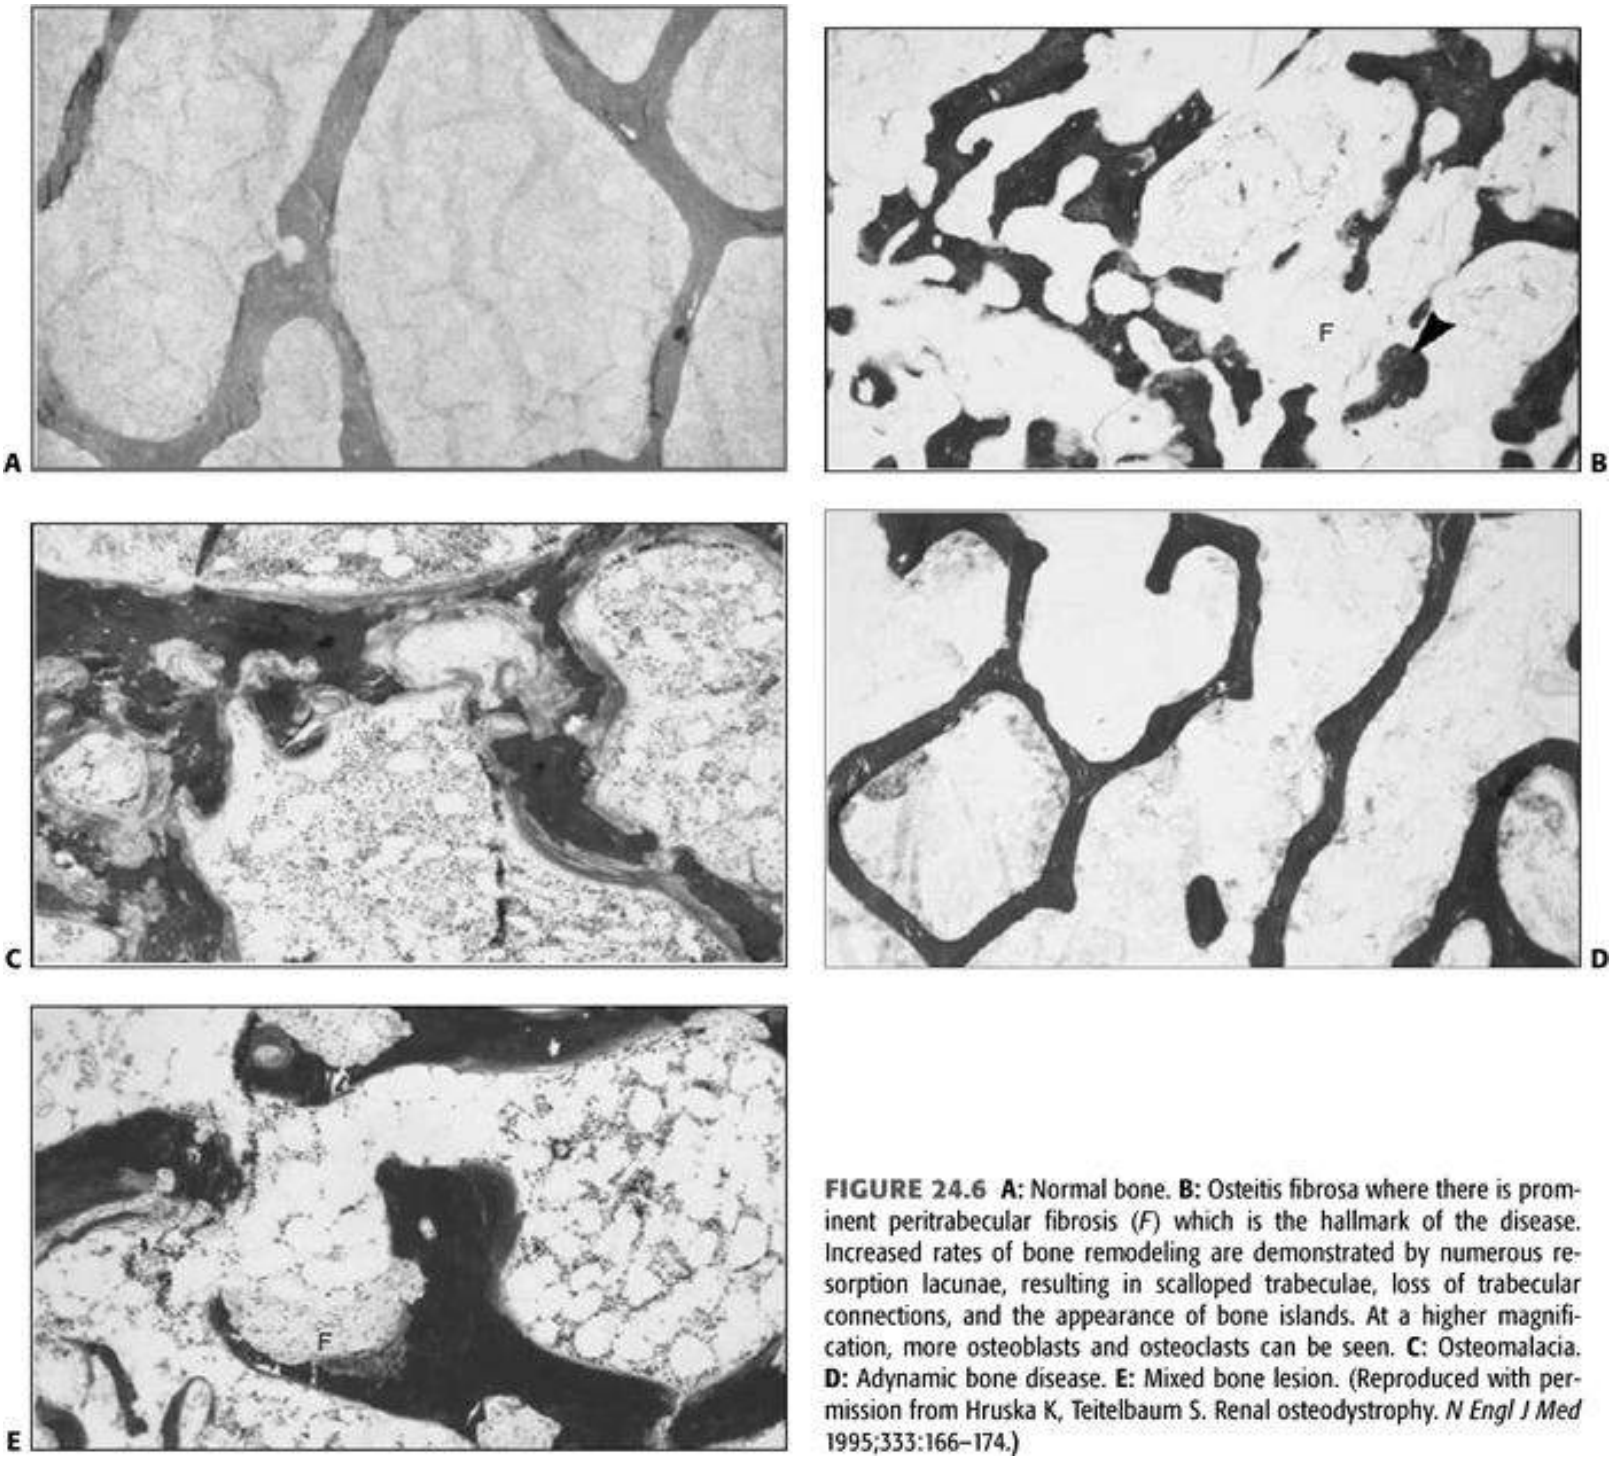

FIGURE 24.6 **A:** Normal bone. **B:** Osteitis fibrosa where there is prominent peritrabecular fibrosis (*F*) which is the hallmark of the disease. Increased rates of bone remodeling are demonstrated by numerous resorption lacunae, resulting in scalloped trabeculae, loss of trabecular connections, and the appearance of bone islands. At a higher magnification, more osteoblasts and osteoclasts can be seen. **C:** Osteomalacia. **D:** Adynamic bone disease. **E:** Mixed bone lesion. The Role of Ionized Calcium in Secondary Hyperparathyroidism

PTH level undergoes diurnal variations, primarily due to changes in serum ionized calcium which modulate the minute-to-minute secretion of PTH. Consequently, ionized calcium concentration remains maintained in the normal range in CKD, largely due to mobilization of calcium from bone by PTH (165). Total serum calcium usually decreases during the course of CKD. This is due to several factors including phosphate retention, decreased $1,25(OH)_2 D_3$ level, and resistance to the calcemic actions of PTH on bone. Hypocalcemia is relatively uncommon in CKD patients and may not be critical in the development

of SHPT (62). However, when present and persistent, it enhances the pre-pro-PTH gene transcription and ultimately promotes the development of PTG hyperplasia. Phosphate retention may cause calcium precipitation in soft tissues, decreases calcium efflux from bone by increasing resistance of bone to PTH action, and inhibits the 1-α-hydroxylase enzyme, leading to further reduction in the already decreased level of calcitriol and decreased intestinal absorption of calcium (61).

More than two decades ago, it was shown that the secretion of PTH is mainly regulated by CaSR, a membrane receptor that responds to small variations in serum ionized calcium (66). The CaSR is a member of the G-protein-coupled membrane receptors that is highly expressed in multiple tissues including the surface of the chief cells of the PTG, kidneys, bone marrow, osteoclasts, osteoblasts, and others (166). It enables the parathyroid cells to sense very small changes in the level of extracellular ionized calcium and rapidly responds to bring about the required changes in PTH secretion. In turn, by increasing bone resorption, stimulating the formation of the active vitamin D (calcitriol) in the kidney and by reducing renal calcium excretion, PTH acts to raise the serum ionized calcium concentration toward normal. In the kidney, CaSR, which is expressed on the basolateral membrane on the cells of the thick ascending limb of the loop of Henle, is a major regulator of urinary calcium excretion (167,168). In addition to calcium, the CaSR can also be activated by magnesium and certain amino acids (169). In summary, CaSR orchestrates changes in the PTG and kidney functions in order to normalize serum calcium concentration. Consequently, CaSR became a target for therapeutic intervention for SHPT and osteitis fibrosa. Calcimimetic agents are now routinely used in clinical practice for treatment of SHPT in patients with ESKD (170).

The Role of Phosphate Retention in and Secondary Hyperparathyroidism

As explained earlier, hyperphosphatemia does not become evident until stage 4 CKD, a tendency toward phosphate retention due to decreased phosphate filtration and excretion occurs as the GFR declines (15,171). Elevations in serum PTH levels may become evident when the GFR falls below 60 mL/min/1.73 m^2 before hyperphosphatemia and hypocalcemia are detectable by routine laboratory measurements. Initially, the “trade-off” hypothesis was proposed to explain this phenomenon, where progressive decline in renal function leads to a new steady state where serum phosphate and calcium are normal at the expense of a higher level of PTH. This “trade-off” continues as the GFR declines further until severe SHPT develops. In this regard, several studies have shown that high phosphate diet results in parathyroid hyperplasia (39,40). Moreover, dietary phosphate restriction in proportion to the reduction in GFR was effective in preventing the initial rise in PTH secretion and the development of hyperparathyroidism (41,42). The mechanism by which phosphate retention plays a role in the pathogenesis of SHPT includes both indirect and direct actions. Beside the reciprocal decline in serum ionized calcium due to transient hyperphosphatemia, phosphate retention may also inhibit the 1-α-hydroxylase enzyme in the kidney and thus may decrease the production of calcitriol. Moreover, it is now clear that phosphorus may directly inhibit the production and secretion of PTH, independent of its effects on serum ionized calcium and calcitriol (43–45). This effect is posttranscriptional and suggests that the stability of PTH mRNA may be regulated by phosphorus and that this effect is mediated by proteins within the PTG that bind to the 3′ untranslated region of the PTH gene transcript (46,47,49). Furthermore, phosphate retention seems to reduce the production of arachidonic acid by parathyroid tissue; this

signaling mechanism may be due to the effect of changes in cytosolic calcium on the phospholipase A2–arachidonic acid pathway (50). On the other hand, the effect of a low-phosphorus diet to prevent parathyroid growth seems to be mediated by an increase in the cell cycle regulator p21 (51).

The Role of Calcitriol

Decreased production of calcitriol in CKD patients removes the inhibitory action of calcitriol on the PTG and leads to increased production of PTH. In turn, high PTH level enhances the activity of 1-α-hydroxylase enzyme in the kidney and tends to increase the plasma level of calcitriol back to the normal range. This action is counter balanced by several other factors: First and most important is the increased level of the phosphaturic hormone FGF-23 in patients with CKD which decreases the production of calcitriol by suppressing the activity of 1-α-hydroxylase enzyme (64,172). Second, phosphate retention resulting from decreased renal function contribute to suppression of 1-α-hydroxylase enzyme and decreased calcitriol production. Third, decreased level of 25(OH)D, the precursor for calcitriol is very common in CKD patients (64,173). Finally, decreased delivery of 25(OH)D that is bound to the vitamin D–binding protein into the cell. This compound is filtered through the glomerulus and is reabsorbed in the proximal tubules by the endocytic receptor megalin. Endocytosis is required to preserve 25(OH)D and to deliver it into the cell for generation of $1,25(OH)_2$ D_3. In CKD, there is decreased delivery of 25OHD to the 1-α-hydroxylase enzyme, particularly in presence of proteinuria due to loss of vitamin D–binding protein in the urine (174). These events lead to decreased intestinal absorption of calcium and hypocalcemia, which in turn stimulates PTH secretion. However, *in vitro* and *in vivo* studies have shown that calcitriol directly inhibits PTH synthesis by acting through the VDR in parathyroid cell nuclei leading to decreased pre-pro-PTH messenger RNA in a dose-dependent manner (175,176). In contrast, calcitriol deficiency may lead to increased PTH production, even in the absence of overt hypocalcemia, by removing its direct suppressive action on PTH secretion. A decrease in calcitriol concentrations also lowers the number of VDRs in the parathyroid cells in experimental animals and in uremic patients (177–180). Moreover, the role of uremic toxins in inhibiting calcitriol receptor binding to vitamin D response elements may contribute to the calcitriol resistance of renal failure (181,182).

The Role of Parathyroid Gland Structure and Function

One of the earliest changes in the PTG during the course of CKD is parathyroid hyperplasia. This structural change develops within few days following experimental CKD and increases in parallel with the progression of renal disease (183). Factors that are involved in triggering hyperplasia are still unclear but include persistent hypocalcemia, calcitriol deficiency, and hyperphosphatemia (184,185). Hypocalcemia is a potent stimulus for PTG growth, and its effect is mediated by the CaSR (184). Moreover, studies have suggested that the set point for calcium-regulated PTH secretion is abnormal in the hyperplastic PTG (186). This is likely due to decreased expression of the CaSR in the hyperplastic PTG of CKD patients (69,187). The CaSRs themselves may contribute to PTG hyperplasia because the use of calcimimetic agents have been shown to prevent PTG hyperplasia (74,170,188).

Decreased calcitriol levels may also contribute to parathyroid hyperplasia. Pertinent to this mechanism is that VDR expression is downregulated in hyperplastic PTG (178,180) and administration of calcitriol is associated with upregulation of expression of VDRs as well as the CaSRs (176,189). The

severity of parathyroid hyperplasia in patients with CKD correlates directly with the reduction of PTG VDR (180). Prolonged PTG stimulation initially leads to diffuse polyclonal hyperplasia, but in patients in whom hyperplasia was allowed to continue, monoclonal expansion of the parathyroid cells develops, leading to the formation of nodules within the PTG (190–192). Studies in genetically modified mice indicate that signal transduction via the CaSR is a key determinant of parathyroid cell proliferation and PTG hyperplasia (193). It seems that parathyroid cell hyperplasia precedes the downregulation of CaSR expression in a uremic rat model (194). When nodular hyperplasia is present, there is decreased expression of both VDRs and CaSRs. This in turn leads to increased set point for the concentration of calcium that is needed to decrease PTH secretion and the response of the PTG to therapeutic maneuvers becomes more difficult leading to refractory SHPT.

The Role of Skeletal Resistance to the Actions of Parathyroid Hormone

Patients with CKD are known to have reduced calcemic response to PTH and thus require a higher PTH level to maintain normal bone turnover (195,196). Thus, in order to keep a normal bone turnover in patients with CKD, the level of PTH must be 2 to 3 times its normal level. On the other hand, excessive suppression of PTH secretion will lower the bone turnover (197). This skeletal resistance to the calcemic action of PTH was demonstrated in patients with acute kidney injury, CKD patients acutely infused with PTH, early CKD patients with high PTH level, advanced CKD, hemodialysis patients, and renal transplant recipients with decreased renal function. The pathogenesis of skeletal resistance to PTH is multifactorial and includes phosphate retention (198), downregulation of the PTH receptors (199,200), low levels of calcitriol (201–203), and inhibition of PTH binding to receptors by the 7-84 PTH fragment (81). Other factors include increased level of osteoprotegerin (OPG), which acts as a decoy receptor for osteoclastogenesis-promoting factor in patients with CKD (204,205) and decreased level of BMP-7 (206). The calcemic response to high PTH may be restored after adequate amounts of both $1,25(OH)_2\ D_3$ and $24,25(OH)_2\ D_3$ (207).

Low Bone Turnover Bone Disease

Adynamic Bone Disease and Osteomalacia

The low turnover lesions are categorized into osteomalacia and ABD. Osteomalacia is characterized by very low rate of bone turnover and marked accumulation of unmineralized osteoid (**FIGURE 24.6C**). Until a decade ago, the most common cause of osteomalacia in patients with ESKD was aluminum toxicity which is known to inhibit bone mineralization. However, the incidence of osteomalacia has decreased with the abandonment of aluminum-based phosphate binders and the introduction of more efficient techniques for treatment of water used in preparing the dialysate. Another possible cause of osteomalacia in CKD patients is deficiency of 25-hydroxyvitamin D.

On the other hand, ABD is being seen with increasing frequency in dialysis and CKD patients, particularly those with diabetes (161,208–210). Moreover, variations in its prevalence can be seen in different geographic regions (211,212). ABD is characterized by low bone turnover in the absence of aluminum overload. The KDIGO Work Group examined bone biopsy studies between 1983 and 2006 and found the prevalence of ABD to be 18% in CKD stages 3 to 5 not yet on dialysis, 19% in hemodialysis patients, and 50% in peritoneal dialysis patients (7). In these studies, ABD has replaced osteomalacia and

exceeded that of osteitis fibrosa (213). Even in patients with advanced CKD not yet on dialysis, the prevalence of low turnover disease has reportedly increased to between 12% and 23% (10,214). Definitive diagnosis of ABD requires bone biopsy showing an overall reduction in cellular activity in bone, including both the number of osteoblasts and osteoclasts (**FIGURE 24.6D**), which leads to very low rate of bone turnover. In contrast to osteomalacia, ABD is characterized by low bone turnover without osteoid accumulation. Moreover, both the rate of collagen synthesis by osteoblasts and its subsequent mineralization are subnormal (208,213).

The pathogenesis of ABD is poorly understood but likely involves multiple factors (215,216). In some patients, bone lesions may be irreversible as seen in patients with diabetes mellitus and those associated with osteoporosis due to old age, menopause, or steroid therapy. ABD may also be caused by the malnutrition–inflammation–cachexia syndrome (MICS) (217). However, in other patients, the bone lesions are reversible and are amenable to therapeutic maneuvers. This is particularly true in patients who develop the disease due to aluminum toxicity; parathyroidectomy; and treatment with large doses of CBPBs, calcitriol, or the use of high dialysate calcium, factors suspected of oversuppressing PTH secretion. High doses of calcitriol may also have PTH-independent inhibitory effects on osteoblastic proliferation and function and thus may induce ABD even in presence of high PTH levels. Interestingly, oxacalcitriol has been shown to control SHPT in uremic dogs without inducing low bone turnover (218). Patients undergoing peritoneal dialysis are particularly at increased risk of developing ABD due to sustained exposure to high calcium concentration in the dialysate. Use of low dialysate calcium concentration or non–calcium-containing binders have been reported to lead to reversal of ABD lesion (219,220). An additional pathogenetic mechanism for ABD was also described. Studies in animal models showed that CKD directly produces ABD by diminishing skeletal growth factors or by producing anabolic inhibitors or both (221). Interestingly, ABD developed when CKD was induced despite the presence of SHPT. Pertinent to this mechanism is the fact that ABD has been described in CKD patients before dialysis (222,223). The mechanism by which CKD causes ABD is not clear but may involve several factors such as uremic toxins, acidosis, increased concentration of OPG and N-terminally truncated PTH fragments, prior use of steroid therapy, malnutrition, and disturbances in growth factors and cytokines. The importance of growth factors in the pathogenesis of ABD was demonstrated in experimental animals in that treatment with the anabolic factor bone morphogenetic protein (BMP)-7 reversed the adynamic bone lesions (224).

Most patients with ABD are asymptomatic, although some may develop bone pain (208,216). Moreover, patients with ABD are at increased risk of fractures and hypercalcemia (225–227). Importantly, patients with ABD are at increased risk of vascular calcification. One study in hemodialysis patients (228) reported an association between low bone turnover and vascular calcification. Another study by the same authors found a significant interaction between the dose of CBPBs and bone activity such that calcium load had a significantly greater impact on aortic calcification and stiffness in patients with ABD (229).

Other Bone Lesions

Mixed bone lesions are now commonly encountered in bone biopsies of patients with CKD. This was observed in 18 of the 259 patients reported by Sherrard et al. (161). The lesion is characterized by an

increase in unmineralized osteoid as seen in osteomalacia and an increase in marrow fibrosis similar to that found in the severe hyperparathyroidism (**FIGURE 24.6E**). Bone formation is increased in this group as a result of elevated PTH level. Sherrard et al. (161) speculated that the high PTH level in patients with this bone lesion was almost certainly due to inadequate calcium replacement as lack of adequate calcium may result in a large amount of unmineralized osteoid. Therefore, under these conditions, although calcium may have been deposited at a very high rate, the overstimulated osteoblasts were forming osteoid at an even higher rate giving rise to the mixed bone lesion. This entity has also been described with a normal or low bone formation. Such a picture may be seen when aluminum toxicity and hyperparathyroidism coexist and produce normal bone formation or even a low bone formation if aluminum toxicity dominates the picture.

Dialysis-related amyloidosis (DRA) is another bone lesion that results from amyloid deposits in articular and periarticular tissues in dialysis patients, particularly in those who have been receiving dialysis for over 10 years (230,231). This entity is not caused by abnormalities in mineral metabolism and has no effect on bone morphology or vascular calcification. As a result, it is not currently included in the KDIGO clinical practice guidelines for the diagnosis, evaluation, prevention, and treatment of CKD-MBD. DRA is a disabling disease characterized by accumulation and tissue deposition of amyloid fibrils consisting of β_2-microglobulin in the bone, periarticular structures, and viscera of patients with CKD (208). This is because reduced renal clearance of this protein in patients with decreased GFR leads to plasma accumulation and slow tissue deposition. β_2-Microglobulin amyloid deposits may also be found at subperiosteal locations (232). There are a number of risk factors associated with DRA including older age, dialysis vintage, use of low-flux dialysis membranes and/or bioincompatible dialysis membrane, and lack of residual renal function (233,234).

Patients with DRA usually complain of shoulder pain related to scapulohumeral periarthritis and rotator cuff infiltration by amyloid. Also, patients may develop symptoms of carpal tunnel syndrome due to amyloid deposition in the carpal tunnel which causes hand pain and numbness and dysesthesias in the distribution of the median nerve. Carpal tunnel syndrome is a recognized complication of amyloid deposits and develops frequently in patients on long-term hemodialysis therapy (235). Large cystic deposits can be seen in the long bones, clavicles, phalanges, carpal or tarsal bones, and pelvis. Fractures through these cysts or into infiltrates in the femoral head are particularly common and heal with difficulty. Of particular note, these large, often cystic deposits are commonly misdiagnosed by radiologists as the “brown tumors” of osteitis fibrosa cystica. In fact, cysts, particularly large cysts, are distinctly uncommon in SHPT. When hyperparathyroid cysts do occur, they are more likely to be found in the mandible or skull, and are usually quite small (230,232). Renal transplant is the most effective treatment modality for amyloid-induced symptoms, but the use of biocompatible dialysis membranes may also be helpful (236). Beside enhancing β_2-microglobulin clearance by dialysis or renal transplantation, treatment of DRA is otherwise palliative. Analgesics help with periarticular and bone pain, but since DRA is a progressive disease, early surgical correction of CTS is warranted.

Diagnosis of Renal Osteodystrophy

Clinical Presentation

Renal bone disease is usually asymptomatic, particularly in the earlier stages of CKD. Even in advanced

stages of CKD, symptoms are often nonspecific and include bone pain, arthralgia, proximal muscle weakness, and spontaneous tendon rupture (**TABLE 24.2**). These symptoms are not helpful in differentiating between SHPT and low turnover bone diseases. However, patients with low turnover disorders, not due to aluminum, have increased incidence of asymptomatic hypercalcemia. Moreover, in one study, 34% of the patients with ABD but without significant aluminum deposition who were reevaluated after 5 years developed bone pain and fractures and had increased mortality (209).

TABLE 24.2 Diagnostic Approach for Renal Bone Disease "Renal Osteodystrophy"

- Clinical presentation
  - Pruritus
  - Bone pain
  - Proximal muscle weakness
  - Arthralgia
  - Spontaneous tendon rupture
  - Fractures
  - Extraskeletal calcification, particularly calciphylaxis
- Laboratory parameters
  - Bone biopsy (gold standard)
  - Serum calcium and phosphorus
  - PTH level
  - 25-Hydroxyvitamin D level
  - Alkaline phosphatases
  - Bone specific alkaline phosphatase
  - Others: osteocalcin, procollagen, propeptides, collagen breakdown products, tartrate-resistant acid phosphatase, and collagen C-terminal telopeptide
- Radiologic diagnosis
  - Subperiosteal bone erosion
  - Rugger-jersey spine
  - Ground glass appearance of skull "pepper pot skull"
  - Brown tumors and bone cysts
  - Bone deformity
  - Chest wall deformity
  - Slipped epiphysis
  - Kyphoscoliosis
  - Growth retardation in children
- Bone mineral density (BMD)

PTH, parathyroid hormone.

Clinical presentation of renal osteodystrophy may also involve extraosseous manifestations that are caused by the pathophysiologic entities that contribute to the development of bone lesions. Widespread calcification of various cardiac structures including the coronary and peripheral arteries, cardiac valves, and skin—the so-called calcemic uremic arteriolopathy (CUA) may be seen particularly in patients with ESKD, even among young adults (11,12,137,148,208,237,238).

Bone Biopsy and Other Laboratory Parameters

The gold standard for precise diagnosis of renal bone lesions is bone biopsy. The procedure involves administration of tetracycline on two occasions separated by 2 weeks (**TABLE 24.3**). This is followed by obtaining bone biopsy, usually from the iliac crest. Quantitation of bone mineralization rate is done by measuring the distance between the two fluorescent tetracycline layers. Based on histomorphometric analysis, Sherrard et al. (161) proposed classification of renal bone disease using parameters of bone turnover, percentage of unmineralized bone (osteoid) and fibrosis. They further divided the various forms of renal osteodystrophy into three groups: high turnover disease (osteitis fibrosa cystica), low turnover bone disease (ABD or osteomalacia), and mixed uremic bone lesions. More recently, the KDIGO initiative recommended standardization of the nomenclature for reporting bone biopsy to reflect the role

of turnover and also incorporate mineralization and volume (8). However, the fact that bone biopsy is quite invasive, requires expertise in processing and interpreting the biopsy, is expensive, and may not be suitable to study progression of renal bone disease or its response to therapies makes it impractical for routine clinical use. Hence, most nephrologists resort to utilizing noninvasive means including biomarkers as well as imaging methods for the diagnosis and follow-up of renal bone disease. **TABLE 24.4** lists the current indications for bone biopsy.

TABLE 24.3 Procedure for Obtaining Bone Biopsy

- Labeling schedule
  - Tetracycline 1,000 mg (15 mg/kg) PO 3 wk before biopsy
  - Demeclocycline 600 mg (9 mg/kg) PO 1 wk before biopsy
- Characteristics of biopsy (iliac crest)
  - Site: 2 cm posterior to anterior superior iliac spine
  - Size: >3 × 8 mm
  - Cancellous (trabecular) bone should predominate
- Fixation[a]
  - Place sample in 10% buffered formalin for 8–24 h
  - Transfer to 70% ethanol for shipping

[a]If osteoclast evaluation is important, specimens should be kept cold (32°F–40°F) but not frozen.

TABLE 24.4 Clinical Indications for Bone Biopsy

- Inconsistencies among biochemical parameters that preclude a definitive interpretation
- Unexplained skeletal fracture or bone pain
- Severe progressive vascular calcification
- Unexplained hypercalcemia
- Suspicion of overload or toxicity from aluminum and possibly other metals
- Before parathyroidectomy if there has been significant exposure to aluminum in the past or if the results of biochemical determinations are not consistent with advanced secondary or tertiary hyperparathyroidism
- Before beginning treatment with bisphosphonates

Laboratory Tests

Laboratory parameters that are useful in the diagnosis of renal bone disease include measurement of serum calcium, phosphate, PTH, and alkaline phosphatase since these factors are known to contribute to the pathogenesis of bone disease particularly osteitis fibrosa. These parameters should be routinely and frequently obtained, and every attempt should be made to keep their values within the goals recommended by the recent KDIGO Clinical Practice Guidelines for Bone Metabolism and Disease in Chronic Kidney Disease guidelines (7). Unfortunately, the use of various PTH assays in the management of renal bone disease is problematic. The first generation two-site immunometric PTH assay used two different affinity-purified antibodies, one directed toward the C-terminal region of PTH and the second directed toward an amino terminal epitope of PTH. This assay has high sensitivity and specificity. The current therapeutic guidelines for treatment of SHPT were based on this assay which was thought to measure intact PTH. However, Brossard et al. (239), using high-performance liquid chromatography (HPLC) to separate the molecular forms of circulating PTH, noted that the two-site IMA appeared to react with an additional molecular form of PTH, the N-terminally truncated PTH fragments such as the PTH 7-84. Consequently, newer PTH assays that specifically measure the PTH 1-84 molecule became available. However, despite initial enthusiasm for these newer assays and the introduction of the ratio between PTH 1-84 and PTH fragments such as 7-84, the intact PTH assays remain widely used in clinical practice. One issue that is

troubling in all intact PTH assays is the significant variation in the results obtained with assays from different manufacturers. These variations are mainly caused by the degree of cross-reactivity of these assays with the circulating N-terminally truncated PTH fragments (240).

An even more relevant issue is the concern about the precision of intact PTH as a surrogate marker of the underlying bone lesions in ESKD patients. Although a decade ago the intact assay was a strong predictor, with values of less than 100 suggesting low turnover bone disorders and those of more than 300 suggesting high turnover lesions (241,242), this may no longer be the case. It has been suggested that this might result from the recent change in therapy in regard to parenteral vitamin D, because these agents may have direct effects on bone, independent of their effects on PTH (243,244). To improve the usefulness of these assays, it was recently proposed to use of the "ratio" of intact PTH 1-84 to C-fragment (245). Unfortunately, this has not been supported by subsequent reports (246).

Besides calcium, phosphorus, and PTH measurements, other biologic markers of bone formation and resorption have been investigated. Of these, the most useful are serum alkaline phosphatase and bone-specific alkaline phosphatase. Circulating alkaline phosphatase is considered a marker of bone turnover in the absence of liver and biliary disease and thus was initially advocated for the diagnosis and management of renal osteodystrophy (247). Recent publications have highlighted the role of bone alkaline phosphatase as a marker of CKD-MBD. Bone alkaline phosphatase is directly related to bone turnover, reflects bone histomorphometry, and predicts outcomes in hemodialysis patients to a better degree than PTH (247,248). A recent study in 185,277 prevalent hemodialysis patients from Japan found that patients in the highest quartile of serum alkaline phosphatase had 46% and 25% higher all-cause and cardiovascular death risk, respectively, as well as a 71% higher incidence of hip fracture events, than those within the lowest quartile (249). The study also found that a higher serum alkaline phosphatase was more strongly linked to a higher mortality in the patients with lower PTH levels.

Procollagen type 1N propeptide (s-P1NP) and procollagen type 1C propeptide (s-P1CP) are markers for bone formation. On the other hand, tartrate-resistant acid phosphatase 5b (TRAP5b) is released by osteoclasts during bone resorption. A recent study in patients with CKD stages 3 to 5 showed that the highest tertile of formation (s-P1NP) and resorption (TRAP5b) markers were independently and positively associated with prevalent fracture (250). However, more studies are needed for further evaluation of these and other biomarkers in patients with renal osteodystrophy. Other biomarkers such as osteocalcins are used mainly for research purposes and do not add significantly to the information obtained from measurement of the parameters described above.

Radiologic Techniques and Bone Mineral Density

The utility of radiologic techniques in the diagnosis of renal bone disease has also changed over the years (251). In the early dialysis era, radiographic features of SHPT were common and florid. However, with adequate dialysis and treatment of abnormalities of mineral metabolism and the use of high doses of vitamin D, radiographic features of SHPT have become less common. Therefore, x-rays are not routinely performed now because they are relatively insensitive for the diagnosis of early renal bone disease. The classical radiologic features that are pathognomonic of severe SHPT include subperiosteal erosion of the radial aspect of the middle phalanges of the second and third phalanges, clavicles, and pelvis, the ground-glass or "pepper pot" appearance of the skull, and osteosclerosis of the vertebrae, the "rugger-jersey"

spine (**FIGURE 24.7A–D**). On the other hand, brown tumors, which represent focal accumulation of giant cells, are usually seen in the long bones of patients with severe hyperparathyroidism and should be differentiated from bone metastases or amyloid bone cysts (**FIGURE 24.7E**).

FIGURE 24.7 **A:** Subperiosteal bone erosion in secondary hyperparathyroidism. **B:** Osteosclerosis or "rugger-jersey" spine in secondary hyperparathyroidism. Osteosclerosis (related to hyperparathyroidism) in the spine that involves the end plates of the vertebrae, giving a striped ("rugger-jersey" spine) appearance. There is an erosion of the upper, anterior margin of one of the vertebra; this may be present in 25% of patients with ESKD and on hemodialysis, and may be an early feature of amyloid deposition disease. Arterial calcification is also present in the abdominal aorta. **C:** Ground glass appearance or "pepper-pot" skull in secondary hyperparathyroidism. **D:** Horizontal fracture of the left femoral neck in a patient with adynamic bone disease. Adynamic bone disease. There is reduced osteoid formation and reduced bone turnover. This results radiographically in reduced bone density and fractures that may appear rather bizarre (horizontal across the bone in this radiograph) and occur in unusual sites (second to the fourth ribs, odontoid process). This is related to aluminum toxicity related to treatment with aluminum hydroxide to reduce serum phosphate or from aluminum in the hemodialysis fluid. **E:** Bone cysts (*arrows*) in a uremic patient with amyloidosis. Amyloid deposition disease. The accumulation of β2-microglobulin (β_2-M) results in juxta-articular, well-corticated cysts in the carpal bones (*right upper panel*) (which precedes the development of carpal tunnel syndrome), and around the large joints (*right lower panel*), as seen in the acetabular margin of the left hip. **C:** Computed tomography (CT) scan showing cystic lesions in the anterior margin of the left femoral neck associated with an adjacent anterior soft tissue mass, which is the inflammatory response found in amyloid deposition disease (*left panel*). Dialysis bone disease. *Semin Dial* 2002;15:277–289.)

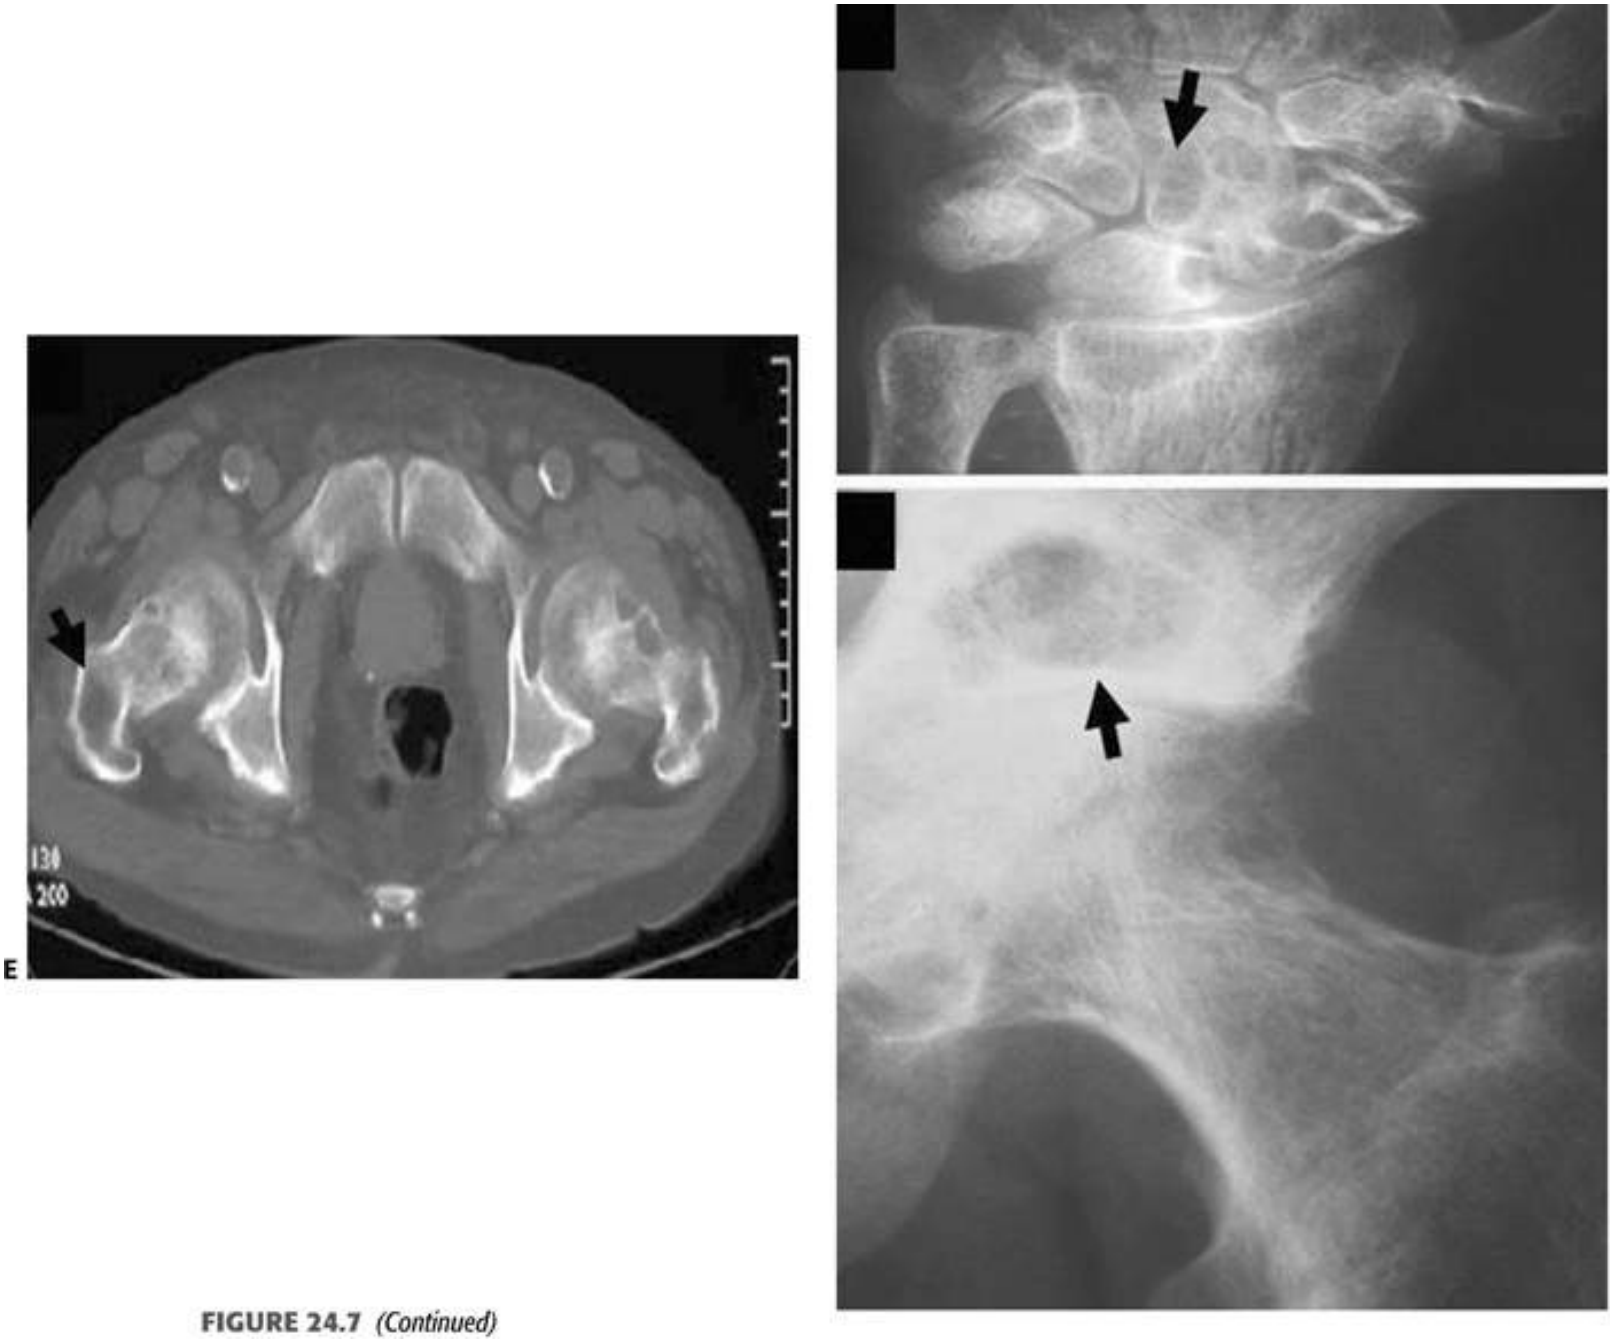

FIGURE 24.7 *(Continued)*

In the general population, measurement of BMD by DXA is predictive of fractures. The value of measuring BMD in patients with CKD is not well established (252). KDIGO recommends DXA to assess fracture risk in patients with CKD stages 1 to 3, if biochemical testing does not suggest CKD-MBD (7). However, for patients with CKD stages 3B to 5, the guideline did not recommend DXA owing to the lack of definitive data demonstrating that DXA predicts fracture in CKD-MBD. Also, DXA evaluates BMD, a measure of bone mass but does not measure bone quality, and there is no correlation between DXA and bone histomorphometry. This is likely due to the multitude of histologic bone lesions encountered in CKD patients. Moreover, the influence of age, diabetes, prior treatment with corticosteroids, extraosseous calcification, as well as vitamin D deficiency makes BMD results difficult to interpret. Despite these limitations, measuring BMD is becoming increasingly popular in the assessment of renal bone disease. In fact, data from two studies support the claim that DXA can predict fracture risk in patients with CKD. In the first study, meta-analysis of six studies totaling 683 dialysis subjects showed that those with fractures had significantly lower BMD at all sites except for the femoral neck (253). Moreover, in a recent study, Yenchek et al. (254) analyzed the effect of CKD on fracture risk prediction by DXA in 587 older adults

with an eGFR <60 mL/min/1.73 m^2 followed for 11.3 years per participant. They found that a low femoral neck BMD was associated with greater than a twofold increased risk of fracture in patients with CKD compared with those without CKD (254).

QCT allows three-dimensional imaging of cross-sections of the central and axial skeleton to provide spatial or volumetric bone mineral density (vBMD). It also allows distinction between cortical and trabecular compartments. The technique also allows the calculation of biomechanical parameters, such as the ability of a bone to resist bending. A recent study which compared DXA with QCT in detection of osteoporosis in dialysis patients found that QCT identified prospectively more bone loss at the hip than DXA (160). However, QCT is expensive and requires high radiation exposure. By contrast, peripheral QCT avoids large dose of radiation exposure for patients by focusing on the tibia and distal radius. A small study in dialysis patients reported that a decrease in distal radial cortical vBMD, cortical area, and cortical thickness as well as decreases in torsional strength and bending strength all associated with the odds of a fracture (255).

MANAGEMENT OF CHRONIC KIDNEY DISEASE-MINERAL BONE DISORDER

In order to manage CKD-MBD, it will be necessary to treat each and every component of this syndrome to the extent possible. Thus, the goals of management should include (a) prevention of the development and control of hyperphosphatemia, hypocalcemia, hypercalcemia, or positive calcium balance; (b) correction of vitamin D deficiency; (c) prevention and treatment of abnormal PTH secretion and avoidance of the development of PTG hyperplasia; (d) decreasing the risk of bone disease and fractures; (e) prevention or reducing the risk of progressive cardiovascular calcification; (f) and finally, and most importantly, is reducing the risk of mortality in CKD patients (**TABLE 24.5**). To achieve these goals, the KDIGO guidelines suggest maintaining serum calcium in the normal range in all stages of CKD, maintaining phosphate levels in the normal range in CKD stages 3 to 5 and decreasing serum phosphate levels toward the normal range in dialysis patients, and maintaining PTH level at >2 to <9 times the upper limit of normal (7) (**TABLE 24.6**). To successfully achieve these goals, the use of combination of measures that simultaneously target most, if not all, components of CKD-MBD is required.

TABLE 24.5 Goals of Management of Chronic Kidney Disease-Mineral Bone Disorder

- Immediate goals: maintenance of calcium, phosphorus, and PTH in the range recommended by the KDIGO guidelines
  - Dietary restriction of phosphorus to 800–1,000 mg/d
  - Prevent hypocalcemia
  - Phosphate binders for hyperphosphatemia
  - Dialysate calcium between 2.0 and 2.5 mEq/L
  - Monitor mineral metabolism monthly
- Long-term goals
  - Start treatment early in the course of CKD
  - Prevent the development of parathyroid gland hyperplasia
    - Dietary restriction of phosphorus early in the course of CKD
    - Calcium supplements to prevent hypocalcemia
  - Treatment of established secondary hyperparathyroidism
    - Phosphate binders for hyperphosphatemia
    - Dialysate calcium between 2.0 and 2.5 mEq/L
    - Vitamin D sterols
    - Calcimimetic agents
    - Parathyroidectomy
    - Monitor mineral metabolism monthly
  - Prevent risk of extraosseous calcification
  - Reduce morbidity and mortality
- Avoid
  - Delaying treatment of secondary hyperparathyroidism or osteomalacia
  - Hypercalcemia
  - Hypocalcemia
  - Oversuppression of PTH

PTH, parathyroid hormone; KDIGO, Kidney Disease: Improving Global Outcomes; CKD, chronic kidney disease.

TABLE 24.6 Kidney Disease: Improving Global Outcomes Treatment Goals for Serum Calcium, Phosphate, and Parathyroid Hormone in Chronic Kidney Disease Stages 3 to 5 and Stage 5D

Mineral	CKD 3–5	CKD 5D
Serum calcium	Within normal range	Within normal range
Serum phosphate	Within normal range	Toward normal
Serum PTH	Unknown	2–9 times upper limit of normal

CKD, chronic kidney disease; PTH, parathyroid hormone.

Prevention and Treatment of Hyperphosphatemia

The principles of therapy for SHPT involve correcting the reversible causes of increased PTH secretion such as hypocalcemia, hyperphosphatemia, and low vitamin D levels. In order to prevent the development of SHPT, therapy should be initiated early in the course of CKD when the GFR decreases to less than 70 mL/min. The primary goal here is to prevent the development of parathyroid hyperplasia. Hypocalcemia is a potent stimulus for PTH secretion and thus should be corrected with calcium supplement taken between meals. Given that phosphate plays a key role in CKD-MBD, potential benefits from controlling serum phosphate are many and may include amelioration of SHPT, avoidance of hypocalcemia, less inhibition of calcitriol production, decreased FGF-23 levels, decreased risk of cardiovascular calcification, and most importantly decreased risk of death. Although the benefits of lowering serum phosphate to a certain target level has not been proved in randomized controlled trials (RCTs), the KDIGO guidelines suggest maintaining phosphate levels in the normal range in CKD stages 3 to 5 and

decreasing serum phosphate levels toward the normal range in dialysis patients (7).

Dietary phosphate restriction and use of phosphate binders are necessary for lowering PTH level and prevention of PTG hyperplasia (7). The typical American diet contains about 1,000 to 1,400 mg/d of phosphate. Dietary phosphate restriction to 800 to 1,000 mg/d should be encouraged as soon as the renal function begins to fall and phosphate intake should be decreased in proportion to the decrease in the GFR (256). This can be accomplished by restricting intake of dairy products, but protein restriction should be modest to avoid malnutrition. In addition, the protein source is also important. Phosphate in plant-based foods is bound to phytic acid or phytate and may be less bioavailable because humans lack the enzyme phytase that is required to degrade the phosphorus-phytate bond. In a crossover trial in nine patients with a mean eGFR of 32 mL/min to directly compare vegetarian and meat diets with equivalent protein and phosphorus contents, subjects had lower serum phosphate levels, a trend toward decreased urine 24-hour phosphorus excretion, and significantly decreased FGF-23 levels in the vegetarian diet compared with the meat-based diet (257). Another aspect of dietary counseling is to encourage consumption of foods with a low phosphate to protein ratio such as egg white (19,27). Finally, counseling patients to avoid processed foods with large amounts of phosphate additives such as soft drinks and cheese can be very effective in treating hyperphosphatemia. This is because processed foods contain a high amount of inorganic phosphate which is more readily absorbed. In fact, >90% of inorganic phosphate may be absorbed from the intestine, as opposed to only 40% to 60% of the organic phosphate present in natural foods (19). Food additives may contribute as much as 1,000 mg/d phosphate to the average American diet (20,258). If serum phosphate remains elevated despite careful dietary restriction, as is the case in stage 4 to 5D CKD, then phosphate binders are indicated. One retrospective study in nondialyzed CKD patients showed that phosphate binder therapy was associated with 23% decrease in mortality (259).

CBPBs such as calcium acetate and calcium carbonate are the preferred agents in patients with CKD not yet on dialysis because these agents correct hypocalcemia, a potent stimulus for PTH secretion. However, other non–calcium-based phosphate binders such as sevelamer and lanthanum carbonate can also be used. A recent randomized placebo-controlled pilot clinical trial by Block et al. (152) showed that therapy with both non–calcium- and calcium-based phosphate binders significantly lower serum and urinary phosphorus and attenuate progression of SHPT among patients with CKD who have normal or near-normal levels of serum phosphorus. However, they also resulted in progression of vascular calcification, albeit to a smaller degree in non–calcium- than in calcium-based phosphate binders.

Management of Dialysis Patients

In patients with ESKD, the use of phosphate binders and active vitamin D sterols is necessary to control SHPT. In general, the same approach as outlined earlier for predialysis patients should be continued. Foremost among the measures needed is control of hyperphosphatemia, an abnormality that is invariably present among patients with ESKD. Hyperphosphatemia remains a very common mineral disorder in patients with ESKD and is considered an important clinical entity. Unfortunately, despite concerted efforts by patients, dietitians, and nephrologists to control serum phosphate, the most recent report by DOPPS show that in the United States, at least 35% of patients had serum phosphate above 5.5 mg/dL and 65% had phosphate above normal (3.5 to 4.5 mg/dL) as recommended by KDIGO (7,260).

Dietary phosphate restriction should be encouraged in patients with ESKD. Unfortunately, although important, it is difficult to accomplish the goal serum phosphate with dietary restriction of phosphorus

alone since these patients are encouraged to consume a diet that contains at least 1.2 g of protein/kg/d in order to prevent protein malnutrition. Intermittent hemodialysis can remove approximately 1,000 mg of phosphate per session. However, since patients may absorb more than 1,000 mg each day, their net phosphate balance is usually greater than 4,000 mg/wk. Intermittent hemodialysis thrice weekly alone also does not adequately control serum phosphorus in most patients (261). However, the use of more frequent dialysis such as short daily dialysis or long nocturnal hemodialysis may be effective in achieving the recommended goal serum phosphate level without the use of phosphate binders (262,263). Unfortunately, these dialysis modalities are not practical and have not yet been widely applied in clinical practice. Consequently, phosphate binders are routinely prescribed for most patients with ESKD in order to reduce intestinal absorption of dietary phosphorus and prevent hyperphosphatemia. To be effective, these medications should be taken with meals in order to bind the phosphate in the food and prevent its intestinal absorption.

Phosphate Binders

Two large observational studies have reported that phosphate binders are associated with decreased mortality among dialysis patients (154,155). The ideal phosphate binder should be effective in small number of pills in binding most dietary phosphate in the intestine without producing significant adverse effects. It should also be safe, not absorbed, and relatively inexpensive because most dialysis patients usually consume relatively large daily doses of the binder. An important but often ignored aspect of phosphate binder therapy is to divide the number of daily binder pills according to the size of the meal. The largest dose should be taken with the main meal. By contrast, no binder should be given if no food is consumed. Unfortunately, none of the currently used phosphate binders fulfill all these requirements. This is best exemplified by aluminum hydroxide which is probably the most cost-effective phosphate binder we ever had. This drug has largely been abandoned because of the risks of aluminum intoxication leading to encephalopathy, microcytic anemia, and osteomalacia (264). Calcium acetate and calcium carbonate replaced aluminum hydroxide as the most widely prescribed phosphate binders. Although cost-effective, concern about the possible role of calcium loading from these binders in progression of cardiovascular calcification has led to more frequent use of the considerably more expensive noncalcium, nonaluminum phosphate binders such as sevelamer hydrochloride and to a much lower extent lanthanum carbonate (265–267). We have shown in an earlier randomized double-blind trial that calcium acetate is significantly more effective than sevelamer in controlling serum phosphorus to the recommended goal levels (268). More recently, Daugirdas et al. (269) showed that sevelamer has the least phosphate binder equivalent dose compared with other phosphate binders. In our experience, patients frequently require higher number of sevelamer pills per meal than other binders to control serum phosphate, and its use may be associated with significant GI adverse events; both are common triggers for patients' nonadherence. On the other hand, two published clinical trials reported that treatment of hyperphosphatemia in hemodialysis patients with sevelamer was associated with slower progression of coronary artery calcification compared with that of CBPB (143,144). However, two other studies have not confirmed these findings (148,149). In the Calcium Acetate Renagel Evaluation-2 (CARE-2) study, we found that treatment with calcium acetate plus atorvastatin for 1-year period was associated with similar degrees of progression of coronary artery calcification to sevelamer in hemodialysis patients (148). Nonetheless, an important issue that is still unclear is whether a decrease in vascular calcification by any means is

associated with improved patients' outcomes. The KDIGO clinical practice guidelines suggest restricting use of CBPB in patients with hypercalcemia, those with low PTH level or ABD and in those with evidence of vascular calcification (7).

Lanthanum carbonate is a potent noncalcium phosphate binder. Its main advantages include a relatively low pill burden, favorable effects on bone turnover, and lowering of serum FGF-23 (270,271). Unfortunately, a small amount of lanthanum is absorbed from the intestine and deposited in various organs including liver and bone (272). Although there was no demonstrable toxicity from lanthanum in these tissues, long-term safety remains a great concern. However, post hoc analysis of four phase III trials with a follow-up of up to 6 years did not find evidence of hepatotoxicity or other organ damage in patients with CKD (273). Other phosphate binders include magnesium salts which bind phosphorus but are less potent than either aluminum or calcium salts (274). Experimental studies suggest that magnesium inhibits phosphate-induced calcification *in vitro* and has a protective role on vascular calcification (275,276). However, large amounts of magnesium can be absorbed and may produce hypermagnesemia unless the dialysate magnesium is reduced. More troubling is the diarrhea produced by virtually all magnesium salts when large doses are ingested. Both magnesium hydroxide and magnesium carbonate have been studied and, although neither is particularly effective, the carbonate salt is the better phosphorous-binding agent.

Finally, a new era of phosphate binders has begun (277). Two iron-based phosphate binders were recently approved by the U.S. Food and Drug Administration (FDA) for clinical use (278,279). In a large phase III RCT, treatment with ferric citrate resulted in significantly higher serum ferritin and transferrin saturation (TSAT) levels compared with active control. Also, subjects receiving ferric citrate required less IV iron than controls over 52 weeks, the percentage of subjects not requiring IV iron was significantly higher and the cumulative erythropoietin-stimulating agent (ESA) dose over 52 weeks was lower than in the control group (278,280). Similar results were also reported in nondialysis CKD patients who had iron deficiency anemia but were not allowed to receive ESA or IV iron (281). Therefore, it appears that ferric citrate not only controls serum phosphate but also simultaneously provides a source of maintenance iron that leads to reduction in IV iron and ESA use while maintaining hemoglobin (Hb) levels in dialysis and CKD patients. By contrast, sucroferric oxyhydroxide, also an iron-based phosphate binder, does not seem to significantly increase iron stores since its active moiety, polynuclear ferric-oxyhydroxide, is insoluble and does not release ferric iron for absorption. However, it has been shown to be as effective as sevelamer in controlling serum phosphate level in dialysis patients with much lower pill burden (279).

Other means of controlling serum phosphate is to inhibit the intestinal sodium-phosphate cotransporter 2b (NaPi-2b) with nicotinamide or niacin (282,283). Nicotinamide is associated with less adverse reactions than niacin. These compounds are particularly useful in nonadherent patients since intermittent phosphate restriction and/or phosphate binder treatment trigger an upregulation of intestinal NaPi-2b allowing greater phosphate absorption after phosphate binder doses are missed. Also the use of chitosan chewing gum as an adjunct to phosphate binders has been shown to help in controlling serum phosphate (284).

Vitamin D Therapy

KDIGO guidelines recommend "maintaining PTH in the normal range for the assay in patients with CKD stages 3 to 5 and of approximately 2 to 9 times the upper limit of normal in CKD stage 5D." The

guidelines further recommend to first correct hypocalcemia, elevated phosphate levels, and vitamin D deficiency by reducing dietary phosphate intake and administering phosphate binders, calcium supplements, and/or native vitamin D (7). The Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines recommend treating 25OHD level <5 ng/mL with ergocalciferol 50,000 IU/wk orally for 12 weeks then monthly for 6 months (285). For levels between 5 and 15 ng/mL, ergocalciferol 50,000 IU/wk orally for 4 weeks and monthly for 6 months should be given. For 25OHD levels that are 16 to 30 ng/mL, treatment with 50,000 IU monthly for 6 months should be given. In all cases, the level of 25OHD should be remeasured at the end of the treatment period. However, our own experience, and those of others, cast doubt on the efficacy of this approach in controlling SHPT (77,256,286). If serum calcium, phosphate and 25OHD levels are normal, but the PTH level remains elevated, active vitamin D preparations such as calcitriol should be added. Given the important role of decreased calcitriol level in the pathogenesis of SHPT, the use of active vitamin D sterols is considered the main treatment modality for lowering the PTH levels among patients with all stages of CKD. Minimal doses should be used first and the dose should be increased slowly, probably no more often than every 3 months. Calcitriol will increase intestinal absorption of both calcium and phosphorous, so their levels will need to be monitored closely and therapy adjusted promptly if elevations occur. Other active vitamin D analogs can also be used in patients with CKD.

For dialysis patients, a number of active vitamin D agents are available for clinical use in the United States, including calcitriol, paricalcitol, and doxercalciferol. There are potential differences between these compounds that should be considered. Calcitriol is effective whether given orally or by intravenous boluses during the hemodialysis procedure. However, it may cause hypercalcemia particularly when used in combination with CBPB (287). Moreover, it has been shown to induce vascular calcification in experimental animals (139,288). Consequently, the search for other vitamin D sterols leads to the introduction of vitamin D prohormones such as 1-α-hydroxyl vitamin D_2 (doxercalciferol) and 1-α-hydroxyvitamin D_3. These two preparations undergo 25 hydroxylation in the liver and are metabolized to the active 1,25-hydroxyvitamin D_2 and 1,25-hydroxyvitamin D_3. Furthermore, in an attempt to selectively suppress PTH production while minimizing the effects of vitamin D on calcium and phosphate metabolism, structural changes in the vitamin D molecule were made and lead to the introduction of several analogs such as 19-nor-1,25-dihydroxyvitamin D_2 (paricalcitol), 22-oxacalcitriol, and 26, 27-hexafluorocalcitriol (falecalcitriol). Although direct head-to-head randomized studies in patients are limited, few studies that compared paricalcitol with doxercalciferol showed more episodes of hyperphosphatemia with doxercalciferol (289). Moreover, in experimental animals, calcitriol and doxercalciferol are associated with vascular calcification, while paricalcitol was not (290).

The value of vitamin D administration to CKD patients may extend beyond its effect on calcium, phosphate, and PTH levels. Teng et al. (291) reported in a historical cohort study that hemodialysis patients who were administered paricalcitol had better survival than those who received calcitriol. However, in a follow-up retrospective study on incident hemodialysis patients, they found that the administration of any vitamin D sterols to dialysis patients may confer survival advantage over that of patients who were not given any vitamin D preparation (291,292). In multivariable analyses, the association of paricalcitol treatment with survival persisted without regard to the serum concentrations of calcium or phosphate. Moreover, vitamin D administration has been shown in observational studies to be

associated with improved survival in predialysis patients with CKD (293,294). The exact mechanism of the beneficial effect of vitamin D on patients' outcome may be related to its antiproliferative effects on myocardial cell hypertrophy and proliferation, its negative regulatory effect on the renin-angiotensin system, as well as its ability to inhibit inflammatory changes that have been established as key in the pathogenesis of atherosclerosis (295). It is interesting that a meta-analysis of 76 clinical trials showed that the use of vitamin D therapy in patients with CKD does not reduce the risk of death or vascular calcification (296). Moreover, administration of active vitamin D analogs has been shown to increase FGF-23 in ESKD patients (297), which has been shown in other studies to be an independent predictor of mortality in patients with ESKD (131). Finally, the Paricalcitol Capsule Benefits in Renal Failure Induced Cardiac Morbidity (PRIMO) study randomized 227 patients with stage 3 and 4 CKD, mild left ventricular hypertrophy, but normal systolic function to either paricalcitol or placebo. The study was based on the hypothesis that paricalcitol directly reduces the adverse effects of the renin-angiotensin system on cardiac remodeling by activation of the VDR in cardiac myocytes. The primary end point was a change in ventricular mass over 48 weeks as assessed by magnetic resonance imaging (MRI). The results showed no significant difference between the two groups (298). Other measures of LV function such as the end-systolic index, end-diastolic index, ejection fraction, aorta compliance, and aorta volume were also not different. However, the risk of hospitalizations was significantly decreased in the paricalcitol group (1.1 per 100 person-years vs. 8.8 per 100 person-years, $p = 0.04$) likely due to decrease in episodes of congestive heart failure and a reduction in atrial enlargement.

Calcimimetic Agents

Although the use of vitamin D has been effective in lowering markedly elevated PTH levels, a number of patients eventually become refractory to vitamin D therapy or become intolerant because of hypercalcemia which often demands cessation of vitamin D therapy. Consequently, the percentage of vitamin D–treated patients who actually achieved and maintain the recommended clinical practice targets for mineral metabolism is rather small. Given that changes in serum ionized calcium are sensed by the CaSRs on parathyroid cells, these receptors became a target for therapeutic intervention by agents that activate the CaSR and lower PTH secretion from the PTG. Cinacalcet is a calcimimetic agent that became commercially available in the United States in May 2004. It binds reversibly to the membrane-spanning portion of the CaSR and lowers the threshold for its activation by ionized calcium (299). This agent results in leftward shift of the set point and in a significant fall in PTH levels at any level of serum ionized calcium. Some authors believe that cinacalcet is the most effective agent currently available for reducing PTH levels in dialysis patients that can be used as an alternative treatment modality for the control of SHPT (300). Studies in hemodialysis patients with SHPT have shown that a single oral dose of cinacalcet resulted in a rapid drop in PTH level to a nadir after 2 to 4 hours (300,301). The degree of reduction in PTH level attributed to cinacalcet correlates with pretreatment PTH level; the higher the PTH level, the greater the reduction in PTH level (302). Of interest, cinacalcet lowers serum calcium and phosphate as well as PTH (170,303). Indeed, concomitant use of cinacalcet and vitamin D in dialysis patients with persistently elevated PTH levels resulted in significantly higher percentage of patients who achieved the KDOQI targets for mineral metabolism (303). Cinacalcet is clearly useful in patients who are receiving CBPB as well as in those who develop hypercalcemia with high doses of vitamin D. However, cinacalcet should not be prescribed to patients with serum calcium concentration <8.4 mg/dL.

Cinacalcet may reduce parathyroid cell proliferation and retard the development of PTG hyperplasia, thus diminishing the need for parathyroidectomy (74,304,305). Also, calcimimetic therapy have been shown to decrease FGF-23 by decreasing PTH levels, whereas vitamin D therapy increases FGF-23 production by a direct effect on gene transcription (306). The implications for these actions of cinacalcet are not clear at the present time.

Two major recent studies that compared outcomes of treatment of SHPT with either cinacalcet or paricalcitol, a vitamin D analog, have been published. The recent Action in Diabetes and Cardiovascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation (ADVANCE) trial in 360 patients showed a trend toward decreasing the progression of vascular and valvular calcification but was only significant for aortic valvular calcification (307). In the Evaluation of Cinacalcet Hydrochloride Therapy to Lower Cardiovascular Events (EVOLVE) study, cinacalcet was compared with placebo in 3,883 hemodialysis patients with SHPT for up to 64 months (308). Most patients in the study were receiving phosphate binders and vitamin D analogs. The study showed that cinacalcet is effective in the treatment of SHPT either as monotherapy or with vitamin D therapy. The unadjusted intention to treat analysis showed that cinacalcet does not significantly reduce the risk of death or major cardiovascular events in patients with moderate-to-severe SHPT who were undergoing hemodialysis (308). Also, after adjustment for differences in baseline characteristics, multiple fractures, and/or events prompting discontinuation of study drug, the trial showed that treatment with cinacalcet reduced the rate of clinical fracture by 16% to 29% (309). Therefore, cinacalcet seems to be a very useful drug for lowering the PTH level, for decreasing PTG hyperplasia, and for decreasing fracture rate in dialysis patients, but the claim that it has beneficial effects on progression of cardiovascular calcification and patient survival remain unsubstantiated.

Two other studies have evaluated the safety and efficacy of cinacalcet in patients with CKD not receiving dialysis (310,311). In both studies, cinacalcet was found to be effective in lowering PTH levels but at the expense of frequent development of hypocalcemia, increased urinary calcium excretion, hyperphosphatemia, and decreased urinary phosphate and citrate excretion. In the only randomized controlled trial in this population, patients randomized to cinacalcet required more active vitamin D analogs and more phosphate binders than the control group (311). Based on the results of these trials, KDIGO Work Group felt that more data were needed before recommending calcimimetics for patients with CKD stages 3 to 5 and SHPT (7). Similarly, the FDA has not approved cinacalcet for use in predialysis patients with CKD.

Parathyroidectomy

Approximately 10% of patients with ESKD undergo parathyroidectomy for refractory SHPT (312). However, the rate of parathyroidectomy in the dialysis population has varied substantially over the past few decades from 12.5 per 1,000 patient-years in 1992 to 5.5 per 1,000 patient-years in 2005 but increased again to 9 per 1,000 patient-years in 2007 (312). A more recent study by Tentori et al. (95) on 35,655 participants from the DOPPS phases 1 to 4 (1996 to 2011) confirmed that, despite increased PTH levels, rates of parathyroidectomy has indeed declined in all regions over the 15-year study period. This decrease is likely related to multiple factors including the new KDIGO recommended level of PTH and the use of cinacalcet which was shown in the aforementioned EVOLVE trial to reduce the rate of parathyroidectomy by more than half (313).

Currently, KDIGO recommends targeting PTH levels to within 2 to 9 times the upper limit of normal for the dialysis population (7). KDIGO also recommend parathyroidectomy for patients with CKD stages 3 to 5D with severe hyperparathyroidism who fail to respond to medical/pharmacologic therapy but did not specify threshold PTH level for parathyroidectomy (7). As a practical guideline, parathyroidectomy is indicated for patients with severe hyperparathyroidism, defined as PTH level greater than 800 pg/mL, particularly if accompanied by symptoms (**TABLE 24.7**). This is because observational studies have consistently showed a higher risk of adverse clinical outcomes in patients whose PTH levels are outside those recommended by KDIGO for dialysis patients. Parathyroidectomy is specially indicated in patients who are noncompliant with diet and phosphate binders and in whom medical therapy becomes ineffective, impractical, or even contraindicated particularly with the development of hypercalcemia (**TABLE 24.7**). A relatively urgent indication for parathyroidectomy is the presence of high PTH level in patients with CUA or calciphylaxis, although its benefits have not been convincingly shown (208).

TABLE 24.7 Indications for Parathyroidectomy

- Refractory secondary hyperparathyroidism
  - Persistently elevated PTH level (>800 pg/mL)
  - Persistent hypercalcemia when using vitamin D
- Severe symptomatic disease
  - Refractory pruritus
  - Fractures
  - Unexplained myopathy
  - Tendon rupture
  - Bone pain
  - Severe bone disease
  - Severe pruritus in presence of high PTH level
  - Calciphylaxis
- Should not wait too long when parathyroidectomy is indicated
- Exclude aluminum toxicity before parathyroidectomy

PTH, parathyroid hormone.

There are presumed benefits of parathyroidectomy on both laboratory parameters and clinical outcomes including fractures. Patients who undergo parathyroidectomy usually experience improvement in various biochemical parameters. However, comparisons between medical and surgical therapy for outcomes of morbidity and mortality are difficult to evaluate. Parathyroidectomy may be associated with adverse events. Only a few studies have systematically evaluated the risks associated with parathyroidectomy. Using USRDS data (1988 to 1999), Kestenbaum et al. (314) found increased 30-day mortality for patients who underwent parathyroidectomy compared with those who did not (3.1% vs. 1.2%). The increased risk continued for 90 days and then inverted at 1 year. Also, Rudser et al. (315) reported a 32% lower risk of hip, vertebra, and distal radius-wrist fractures after parathyroidectomy in a nationwide cohort of patients who underwent parathyroidectomy compared with matched controls. More recently, Ishani et al. (316) reported that parathyroidectomy is associated with significant morbidity in the 30 days after hospital discharge and in the year after the procedure. Most pronounced were high rehospitalization rates, more intensive care unit (ICU) visits, more hospital days, and 2% mortality within 30 days of hospital discharge after the procedure.

The choice of surgical procedure depends on the experiences of the surgeon. An important factor to consider is that 5% of patients have fewer than four PTG and 10% have more than four. The most commonly performed procedure is subtotal parathyroidectomy or total parathyroidectomy with reimplantation of non-nodular parathyroid tissue in the forearm. However, another option is total

parathyroidectomy for patients who are not renal transplant candidates because recurrence of hyperparathyroidism may develop in 10% of patients who have subtotal resections (317). There is no evidence that total parathyroidectomy with immediate ectopic parathyroid tissue reimplantation is superior or inferior to subtotal parathyroidectomy (7). In patients with severe hyperparathyroidism who are likely to be transplanted, total parathyroidectomy with reimplantation of a remnant into the arm may be preferred. Unfortunately, identifying and removing the parathyroid tissue from the forearm may be difficult in case of recurrent hyperparathyroidism. Moreover, malignancy in these transplanted remnant parathyroid tissue may develop (318). Persistent hyperparathyroidism after surgery indicates the presence of an extra gland that was missed during surgery. An essential point to consider before parathyroidectomy is to rule out coexisting aluminum toxicity by using deferoxamine (DFO) testing or even bone biopsy in patients who have history of use of aluminum-based phosphate binders. This is because parathyroidectomy in this situation may precipitate the development of osteomalacia.

Hungry bone syndrome usually occurs in parathyroidectomized uremic patients who had successful surgery. This syndrome is defined as development of serum calcium <6.0 mg/dL immediately after parathyroidectomy requiring intravenous calcium infusion to control such severe degree of hypocalcemia despite higher dialysate calcium concentration, calcitriol, and oral calcium carbonate supplementation. The syndrome has been reported in 27.8% to 51.2% of patients in different studies (319,320). Due to the development of an abrupt decrease in the plasma concentrations of calcium and phosphate, these patients experience muscle cramps, tingling, tetany, seizures, and cardiac arrhythmias. The sudden decrease in PTH levels results in an almost immediate decrease in bone resorption, while bone formation continues at a very high rate. Thus, large amounts of calcium are shifted to the skeleton, but little moves out. Patients who received high-dose parenteral vitamin D for hyperparathyroidism before parathyroidectomy may not develop hungry bone syndrome. This may be due to PTH-independent actions of vitamin D on bone (205,243). Witteveen et al. (321) suggested that between 6 and 12 g/d of calcium supplementation will be required to treat the severe hypocalcemia. They also suggested that initially, calcium should be given intravenously, but treatment with oral preparations should be initiated as early as possible. Serum calcium must then be measured every 6 hours for 24 to 48 hours. Moreover, calcitriol should be administered in 2 to 4 μg daily doses or even higher along with magnesium to correct concomitant hypomagnesemia. Finally, they suggested that preoperative administration of bisphosphonates may reduce the severity and duration of hypocalcemia.

The weight of the parathyroid tissue removed may predict the degree of hypocalcemia and also provides an excellent guide to the amount of calcium required postoperatively. For every gram of tissue resected, patients will require 1 g of calcium chloride over the following 24 hours. This rule has been useful in the management of more than 50 patients with removed tissue weighing 1.5 to 17 g (161). In some patients, high doses of oral calcium (up to 10 g daily) and calcitriol (up to 4 μg daily) may be necessary for as long as 1 to 2 months after surgery.

BONE DISEASE IN RENAL TRANSPLANT RECIPIENTS

Renal transplantation is recognized as the optimal treatment for patients with ESKD. Besides improving the quality of life, transplantation is clearly associated with improved patient survival compared to dialysis. Moreover, clinical consequences of renal failure such as anemia and mineral metabolism

substantially improve after transplantation. Unfortunately, CKD-MBD may worsen after renal transplantation despite restoring near-normal renal function in most patients. The fracture risk for a kidney transplant recipient is fourfold higher than in the general population (322), and the high fracture rate seen in dialysis patients increases even further after successful kidney transplantation, especially in diabetics (323–325). The pathophysiology of bone disease in renal transplant recipients is complex since it may represent a continuum of structural changes in bone from the earlier stages of CKD, throughout the dialysis period and then after renal transplantation. The prevalence of various histologic patterns of bone disease after transplantation is not well described but almost all types of renal osteodystrophy are represented, with low turnover bone disease being the most prevalent (326). Prior to transplantation, many patients have been exposed to treatments with active vitamin D analogs, steroids, other immunosuppressive drugs, or anticonvulsant medications. Moreover, some may suffer from preexisting diabetes, osteoporosis, immobilization, malnutrition, and impaired gonadal function. Thus, patients awaiting renal transplantation already have significant underlying bone pathologies.

Unfortunately, this picture does not improve but instead accelerates, particularly in the first 6 to 12 months after transplantation. Julian et al. (327) reported a 6.8% decrease in vertebral BMD 6 months after renal transplantation compared to baseline. This is because renal transplant recipients are subjected to many risk factors that contribute to the type and/or severity of posttransplant bone disease. Besides the aforementioned preexisting renal osteodystrophy, the use of immunosuppressive drugs such as steroids and calcineurin inhibitors and other transplantation-specific therapies as well as worsening graft function also contribute to the transplant bone disease (323). Persistent hyperparathyroidism, hypercalcemia, hypophosphatemia, hypomagnesemia, and loop diuretics also increase the risk for bone disease after transplantation. Other immunosuppressive agents such as azathioprine, mycophenolate mofetil, and sirolimus have not been shown to have any negative effects on bone health. It must be emphasized, however, that the bone diseases associated with transplantation are not unique to kidney transplants but may develop with other types of organ transplants (323).

Steroids play a major role in accelerating bone loss during the first 6 months after transplantation (328,329). Rojas et al. (330) performed serial bone biopsies in 20 renal transplant recipients at 22 and 160 days after transplantation and found impaired osteoblastogenesis and early osteoblast apoptosis. Steroids increase bone resorption and decrease bone formation by numerous mechanisms, including reduction of osteoblast proliferation, increased osteoblast apoptosis, downregulation of collagen I, osteocalcin, BMPs, and TGF-β. Moreover, steroids accelerate osteoclastogenesis as a result of their action in decreasing OPG and increase in receptor activator of nuclear factor κB ligand (RANKL). These detrimental effects of steroids on bone are attributed to the cumulative dose in renal transplant recipients. Steroids may also induce negative calcium balance by reducing intestinal calcium absorption and increasing urinary calcium excretion which in turn may play a role in the development of osteoporosis and hyperparathyroidism (331). On the other hand, the effects of the two calcineurin inhibitors, cyclosporine and tacrolimus, on bone are incompletely understood but their main effect includes acceleration of bone resorption (329,332). One study that examined the independent potential of cyclosporine and tacrolimus on bone formation and bone resorption using serum markers to measure bone turnover found no significant difference between these two immunosuppressive drugs (333).

Avascular Necrosis

Avascular necrosis (AVN) is a debilitating complication of renal and other organ transplantation. Previous studies suggested an incidence of approximately 15% within 3 years of the transplant (334). In an interesting prospective study of 48 patients without evidence of femoral osteonecrosis prior to renal transplantation, AVN was documented in 4% by MRI at 6 months following the procedure (334). AVN affects all weight-bearing joints, particularly the hip, and more than half of affected patients have more than one joint involved. In this disorder, the weight-bearing surface such as the femoral head undergoes necrosis. This results in additional stress on adjacent bone, which may also be damaged. AVN occurs in 5% to 30% of renal transplant patients, usually in the first year after transplant (335). It occurs more frequently in patients who receive high doses of steroid. The exact etiology is not well understood but is likely multifactorial. One theory suggests that steroids induce fat cells to proliferate in the marrow space leading to marked increase in intraosseous pressure which in turn interferes with perfusion of bone leading to ischemic necrosis. The diagnosis of AVN is usually made after the patient presents with hip pain. Routine x-rays are not sensitive and are usually negative but may eventually show a defect in the femoral head. MRI is the most sensitive and definitive diagnostic test and often reveals the lesion even before symptoms develop (**FIGURE 24.8**) (336). It is likely that the frequency of AVN will decrease with the current trend for using lower dose protocols for renal transplant recipients.

FIGURE 24.8 Magnetic resonance images from a transplant patient. **A:** Normal x-ray of the pelvis with no pathologic findings in the femoral heads 3 months after renal transplantation. **B:** Avascular necrosis of the femoral heads 3 months after transplantation. The T1-weighted image 3 months after transplantation showed small isointense necrotic areas and hypointense demarcation rims in both femoral heads. X-ray image of the pelvis 3 months after transplantation. No pathologic findings in both femoral heads. (Reproduced with permission from Fink B, Degenhardt S, Paselk C, et al. Early detection of avascular necrosis of the femoral head following renal transplantation. *Arch Orthop Trauma Surg* 1997;116:151–156.)

Management of Posttransplant Bone Disease

Unfortunately, the lack of RCTs in renal transplant recipients with bone disease makes it difficult to recommend bone-specific therapies, particularly during the first 12 months after kidney transplantation. However, prevention and/or treatment of pretransplant bone disease clearly have an impact on the

management of posttransplant bone disease. Every effort should be made to avoid significant bone disease at the time of transplantation. Moreover, it is suggested that potential transplant recipients undergo assessment of their bone status before transplantation. This assessment should include parameters of mineral metabolism, PTH level, x-rays of the spine, and measurement of BMD of the hip, spine, and radius. KDIGO developed recommendations for the evaluation and treatment of bone disease in renal transplant recipients (7). These recommendations include monitoring serum calcium, phosphate, 25OHD, PTH, and alkaline phosphatase at specific intervals. Moreover, the guidelines also recommended measuring BMD in the first 3 months after kidney transplant if they receive corticosteroids or have risk factors for osteoporosis. Strategies to avoid or slow the bone loss that routinely develops in transplant recipients include: *First*, calcium supplements (800 to 1,200 mg elemental calcium per day) can be given along with nutritional vitamin D to correct vitamin D deficiency and active vitamin D analogs in order to increase positive calcium balance. *Second*, use the lowest possible dose of steroids. As cyclosporine has also been incriminated, replacing steroids with high doses of this agent is also problematic. Newer agents that permit very low doses of steroids or even steroid-free regimens offer great hope. *Third*, the use of antiresorptive agents such as bisphosphonates should be considered in patients who are at high fracture risk (337). Bisphosphonates are used to prevent bone mass loss and to treat osteoporosis. In renal transplant recipients, small doses of intravenous pamidronate, ibandronate, or zoledronate given at the time of transplantation have been reported to be associated with prevention of bone loss (338). A recent meta-analysis of RCTs concluded that bisphosphonates are effective in preventing bone loss in the early posttransplant period (339). Similar efficacy has been reported for heart transplantation, and others have found pamidronate very effective in preventing bone loss in patients treated with steroids for a variety of reasons (339). Its safety is well established in patients with renal disease (340). However, caution should be exercised with all bisphosphonates since they may induce or worsen the development of low turnover bone disease. Thus, KDIGO suggests to consider bone biopsy before the use of bisphosphonates due to the high incidence of ABD (7).

Unfortunately, once AVN develops, hip replacement will usually be required. However, for a small, asymptomatic lesion, inactivity and limited weight bearing may permit healing and recovery. Lesions greater than about 5 mm, however, usually will not respond to this conservative approach.

CHAPTER 25

Acid–Base Considerations in End-Stage Kidney Disease

F. John Gennari and Dana Negoi

Maintenance of normal body pH and P_{CO_2} depends on daily replenishment of body alkali stores that are either consumed, neutralizing strong acids produced by normal body metabolism, or lost in the stool (1–4). This task is normally accomplished by the kidneys through an incompletely defined system of sensors and effectors that regulate H^+ and NH_4^+ excretion (4). The result is acid balance, achieved by reabsorption of all the filtered HCO_3^- and, in addition, excretion of just enough acid (primarily as NH_4^+) to replenish the HCO_3^- lost from the body (**FIGURE 25.1**). This balance is flexible, responding rapidly to changes in acid production, and precise, maintaining blood [HCO_3^-] remarkably constant from day to day.

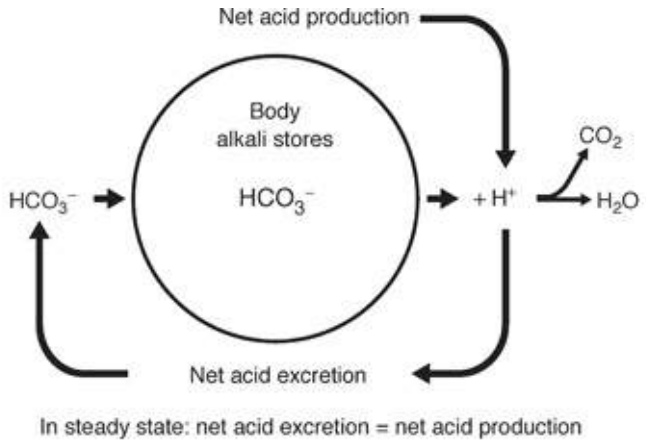

FIGURE 25.1 Normal acid–base balance. Net acid production, comprising endogenous acid production and the difference between the alkali added by the diet and the alkali lost in the stool, adds new H^+ to the body fluids. These ions react with HCO_3^-, yielding CO_2 and H_2O. In the steady state, through a complex signal pathway that is incompletely understood, the kidney adjusts net acid excretion (NH_4^+ plus titratable acid excretion minus any HCO_3^- lost in the urine) to match net acid production, thereby adding back an equivalent amount of HCO_3^-.

As kidney disease progresses, renal regulation of acid balance is lost and metabolic acidosis ensues, due primarily to impaired acid excretion. Initiation of renal replacement therapy addresses this problem not by removing H^+ but by adding HCO_3^- to the body on a regular basis. Net addition of HCO_3^- during dialysis therapy is regulated not by any physiologic feedback mechanism but by the physical principles of

diffusion and convection (5–7). This switch has major implications for acid–base homeostasis, changing the way one thinks about both normal and disordered acid balance.

Throughout this chapter, the term [HCO_3^-] is used both for serum and bath concentrations. In most instances, however, serum [HCO_3^-] is actually measured as serum [total CO_2]. Keep in mind that serum [total CO_2] includes dissolved CO_2 as well as HCO_3^- and is on average about 1 mmol/L higher than serum [HCO_3^-].

GENERAL PRINCIPLES

Regardless of the alkali source added to the dialysis bath or infused during renal replacement therapy, a new equilibrium is achieved that is driven primarily by variations in endogenous acid production, just as in individuals with normal kidney function (5–7). The fundamental reason for this linkage is that the net gain of HCO_3^- is directly related to its transmembrane concentration gradient. Therefore, the lower the concentration of HCO_3^- in the body fluids at the onset of treatment, the greater will be the net entry of alkali. In patients receiving renal replacement therapy, the prevailing serum [HCO_3^-] is determined jointly by the dialysis treatment itself and by endogenous acid production. Because the dialysis prescription is fixed, the variable component is endogenous acid production, which likely accounts for most of the variability in serum [HCO_3^-] in patients with end-stage kidney disease (ESKD) (5–7). Although less flexible than functioning kidneys, this property of dialysis therapy allows for variations in endogenous acid production to be matched by variable amounts of net HCO_3^- addition during treatment. The details of how this equilibrium is achieved are discussed first for peritoneal dialysis (PD) and then for hemodialysis (HD).

ACID–BASE HOMEOSTASIS IN PERITONEAL DIALYSIS

In recent years, there has been a resurgence of PD as a treatment for ESKD. The number of incident PD patients increased from 7,588 in 2000 to 9,451 in 2012 (8). Monthly prevalent counts increased by 24% between January 2010 and October 2012, compared to only 9.6% increase in HD (9). This resurgence is likely due to the finding that PD is as beneficial as HD but less expensive and also to new financial incentives for initiation of PD (9).

Automated peritoneal dialysis (APD) is now more commonly used than continuous ambulatory peritoneal dialysis (CAPD) as a result of improvement in technology and better perceived quality of life (10); patients have more freedom during the day as the therapy is delivered primarily at night with the help of a machine that is easy to use. With this resurgence, attention has been directed at trying to identify the best solution to restore body alkali stores and at the same time minimize damage to the peritoneal membrane. In general, it is recommended that plasma bicarbonate be maintained in the high normal range: Protein catabolism is reduced at bicarbonate levels around 30 mmol/L and nutritional status seems to be improved (11). On the other hand, there is a concern that higher bicarbonate levels may be associated with soft tissue calcifications and adynamic bone disease, but these complications have not been shown to occur in PD so far (11).

Alkali Source in the Peritoneal Dialysis Solutions

As in the case of HD, the first PD solutions contained bicarbonate (12). At that time, commercially prepared dialysis solutions were not available for clinical use, and fresh solutions were prepared in the hospital at the time PD was performed. In order to avoid precipitation of calcium carbonate if bicarbonate solutions were to be stored for longer periods of time, calcium was added shortly before inflow into the abdomen (12). As commercial solutions were developed in the 1950s, another problem became apparent. The high pH in bicarbonate-based PD solutions facilitated caramelization of glucose during the sterilization process and generation of glucose degradation products that were thought to contribute to peritoneal membrane damage after prolonged exposure. In short order, bicarbonate was removed from most PD solutions and replaced with acetate or lactate, organic anions that are absorbed and metabolized to bicarbonate in the body. Acetate-containing solutions were abandoned quickly because of the untoward effects on the peritoneal membrane from local vasodilation. These effects included increased membrane permeability with loss of ultrafiltration, and encapsulating peritoneal sclerosis (13). Lactate quickly became the standard alkali source because it is rapidly metabolized to HCO_3^- while serum lactate concentration remains low. Initially, solutions contained sodium lactate at a concentration 35 mmol/L, but almost all standard solutions now contain at a concentration of 40 mmol/L because serum [HCO_3^-] is higher using the latter concentration (14–16) (**TABLE 25.1**). Lactate-based solutions have been well tolerated, but concerns remain about damage to the peritoneal membrane after long-term exposure to the low pH of the solution when first introduced into the abdomen. Within 15 minutes, of course, pH rises in the peritoneal space due to rapid entry of HCO_3^- across the peritoneal membrane (**FIGURE 25.2**) (13).

TABLE 25.1 Steady-State Acid–Base Values in Patients Treated with Peritoneal Dialysis

Type	Bath [Lactate] mmol/L	*N*	Venous [Total CO_2] mmol/L	Year	Reference
CAPD[a]	35	31	23.9 ± 4.0	1983	(16)
CAPD	35	33	21.5 ± 2.4	2003	(13)
CAPD	40	25	27.4 ± 3.3	1983	(16)
		20	26.3 ± 2.5	1990	(17)
		8	28.8 ± 3.0	1983	(15)
		175	25.3 ± 3.2	2003	(18)
		11	27.5 ± 3.3	1995	(19)
APD[b]	40	75	25.7 ± 3.2	2003	(18)
CAPD[c]	0	13	27.1 ± 2.1	2004	(20)
CAPD[d]	15	70	27.7 ± 2.7	2000	(21)

All values, mean ± 1 *SD*

[a]Continuous ambulatory peritoneal dialysis, four exchanges per day.

[b]APD, automated overnight cycling peritoneal dialysis.

[c]Bath contains HCO_3^-, 34 mmol/L, arterial [HCO_3^-] calculated from pH and P_{CO_2}.

[d]Bath contains HCO_3^-, 25 mmol/L in addition to 15 mmol/L lactate.

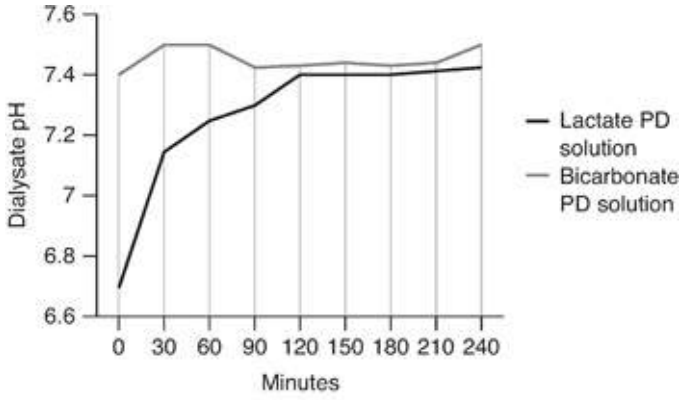

FIGURE 25.2 Changes in dialysate pH over time during equilibrium in abdomen. The *black line* indicates a dialysis solution containing 40 mmol/L of lactate and no bicarbonate. The *gray line* indicates a solution containing 25 mmol/L of bicarbonate and 15 mmol/L of lactate. [Redrawn using data in Heimburger O, Mujais S. Buffer transport in peritoneal dialysis. *Kidney Int* 2003;64(Suppl 88):S37–S42.]

The search for biocompatible PD solutions has brought bicarbonate-based solutions back into the forefront (13,20–22). Packaging the PD solution in a two-compartment bag system allows for separation of HCO_3^- from glucose, calcium, and magnesium salts. The two bags are mixed just prior to infusion into the abdomen, and rapid equilibration of the mixed solution with body P_{CO_2} keeps the pH in a range at which calcium and magnesium salts do not precipitate. This solution can be used in both APD and CAPD. Another advantage of the bicarbonate-based solutions is the lower incidence of in-flow pain due to the physiologic pH of the solution as compared to low initial pH in lactate-based solutions (22).

Buffer Transport in Peritoneal Dialysis Using a Lactate-Containing Solution

During PD, the peritoneal cavity is filled with fresh dialysis solution, which is allowed to dwell for a variable amount of time. The standard lactate-based PD fluid composition is shown in **TABLE 25.2**. During the dwell, HCO_3^- and lactate cross the peritoneal membrane down their respective concentration gradients causing a gradual decline in dialysate [lactate] and increase in dialysate [HCO_3^-]. The rate of HCO_3^- movement into the bath diminishes as the concentration rises in the dialysate, but even after a 6-hour dwell, equilibrium is not achieved (**FIGURE 25.3**) (19). At the end of the dwell, the spent dialysate is drained, and fresh PD fluid is infused into the peritoneal cavity. PD is in most instances a continuous procedure; PD fluid is present in the peritoneal space 24 hours a day, 7 days a week. As a result, serum [HCO_3^-] is stable and does not fluctuate as it does with intermittent HD (see later).

TABLE 25.2 Composition of Standard 40 mmol/L Lactate Peritoneal Dialysis Solution

Sodium (mmol/L)	134
Potassium (mmol/L)	2
Calcium (mmol/L)	0–1.75
Magnesium (mmol/L)	0.25–0.75
Chloride (mmol/L)	95
Lactate (mmol/L)	40
Glucose (g/dl)	1.5–4.25
pH	5.2–5.5
Osmolality (mOsm/kg H_2O)	358–511

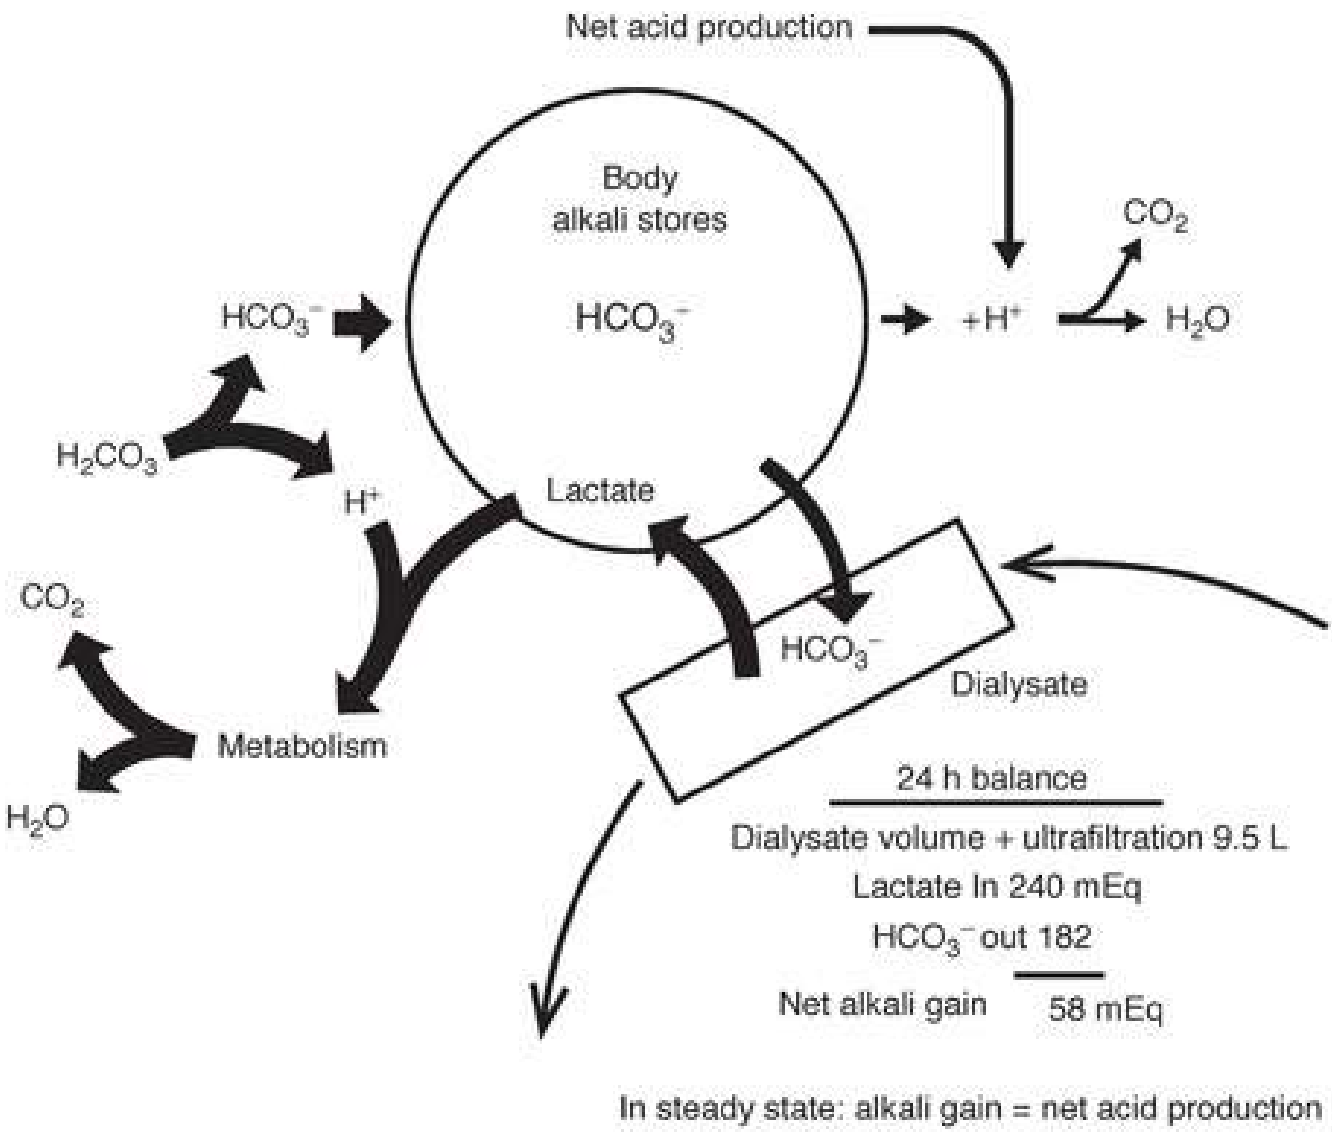

FIGURE 25.3 Acid balance in peritoneal dialysis. To replenish HCO_3^- stores that have been consumed in buffering endogenous acid production, lactate is added from the dialysis fluid and metabolized to produce new HCO_3^-. A large portion of the newly generated HCO_3^- is lost by diffusing back into the peritoneal dialysis fluid. The rate of HCO_3^- loss (and therefore the net gain of alkali) depends on its transmembrane concentration gradient. As shown in the example, the serum [HCO_3^-] is maintained at a level at which the difference between lactate added and HCO_3^- lost each day is equal to daily net acid production.

Because blood lactate concentration is approximately 1 mmol/L, lactate diffuses from the peritoneal cavity into the systemic circulation across the peritoneal membrane. The absorbed lactate is metabolized primarily in the liver to generate an equivalent amount of new HCO_3^-. As a result of rapid metabolism, serum [lactate] does not increase notably during PD, allowing for a favorable concentration gradient to be maintained during the dwell. When the PD fluid is left in the peritoneal cavity for 6 hours, approximately 75% of the lactate is absorbed and metabolized, yielding an equivalent amount of new bicarbonate (19). A portion of the newly generated HCO_3^- is consumed in buffering endogenous acids produced by body metabolism on a daily basis. Because the PD solution contains no HCO_3^-, a large portion of the newly generated HCO_3^- also diffuses from the patient into the peritoneal cavity down its concentration gradient (5,7,23). Its rate of diffusion is determined by the same principles that govern lactate transport, and its concentration in the peritoneal cavity increases during the dwell. After 6 hours, PD fluid [HCO_3^-] is about 80% of the serum level (Figure 23.3) (19). The net alkali gained for any given period is equal to the

difference between the systemically added lactate and the loss of HCO_3^- into the PD fluid. (5,7,19).

Based on the relative diffusion rates of HCO_3^- and lactate, one can estimate the net alkali gain for a standard CAPD prescription (23). In the model shown in Figure 23.3, serum [HCO_3^-] is 24 mmol/L and the patient is receiving four 2-L exchanges, each with a dialysate lactate concentration of 40 mmol/L each day. For this prescription, total lactate content in the PD fluid each day will be 8 × 40 = 320 mmol/d, and total lactate added to the body fluids is 320 × 0.75 = 240 mmol/d. If dialysate [HCO_3^-] is 80% of the serum concentration at the end of the dwell period, dialysate [HCO_3^-] will be 24 × 0.8 = 19 mmol/L. Assuming the additional removal of 1.5 L of fluid during a 24-hour period of dialysis, the total spent dialysate volume will be 8 + 1.5 = 9.5 L. Total HCO_3^- content in the spent dialysate will be 9.5 × 19 = 182 mmol/d. Total systemic alkali gain is therefore 240 − 182 = 58 mmol/d. If this net alkali gain exceeds the rate of endogenous acid production, serum [HCO_3^-] will rise, increasing the amount of HCO_3^- lost, until net alkali gain matches endogenous acid production. At this point, an equilibrium will be achieved in which net alkali gained will equal net acid production. These theoretical considerations are supported by direct measurements, showing that patients treated with PD are in acid balance, with serum [HCO_3^-] related inversely to endogenous acid production (19).

Bicarbonate-Based Solutions

Bicarbonate-based PD solutions are now commercially available in Europe and Canada, using a two-bag system to prevent precipitation of calcium and magnesium salts during storage. When this system is used, acid–base status is improved in patients with low serum [HCO_3^-] when bath [HCO_3^-] is increased from 34 to 39 mmol/L (14,20). Newer solutions are now available containing a mixture of bicarbonate and lactate (B/L) (11,13,21). The B/L solutions are also packed in a two-bag system. The B/L dialysis solutions made by Baxter contain [HCO_3^-] at 25 mmol/L and [lactate] at either 10 or 15 mmol/L. Unfortunately, neither bicarbonate nor B/L solutions are available for use in the United States.

The proposed advantage of the B/L solutions is a physiologic pH and P_{CO_2}, thereby reducing glucose-degradation products (11). Clinical experience with B/L solutions showed efficient acid–base control and reduction in infusion pain due to physiologic pH of the solution (pH of 7.4) compared to 5.5 in lactate-only solutions (10,13,21,22). A modest but significant increase in ultrafiltration was observed in patients using a B/L solution compared to lactate (21).

Effect of Automated Peritoneal Dialysis on Serum [HCO_3^-]

As APD is the predominant form of PD, it is important to consider its effect on the patient's acid–base status. In APD, patients are exposed to higher total volume of dialysis solutions, but most of the dwells are shorter in duration. Current experience shows that good control of acid–base balance can be obtained regardless of whether CAPD or APD is used (**FIGURE 25.4**). As seen in the figure, most patients achieve a plasma bicarbonate concentration of 22 to 30 mmol/L, irrespective of modality status, and there is no notable difference in average serum [HCO_3^-] (10,18).

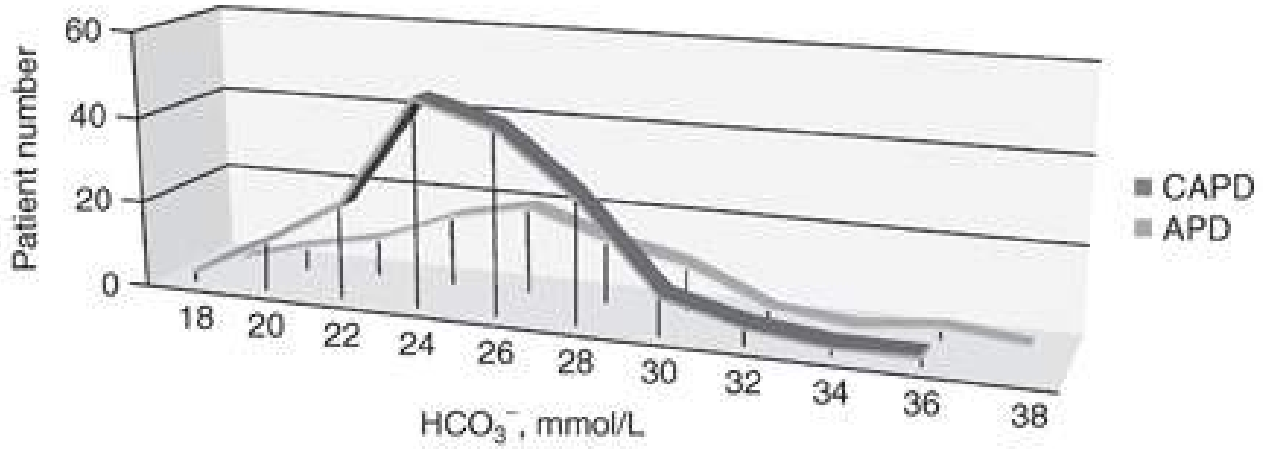

FIGURE 25.4 Ranges of steady-state serum [HCO_3^-] in 175 patients treated with continuous ambulatory peritoneal dialysis (CAPD) and in 77 patients treated with automated peritoneal dialysis (APD). Bicarbonate concentration is plotted against the number of patients for each value. [Redrawn from data in Mujais S. Acid-base profile in patients on PD. *Kidney Int* 2003;64(Suppl 88):S26–S36.]

Lactate and bicarbonate are transported faster across the peritoneal membrane in high transporters compared to low transporters. For this reason in CAPD, serum bicarbonate concentration might be slightly higher in high transporters compared to low transporters, but the difference has no physiologic consequence (18). In APD, there is no difference in serum [HCO_3^-] among different type of transporters due to higher volume of dialysate used (10).

ACID–BASE HOMEOSTASIS IN HEMODIALYSIS

Conventional HD is an intermittent treatment, in contrast to the continuous nature of PD. As a result, there is no day-to-day steady state with regard to alkali stores and serum [HCO_3^-]. As shown in **FIGURE 25.5**, alkali is added rapidly during a 3- to 4-hour treatment three times a week. This added alkali then gradually dissipates during the period between treatments, as HCO_3^- is consumed by endogenous acid production and diluted by fluid retention (7). Thus, from an acid–base perspective, HD patients undergo a continuous back-and-forth fluctuation from a postdialysis serum [HCO_3^-] in the high normal or slightly alkaline range to a predialysis serum [HCO_3^-] in a range that is usually slightly below normal. Given that serum [HCO_3^-] falls by as much as 7 to 8 mmol/L from the end of one dialysis to the beginning of the next, it is important to note when acid–base status is assessed. By convention, one usually reports the predialysis value and, ideally, the nadir value obtained after the longest interval between treatments (**TABLE 25.3**).

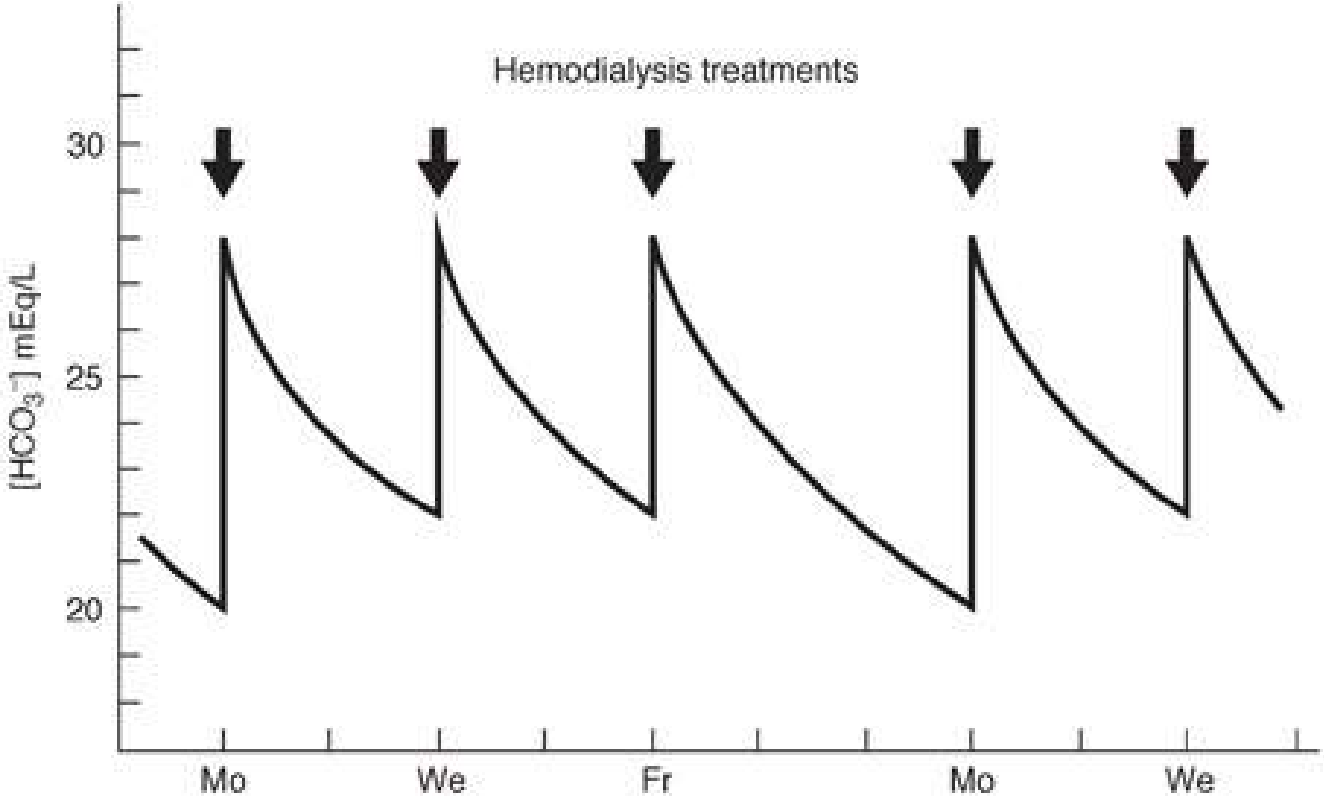

FIGURE 25.5 Schematic representation of the pattern of serum [HCO_3^-] in a patient receiving hemodialysis treatments thrice weekly [Monday (Mo), Wednesday (We), and Friday (Fr)]. Serum [HCO_3^-] rises with each dialysis and then falls during the interval between treatments, reaching a nadir once a week at the end of the long interval between treatments.

TABLE 25.3 Steady-State Predialysis Acid–Base Values in Stable Patients Treated with Conventional Hemodialysis[a]

Year	N	[Total CO_2] mmol/L			Reference
1990[b]	22	21.4 ± 2.4			(17)
1993	38	19.0 ± 3.1			(24)
1999	995	21.6 ± 3.4			(25)
2000[c]	7,123	22.8 ± 3.5			(26)

[a]Thrice weekly with a bicarbonate bath (final concentration 32 to 36 mmol/L).
[b]Values obtained after longest interval between treatments.
[c]Midweek predialysis value.
[d]Unpublished observations.
[e]Recall that serum [HCO_3^-] is lower than serum [total CO_2] by approximately 1 mmol/L because the latter measurement includes dissolved CO_2.

Alkali Source

When HD was first developed, the bath solution contained HCO_3^- in a concentration of 26 mmol/L (32), but the concentration was empirically increased to 35 mmol/L over the next decade to improve alkali transfer (33). To prevent precipitation of $CaCO_3$, bath pH had to be adjusted to 7.4 by aeration with a carbon dioxide/oxygen gas mixture. Acetate was first introduced as an alkali precursor in 1964 (34). This organic anion was chosen because it was metabolized readily by most tissues in the body (35), allowing for rapid HCO_3^- production during treatment. Because acetate obviated the need for aerating the bath with CO_2, it allowed for a central bath solution preparation system that could be used for multiple patients, and it quickly replaced HCO_3^- as an alkali source.

This change created a bidirectional dynamic similar to that for PD with lactate, although much more rapid and impressive in magnitude. Almost as quickly as the acetate added from the bath to the patient was metabolized to HCO_3^- during HD, the new HCO_3^- diffuses back into the bath (6). As a result, the only way to add substantial amounts of HCO_3^- to the body stores was to add sufficient acetate to overcome its rate of metabolic conversion and raise its concentration in the blood by the end of the treatment. After the dialysis session, this unmetabolized acetate (as high as 3 to 4 mmol/L) is converted to HCO_3^- and the new HCO_3^- is now retained by the patient. By trial and error, a bath acetate concentration

of 37 mmol/L was settled on to achieve this goal. This concentration represented a compromise between providing sufficient substrate for HCO_3^- generation during each treatment and limiting the rate of acetate delivery to an amount that could be metabolized without producing toxic levels (36–38).

Despite the ease of bath preparation, alkali repletion using acetate is a remarkably inefficient process. During a 4-hour HD treatment, for example, more than 700 mmol of HCO_3^- is lost into the bath (6,37). This loss limits alkali replenishment, so that patients receiving this form of dialysis have predialysis serum [HCO_3^-] values of less than 18 mmol/L, on average (6,17,37,39). As blood-flow rates and dialyzer membrane permeability increased, the amount of acetate delivered also increased and serum acetate concentration often reached toxic levels, causing hypotension and other symptoms (30,36,38,40–42). An additional problem with using acetate-based dialysis solutions was CO_2 loss from the patient to the bath, an effect that decreased ventilatory drive and contributed to dialysis-induced hypoxemia (42,43).

Because of these problems, HCO_3^- was again introduced as the source for alkali replenishment in the early 1980s (29,43,44). Reintroduction of HCO_3^- into the bath solution was made possible by a new technology, the use of a proportioning system that allowed continuous production of dialysate from concentrated salt solutions either in a central delivery system or individually for each patient. In such a system, $NaHCO_3$ is added to the rest of the bath solution just before delivery to the dialysis membrane. At the moment of HCO_3^- addition, the pH of the bath is prevented from rising too high by the presence of a small amount of acetic acid. The acetic acid reacts rapidly with the added HCO_3^-, yielding carbonic acid and acetate anions. The final bath solution after $NaHCO_3$ addition has a pH of approximately 7.05 and contains HCO_3^- (most commonly at a concentration of 35 mmol/L), acetate (4 mmol/L in most systems), and dissolved CO_2 (4 mmol/L, equivalent to a P_{CO_2} of 133 mm Hg). The P_{CO_2} in the bath falls rapidly as it diffuses across the dialysis membrane, raising the P_{CO_2} in the postfilter blood to only approximately 50 mm Hg (37). The inward diffusion of CO_2 reverses the loss from the patient that occurred with acetate dialysis (see earlier) but has no notable impact on systemic P_{CO_2} or ventilation (43,44). The acetate produced by this reaction also diffuses across the dialysis membrane into the blood, providing a small additional source of new HCO_3^- as it is metabolized.

Reintroduction of HCO_3^- into the HD bath solution increased predialysis serum [HCO_3^-] by 3 to 4 mmol/L (29,30,42,45–47) and decreased patient symptoms dramatically (29,30,45,48). By 1990, this technology essentially completely replaced acetate HD. Bath solutions currently used for conventional HD most commonly combine a 39-mmol/L HCO_3^- solution with a solution containing 4 mmol/L of acetic acid, yielding a final bath [HCO_3^-] of 35 mmol/L and [acetate] of 4 mmol/L when mixed. One formulation uses sodium diacetate, which yields an [acetate] of 8 mmol/L. The acetate anions cross the dialysis membrane into the blood and are rapidly metabolized, producing 4 or 8 mmol/L of new HCO_3^-. This additional HCO_3^-, however, has no impact on end-dialysis [HCO_3^-] because, to the extent the new HCO_3^- is not consumed by buffering or organic acid production and is retained in the blood, it simply reduces the transmembrane HCO_3^- gradient and slows the rate of HCO_3^- entry from the bath. The end-dialysis [HCO_3^-] is determined by the bath [HCO_3^-] and by the magnitude of the increase in organic acid

production during the treatment engendered by the abrupt alkalinization of the body fluids (see later). Because of continued concerns about the effects of acetate on body metabolism even at low concentrations, citric acid has replaced acetic acid in many dialysis units as the organic acid used to control bath pH before HCO_3^- addition. This trivalent acid is effective at lower concentrations, and the citrate anions produced are rapidly metabolized to generate bicarbonate. In a standard citrate-based dialysis bath solution, metabolism of citrate yields 2.7 mmol/L of HCO_3^-.

Acid–Base Balance

Although the transient events are more complex than in PD, a similar equilibrium is established between net acid production and alkali addition in patients receiving intermittent HD. The amount of HCO_3^- added from the bath to the patient during an HD session is primarily dependent on the dialysance of this anion (a function of dialysis membrane surface area and permeability) and the transmembrane concentration gradient (**FIGURE 25.6**). Because the bath [HCO_3^-] is fixed, as are the surface area and permeability of the membrane, the variable factor in this relationship is serum [HCO_3^-]. The serum [HCO_3^-] at the beginning of each treatment is determined primarily by the rate of acid production in the interdialytic period and to a lesser extent by fluid retention (see later). The lower the initial value, the greater the initial rate of HCO_3^- addition, and vice versa.

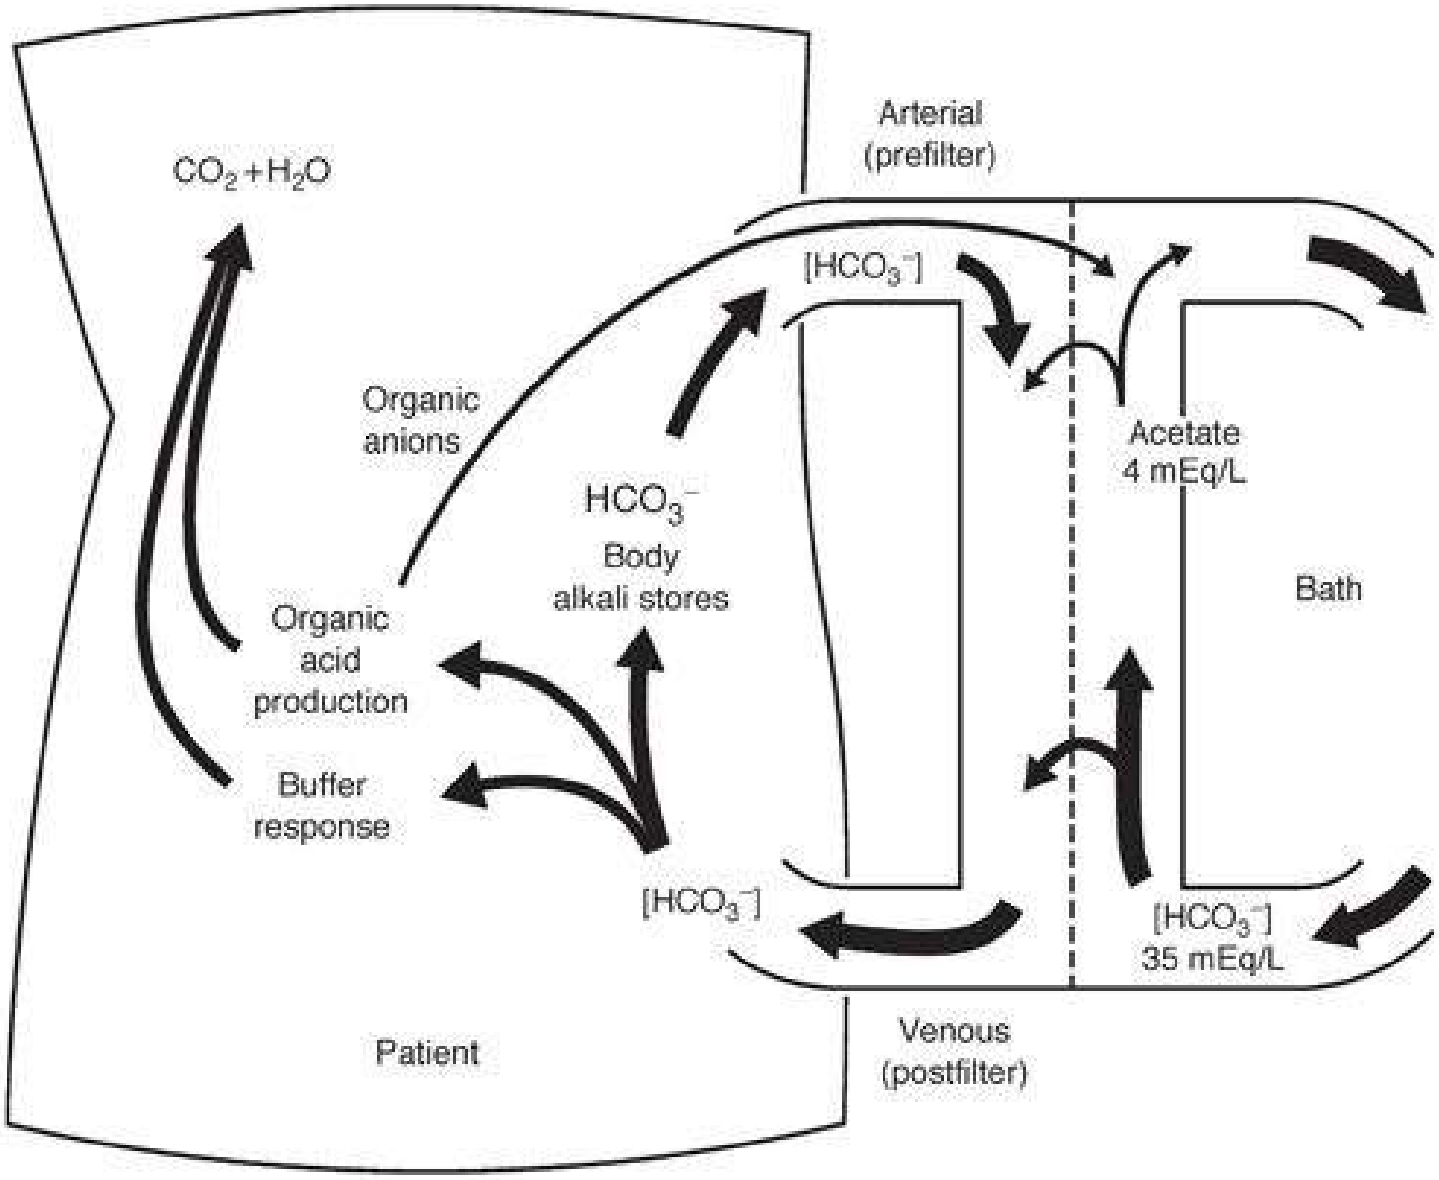

FIGURE 25.6 Alkali addition and disposition during hemodialysis. During each treatment, body HCO_3^- stores are replenished by the addition of HCO_3^- and acetate from the bath (the latter anion metabolized to form HCO_3^-). Added and newly generated HCO_3^- is partially consumed by titration with body buffers and by organic acid production. The remaining HCO_3^- is added to the pool and raises $[HCO_3^-]$ in the blood returning to the hemodialysis membrane, reducing the transmembrane concentration gradient, and limiting further HCO_3^- addition. The total HCO_3^- added is determined by its dialysance (D_{HCO_3}) and by the integrated transmembrane HCO_3^- concentration gradient over the time of treatment, $o\int^t$ (Bath $[HCO_3^-]$ – Blood $[HCO_3^-]$). Because the variable component of this gradient is blood $[HCO_3^-]$, equilibrium is achieved at a predialysis blood $[HCO_3^-]$ at which the alkali added with each treatment is equivalent to endogenous acid production over the interval between treatments.

The total amount of HCO_3^- added during each HD treatment is determined not only by the initial transmembrane concentration gradient but also by the rate of change in the gradient as the treatment progresses. To the extent that newly added HCO_3^- is retained in the extracellular fluid (ECF) compartment, its concentration in the blood will rise, diminishing the gradient across the dialysis membrane. The minute-to-minute change in this gradient is determined by the extent to which the added HCO_3^- is consumed by the production of new H^+ in the body (**FIGURE 25.6**). The response to rapid

alkalinization of the body fluids includes not only the release of H^+ from nonbicarbonate buffers but also the stimulation of cellular organic acid production (4,7,47,48).

Increases in the production of organic acids that dissociate at the pH of the body fluid can produce almost unlimited amounts of new H^+ to titrate and remove added HCO_3^- from the extracellular compartment. If the organic anions produced by this titration were retained, they would eventually be metabolized and thereby regenerate the HCO_3^- titrated by their formation. Organic anions, however, readily cross the dialysis membrane and are lost into the dialysate (**FIGURE 25.6**) (46,47). At blood-flow rates much lower than are now customarily used, losses of 30 to 50 mmol of organic anions have been measured during a standard HD treatment (46,47). Because many more organic acids are produced than were measured in these studies, and because blood-flow and therefore clearance rates have increased, it seems likely that organic anion losses are now even higher (7). The magnitude of this response to added HCO_3^- remains undefined, but it is clear that organic acid production and loss of the organic anions formed can have a major influence on net alkali addition during HD.

The transmembrane HCO_3^- concentration gradient could also be influenced if the blood returning to the dialyzer contained an admixture of slowly mixing pools with differing HCO_3^- concentrations, but whether this occurs to any measurable degree is unknown. In addition, there may be ionic constraints on HCO_3^- diffusion, despite the presence of a favorable chemical concentration gradient, as it competes with Cl^- and negatively charged proteins (Gibbs-Donnan effect) for charge balance with the cations in the blood, particularly during the latter half of the treatment. These factors probably influence net alkali addition to a much smaller extent than the buffer and organic acid responses, but their contribution remains undefined.

Assuming the factors controlling alkali addition during HD are constant from treatment to treatment, the amount of HCO_3^- added with each treatment is determined primarily by the predialysis serum $[HCO_3^-]$. This value, in turn, is determined by the rate of endogenous acid production in the period between treatments and to a lesser degree by the amount of fluid retained. Eventually, a new equilibrium is achieved in which the interplay between intradialytic and interdialytic events serves to maintain predialysis serum $[HCO_3^-]$ relatively constant. One should emphasize, of course, that the predialysis value for serum $[HCO_3^-]$ is the nadir in a descending trend, with the peak value occurring immediately after dialysis and falling gradually until the next session (**FIGURE 25.5**). Because of the complex nature of the response to alkali addition during HD and its variability from patient to patient, as well as differences in net acid production and fluid retention between treatments, predialysis serum $[HCO_3^-]$ varies more widely in patients receiving intermittent HD than in individuals with normal kidney function (25,26).

Determinants of Postdialysis Serum $[HCO_3^-]$

FIGURE 25.7 shows the pattern and magnitude of the increase in serum $[HCO_3^-]$ during a single HD treatment in seven stable patients. This figure shows the increase in serum $[HCO_3^-]$ induced by 4 hours of HD (7). The striking feature shown in this figure is that serum $[HCO_3^-]$ changes little, if at all, during the last 2 hours of dialysis, despite a 4- to 6-mmol/L concentration gradient (after Gibbs-Donnan adjustment) for HCO_3^- entry across the dialysis membrane. This pattern has been confirmed by other investigators

(44,49). While the observations shown in **FIGURE 25.7** are characteristic, serum [HCO_3^-] actually falls during dialysis in a small subset of patients (7). The fall in these patients most likely is due to a surge in lactic acid production, resulting from tissue hypoxia and hypotension.

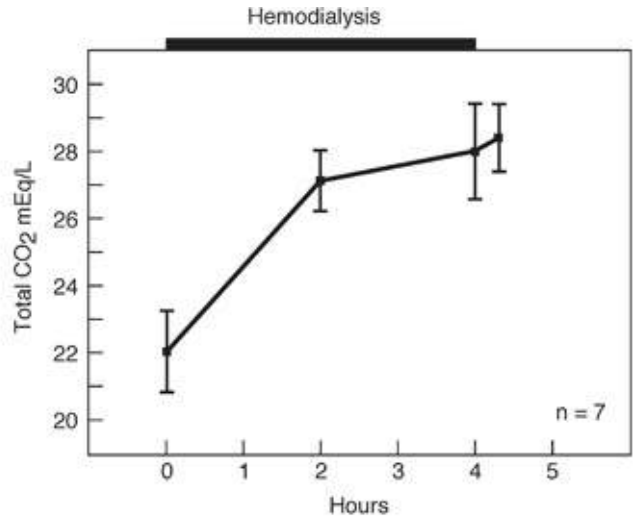

FIGURE 25.7 Pattern of change in serum [total CO_2] during 4 hours of hemodialysis treatment based on measurements in seven stable, nondiabetic patients (7). In these patients, [total CO_2] was measured before dialysis, after 2 hours, at the end of dialysis, and 15 minutes after completion of dialysis. The brackets around the data points are equal to ± standard error. Note that virtually the entire increase in [total CO_2] occurs during the first 2 hours of treatment.

Although the factors responsible for determining end-dialysis serum [HCO_3^-] remain to be completely elucidated, this value is of critical importance because it sets the platform from which [HCO_3^-] slowly falls in the period between treatments. Assuming no intervening events, the postdialysis serum [HCO_3^-] is normally determined primarily by the specific dialysis [HCO_3^-] prescribed for any given patient.

Determinants of Predialysis Serum [HCO_3^-]

In the interval between HD sessions, the two major determinants of the rate of fall in serum [HCO_3^-] are the rate of endogenous acid production and the rate of fluid retention. Endogenous acid production between treatments is determined primarily by diet; patients ingesting a diet low in sulfur-containing proteins will have low rates of endogenous acid production and *vice versa* (1,2). Although there is no information on the effect of specific diets on predialysis serum [HCO_3^-], a clear inverse correlation between normalized protein catabolic rate (an indirect measure of dietary protein intake) and predialysis serum [HCO_3^-] is evident in patients receiving HD (25–27,50).

On the basis of these observations and a few assumptions, one can estimate the magnitude of the effect of variations in endogenous acid production on predialysis serum [HCO_3^-]. If one assumes that all the acid produced is retained and that the buffer space for the retained H^+ is 50% of body weight [an assumption supported by measurements in HD patients (50)], such an analysis predicts that variations in acid production will alter predialysis serum [HCO_3^-] by as much as 6 mmol/L (**TABLE 25.4**). Given these assumptions, variations in daily acid production can mean the difference between a low normal and frankly acidotic predialysis serum [HCO_3^-] in patients receiving exactly the same dialysis prescription.

Although the major determinant of endogenous acid production is dietary protein intake, the catabolic state of the patient will also influence acid production.

TABLE 25.4 Effect of Endogenous Acid Production and Fluid Retention on Predialysis Serum [HCO_3^-] in Patients Treated with Conventional Hemodialysis

Acid Production mmol/d	Fluid Retention[a] L per Interval	Predialysis [HCO_3^-][b] mmol/L
40	2	23.4
80	2	20.4
120	2	17.3
60	0	23.1
60	3	21.3
60	6	19.8

Assumptions: weight = 70 kg, postdialysis serum [HCO_3^-] = 28 mmol/L, and HCO_3^- buffer space = 0.5 × body weight (kg).
[a]Liters retained during longest interval between treatments.
[b]After longest interval between treatments (68 hours).

For the analysis shown in the first half of **TABLE 25.4**, it is assumed that 2 L of fluid is retained between each treatment, highlighting the importance of the second factor, fluid retention between runs. For any given rate of endogenous acid production, fluid retained without proportionate alkali between treatments will also decrease predialysis serum [HCO_3^-]. This is a true "dilution acidosis" caused by an increase in the fluid compartment in which the existing HCO_3^- stores are distributed. Using a fixed value for endogenous acid production of 60 mmol/d, keeping the same assumptions for buffering, and assuming that changes in ECF volume do not have any special effects on the buffer response, one can also predict the effect of variations in fluid retention on predialysis serum [HCO_3^-]. As shown in the lower portion of **TABLE 25.4**, this effect is almost as profound as changes in acid production. This theoretic analysis also has experimental support. A difference of only 1 L in fluid retention between dialysis treatments has been shown to affect predialysis serum [HCO_3^-] by more than 1 mmol/L (51). The implications of these effects for the management of acid–base equilibrium in patients receiving HD are discussed further later.

Normal Values for Predialysis Serum [HCO_3^-]

The average predialysis serum [HCO_3^-] (measured in most instances as [total CO_2]) for stable patients receiving three HD treatments a week ranges from 20 to 24 mmol/L (**TABLE 25.3**) (7,24–28). These values are generally lower than those in individuals with normal renal function and in patients receiving PD therapy, and they show a much wider range. For reasons that are unclear, average predialysis serum [HCO_3^-] has risen by approximately 2 mmol/L over the last 10 to 15 years without any major change in dialysis technique or bath composition (**TABLE 25.3**). This increase may reflect the aging of our dialysis population and the likely associated decrease in dietary intake. The respiratory response to hypobicarbonatemia is normal in ESKD (6,30,38,39,47,52), and therefore, P_{CO_2} is appropriately reduced when serum [HCO_3^-] is low. As a result, average blood pH is either within the normal range or only slightly reduced (**TABLE 25.3**) (29–31,46).

EFFECTS OF METABOLIC ACIDOSIS ON BONE AND MUSCLE METABOLISM

In two studies, a steady-state predialysis serum [HCO_3^-] of less than 19 mmol/L was associated with impaired parathyroid hormone responsiveness to changes in serum calcium concentration and with more severe bone disease (53,54). In one of these studies, predialysis serum [HCO_3^-] was increased from 15.6 to 24 mmol/L by increasing bath [HCO_3^-] (Table 23.5). This change arrested the progression of both high- and low-turnover bone disease, despite otherwise equivalent management (53). In the second study, predialysis serum [HCO_3^-] was increased from 18.6 to 25.3 mmol/L using the same approach (**TABLE 25.5**), and this maneuver improved the sensitivity of parathyroid hormone to changes in serum calcium concentration (53).

TABLE 25.5 Studies in which Predialysis Serum [HCO_3^-] Was Increased in Conventional Hemodialysis: Techniques and Results

		[HCO_3^-] mmol/L			
N	Duration (mo)	Baseline	Treatment	Technique	Reference
11	18	15.6	24.0	↑ Bath [HCO_3^-] to 40–48 mmol/L	(54)
38	3	19.0	24.8	↑ Bath [HCO_3^-] to 39 mmol/L	(24)
8	1	18.6	25.3	↑ Bath [HCO_3^-] to 40 mmol/L	(53)
21	6	20.4	23.3	↑ Bath [HCO_3^-] to 40 mmol/L	(55)
25	6	22.5	26.7	↑ Bath [HCO_3^-] to 40 mmol/L	(55)
6	1	18.5	24.8	↑ Bath [HCO_3^-] to 40 + oral $NaHCO_3$	(56)
9	1	20.0	25.0	↑ Bath [HCO_3^-] to 40 + oral $NaHCO_3$	(49)
12	6	18.8	23.1	↑ Bath [HCO_3^-] to 36 + oral $NaHCO_3$	(57)

A low predialysis serum [HCO_3^-] also appears to have adverse effects on protein metabolism. In one study, a low predialysis serum [HCO_3^-] (18.5 mmol/L) was associated with abnormally high muscle protein turnover, a measure of muscle catabolism (55). When predialysis serum [HCO_3^-] was increased to 24.8 mmol/L by raising bath [HCO_3^-] (**TABLE 25.5**), muscle protein turnover was reduced. Additional studies have shown a beneficial effect on increasing predialysis serum [HCO_3^-] on muscle metabolism (57,58). A similar reduction in protein turnover in patients receiving PD was seen when steady-state serum [HCO_3^-] was increased from 19 to 26 mmol/L by giving oral $NaHCO_3$ supplements (59).

EFFECT OF PREDIALYSIS SERUM [HCO_3^-] ON MORTALITY

The relative risk of death in HD patients dialyzed with the same bath [HCO_3^-] is increased in patients who either have very low or very high values for predialysis serum [HCO_3^-] (as compared with a reference group with values between 19 and 23 mmol/L) (27,28,60,61). In two large cohort studies (7,000 and 20,000 patients, respectively), the relative risk of mortality increased by 10% to 15% for predialysis [total CO_2] values less than 19 mmol/L, as compared to patients with values of 19 to 22

mmol/L, and 19 to 24 mmol/L, respectively (60,61). In a third cohort study, with an even larger number of patients, mortality risk increased by 10% for patients with serum [total CO_2] values less than 19 mmol/L (27). All three studies also showed a higher mortality risk when serum [total CO_2] was high, but this effect largely disappeared when the cases were adjusted for indicators of malnutrition and inflammation (27). As discussed earlier, a high predialysis serum [HCO_3^-] occurring without an upward adjustment in bath [HCO_3^-] likely reflects low dietary protein intake, which may be a marker of other comorbidities that increase mortality risk. A low predialysis serum [HCO_3^-] appears to have a more direct effect on mortality. It should be emphasized that none of these studies assessed pH and P_{CO_2}, and it is likely the effect of changes in pH on cell function and is more important than the prevailing serum [HCO_3^-] with regard to mortality. In one study in which pH was measured predialysis, mortality risk was increased only when the value was ≥7.40, underscoring concerns about excess alkalinity (62).

MANAGEMENT OF PATIENTS WITH LOW SERUM [HCO_3^-]

Based on the evidence cited above for patients with low predialysis serum [HCO_3^-], the 2000 Kidney Disease Outcome Quality Initiative (KDOQI) guidelines recommended increasing the value to 22 mmol/L or higher in all patients by increasing bath [HCO_3^-] if necessary (63). Many dialysis units have worked to meet this guideline, but it is unclear whether such an effort is justified. A recent large cohort study has found an increase in mortality risk of 8% for every 4 mmol/L increase in bath [HCO_3^-] (64). This risk is independent of the predialysis serum [HCO_3^-]. Although this is a single study, one should probably not raise bath [HCO_3^-] more than 1 to 3 mmol/L, and such an intervention should be limited to patients with predialysis values of <19 mmol/L.

Before considering any increase in bath [HCO_3^-], one should try to determine the cause of the low predialysis serum value. This assessment should include an analysis of both the events between treatments and during dialysis. The rate of fall in serum [HCO_3^-] between treatments can be assessed by comparing the postdialysis value with the next predialysis value. As discussed earlier, the key factors influencing the rate of decline are nutrition (specifically, protein intake) and fluid retention. If dietary adjustments are called for, one must be careful to ensure that overall nutrition remains adequate, as protein malnutrition will certainly not be beneficial for the patient (26,60). If fluid retention is excessive, a reduction in intake between treatments should be encouraged, recognizing that this is a difficult undertaking. For completeness, one should also determine whether patients are losing large amounts of HCO_3^- in their urine (if they still have significant urine output) or in their stool (diarrhea states, see later). To assess net alkali gain during dialysis, serum [HCO_3^-] can be measured before and immediately after the treatment. This measurement can answer the question of whether the alkali added from the bath has been retained or consumed by excessive organic acid production. Normally, serum [HCO_3^-] should increase by 6 to 10 mmol/L during each treatment (**FIGURE 25.7**).

Regardless of the cause, predialysis serum [HCO_3^-] can easily be increased by increasing bath [HCO_3^-] (23,47,53–57,59). **TABLE 25.5** summarizes the results of studies in which bath [HCO_3^-] was

increased to improve predialysis serum [HCO_3^-]. These studies demonstrate that postdialysis [HCO_3^-] is directly related to bath [HCO_3^-], and this value in turn exerts a parallel effect on the nadir serum [HCO_3^-] before the next treatment. In these studies, postdialysis serum [HCO_3^-] increased to between 30 and 34 mmol/L, and this relative (and transient) alkalemia was not associated with any adverse events. However, given the possible long-term risk to the patient of increasing bath [HCO_3^-] (see above) (64), this maneuver is no longer recommended, unless predialysis serum [HCO_3^-] is persistently less than 19 mmol/L and cannot be corrected by any other means. An alternative (or supplemental) approach is to administer oral sodium bicarbonate on a daily basis. This supplement will effectively increase predialysis serum [HCO_3^-] but may also increase fluid retention (49,56,57).

MANAGEMENT OF PATIENTS WITH HIGH SERUM [HCO_3^-]

A new concern is in patients with very high predialysis serum [HCO_3^-] who clearly have an increased mortality risk (65). As many as 15% of patients now receiving dialysis have values >26 mmol/L. The available evidence suggests that, unlike low predialysis serum [HCO_3^-], high values are a marker for nutritional deficiency or inflammatory events, rather than an independent risk factor, and thus reducing bath [HCO_3^-] is unlikely to be beneficial (27). In these patients, attention should be focused on addressing nutrition and modifiable inflammatory factors, rather than making any adjustments in the HD prescription. These patients represent a quandary, however, and the best approach to treatment remains to be determined.

DAILY HEMODIALYSIS

The use of daily HD treatments, either in critically ill inpatients or in stable outpatients, quickly normalizes serum [HCO_3^-] and pH (see Chapter 8) (66–69). In stable outpatients receiving daily nocturnal HD treatments, the difference between predialysis and postdialysis serum [HCO_3^-] is reduced to less than 1 mmol/L, and bath [HCO_3^-] has been reduced to 28 to 32 mmol/L to avoid metabolic alkalosis. Similar outcomes have been observed with daily short HD treatments. These results are not surprising, given the dynamic changes in serum [HCO_3^-] described earlier for intermittent HD. One form of daily HD differs from the others: It uses a lactate-containing bath in an enclosed cartridge (70). In this form of HD, the dynamics of alkali addition are similar to PD—loss of HCO_3^- into the bath and gain of lactate into the blood, and serum [HCO_3^-] levels are maintained in the normal range by adjusting bath lactate concentration.

CONTINUOUS RENAL REPLACEMENT THERAPIES

Continuous hemofiltration, hemofiltration plus dialysis, and slow low-efficiency HD are all currently used for the treatment of kidney failure in critically ill patients (see Chapter 10) (66,71–74). With these techniques, the same principles hold with regard to acid–base homeostasis as discussed earlier for

conventional HD. With continuous hemofiltration, HCO_3^- loss is related to the serum concentration and the ultrafiltration rate as well as to the ongoing rate of endogenous acid production. Replacement is achieved with a continuous infusion of either an HCO_3^- or lactate-containing solution (74,75), and serum [HCO_3^-] is readily maintained within the range of normal (66). With continuous slow, low-efficiency dialysis, serum [HCO_3^-] becomes essentially equal to the concentration in the dialysis bath solution and the latter must be reduced to 24 to 28 mmol/L to prevent the development of metabolic alkalosis.

Hemofiltration and Hemodiafiltration

Hemofiltration uses the principle of convection rather than diffusion for toxin removal and can be used as an intermittent therapy. To achieve adequate toxin removal, high-volume ultrafiltration occurs during the procedure necessitating the rapid infusion of replacement fluids (at ~100 mL/min) (76). Although acetate-containing solutions were originally used for this procedure, replacement solutions containing HCO_3^- are necessary for adequate acid–base homeostasis (76). The high-volume ultrafiltration and rapid infusion of replacement solutions make the technique more complex and subject to risk than conventional HD, and it is rarely used.

Hemodiafiltration combines the high convective characteristics of intermittent hemofiltration with a bath solution containing either acetate or HCO_3^- (77,78). For this treatment, replacement solutions containing HCO_3^- are necessary to achieve positive net alkali addition, and the procedure has the same complexity as hemofiltration and little advantage over conventional HD from an acid–base perspective.

Acetate-free biofiltration is a hemodiafiltration technique in which the dialysate contains no HCO_3^- or acetate but does contain other key solutes (79). High-volume ultrafiltration is carried out, and isotonic $NaHCO_3$ is continually infused into the postfilter blood. One proposed advantage for this procedure is the removal of all acetate from the bath, but there is no evidence that the small amount of acetate currently used in bath solutions has any clinically important toxicity. As opposed to regular hemodiafiltration where the replacement solution contains all electrolytes, only $NaHCO_3$ is reinfused with this procedure, allowing for high concentrations of HCO_3^- to be used. Using this technique, one can predictably increase serum [HCO_3^-] to the level desired in each patient (79). As discussed earlier, the same goal can be achieved with conventional HD by simply adjusting the bath [HCO_3^-], and acetate-free biofiltration is only rarely used for the treatment of ESKD. Despite the lack of evidence for acetate toxicity at low levels, conventional HD bath solutions are also now commonly using citric acid rather than acetic acid to stabilize pH for HCO_3^- addition (see earlier), eliminating the rationale for this complex dialysis technique.

ACID–BASE DISORDERS IN PATIENTS WITH END-STAGE KIDNEY DISEASE

Thus far, we have considered the factors determining the “normal” values for serum [HCO_3^-] in patients receiving renal replacement therapy. This section is directed at identifying and managing acute or chronic superimposed acid–base disorders in this population of patients. Such disorders are heralded by

deviations from the expected normal values for serum [HCO_3^-] and P_{CO_2} (**TABLES 25.1** and **25.3**). In general, an abrupt change in serum [HCO_3^-] of 3 mmol/L or greater from the usual value should signal the presence of a new metabolic acid–base disorder. Respiratory acid–base disorders, by contrast, are not associated with any change in serum [HCO_3^-] and must be suspected by the clinical presentation and history (80,81).

Given the wide variation in predialysis serum [HCO_3^-] in this unique group of patients, identification of superimposed disorders seems a formidable task. Fortunately, an ongoing log of monthly values for serum [HCO_3^-] is available to use for comparison with a suspected abnormal value. Identifying an abnormality in P_{CO_2} is a more difficult undertaking because no laboratory trail exists for this parameter. The ventilatory response to variations in serum [HCO_3^-] is normal in patients with kidney failure (6,30,38,39,46,47), and so one can use the following formulas to estimate the expected P_{CO_2} for any given serum [HCO_3^-] if one has a clinical suspicion that a ventilatory problem is present:

For serum [HCO_3^-] values 24 mmol/L or less:

$$P_{CO_2}\ (\text{mm Hg}) = 40 - 1.2 \times (24 - [HCO_3^-]) \quad (25.1)$$

For serum [HCO_3^-] values greater than 24 mmol/L:

$$P_{CO_2}\ (\text{mm Hg}) = 40 + 0.7 \times ([HCO_3^-] - 24) \quad (25.2)$$

These equations should be considered only as approximations, but they can be used to determine whether a measured P_{CO_2} deviates notably from the expected value. Given the normal variability in the ventilatory response to a given serum [HCO_3^-], one should consider the measured P_{CO_2} to be abnormal only if it is 5 mm Hg or more different from the expected value.

Once an abnormal P_{CO_2} or serum [HCO_3^-] has been identified, the approach to characterizing the abnormality is the same as that in patients with normal kidney function:

1. Identify the primary disorder (e.g., metabolic acidosis or alkalosis, respiratory acidosis or alkalosis).
2. Determine whether the secondary response is appropriate.
3. Determine the cause of the disorder.

Although the general approach is the same, the diagnostic process is actually simpler than in patients with kidney function (**FIGURE 25.8**). In patients with ESKD, for example, there is no kidney adaptive response to respiratory acid−base disorders. In addition, one need not consider kidney causes for either metabolic acidosis or alkalosis. The approach to each of the four cardinal acid–base disorders is discussed in following sections.

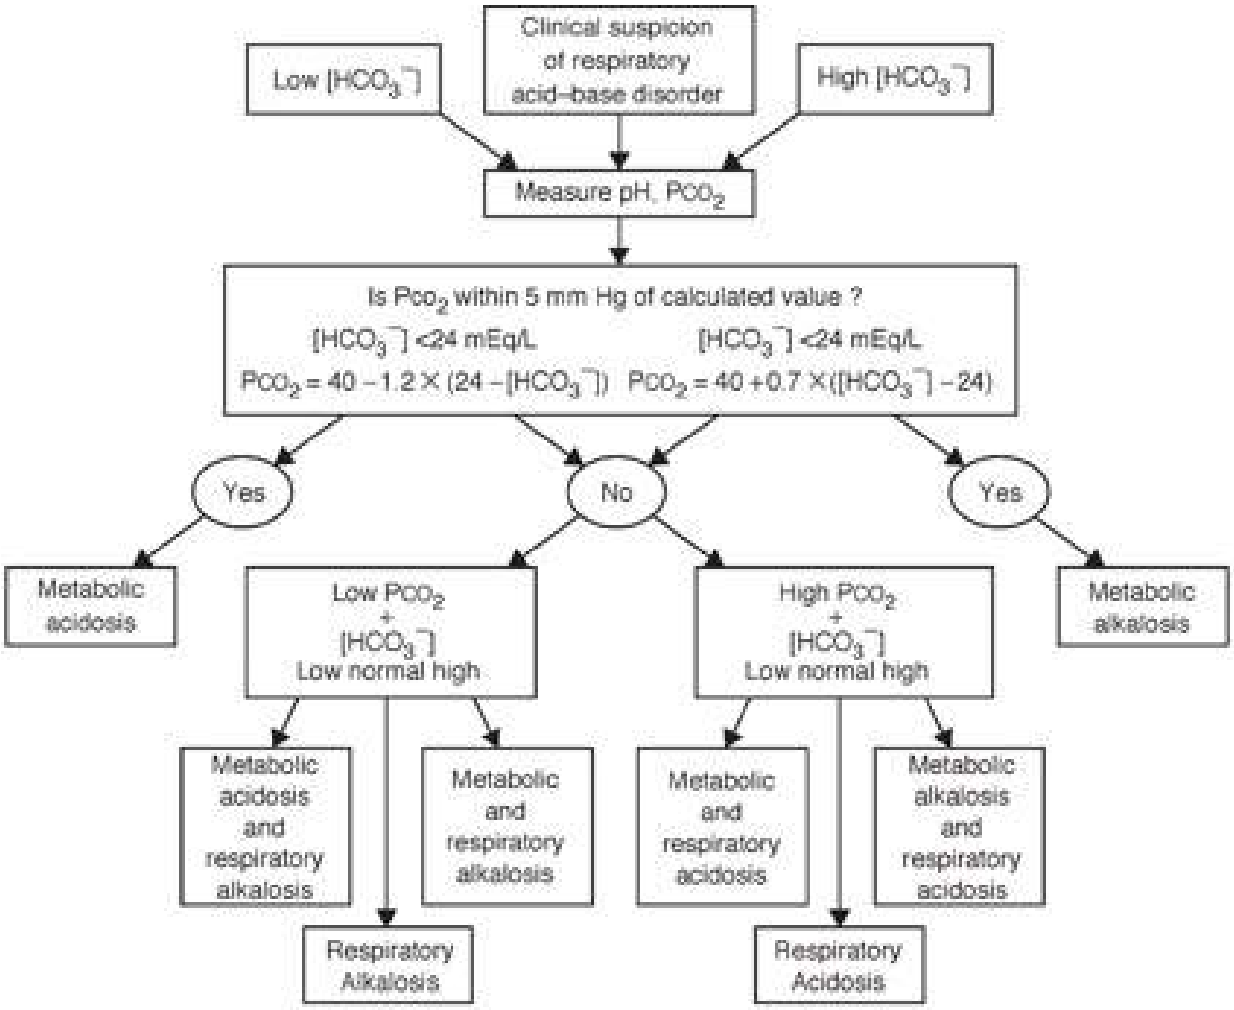

FIGURE 25.8 Approach to the evaluation of acid–base disorders in patients with end-stage kidney disease (ESKD). The terms *low* $[HCO_3^-]$ and *high* $[HCO_3^-]$ in the diagram refer to values that are 3 mmol/L or more either lower or higher than the average values found in patients receiving renal replacement therapy (**TABLES 25.1** and **25.2**).

Metabolic Acidosis

A new metabolic acidosis can be diagnosed in a patient with ESKD when serum $[HCO_3^-]$ falls by 3 mmol/L or more from the usual value (80,81). Unlike patients with kidney function, one does not have to consider the possibility that chronic respiratory alkalosis is responsible because the secondary reduction in $[HCO_3^-]$ induced by hypocapnia requires kidney function. Although a primary respiratory alkalosis cannot be the cause of the low serum $[HCO_3^-]$ in patients with ESKD, blood pH and P_{CO_2} should be measured to determine whether the ventilatory response to metabolic acidosis is appropriate. In patients with functioning fistulas, this information can be easily obtained without a separate arterial puncture (82). The expected ventilatory response to metabolic acidosis decreases P_{CO_2} by approximately 1.2 mm Hg for each 1 mmol/L fall in serum $[HCO_3^-]$ (**EQUATION 25.1**) (52). If the measured P_{CO_2} deviates from the expected value by 5 or more mm Hg, then the patient likely has a mixed disorder (see later). If the fall in P_{CO_2} is within the expected range, then the patient most elikely has an uncomplicated metabolic acidosis (**FIGURE 25.8**), and attention should be directed at diagnosing its cause. In all instances, the history and physical examination findings should be used in conjunction with these equations to determine whether a simple or mixed disorder is present.

Causes

Metabolic acidosis can be produced either by the sudden addition of a new acid to the body fluids or by the loss of HCO_3^- (**TABLE 25.6**). The most common cause is acid generation as a result of abnormalities in body metabolism or through toxin-induced stimulation of acid production. The only site for abnormal HCO_3^- losses in patients without kidney function is from the gastrointestinal tract.

TABLE 25.6 Causes of Metabolic Acidosis in End-Stage Kidney Disease

Increased Anion Gap[a]	No Increase in Anion Gap
Diabetic ketoacidosis	Gastrointestinal alkali loss
Lactic acidosis	Diarrhea
Alcoholic ketoacidosis	Pancreatic drainage
Toxin ingestions	Hemofiltration with NaCl replacement
Methyl alcohol	Ammonium chloride ingestion
Ethylene glycol	
Salicylates	
Paraldehyde	
Catabolic state	
High protein intake	
High salt and water intake	

[a]Increase from the usual level in the patient by greater than 3 mmol/L.

Separation of the causes of metabolic acidosis by assessment of whether the anion gap is increased or not is less useful in patients with ESKD than in patients with functioning kidneys. The anion gap must be corrected for the serum albumin concentration and is often already increased in these patients (80,81). In addition, most causes of metabolic acidosis in HD patients are associated with a further increase. The most useful tool is a baseline anion gap to allow assessment of any change. In the absence of baseline data, an anion gap of more than 20 mmol/L should be considered abnormally high.

Organic Acidosis

The most common cause of a new metabolic acidosis in patients with ESKD is a pathologic process that leads to overproduction of one or more organic acids. Diabetic ketoacidosis is the most common culprit, but one also should consider other causes such as alcoholic ketoacidosis, lactic acidosis, and toxin ingestions (**TABLE 25.6**). The organic acids produced by these disorders titrate and replace HCO_3^- in the body fluids, causing the anion gap to increase as the anions of these acids accumulate in the serum. In contrast to patients with functioning kidneys, patients with ESKD cannot excrete these newly formed anions, and they remain available to be metabolized unless they are removed by dialysis. Thus, once the pathologic process leading to their generation is reversed, they are able to regenerate all the HCO_3^- that was consumed. This sequence of events is illustrated in **FIGURE 25.9** in a patient with ESKD with diabetes mellitus who developed diabetic ketoacidosis (83). In this patient, the ketoacidosis rapidly lowered serum [HCO_3^-] and increased the anion gap. Insulin therapy alone decreased the anion gap and increased serum [HCO_3^-] from 14 to 25 mmol/L over 10 hours. Note that this recovery occurred without an intervening dialysis treatment and required only minimal fluid replacement and no exogenous alkali; these patients lose neither fluid nor organic anions when they develop ketoacidosis.

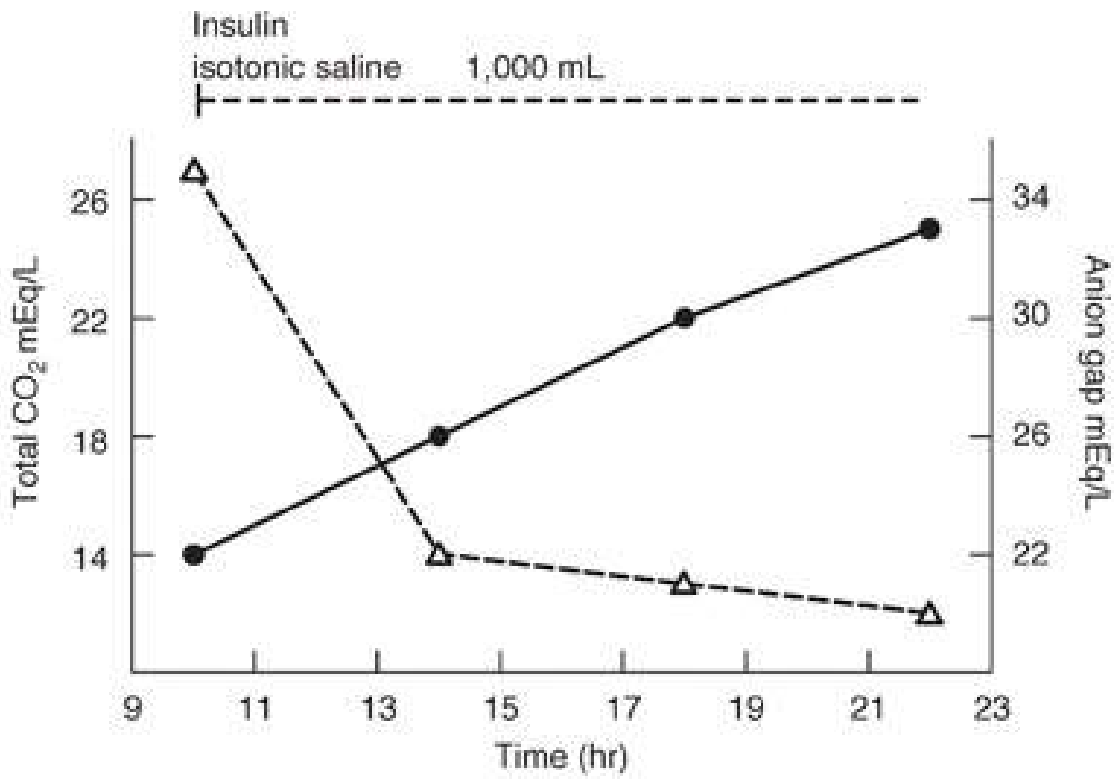

FIGURE 25.9 Correction of diabetic ketoacidosis in a patient with end-stage kidney disease (ESKD) without HCO_3^- administration or dialysis treatment. Serum [total CO_2] and serum anion gap were restored to preacidosis levels by the administration of insulin and 1 L of isotonic saline. (Reprinted with permission from Gennari FJ. Acid–base disorders in end-stage renal disease. Part I. *Semin Dial* 1990;3:81–85.)

Although diabetic ketoacidosis is rapidly reversed by insulin therapy, production of other organic acids cannot be so easily halted. Therefore, dialysis is often required both to remove the organic anions and to rapidly replace them with HCO_3^-. HD therapy is particularly useful when toxin ingestions lead to metabolic acidosis in anephric individuals, as this mode of therapy is the most effective in removing the offending toxins. In some types of lactic acidosis, production of lactic acid cannot be halted (84,85), and HD in this setting offers a means to replace HCO_3^- rapidly without causing fluid overload. Although rapid alkalinization using HD accelerates lactic acid production (84), continuous HD can overcome this increase and can produce a sustained increase in serum [HCO_3^-] until lactic acid production can be halted (86). As with all organic acidosis, reversal of the cause of the increase in acid production is key to sustained correction of the metabolic acidosis.

Other Causes

As discussed earlier, an increase in dietary protein intake or an increase in body protein catabolism will reduce predialysis serum [HCO_3^-] (**TABLE 25.6**). Because the increase in endogenous acid production engendered is associated with anions other than chloride, this type of acidosis also increases the anion gap. An increase in fluid retention, due to high NaCl and water intake between HD treatments, will also lower predialysis serum [HCO_3^-] by diluting body alkali stores (**TABLE 25.4**). The dilution occurs without a change in the concentration of other electrolytes, and therefore, the anion gap increases, although the change in this instance is likely to be minimal. Neither an increase in ECF volume nor an increase in protein catabolism is likely to produce a severe metabolic acidosis. If serum [HCO_3^-] falls by more than 6 to 8 mmol/L acutely, one can be virtually certain that an organic acidosis is responsible.

Induction of metabolic acidosis from gastrointestinal HCO_3^- losses requires the development of severe diarrhea or could occur from surgical drainage of fluid rich in pancreatic secretion. This form of metabolic acidosis does not increase the anion gap above the usual level, as the acidosis is associated with the disproportionate loss of HCO_3^- and therefore an increase in serum [Cl^-]. Inadvertent replacement of alkali in the bath with a chloride-containing solution is a technique error that will induce a severe metabolic acidosis without increasing the anion gap (87). An extremely rare cause of metabolic acidosis without a further increase in the anion gap is the deliberate or accidental ingestion of ammonium chloride. In patients with no kidney function, renal tubule acidosis need not be considered as a cause of metabolic acidosis.

In patients treated with continuous hemofiltration, metabolic acidosis can be induced if an inappropriate replacement solution is used. If Ringer's lactate is used in a patient who is unable to metabolize this organic anion, the resulting metabolic acidosis will be associated with an increase in the anion gap, although the acidosis is induced by HCO_3^- loss through hemofiltration. If sodium chloride is used as the replacement solution, then the acidosis will be associated with hyperchloremia and no increase in anion gap.

Metabolic Alkalosis

Metabolic alkalosis is diagnosed by the finding of an increase in serum [HCO_3^-]. In patients with ESKD, chronic respiratory acidosis is not a consideration because the increase in serum [HCO_3^-] engendered by sustained respiratory acidosis requires kidney function. Metabolic alkalosis is generated by the selective loss of chloride from the body fluids (e.g., from vomiting or nasogastric drainage) or by the addition of new alkali. Unlike patients with functioning kidneys, the disorder is sustained once initiated, regardless of dietary intake (88,89). In addition, because the hypokalemia associated with metabolic alkalosis is primarily caused by renal K^+ losses, serum [K^+] is unchanged from its usual value when metabolic alkalosis occurs in patients with ESKD (88,89). In these patients, vomiting or nasogastric drainage can cause very severe metabolic alkalosis because they cannot excrete any of the newly generated HCO_3^- (89). Kidney causes of metabolic alkalosis (e.g., Bartter syndrome, primary hyperaldosteronism) need not be considered, nor is it necessary to partition the causes into chloride-sensitive and chloride-resistant groups.

An increase in serum [HCO_3^-] of 3 mmol/L or more from the usual value in a patient with ESKD is the working rule for diagnosing a new metabolic alkalosis, but because serum [HCO_3^-] is lower than that of individuals with normal renal function, the diagnosis is often not recognized unless a much larger increase is present—some 8 to 10 mmol/L (90). Although one does not have to consider chronic respiratory acidosis as a cause of the increase in serum [HCO_3^-], one should measure blood pH and P_{CO_2} to ensure that the respiratory response to the metabolic alkalosis is in the expected range. The normal response to an increase in serum [HCO_3^-] is hypoventilation: for each 1 mmol/L increase in [HCO_3^-], P_{CO_2} increases by 0.7 mm Hg (**EQUATION 25.2**). If the measured P_{CO_2} is within 5 mm Hg of the expected value, the patient has an uncomplicated metabolic alkalosis (**FIGURE 25.8**). If the value deviates from this range, the patient likely has a mixed disorder (see later).

Causes

TABLE 25.7 presents the causes of metabolic alkalosis in patients with ESKD. There are only two categories to consider: loss of acid or the addition of new alkali. The former occurs only with vomiting or nasogastric drainage, and the diagnosis is almost always immediately apparent. However, bulimic patients may deny vomiting (90). The potential sources of alkali range from $NaHCO_3$ to certain anionic amino acids (**TABLE 25.7**). Administration of $NaHCO_3$ in a dose of 2 mmol/kg body weight will increase serum [HCO_3^-] by 4 to 5 mmol/L (91). Calcium salts containing carbonate, acetate, or citrate only add alkali to the body to the extent that calcium is ionized and absorbed. Therefore, they rarely cause significant metabolic alkalosis.

TABLE 25.7 Causes of Metabolic Alkalosis in End-Stage Kidney Disease

Vomiting
Nasogastric drainage
Exogenous alkali/alkali precursor
Sodium bicarbonate
Potassium bicarbonate
Calcium carbonate
Lactate
Acetate
Citrate
Glutamate
Proprionate
Aluminum hydroxide + Kayexalate

A rare cause of metabolic alkalosis in patients with ESKD is the combined use of sodium polystyrene sulfonate (Kayexalate) and aluminum hydroxide (92). Aluminum hydroxide is usually converted to aluminum phosphate or chloride by gastric acid, and a portion of these salts dissociate in the duodenum, allowing aluminum ions to bind to HCO_3^- secreted by the pancreas. When Kayexalate is present, however, aluminum ions bind to it instead forming a compound that does not dissociate. As a result, HCO_3^- is neither neutralized nor bound, and this alkali is reabsorbed by the small intestine and retained in the body fluids.

Management

Management of metabolic alkalosis in patients with ESKD should be directed at removing the cause. Treatment of the cause of vomiting and removal of any sources of exogenous alkali in most instances will lead to eventual correction of the disorder. If these interventions fail to correct the disorder and if the high serum [HCO_3^-] is causing symptoms or interfering with management (e.g., ventilator dependence), serum [HCO_3^-] can be reduced by decreasing bath [HCO_3^-], an option easily managed with the dialysis machines now available (89). Metabolic alkalosis in the anephric patient in the intensive care unit can also be corrected by using continuous hemofiltration and replacing losses with only sodium chloride (88) or by using slow, low-efficiency HD with a bath [HCO_3^-] of 25 mmol/L.

Respiratory Acidosis

Respiratory acidosis is caused by alveolar hypoventilation and is manifested by an increase in arterial

P_{CO_2}. The normal secondary response to this disorder has two components (93). The first is an acute buffer response that produces a very small increase in serum [HCO_3^-]; the second and major component is produced by renal HCO_3^- generation. In patients with ESKD, this latter response cannot occur; therefore, no notable increase in serum [HCO_3^-] occurs to signal the presence of hypercapnia. One must have a clinical suspicion for the disorder and measure blood pH and P_{CO_2} to confirm it (**FIGURE 25.8**). A P_{CO_2} value of 5 mm Hg or higher than the expected value for the prevailing serum [HCO_3^-] establishes the diagnosis (**EQUATIONS 25.1** and **25.2**). One need not evaluate whether the serum [HCO_3^-] is appropriate; serum [HCO_3^-] is determined by the dialysis treatment rather than by P_{CO_2} in patients with ESKD.

Because there is no renal secondary response, hypercapnia leads to a sustained and severe acidemia in patients with ESKD. In a patient with kidney function, a sustained P_{CO_2} level of 55 mm Hg will result in only a minor reduction in blood pH because this increment in P_{CO_2} will induce a secondary increase in serum [HCO_3^-] to 30 to 33 mmol/L. By contrast, a patient with ESKD with the same P_{CO_2} level may have a predialysis serum [HCO_3^-] of 20 to 22 mmol/L with a resultant blood pH of 7.18 to 7.22.

Management

Management of respiratory acidosis should be directed at reversing the hypercapnia if at all possible. If the P_{CO_2} cannot be reduced to a safe level, one can increase bath [HCO_3^-] to try to raise the serum level. Other approaches include daily or continuous HD or PD. Bicarbonate supplementation is also an option, but this therapy may lead to fluid overload, further embarrassing pulmonary gas exchange.

Respiratory Alkalosis

Respiratory alkalosis is caused by alveolar hyperventilation and is manifested by a decrease in arterial blood P_{CO_2}. The normal secondary response to this disorder has two components: an acute buffer response that lowers serum [HCO_3^-] within minutes and a chronic kidney response that lowers serum [HCO_3^-] further (94). Both responses are obliterated in patients receiving dialysis therapy. The chronic response requires kidney function and the acute response is overwhelmed by the effect of dialysis on serum [HCO_3^-]. Therefore, severe alkalemia is to be expected in patients with ESKD. Because serum [HCO_3^-] does not change notably, one must have a clinical suspicion that the disorder is present and measure blood pH and P_{CO_2} to establish the diagnosis. The presence of a P_{CO_2} level that is 5 mm Hg or more lower than expected for the prevailing serum [HCO_3^-] indicates the presence of respiratory alkalosis (**EQUATIONS 25.1** and **25.2** and **FIGURE 25.8**).

Causes and Management

Many pathologic events can cause respiratory alkalosis (**TABLE 25.8**). In contrast to patients with normal kidney function who can tolerate hypocapnia without serious complications, patients with renal failure can develop severe and sustained life-threatening alkalemia. Blood pH levels greater than 7.70 have been reported in patients with sustained respiratory alkalosis receiving PD therapy (83,95). In one patient with sustained respiratory alkalosis receiving conventional HD, an arterial pH greater than 7.90 was observed.

If hypocapnia cannot be corrected, one can attempt to reduce serum [HCO_3^-] by continuous hemofiltration without alkali replacement (using only saline) in an intensive care unit setting, but mortality is high if the problem persists.

TABLE 25.8 Causes of Respiratory Alkalosis

Nicotine
Progesterone

[a]Independent of hypoxemia.

Mixed Acid–Base Disorders

Mixed acid–base disorders occur when two or more primary acid–base abnormalities are present at the same time. In patients with ESKD, the spectrum of possible mixed disorders is narrower than in patients with kidney function because of the absence of any secondary response to hypo- and hypercapnia (**TABLE 25.9**). The most common mixed disorders are a combination of metabolic and respiratory disturbances. These are diagnosed by measuring P_{CO_2} and using **EQUATIONS 25.1** and **25.2** to determine if the value is appropriate for the concomitantly measured serum [HCO_3^-]. If the serum [HCO_3^-] is low (metabolic acidosis), the ventilatory response can be inadequate (superimposed respiratory acidosis) or greater than expected (respiratory alkalosis). The former is more common and can be associated with severe acidemia. Urgent intubation and assisted ventilation is needed for such patients in addition to management of the metabolic acidosis. If the serum [HCO_3^-] is high (metabolic alkalosis), this disorder can also be associated with an inadequate or greater than normal ventilatory response. When primary hyperventilation (respiratory alkalosis) complicates metabolic alkalosis, life-threatening increases in pH can occur. Attention should be directed at increasing P_{CO_2} if possible, or urgently reducing serum [HCO_3^-].

TABLE 25.9 Mixed Acid–Base Disorders in End-Stage Kidney Disease

Mixed Metabolic and Respiratory Disorders
↓[HCO_3^-]
P_{CO_2} > expected = metabolic + respiratory acidosis
P_{CO_2} < expected = metabolic acidosis + respiratory alkalosis
↑[HCO_3^-]
P_{CO_2} > expected = metabolic alkalosis + respiratory acidosis
P_{CO_2} < expected = metabolic + respiratory alkalosis
Metabolic alkalosis + metabolic alkalosis
Serum [HCO_3^-] + Δ anion gap[a] >30 mmol/L
Triple disorders
Metabolic acidosis + metabolic alkalosis +:
P_{CO_2} > expected = respiratory acidosis
P_{CO_2} < expected = respiratory alkalosis

[a]Δ anion gap = anion gap at time of presentation–usual anion gap in that patient.

More rarely, a mixed metabolic alkalosis and acidosis can occur. The sequence that might cause such a disorder in a dialysis patient would be the administration of exogenous alkali, increasing serum [HCO_3^-], followed by the development of a lactic acidosis or diabetic ketoacidosis. Such a sequence might fortuitously result in a serum [HCO_3^-] at or near normal levels, but the disorder is uncovered by finding an increase in the anion gap. Because of the variability in anion gap, such a diagnosis should only be made if the value is increased by 6 or more mmol/L. If the respiratory response to the final serum [HCO_3^-] in such a patient is abnormal, then a triple disorder is diagnosed.

SUMMARY

From an acid–base perspective, two issues should be addressed in the management of patients with ESKD. First, one must understand the forces determining the steady-state serum [HCO_3^-], so that modifications in treatment can be instituted as necessary to maintain this value in an optimal range. Second, one must recognize and treat superimposed acid–base disorders in these patients. The approach to diagnosing these disorders is less complex in patients with no kidney function. One need not consider metabolic acid–base disorders caused by changes in kidney alkali or acid excretion, nor need one consider secondary kidney responses to respiratory acidosis or alkalosis. The laboratory data normally accumulated in these patients facilitate the quick identification of changes in serum [HCO_3^-] caused by either metabolic acidosis or alkalosis, but respiratory acid–base disorders must be suspected on clinical grounds. Diagnosis and management of uncomplicated acid–base disorders are straightforward. Although relatively uncommon, mixed disturbances can occur in patients with renal failure, and their recognition and management can be lifesaving.

CHAPTER 26

Respiratory Disorders in End-Stage Kidney Disease

Vibhu Sharma and Michael Achilles Markos

The kidneys and the lungs are responsible for acid–base homeostasis. Pulmonary kidney cross talk is intimate and denotes, on a macroscopic and microscopic level, interactions between the pulmonary and kidney circulation and physiology. This chapter reviews basic physiology as it relates to pulmonary kidney interactions, and offer practical narratives on the most common conditions that a nephrologist might encounter that have a direct bearing on the pulmonary system.

PHYSIOLOGY

The lungs and the kidneys interact closely to maintain an acid–base balance. HL Mencken, a noted American satirist, wrote in the *Baltimore Sun*, "Life is a battle against hydrogen ions." Any perturbation in the hydrogen ion balance whether by addition of mineral (nonvolatile) acid such as lactic acid, formic acid, or hydrochloric/sulfuric acid; by a reduction in serum HCO_3; or by an increase in carbon dioxide (volatile acid: carbonic acid) in an organism stimulates a compensatory response that attempts to revert the organism closer to a steady state. In the first two scenarios (metabolic acidosis, as defined by a reduction in serum HCO_3) (1), an immediate respiratory compensation develops that can drive the $PaCO_2$ to ≤10 mm Hg in an attempt to maintain a life-conserving pH. This extreme compensation is illustrated dramatically in presentations of diabetic ketoacidosis (DKA). An increased secretion of hydrogen ions eventually occurs in the kidneys with an attempt to further normalize pH if the metabolic acidosis persists.

In the third scenario above (respiratory acidosis, defined by an increase in $PaCO_2$) (2), the kidneys retain HCO_3 to allow for a more normal pH. Respiratory acidosis is typically seen in patients with chronic obstructive pulmonary disease (COPD) and obesity hypoventilation syndrome (OHS) in addition to respiratory failure due to neuromuscular disease (e.g., myasthenia gravis and acute inflammatory demyelinating polyneuropathy).

Conversely, the emergence of a primary metabolic alkalotic state (defined by an increase in serum HCO_3) (3) produces a drop in alveolar ventilation mediated by medullary chemoreceptors to allow carbon dioxide levels (and thus hydrogen ion concentration borne of carbonic acid) to rise to allow

reversion closer to steady state. Compensatory hypercapnia in this setting is usually modest (expected $Paco_2$ 48 to 50 mm Hg with arterial pH not infrequently in excess of 7.60). Primary metabolic alkalosis is most frequently seen in the setting of vomiting and diuretic use.

A reduction in carbon dioxide tension in the organism due to primary respiratory alkalosis triggers an "alkaliuresis," again with the goal to revert pH to a more normal state. Primary respiratory alkalosis may be seen in patients presenting with stroke, head injury, or salicylate intoxication, in addition to asthma and pulmonary embolism (PE), for example.

Respiratory responses to primary acid–base perturbations occur almost instantly (minutes), while kidney compensation is slower, taking days to reach a peak response, and therefore, the ability of an organism to respond to a major insult to the acid–base balance is limited by the intensity of response that may be required and coexistent morbidities affecting either organ system. For example, a limitation in ventilation due to airway disease may prevent an adequate response to a severe metabolic acidosis in the setting of sepsis or poisoning, similarly, presence of end-stage kidney disease (ESKD) and a concomitant new respiratory acidosis may result in a lower pH than if the kidneys were functional. Given the rapidity of respiratory perturbations in acid–base disturbances, more extreme changes in arterial pH can be expected compared to the relatively slower (and weaker) perturbations in metabolic alterations.

There are three major methods by which physiologic interactions between the lung and kidney may be described: using HCO_3 to quantify the metabolic component, the strong ion difference (SID), and the standard base excess (SBE). All three are essentially clinically indistinguishable (4,5) with regard to predicting secondary directional changes in metabolic parameters.

Pulmonary kidney interactions are defined mathematically by the Henderson-Hasselbalch equation (5) encapsulating the essential and intimate relationship between the lungs and the kidney to maintain life (**EQUATION 26.1**):

$$pH = 6.1 + \log \left(\text{serum } HCO_3 \text{ concentration} / 0.03 \times Paco_2 \right) \qquad (26.1)$$

Detailed acid–base disturbance reviews have recently been published and are out of the scope of this basic review (6).

The kidneys also play a major role in the regulation of volume status; major perturbations in kidney function will necessarily impact pulmonary function due to changes in total lung water. This is discussed further below.

Key Points

- Respiratory perturbations in acid–base disturbances result in more extreme changes in arterial pH compared to the relatively slower (and weaker) perturbations in metabolic alterations.
- There are three major methods to describe secondary directional changes in acid–base disturbances: using HCO_3 to quantify the metabolic component, the strong ion difference (SID), and the standard base excess (SBE). All three are essentially clinically indistinguishable and may be used interchangeably.

CHRONIC KIDNEY DISEASE AND LUNG FUNCTION

A major consideration in patients with chronic kidney disease (CKD) is volume status; this may be

especially important not only in patients in the intensive care unit (ICU) but also in the ambulatory patient assessed for dyspnea. Volume homeostasis is typically preserved until the estimated glomerular filtration rate (eGFR) falls to 10 to 15 mL/min/1.73m^2. These patients may however be at risk for volume overload with small perturbations in sodium and/or water intake.

For the physician caring for a dyspneic patient with ESKD on hemodialysis (HD), it is important to assess interdialytic weight gain which may be a marker for hypervolemia (7). Pulmonary edema is a recognized complication of fluid overload in patients with CKD stage 5 whether or not dialysis is ongoing and substantial pulmonary congestion in patients with ESKD may be present without symptoms or signs or with subtle signs (8). Lung ultrasound is a useful noninvasive technique to determine lung congestion in the setting of HD.

B-lines (also called "comet tails," "ultrasound comets," or "lung comets") (**FIGURES 26.1–26.4**) are reverberation artifacts that occur due to reflection of the ultrasound beam off thickened interlobular septae in the setting of pulmonary congestion (9). The absence of B-lines is a good predictor of a low-wedge pressure (9), and positive correlations have been found between extravascular lung water (EVLW) determined by the PiCCO system, wedge pressure, and the number of B-lines counted across the chest ("comet-score") (10) (**FIGURES 26.5** and **26.6**).

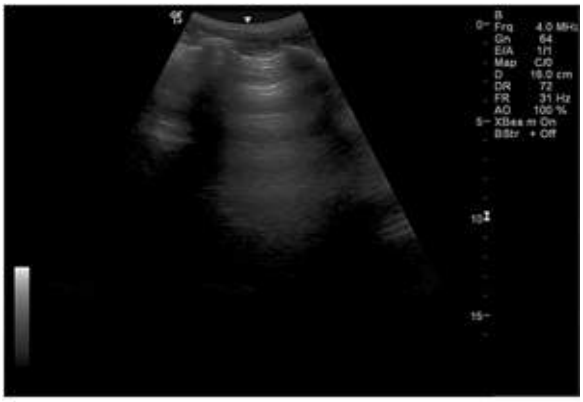

FIGURE 26.1 Normal lung.

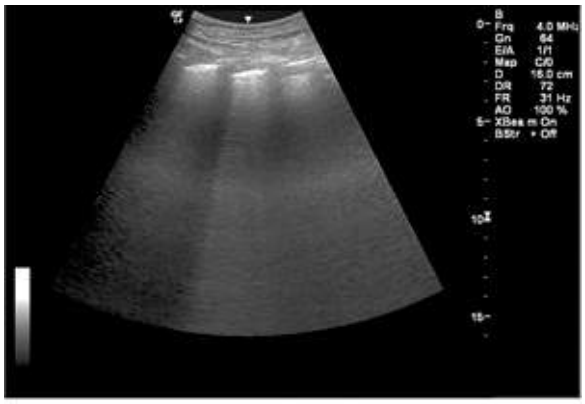

FIGURE 26.2 B-line count 2.

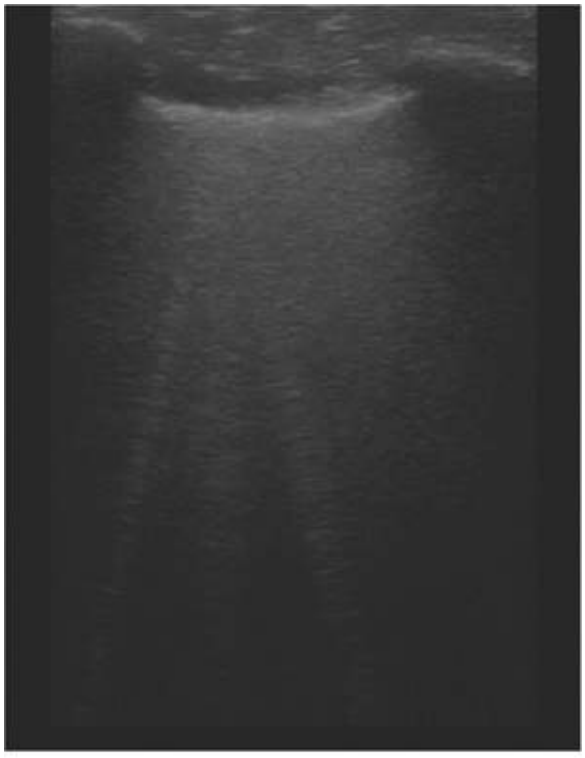

FIGURE 26.3 B-line count 3.

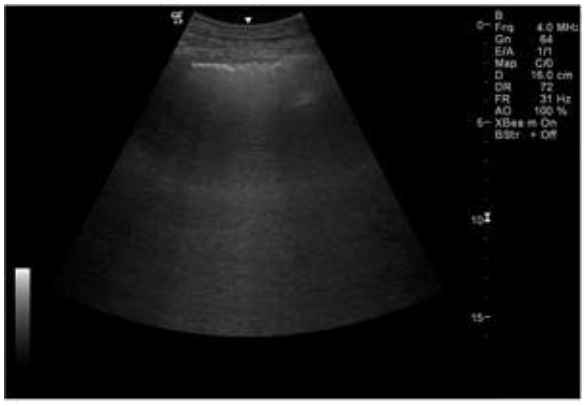

FIGURE 26.4 Numerous B-lines.

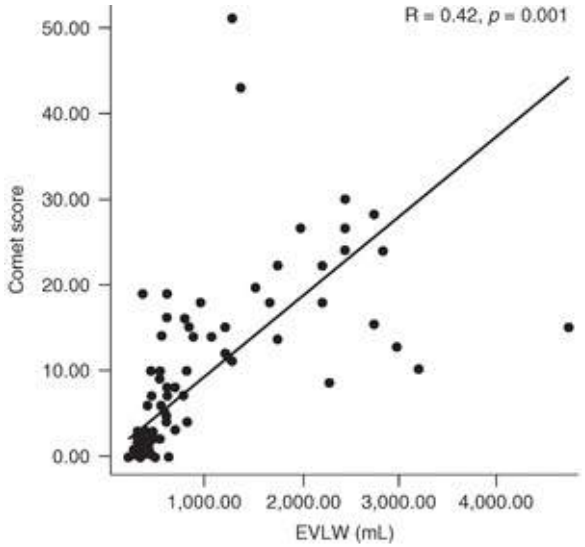

FIGURE 26.5 Correlation of ultrasound determined comet score and extravascular lung water determined by thermodilution. EVLW, extravascular lung water.

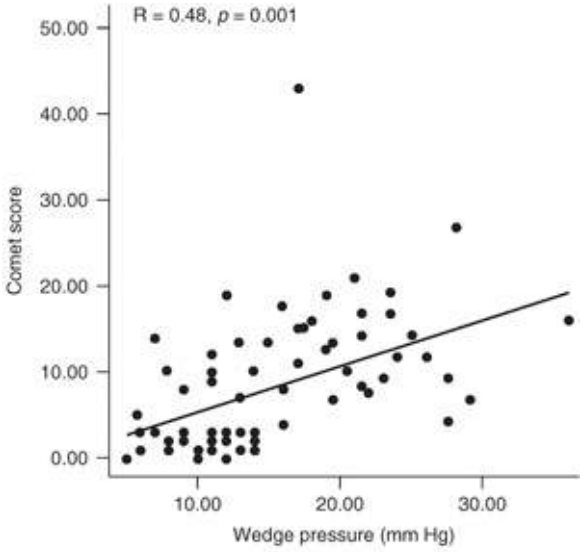

FIGURE 26.6 Positive linear correlation between comet score and wedge pressure determined using the pulmonary artery catheter.

Pulmonary congestion as determined by B-line scores on lung ultrasound is highly prevalent in both symptomatic and asymptomatic patients on HD (11). These scores increase as New York Heart Association (NYHA) functional class worsens. B-line scores have been shown to decrease as fluid is removed during the course of dialysis in linear fashion and can be followed in real time (12); these scores also correlate with weight reduction during HD (13). Quantification of B-lines (a surrogate for lung congestion) has been shown to predict mortality in asymptomatic outpatients on HD (8). Lung ultrasound is easy to learn and is thus an attractive noninvasive test to assess pulmonary congestion in patients with CKD whether or not they are being dialyzed. Automated counting of B-lines is a promising technique described recently (14) that may standardize B-line scoring allowing for wider use in the setting of ESKD.

A hyperinflation pattern on pulmonary function testing (increased total lung capacity and residual volume), diminished inspiratory respiratory muscle strength (**TABLE 26.1**) (15), and a reduced diffusion capacity for carbon monoxide (DLCO or KCO) (**TABLE 26.1** and **FIGURE 26.7**) (16) may be seen among patients with CKD. Other studies (17) have shown a restrictive pattern, reduced DLCO, and diminished inspiratory respiratory muscle strength in patients on HD. These abnormalities seem to remit slowly with transplantation (**TABLE 26.2**) (17).

TABLE 26.1 The Pulmonary Function Test Results for the Study Groups (All Values Expressed as Percentage of Predicted Value)

	CAPD (n = 22)	HD (n = 27)	RT (n = 24)	p
FVC (%)	83.0 ± 19.3	82.6 ± 13.5	84.7 ± 11.5	NS
FEV_1 (%)	88.95 ± 15.2	85.0 ± 16.1	90.1 ± 14.7	NS
FEF_{25-75} (%)	86.9 ± 29.4	80.6 ± 26.4	91.7 ± 29.1	NS
TLC (%)	104.7 ± 18.5	105.5 ± 17.0	84.5 ± 18.2	<0.001
VC (%)	89.0 ± 21.7	84.8 ± 14.7	86.1 ± 11.9	NS
RV (%)	139.6 ± 43.5	148.8 ± 44.5	79.0 ± 38.0	<0.001
DLCO (%)	94.8 ± 20.8	112.4 ± 28.0	96.2 ± 19.7	<0.05
PI_{max} (%)	49.9 ± 19.9	66.5 ± 23.4	54.7 ± 19.5	<0.05
PE_{max} (%)	31.1 ± 12.1	34.7 ± 13.3	31.5 ± 11.9	NS

CAPD, continuous ambulatory peritoneal dialysis; HD, hemodialysis; RT, renal transplantation; FVC, forced vital capacity; FEV_1; forced expiratory volume in 1 second; FEF_{25-75}, forced expiratory flow between 25% and 75% of vital capacity; TLC, total lung capacity; VC, vital capacity; RV, residual volume; DLCO, diffusion capacity of the lung for carbon monoxide; PI_{max}, inspiratory muscle strength; PE_{max}, expiratory muscle strength; NS, not significant.

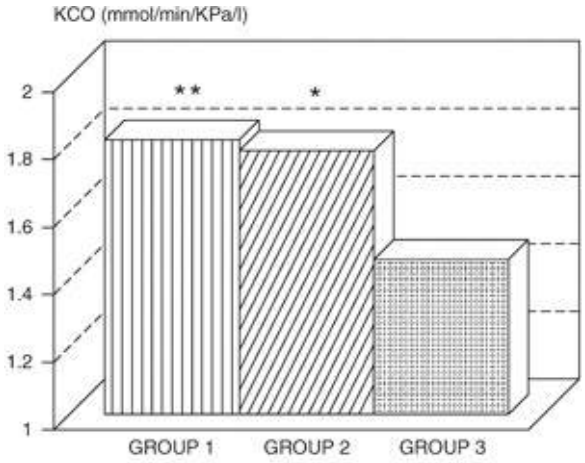

FIGURE 26.7 Absolute values of KCO in the three groups of patients (*p < 0.05 and **p < 0.01 vs group 3). Group 1: CKD EGFR <25 mL not on HD. Group 2: HD <12 months. Group 3: HD × >5 years. CKD, chronic kidney disease; EGFR, estimated glomerular filtration rate; HD, hemodialysis.

TABLE 26.2 The Effect of Kidney Transplantation on Pulmonary Function and Respiratory Muscle Strength in Patients with End-Stage Kidney Disease

Parameter	Predicted (*SD*)	Preop (*SD*)	Postop 2 (*SD*)	Postop 3 (*SD*)
Chest expansion (cm)		3.24 (±1.13)	4.27 (±1.39)	4.31 (±1.23)
OCD (mm)		69.82 (±20.29)	86.17 (±16.91)	86.17 (±18.36)
MIP (cm H_2O)	113.115	101.8 (±37.53)	140.48 (±43.30)	134.2 (±41.99)
MEP (cm H_2O)		98.55 (±30.03)	122.27 (±34.05)	122.55 (±37.37)
SNIP (cm H_2O)		7.8 (±24.6)	84.59 (±19.7)	95.18 (±28.53)
Inspiratory capacity (IC in L)	2.73 (±0.30002)	2.15 (±0.611)	2.25 (±0.664)	2.36 (±0.5151)
Tidal volume (VT in L)	0.453 (±0.796)	1.16 (±0.794)	0.965 (±0.7)	0.815 (±0.401)
Forced vital capacity (FVC in L)	4.064 (±0.558)	3.18 (±0.818)	3.327 (±0.811)	3.365 (±0.745)
Forced expiratory volume (FEV1 in L)	3.463 (±0.494)	2.675 (±0.682)	2.83 (±0.783)	2.93 (±0.678)
Maximum midexpiratory flow rate (MMEFR in L/s)	3.703 (±0.557)	3.081 (±1.079)	3.249 (±1.199)	3.621 (±1.277)
Peak expiratory flow rate (PEFR in L/s)	8.428 (±0.973)	6.552 (±2.218)	6.862 (±2.098)	7.813 (±2.131)
Diffusion capacity of carbon monoxide (DLCO in mL/min/mm Hg)	19.8 (±2.29)	9.71 (±2.58)	11.1 (±3.69)	12.45 (±3.732)
Arterial blood gas analysis				
pH		7.392 (±0.067)	7.383 (±0.040)	7.34 (±0.059)
pO_2 (mm Hg)		94.34 (±26.29)	93.82 (±28.9)	92.95 (±25.01)
pco_2 (mm Hg)		32.61 (±5.11)	33.72 (±5.06)	34.06 (±6.05)
HCO_3 (mmol/L)		19.48 (±4.08)	19.76 (±3.46)	18.51 (±3.88)
SpO_2 (%)		95.61 (±3.52)	95.12 (±7.92)	95.49 (±6.05)
$AaDO_2$ (mm Hg)		15.85 (±25.34)	13.14 (±22.87)	11 (±17.1)

Predicted, predicted values; Preop, mean of preop values recorded; Postop 2, mean of postop day 30 values; Postop 3, mean of postop day 90 values; SD, standard deviation; OCD oxygen cost diagram; MIP, maximal inspiratory pressure; MEP, maximal expiratory pressure; SNIP, sniff nasal inspiratory pressure; pO_2, partial pressure of oxygen; Pco_2, partial pressure of carbon dioxide; HCO_3, bicarbonate; SpO_2, estimate of arterial oxygen saturation; $AaDO_2$, alveolar–arterial oxygen difference.
From Guleria S, Agarwal RK, Guleria R, et al. The effect of renal transplantation on pulmonary function and respiratory muscle strength in patients with end-stage renal disease. *Transplant Proc* 2005;37:664–665.

For the patient in the ICU presenting with dyspnea due to pulmonary congestion, supportive measures include noninvasive ventilation, oxygen, and fluid removal with dialysis as soon as feasible. Nondialytic measures to treat pulmonary edema in the setting of hypertensive urgencies or emergencies include intravenous nicardipine (slow onset of action and long half-life) (18), intravenous labetalol, or intravenous fenoldopam (19). Intravenous nitroglycerine may also be indicated in the right clinical setting (e.g., coronary ischemia). Studies of the effect of loop diuretics on central hemodynamics in this setting are conflicting, some showing favorable improvement (20) and others no change (21). Patient characteristics may account for some of the differences in the outcomes of these studies.

Key Points

- Interdialytic weight gain may be a marker for hypervolemia in apparently stable outpatients with ESKD.
- Assessment of B-lines using ultrasound is a useful and validated technique to assess congestion in relatively stable outpatients with ESKD. Pulmonary congestion assessed by ultrasound correlates with mortality among patients with ESKD.
- Restrictive and obstructive pulmonary function abnormalities remit with dialysis.

CHRONIC KIDNEY DISEASE AND PULMONARY

HYPERTENSION

The Fifth World Symposium on Pulmonary Hypertension (PH) classifies PH-associated with ESKD as Group 5 (“of unknown or multifactorial origin”) (22). Dyspnea in a patient with CKD that remains unexplained ought to trigger a workup for PH. The diagnosis of PH requires right heart catheterization (RHC), performed after HD in the dialysis-dependent patient.

PH, defined as a mean pulmonary artery pressure ≥25 mm Hg determined by RHC (23), is common among patients with both dialysis-dependent and non–dialysis-dependent CKD stage 5. The prevalence of PH in non–dialysis-dependent CKD stage 5 ranges from 9% to 39% (24) and is higher in patients on HD (25). While connective tissue disorders and systemic illnesses may contribute, it is increasingly being recognized that abnormal kidney function *per se* is a trigger for the development of PH. Endothelial dysfunction is universal in patients with CKD and may contribute with other kidney-specific factors thought to be important including the presence of arteriovenous fistulas, exposure to dialysis membranes, secondary hyperparathyroidism, and anemia (24).

Most cases of PH in the setting of CKD, however, are Group 2 (secondary to left heart dysfunction) (26). It is important to ensure that reversible and treatable causes of PH are systematically investigated, the two major ones being venous thromboembolism and sleep apnea. PE is more frequent in patients with ESKD on HD than those with CKD. ESKD and CKD independently confer an increased risk of PE compared with patients with normal kidney function (27).

Sleep apnea (discussed later in this chapter) is intimately linked with volume overload both of which lead to nocturnal hypoxemia that may drive the development or progression of PH (28,29).

Assessment of pulmonary congestion with ultrasound as described previously in this chapter may assist in identifying some of these patients. The treatment of PH in the setting of CKD centers on the treatment of modifiable risk factors, aggressive control of blood pressure, and pulmonary congestion. In the absence of trials of specific vasodilator agents in this setting, a recommendation for vasodilator therapy cannot be made, although PH-specific therapies can be considered on a case-by-case basis for those with defined class I disease.

It is important to note that kidney transplantation results in substantial improvements in left ventricular (LV) dysfunction and PH (30,31). Established PH, while not a contraindication to kidney transplantation, was associated with an increased risk of mortality in kidney transplant recipients especially if it was severe [defined as pulmonary artery systolic pressure (PASP) >50 mm Hg] (32). Severe PH despite aggressive treatment is typically considered a contraindication to kidney transplantation.

Key Points

- The prevalence of PH in non–dialysis-dependent CKD stage 5 is higher than in the general population and is even higher in patients on HD.
- Most cases of PH in the setting of CKD are Group 2 (secondary to left heart dysfunction).
- PE is more frequent in patients with ESKD on HD than those with CKD.
- ESKD and CKD independently confer an increased risk of PE compared with patients with normal kidney function.
- Kidney transplantation results in substantial improvements in LV dysfunction and PH.

- Severe PH despite aggressive treatment is typically considered a contraindication to kidney transplantation.

PULMONARY KIDNEY INTERACTIONS IN SEPSIS

There is increasing appreciation for pulmonary kidney cross talk in the setting of acute kidney injury (AKI). Preexisting AKI increases the susceptibility of the lungs to an endotoxin insult (33). Additionally, in animal studies, absent obvious fluid overload, ischemic AKI has been demonstrated to increase lung water via altered Na-K aquaporin channels and pulmonary endothelial cell death (34). Increased lung endothelial cell apoptosis and increased lung inflammation as demonstrated by increased bronchoalveolar lavage fluid (BALF) protein, myeloperoxidase activity, and neutrophil cell counts has been demonstrated with primary ischemic AKI (35,36). This response is distinct from the response to experimental nephrectomy (37). AKI also induces cardiac cell apoptosis, which in turn may worsen EVLW (38). These cardiopulmonary effects are mediated by host activation of the tumor necrosis factor receptor 1 (TNFR1) gene superfamily and other proapoptotic pathways that activate programmed cell death and vascular leak (38). An upregulation of complement, proinflammatory cytokines, and Toll-like receptors has been shown after AKI has occurred (39).

Sepsis is a multisystem disorder; AKI independently predicts mortality in the setting of sepsis. AKI is defined as an absolute increase of ≥0.3 mg/dL in serum creatinine from baseline within 48 hours from the presumed insult (40). Fluid management is a key intervention in the management of sepsis and affects both kidney outcomes and pulmonary outcomes. The Fluid and Catheter Treatment Trial (FACTT) (41) assessed the outcomes of patients with sepsis assigned to two arms, a fluid conservative management arm whereby fluid balance was net zero at 7 days, or usual therapy where fluid balance was substantially positive at day 7. Patients with positive fluid balance had prolonged lengths of stay in the ICU and prolonged mechanical ventilation.

Fluid administration itself may influence serum creatinine by causing dilution. There is an important relationship between fluid balance and the newer definitions of AKI, and it has been suggested that creatinine be adjusted for fluid balance to better quantify changes in creatinine and account for the dilutional effect of fluid expansion. In one retrospective analysis of the FACTT (42), once serum creatinine had been adjusted for fluid balance, the incidence of mild AKI (AKIN1) increased in patients managed with a liberal fluid strategy. In a second retrospective analysis of the FACTT (43), 306 patients developed AKI in the first 2 days after randomization. In this group of patients, a net positive fluid balance was associated with increased mortality; diuretic therapy to reduce net positive fluid balance was associated with reduced mortality.

Both these retrospective analyses of the FACTT from a kidney perspective suggest that early AKI and AKI adjusted for creatinine are associated with a positive fluid balance. Low tidal volume ventilation is the cornerstone of management of the acute respiratory distress syndrome (ARDS); this intervention attenuates the risk of AKI resulting in a reduction in the need for kidney replacement therapy. Application of positive end expiratory pressure (PEEP) is a key intervention in the management of ARDS as well and may result in a reduction in cardiac output and kidney perfusion, and those patients with severe ARDS requiring PEEP greater than 10 cm H_2O are also at greater risk for alterations in kidney hemodynamics,

especially if not adequately fluid resuscitated (44). High levels of PEEP lead to an increase in the levels of renin and aldosterone, further impairing kidney microcirculation (45).

For reasons delineated above, close attention to fluid management is imperative to improve not just lung-specific outcomes but kidney outcomes as well. Not infrequently, fluid management requirements will need to be balanced to keep the lungs "dry" and the kidney well perfused.

Early in sepsis while diuresis is preserved, the kidney removes cytokines from the systemic circulation (46). Some studies (47) have assessed the efficacy of dialytic removal of inflammatory cytokines and endotoxin in the setting of sepsis and AKI, and a few have shown improvement in survival among ICU patients (48). While this is an exciting development, the larger scale impact of these technologies remains to be proven.

Patients with ESKD frequently have multiple comorbidities and may need care in critical care settings. A recent systematic review (49) of ICU-specific outcomes among patients with ESKD addressed frequency of admission to the ICU (more frequent than patients without ESKD), reasons for admission of these patients to the critical care unit (most frequently for pulmonary edema), outcomes in the setting of sepsis (noting an increased incidence of sepsis and risk of death from sepsis in ESKD compared to those without), and outcomes by type of ICU (higher mortality if admitted for a medical compared to a surgical reason). When compared to AKI requiring renal replacement therapy (RRT), however, patients with ESKD admitted to the ICU have a more favorable short- and long-term prognosis (49).

Key Points

- AKI is defined as an absolute increase of ≥0.3 mg/dL in serum creatinine from baseline within 48 hours from a presumed insult.
- AKI independently predicts mortality in the setting of sepsis.
- Antecedent AKI increases the susceptibility of the lungs to an endotoxin insult.
- Ischemic AKI increases lung water via altered Na-K aquaporin channels and pulmonary endothelial cell death.
- Serum creatinine adjusted for fluid balance in the setting of "resuscitated sepsis" increases the incidence of mild AKI (AKIN1) in patients managed with a liberal fluid strategy.
- Diuretic therapy to reduce net positive fluid balance in resuscitated sepsis is associated with reduced mortality.
- High levels of applied PEEP (≥10 cm H_2O) in mechanically ventilated patients with ARDS can impair kidney microcirculation.
- Patients with ESKD have better outcomes in ICU settings compared to those with AKI requiring RRT.

THE PLEURA AND PERICARDIUM IN CHRONIC KIDNEY DISEASE

Uremic pericarditis and pleuritis are common complications of CKD that remain undiagnosed until late in the course. Both are intensely inflammatory and for the most part reverse with HD.

Cardiac tamponade is not infrequently the first presentation of ESKD. A classic study published in 1968 (50) described the epidemiology of this condition noting that while pleuritic symptoms accompanied

most presentations, pleural effusions were unusual. A friction rub was usual but may be intermittent. All had an abnormal chest x-ray, but only the minority had an abnormal diagnostic electrocardiogram (ECG) with nonspecific ST-T changes being most common. The pericarditis is fibrinous, maybe hemorrhagic, and may be associated with adhesions and loculations.

Pleural effusions related to uremia are uncommon (~3%) but may be large, are usually unilateral and are usually exudative, and may be hemorrhagic (51). All acute and chronic complications associated with intensely inflammatory effusions can occur in this setting (fever, severe pleuritic chest pain, and fibrothorax) (52).

Hydrothorax associated with peritoneal dialysis (PD) ("sweet hydrothorax") (53) has been described and occurs due to translocation of fluid across defects in the diaphragm. Large collections can lead to dyspnea and pose diagnostic dilemmas. These usually remit with surgical closure of diaphragmatic defects, and PD can usually resume (54).

It is important to remember that patients with CKD are immunocompromised, and therefore, pleural effusions or pericardial effusions due to tuberculosis ought to be kept in mind (55).

Key Points

- Cardiac tamponade is not infrequently the first presentation of ESKD.
- A minority of patients with uremic pericarditis have an abnormal diagnostic ECG with nonspecific ST-T changes being most common.
- Pleural effusions related to uremia are uncommon.
- Hydrothorax associated with PD (sweet hydrothorax) is due to anatomical defects in the diaphragm and usually remit with surgical closure of these defects.
- Tuberculosis should be considered a major differential in pleuropericardial disease associated with CKD.

CHRONIC KIDNEY DISEASE AND SLEEP-RELATED DISORDERS

Sleep disorders are categorized broadly as sleep apnea (obstructive or central), insomnia, excessive daytime sleepiness, restless legs syndrome (RLS), and periodic limb movement disorder (PLMD). Obstructive sleep apnea (OSA) is more common in the patient population with ESKD than in the general population (50% to 70% vs. 3% to 4%) (56,57). Patients with ESKD may lack classic risk factors (e.g., obesity) for OSA (58), thus necessitating a high index of suspicion for sleep apnea.

While it is apparent that preexisting upper airway (UAW) abnormalities are important prerequisites for development of OSA, nocturnal changes in neck circumference correlate with the amount of fluid displaced from the legs (59), and thus, volume shifts to the oropharynx are thought to play an important role in the pathogenesis of OSA in patients with ESKD. The coexistence of congestive heart failure in many of these patients adds another dimension to sleep-disordered breathing. It is important to pay special attention to the volume status of these patients given that apparently euvolemic patients on conventional HD (CHD) or PD may have significant congestion (60).

Pulmonary congestion is easily assessed with lung ultrasound as has been discussed elsewhere in this

chapter. Pulmonary congestion also causes restrictive abnormalities in the lung and also allows for development of airway obstruction (61), both of which contribute to hypoxia and ventilatory instability during sleep. Experimental volume expansion seems to worsen OSA (62) rounding out the importance of volume status contributing to OSA. In a recent study (63), ultrafiltration alone ameliorated sleep apnea severity as assessed by the apnea hypopnea index without changes in metabolic parameters. Patients converted from CHD to nocturnal hemodialysis (NHD) seem to have improvement in OSA severity as measured by the apnea–hypopnea index (AHI) (64). The mechanism goes beyond improvement in UAW diameter, perhaps relating to enhanced chemoreceptor sensitivity and ventilation stability. Patients on PD have similar risk profiles as it relates to OSA when compared to patients on HD. Nocturnal PD seems to ameliorate OSA better than continuous ambulatory PD (65).

A few cases of resolution of sleep apnea syndromes with kidney transplantation have been reported (66).

Excessive daytime sleepiness, RLS, and PLMD occur with increased frequency in patients with ESKD (67). While the true pathophysiology of RLS and PLMD are unknown, the major driving factors are thought to be uremia and/or iron deficiency (67). The diagnosis of RLS is based on a characteristic history of an incessant sensation of needing to move the legs with associated paresthesias. PLMD is diagnosed during an overnight polysomnogram and is characterized by a sudden repetitive movement of the legs that have a characteristic appearance and is thought to be rare in the general population (68). The true prevalence of both disorders among patients with ESKD has been difficult to discern given the small sample size in studies assessing prevalence and the small number of studies. Gabapentin (69), intravenous iron (70), and ropinirole (71) are useful in treating sleep-related RLS. RLS may occur while patients are on dialysis, and in this setting, aerobic exercise during dialysis (72) and pramipexole (73) as well as cooling the dialysate (74) have been shown in small trials to improve symptoms. RLS has been reported to improve (75) and in one case report (76) resolve after kidney transplantation. The etiology of excessive daytime sleepiness among patients with ESKD is thought to be due to day/night sleep reversal attributed to uremia (67,77) but also hypothesized to be associated with abnormal melatonin dynamics (78), tyrosine deficiency leading to neurotransmitter deficiency (79), and possibly up titration of inflammatory and sleep-inducing cytokines during dialysis (80,81), making the treatment of excessive daytime sleepiness in this population difficult.

Key Points

- Patients with ESKD may lack classic risk factors (obesity or large neck circumference) for OSA.
- Nocturnal fluid shifts to the oropharynx play an important role in the pathogenesis of OSA in patients with ESKD.
- Ultrafiltration alone ameliorates OSA in patients with OSA.
- Nocturnal HD and PD ameliorate OSA better than diurnal HD and PD perhaps relating to enhanced chemoreceptor sensitivity.
- Excessive daytime sleepiness, RLS, and PLMD occur with high frequency in patients with ESKD.
- Sleep-related disorders improve after kidney transplantation; case reports have informed the possibility of almost complete resolution of all categories of sleep disorders after kidney transplantation.

SUMMARY

The lungs and the kidneys work in tandem to maintain life. HD is a lifesaving and life-preserving modality with an immeasurable impact on kidney disease. Respiratory failure remains a difficult problem and a prominent cause of mortality in patients with severe multiorgan failure where the kidneys have been artificially replaced. Respiratory dialysis (RD) with extracorporeal removal of CO_2 (82–85) promises to revolutionize the management of these patients closing a large gap in the treatment of severely ill patients and hopefully making RD as commonplace as HD.

CHAPTER 27

Malnutrition and Intradialytic Parenteral Nutrition in End-Stage Kidney Disease Patients

Joel D. Kopple, Anuja Shah, and Kamyar Kalantar-Zadeh

PROTEIN-ENERGY WASTING IN MAINTENANCE DIALYSIS PATIENTS

Causes and Treatment of Protein-Energy Wasting

Protein-energy wasting (PEW) refers to the loss or reduced amounts of protein, fat, and/or carbohydrates in the body to an unhealthy degree. The term PEW rather than protein-energy malnutrition (PEM) is used because there are many causes of PEW which are not related to suboptimal nutrient intake. The many causes for PEW in maintenance dialysis (MD) patients are listed in **TABLE 27.1** (1).

TABLE 27.1 Causes for Protein-Energy Wasting in Maintenance Dialysis Patients

1. Anorexia and decreased food intake caused by uremic toxins, inflammation, superimposed illnesses, depression or other psychiatric disorders, inadequate funds to purchase foods
2. Nutrient losses into dialysate
3. Slightly increased fecal nitrogen excretion
4. Uremic milieu
   i. Inflammation; superimposed inflammatory or other illnesses
      - Clinically apparent illnesses (e.g., infection, heart failure, thromboembolic events, surgery, or other trauma)
      - Clinically unapparent illness (e.g., increased serum CRP, TNF-α, IL-1, IL-6 in the absence of superimposed clinical illness); exposure to inflammatory stimulants (e.g., uremic toxins, catheters, tubing, hemodialyzer membranes, impure dialysate, old thrombosed AV grafts)
   ii. Increased levels of counter regulatory hormones (e.g., glucagon, parathyroid hormone)
   iii. Resistance to anabolic hormones (insulin, growth hormone, IGF-I)
   iv. Increased oxidant levels
   v. Decreased levels of antioxidants (vitamin E, vitamin C, selenium, GSH)
   vi. Carbonyl stress (e.g., β_2-microglobulin, pentosidine)
5. Acidemia
6. Physical deconditioning—sarcopenia

CRP, C-reactive protein; TNF-α, tumor necrosis factor alpha; IL, interleukin; AV, arteriovenous; IGF-I, insulin-like growth factor-I; GSH, glutathione.

Reduced nutrient intake and nutrient losses into dialysate are important causes of PEW. Many studies indicate that dietary protein and energy intake are frequently low in MD patients (1,2). Dietary protein and energy intake often average 20% and 30%, respectively, below recommended intakes for maintenance hemodialysis (MHD) and chronic peritoneal dialysis (CPD) patients (1,2). Reports from uncontrolled studies of patients undergoing MHD at more frequent intervals (e.g., daily hemodialysis) and/or for more hours than the usual 3 to 4 hours of hemodialysis three times weekly indicate that their appetite and nutritional status improve (3). These findings suggest that MHD patients treated with standard dialysis therapy tend to remain somewhat anorexic, possibly because their uremia is less adequately treated. Hemodialysis with high-flux membranes removes about 8.0 ± 2.8 (SD) g and 9.3 ± 2.7 g of amino acids from postabsorptive and postprandial patients, respectively (4,5). Approximately 2 to 3.5 g/d of free amino acids are removed during continuous ambulatory peritoneal dialysis (CAPD) (6). Normally, little protein, perhaps 1 or 2 g of protein, is lost during hemodialysis. About 8.8 ± 0.5 standard error of the mean (SEM) g/d of total protein and 5.7 ± 0.4 g/d of albumin are lost into the dialysate with CAPD (7). With mild peritonitis, the quantity of protein removed increases to an average of 15.1 ± 3.6 g/d (7); protein losses can rise markedly with severe peritonitis. Such losses fall rapidly with antibiotic therapy but may remain elevated for many days to weeks, particularly if the peritoneal infection becomes well established before it is eradicated (7).

In normoglycemic individuals, approximately 15 to 25 g of glucose may be removed during hemodialysis when glucose-free dialysate is used (8). When the hemodialysate contains 200 mg/dL of glucose (180 mg/dL of anhydrous glucose), there is net absorption of approximately 10 to 12 g of glucose with each dialysis. Water-soluble vitamins and other bioactive compounds are removed by both hemodialysis and peritoneal dialysis (PD) (4–6,9). These vitamin losses can be easily replaced from the diet, but in patients with poor nutrient intake, such losses may enhance vitamin malnutrition. Patients with

kidney disease often lose substantial quantities of blood secondary to occult gastrointestinal bleeding, frequent blood sampling for laboratory testing, and the sequestration of blood in the hemodialyzer (10). Since blood is rich in protein, these blood losses may contribute to protein wasting. The problem of maintaining adequate protein nutrition is potentially more difficult for CPD patients because the combined losses of proteins, peptides, and amino acids are greater than they are in patients undergoing hemodialysis, particularly since the losses with CPD occur every day, whereas hemodialysis is usually performed only three times weekly. Although the nutritional disorders most commonly associated with chronic kidney disease (CKD) are PEM and iron and vitamin D (e.g., 25-hydroxycholecalciferol and 1,25-dihydroxycholecalciferol) deficiencies (1,2,10–12), other deficiencies, particularly for vitamins B_6 and C, folic acid, and possibly carnitine and zinc, occur frequently if the patient does not receive supplemental nutrients (9,13,14).

It is apparent from **TABLE 27.1** that some of the causes of PEW in MD patients are not nutrition related. Other etiologic factors engendering PEW include inflammatory processes, the altered hormonal milieu of the patient with kidney disease, and both oxidant and carbonyl stress (15). Acidemia and physical deconditioning, which may be profound, may contribute to PEW. Because of the multifactorial nature of the wasting syndrome in patients with CKD, the term PEW (1) has been proposed as a more appropriate appellation for the wasting syndrome that occurs in CKD (16).

The multiple causes of PEW in MD patients require that therapeutic strategies to prevent and treat this condition should be directed into several areas. Some of these are indicated in **TABLE 27.2**.

TABLE 27.2 Therapeutic Strategies to Prevent and Treat Protein-Energy Wasting in Maintenance Dialysis Patients

1. Start maintenance dialysis in a timely manner before clinically apparent anorexia, reduced nutrient intake, and protein-energy wasting occur.
2. Ensure optimal frequency/duration/dose of dialysis.
3. Appropriate dietary energy and protein intake with periodic dietary counseling and monitoring of nutrient intake and protein-energy status, as needed
4. Maintain or increase protein/amino acid and energy intake.
5. Food supplements, intradialytic nutrition, tube feeding, and possibly nutritional peritoneal dialysis, nutritional hemodialysis, and total parenteral nutrition as needed
6. Treat acute and chronic superimposed illnesses aggressively.
7. Prevent or treat acidemia.
   - Optimal arterial blood pH 7.40 to 7.45?
8. Less well-proven methods to maintain healthy protein-energy status
   a. Hormones and other compounds with anabolic effects[a]
      - Pentoxifylline
      - Insulin
      - Growth hormone
      - Insulin-like growth factor-I (IGF-I)
      - Testosterone
      - Carnitine
   b. Anti-inflammatory agents, antioxidants, anticarbonyl compounds. Several clinical trials are in progress.
   c. Exercise training
   d. Ketoacid supplements

[a]Except when the patient is deficient in a hormone, there is currently no strong evidence for the effectiveness of these compounds as anabolic or anticatabolic agents when given chronically to advanced chronic kidney disease patients.

Therapeutic strategies should be directed toward inaugurating MD in a timely manner, before patients with end-stage kidney failure develop frank PEW. PEW tends to occur as patients approach end-stage

kidney failure (17,18) and inauguration of chronic dialysis treatment is associated with an improvement in PEW (19). In this regard, chronic dialysis patients are frequently anorectic (20). Therapeutic strategies for reduced nutritional intake include dietary counseling, food supplementation, intradialytic parenteral nutrition (IDPN), gastric or intestinal tube feeding, nutritional PD, or nutritional hemodialysis. In exceptional cases, total parenteral nutrition, given on a continuing basis, may be necessary (15).

Since MD patients frequently sustain intercurrent catabolic illnesses, it is important to treat such comorbid conditions aggressively and to ensure that there is adequate nutritional support during such treatment. MD patients are often in an inflammatory state and may have oxidant and/or carbonyl stress—even when there are no apparent superimposed complicating illnesses. It is believed that that elevated levels of inflammatory, oxidant, and carbonyl reactive compounds are important causes of morbidity and PEW in MD patients. CKD patients often have low circulating levels of certain anabolic hormones, increased levels of some catabolic hormones, and resistance to other anabolic hormones (15), and a number of studies have examined whether anabolic hormones may improve the protein-energy state of MD patients with PEW. Short-term studies in MHD or CPD patients given repetitive doses of growth hormone, insulin-like growth factor-1, or carnitine have shown anabolic effects of each of these agents (21–23).

Since acidemia can promote protein degradation (24), it is important to prevent and treat acidemia in these patients. In patients undergoing MHD thrice weekly, acidemia is particularly likely to occur immediately prior to a hemodialysis treatment, and it may be necessary to give such individuals alkali supplements during the end of their interdialytic period. MD patients with substantial residual renal function also may develop hyperchloremic acidosis due to excessive urinary bicarbonate losses. The optimal arterial blood pH for such patients has been reexamined in clinically stable patients undergoing CAPD. Metabolic balance studies in these patients indicate that arterial blood pH in the range of 7.43 to 7.45 is often associated with more positive protein balance than when their arterial blood pH is 7.36 to 7.38 (25).

Exercise training can improve both cardiopulmonary exercise capacity and strength in MD patients (26). Whether this treatment may be associated with protein accrual or increased muscle mass is not clear. We have found that exercise training in such patients is associated in skeletal muscle with increases in the gene transcripts for a number of growth factors and a reduction in the gene transcripts for myostatin, an antihypertrophic protein (27). However, these changes were not associated with an increase in skeletal muscle mass possibly because patients did not exercise sufficiently vigorously or that kidney failure is an antianabolic state. The increased gene transcripts may have induced protein remodeling that resulted in the increased exercise capacity that occurs in MD patients who exercise train (26). It should be emphasized that there are no randomized, prospective, controlled clinical trials that have examined whether improving the protein-energy state of wasted MD patients will reduce morbidity or mortality or improve quality of life. However, retrospective analyses of patients receiving intradialytic nutrition suggest that nutritional support in these patients is associated with reduced mortality (28–30), and exercise training, at least in the short term, may improved quality of life scores.

Effects of Protein-Energy Wasting on the Clinical Course of Maintenance Dialysis Patients

Many epidemiologic studies indicate that the PEW status of MHD and CPD patients is strongly associated with increased morbidity and mortality. MD patients who either have PEW or who have worsening protein-energy status have substantially higher mortality rates; the increase in mortality is largely due to cardiovascular events (20,31). MD patients who ingest inadequate quantities of protein and energy are more likely to develop PEW and to have higher mortality (20,32). Serum albumin is one of the strongest predictors of mortality in MHD patients (31,33,34). There is a direct relationship morbidity or mortality rates in MHD patients and poor appetite; spontaneous low dietary protein intake; decreased body-weight-for-height [i.e., body mass index (BMI)]; anthropometric measures of skeletal muscle mass and total body fat; and low serum albumin, urea, creatinine, cholesterol, and potassium (20,31–34). Similar relationships with morbidity and mortality, based on smaller sample sizes, usually (33,35), but not always (36), have been shown for CPD patients. The relative contributions of PEM and inflammation to the high morbidity and mortality of CKD patients are unclear, particularly because the syndrome of PEM shares many clinical manifestations with inflammation. Because inflammatory processes may cause endothelial injury and/or predispose to atherosclerosis and vascular thrombosis, it is easy to perceive why there could be a causal connection between inflammation and morbidity and mortality from vascular disease.

DIETARY THERAPY FOR MAINTENANCE DIALYSIS PATIENTS

General Approach to Dietary Management

The widespread nutritional and metabolic alterations and high incidence of malnutrition in CKD patients indicate that nutritional therapy is a critical aspect of their management. The three main goals for dietary treatment are to maintain good nutritional status; to prevent or ameliorate uremic toxicity and the metabolic disorders of kidney disease; and to reduce the risks of cardiovascular, cerebrovascular, and peripheral vascular disease. Adherence to specialized diets is often a difficult and frustrating endeavor for patients and their families. Patients following low-protein diet usually must make fundamental changes in their behavior patterns and forsake some of their traditional sources of daily pleasure. Often, the patients must procure special foods, prepare special recipes, forego or severely limit their intake of favorite foods, or eat foods that they may not desire. To ensure successful dietary therapy, patients with kidney disease must undergo extensive training concerning the principles of nutritional therapy and the design and preparation of diets, and they need to be repetitively encouraged to adhere to the prescribed diet. They usually require repeated training regarding their nutritional therapy. Without careful monitoring of nutritional intake, retraining, encouragement, and sensitivity to their cultural background, psychosocial condition, and lifestyle, patients will be more likely to adhere poorly to their dietary prescription. They may eat too little rather than too much of some essential nutrients.

Monitoring Compliance

In general, to maintain good dietary adherence and to maintain a healthy clinical, fluid and electrolyte, and nutritional status, the physician must review the patient’s nutritional status and dietary compliance at frequent intervals. Since nutritional status may begin to deteriorate in patients with chronic progressive kidney disease when the glomerular filtration rate (GFR) falls below 35 to 50 mL/min/l.73m^2 (17,18),

careful attention to nutritional status should begin at this time or earlier. This is particularly important because CKD patients appear to be at greatest risk for malnutrition from the time that the GFR falls below 10 mL/min until the patient is established on MD therapy (18,37). Also, although nutritional status often improves after commencing hemodialysis (19), nutritional status of patients at the onset of chronic dialysis treatment is a good predictor of their nutritional status 2 to 3 years later (37,38). Moreover, measures indicating PEW at the onset of MD therapy predict increased morbidity and mortality (33,39). Hence, particular effort should be given to prevent malnutrition as the patient approaches dialysis therapy and during the first few weeks of MD treatment. These efforts should be directed toward maintaining good nutritional intake during this period, rapidly instituting therapy for superimposed illnesses, and maintaining good nutritional support during such illnesses.

Monitoring Nutritional-Inflammatory Status

Since diets prescribed for renal insufficiency are often marginally low in some nutrients (e.g., protein) and high in others (e.g., calcium) and PEW is not infrequent, it is important to periodically evaluate the adequacy of the patient's diet and protein-energy status. The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF K/DOQI) Clinical Practice Guidelines for Nutrition in Chronic Renal Failure (40) recommends that panels of nutritional measures should be used to assess protein-energy nutritional status in MD patients. The recommended panel of measurements of PEW status for MHD and CPD patients is indicated in **TABLE 27.3**. A predialysis serum specimen for these measurements is obtained from an individual immediately before the initiation of a chronic hemodialysis or intermittent peritoneal dialysis (IPD) treatment. A stabilized serum measurement is obtained after the patient has stabilized on a given dose of CAPD or IPD. There are other nutrition-related parameters that often will require monitoring, for example, serum albumin, potassium, phosphorus, calcium, parathyroid hormone, iron, ferritin, transferrin, total low-density lipoprotein (LDL) and high-density lipoprotein (HDL) cholesterol and triglycerides, interdialytic weight gain, and, if relevant, bone densitometry or radiography (15). Measures of inflammation or oxidant or carbonyl stress are often very helpful. Such measures usually include serum quantitative high sensitivity C-reactive protein (CRP) and serum interleukin-6 (15). Dietitians are often best qualified to perform anthropometric measurements of nutritional status because of training and experience.

TABLE 27.3 Recommended Methods for Assessing Protein-Energy Status[a]

Category	Measure	Minimum Frequency of Measurement
I. Measurements that should be performed routinely in all patients	• Body weight predialysis or post peritoneal dialysis drain	• Monthly
	• BMI	• Monthly
	• Predialysis or stabilized serum albumin	• Every 1–2 mo
	• Appetite	• Monthly
	• Percentage of usual postdialysis (MHD) or postdrain (CPD) body weight or percentage of standard (NHANES II) body weight	• Every 6 mo
	• Subjective global assessment (SGA)	• Every 6 mo
	• Dietary history with or without a diary	• Monthly for MHD; every 2–3 mo for CPD
	• nPNA	• Monthly for MHD; every 2–3 mo for CPD
	Simple screening studies	
	• Predialysis or stabilized serum	
	- Creatinine	• Every 1–2 mo
	- Urea nitrogen	• Every 1–2 mo
	- Cholesterol	• Every 1–2 mo
II. Measures that can be useful for a more rigorous assessment of protein-energy status but that may be more costly or labor intensive	• Predialysis or stabilized serum prealbumin (<30 mg/dL)	• All as needed
	• Serum CRP	
	• Serum IL-6	
	• Skinfold thickness	
	• Mid arm muscle area, circumference, or diameter	
	• Dual energy x-ray absorptiometry	
	• Bioelectric impedance assessment	

BMI, body mass index; MHD, maintenance hemodialysis; CPD, chronic peritoneal dialysis; NHANES II, Second National Health and Nutrition Evaluation Survey; nPNA, normalized protein equivalent of total nitrogen appearance [determined from the urea nitrogen appearance (38,40)]; CRP, C-reactive protein; IL, interleukin.

Adapted from K/DOQI Nutrition Workgroup. National Kidney Foundation Kidney Disease Outcomes Quality Initiative. Clinical practice guidelines for nutrition in chronic renal failure. *Am J Kid Dis* 2000;35(Suppl 2):S19–S56.

RECOMMENDED DIETARY INTAKES

The nutritional needs of patients treated with more frequent hemodialysis have not been systematically investigated. Uncontrolled reports indicate that patients treated with more frequent hemodialysis have greater appetites and food intake (3). It is anticipated that such individuals will probably have increased daily needs for certain nutrients than are discussed in this chapter and listed in **TABLE 27.4**. Such patients may also have greater tolerance for some nutrients than is indicated here. The benefits of more frequent hemodialysis have not yet been established in randomized, prospective clinical trials, although less well controlled data are very encouraging (41,42).

TABLE 27.4 Recommended Dietary Protein, Energy, and Fiber Intake for Patients Undergoing Maintenance Hemodialysis or Chronic Peritoneal Dialysis

	Maintenance Hemodialysis	Continuous Ambulatory Peritoneal Dialysis or Automated Peritoneal Dialysis
Protein	1.1–1.2 g/kg/d 50% high biologic value[a]	1.2–1.3 g/kg/d 50% high biologic value protein[a]
Energy (kcal/kg/d)	35 kcal/kg/d for individuals younger than 60 years old and 30–35 kcal/kg/d for patients 60 years old or older. Patients with relative body weight >120% or patients who are afraid of gaining unwanted weight may be prescribed lower energy intakes. Energy intake includes energy obtained from diet and, if applicable, from hemodialysate or peritoneal dialysate.	
Fat (percentage of total energy intake)[b,c]	25–35	25–35
Polyunsaturated fatty acids[b,c]	Up to 10% of total calories	Up to 10% of total calories
Monounsaturated fatty acids[b,c]	Up to 20% of total calories	Up to 20% of total calories
Saturated fatty acids[b,c]	<7% of total calories	<7% of total calories
Cholesterol[c]	250 mg/d or lower	250 mg/d or lower
Carbohydrate[b,c,d]	50%–65% of total calories	50%–65% of total calories
Total fiber intake (g/d)[b,c]	20–30	20–30

[a]When recommended intake is expressed per kilogram body weight, this refers to the adjusted edema-free body weight. Some studies, not widely confirmed, recommend for CPD patients an 0.8 g protein/kg/d diet supplemented with about 0.1–0.12 g/kg of a mixture of four ketoacid analogs of essential amino acids, one hydroxy acid analog of methionine, and the other four essential amino acids, sometimes with one urea cycle amino acid added (56).
[b]Refers to percentage of total energy intake (diet plus dialysate); if triglyceride levels are very high, the percentage of fat in the diet may be increased to about 40% (to decrease the amount of carbohydrate consumed). Otherwise, 35% or less of total calories from fat is preferable. The recommendations regarding fat, carbohydrate, and fiber intake follow the NCEP TLC (National Cholesterol Education Program Therapeutic Lifestyle Changes) diet.
[c]These dietary recommendations are considered less crucial than the others. They are only emphasized if the patient has a specific disorder that may benefit from this modification or is complying well to the other, more important aspects of the dietary treatment (see text).
[d]Should be primarily complex carbohydrates.

Protein

Maintenance Hemodialysis

Protein requirements are increased in MHD patients because of the removal of amino acids and peptides by the dialysis procedure (4,5) and because the hemodialysis treatment appears to stimulate protein catabolism by engendering an inflammatory, catabolic response (43). Nitrogen balance studies suggest that many MHD patients may require at least 1.0 g protein/kg/d to maintain both protein balance and normal total body protein mass (44). However, for a safe protein intake that will maintain protein balance in almost all clinically stable MHD patients, the NKF K/DOQI Clinical Practice Guidelines on Nutrition in CKD recommend 1.2 g protein per kilogram body weight per day (40) and the European Best Practice Guidelines (EBPG) recommend at least 1.1 g protein per kilogram ideal body weight (IBW) per day (45). To ensure adequate intake of essential amino acids, it is recommended that at least half of the dietary protein should be of high biologic value, although experimental evidence to prove this contention is lacking. For most individuals undergoing more frequent MHD, 1.2 g protein/kg/d probably will also provide an adequate protein intake.

Chronic Peritoneal Dialysis

A diet providing 1.2 to 1.3 g protein/kg/d appears to be a safe protein intake for CAPD patients and is consistent with the recommendations of the NKF K/DOQI Clinical Practice Guidelines on Nutrition in CKD (40) and with complete nitrogen balance studies on CAPD patients (46). Daily losses of amino acids and protein into dialysate of patients undergoing automated daily peritoneal dialysis (APD) are

similar to the losses with CAPD (6,7,47). Thus, although there are no complete nitrogen balance studies of dietary protein requirements in APD patients, one would expect that the dietary protein requirements would be similar to those of patients undergoing CAPD. Again, it is recommended that at least 50% of the dietary protein should be of high biologic value (40). It is possible that CAPD and APD patients who are protein depleted or hypercatabolic may become more anabolic when they ingest up to 1.5 g protein/kg/d, although this has not been clinically investigated.

Patients classified as high peritoneal transporters by the peritoneal equilibration test lose more protein and amino acids into peritoneal dialysate than those classified as low transporters (e.g., typical 24-hour losses in high vs. low transporters: albumin, 4.9 ± 2 (SD) vs. 3.2 ± 1 g/d, p <0.03, total free amino acids, 15.4 ± 4 vs. 10 ± 4 mmol/d, p = 0.002) (48,49). This trend is shown in all studies of high versus low transporters. The high transporters also have, on average, lower serum albumin levels (48,49). However, the difference in protein and amino acid losses with high versus low transporters is not great, and dietary protein intakes of 1.2 to 1.3 g/kg/d should provide sufficient amounts of protein and amino acids to compensate for these increased peritoneal losses if the ability to synthesize these serum proteins is normal.

Some nephrologists report MHD or CPD patients who habitually ingest somewhat lesser amounts of protein or calories than are recommended and yet do not show evidence of PEW and lead physically active, rehabilitated lives. These observations raise questions as to whether the foregoing recommended dietary protein and energy intakes for chronic dialysis patients may be excessive. Several comments may be pertinent in this regard. First, some MD patients who appear to be doing well will, on close inspection, turn out to have evidence for malnutrition. Epidemiologic studies have associated protein depletion, even in mild forms, with increased mortality (31–35,50). Second, subtle forms of malnutrition are particularly difficult to detect, and the recommended intakes may provide some protection against mild forms of PEM. Third, the concept of dietary allowances presupposes that in order to ensure a sufficient nutrient intake for virtually all individuals (i.e., about 97%) in a given population, the recommended allowance must be greater than the actual requirement for a large proportion of that population (51). This reasoning is similar to that used by the World Health Organization and the Food and Nutrition Board of the National Academy of Sciences to determine the recommended dietary protein intakes for normal adults (52). Thus, it is expected that some individuals will ingest less protein or calories than is recommended without developing protein malnutrition. At present, there is no method that will identify in advance, under the conditions of clinical practice, which patients can safely ingest lower protein or energy intakes. Hence, to be safe, unless the patient can be shown to maintain a healthy nutritional status on a lower nutrient intake, he or she should be prescribed the dietary allowances described here.

Recently, a number of studies have reported that patients with far advanced or end-stage CKD may be treated with low-protein or very low-protein diets (e.g., 0.60 g protein/kg/d or 0.3 to 0.4 g protein/kg/d) supplemented with ketoacid or hydroxyacid analogs of usually five essential amino acids plus the other four essential amino acids. These studies indicate that for many patients, this treatment may safely delay the need for chronic dialysis therapy (53), may safely allow time for a PD access or a hemodialysis vascular access to mature without, for example, resorting to tunnel catheters (54), or may allow for a lower dose of dialysis treatment, at least as long as some residual kidney function is preserved (55).

Some data suggest that these low-protein or supplemented very low-protein diets may delay the loss of residual kidney function (55,56). These diets appear to attain these results without inducing protein or energy wasting, serious metabolic abnormalities, or uremic toxicity. Some data suggest that the ketoacid and essential amino acid preparations may induce an anti-inflammatory effect (57). For the low-protein diets or a combination of low-protein diets and dialysis treatments to be safe and effective for patients with advanced CKD or end-stage kidney disease (ESKD), it would seem that the patient must be very motivated to adhere to the protein-restricted diets.

Energy

In most studies, energy expenditure in patients undergoing MHD or CAPD, measured by indirect calorimetry, appears to be normal during resting and sitting, following ingestion of a standard meal, and with defined exercise (58). What is most impressive about these foregoing studies is that there is no report of decreased energy expenditure in CKD, MHD, or CPD patients. Dietary energy intake in MHD and CPD patients is commonly reported to be lower than their recommended intakes (1,2). Many CPD patients tend to gain body fat and weight, probably due to the glucose uptake from peritoneal dialysate. The surges in plasma insulin that accompany the glucose absorbed from peritoneal dialysate may contribute to the increase in body fat that is not uncommonly observed in CPD patients.

The NKF K/DOQI Clinical Practice Guidelines for Nutrition in CKD recommend an energy intake of 35 kcal/kg/d for MHD and CPD patients who are younger than 60 years of age and 30 to 35 kcal/kg/d for those who are 60 years of age or older (**TABLE 27.4**) (40). This intake includes energy derived from the diet as well as from any fuels taken up from dialysate. Because individuals older than 60 years old tend to be more sedentary and their muscles often constitute a smaller proportion of their body mass, their recommended energy intake is somewhat lower. These recommendations are similar to the EBPG of 30 to 40 kcal/kg IBW/d adjusted for age, gender, and estimated physical activity (45). These intakes are also rather similar to those for normal individuals engaged in light to moderate activity as put forth in the RDA by the Food and Nutrition Board, National Academy of Sciences (51). Patients who are obese with an edema-free body weight greater than 120% of desirable body weight may be treated with lower calorie intakes. Some patients, particularly young or middle-aged women, may become obese on this energy intake or may refuse to ingest the recommended calories out of fear of obesity. These individuals may require a lower energy prescription. There are many readily prepared or commercially available high-calorie foodstuffs that are low in protein, sodium, and potassium which can be recommended by the renal dietitian.

TREATMENT OF RISK FACTORS FOR VASCULAR DISEASE

Lipids

There are a number of reviews of the causes for the abnormal serum lipids and lipoproteins in MHD and CPD patients, and space constraints do not allow a full discussion of these abnormalities or their causes (59). In brief, MHD and CPD patients often have increased serum triglyceride levels, intermediate density lipoprotein (IDL), and very low-density lipoprotein (VLDL), and serum lipoprotein(a) [Lp(a)]; serum HDL cholesterol is often low. CPD patients often have higher serum total cholesterol, triglycerides, LDL cholesterol, and apolipoprotein B levels than do MHD patients. Qualitative changes in the

apolipoprotein concentrations also occur; among these is an increase in small dense low-density lipoprotein (sd LDL) (60). Since alterations in lipid metabolism and serum lipids may contribute to the high incidence of atherosclerosis and cardiovascular cerebrovascular and peripheral vascular disease in CKD patients, attention has been directed toward reducing serum triglycerides and LDL cholesterol and increasing HDL cholesterol.

Treatment of altered lipid levels and the risk of cardiac and vascular disease normally involves three components: nutrient intake, medicines, and exercise. In MHD patients, clinical trials do not indicate that cholesterol-lowering agents reduce adverse cardiovascular events (59), and there are no clinical trials examining whether any dietary lipid therapy reduces cardiovascular risk. On the other hand, *epidemiologic studies* indicate that serum levels that are low in phosphorus and a lower serum calcium–phosphorus product are associated with less cardiovascular disease (61,62).

Until more evidence is available, based on data from the general population, we encourage MD patients to follow a dietary plan that is based upon the National Cholesterol Education Program (NCEP) Therapeutic Lifestyle Changes (TLC) diet for all MHD and CPD patients, especially if their serum LDL levels are over 100 mg/dL (63). Since these patients are at high risk for cardiovascular, cerebrovascular, and peripheral vascular disease, we prefer to set a target LDL cholesterol of 70 mg/dL. The TLC diet provides the following (63): no more than 25% to 35% of total calories from fat, polyunsaturated fatty acids providing up to 10% of total calories, monounsaturated fatty acids providing up to 20% of total calories, saturated fatty acids providing less than 7% of total calories, and a cholesterol content of 200 mg/d or lower. Carbohydrate intake should be 50% to 60% of total calories and derived predominantly from foods rich in complex carbohydrates. Fiber intake should be 20 to 30 g/d (63). Since the TLC diet may be less palatable to many patients, their energy intake should be monitored to ensure that it remains adequate (see the subsequent text). Patients are encouraged to control calorie intake to avoid becoming substantially overweight or frankly obese. (i.e., avoid a BMI greater than about 28 kg/m^2). It is recognized that most individuals will not be able to adhere exactly to the TLC diet. However, there is reason to believe that even some modifications of dietary intake in the direction of lowering serum cholesterol may reduce the risk of adverse vascular events (64). Moreover, if MD patients are not counseled on the characteristics and rationale underlying this diet, they may eat even a less healthy diet as they grow older.

Omega-3 fatty acids (e.g., eicosapentaenoic acid and docosahexaenoic acid, which are found in fish oil) lower serum triglycerides and have more variable effects on serum LDL cholesterol and HDL cholesterol (65). Fish oil also decreases platelet aggregation and appears to exert anti-inflammatory effects, and omega-3 fatty acids may enhance immune function. 3-Hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins) lower LDL-cholesterol; may slightly increase serum HDL-cholesterol; appear to be anti-inflammatory, antithrombotic, and fibrinolytic; improve impaired endothelial function; and, in animals, protect against progressive renal injury (66). It is emphasized that evidence that manipulation of lipid intake may reduce cardiovascular risk in MHD and CPD patients is currently lacking.

Other Potential Nonnutritional Techniques for Reducing Cardiovascular Risk

Evidence for the protective nature of other methods for reducing cardiovascular risk is largely obtained from clinical trials in the general population. Antiplatelet therapy, such as aspirin, has been shown to reduce the risk of myocardial infarction in adult high-risk CKD patients (67,68). In CKD patients,

impaired hemostasis caused by aspirin may increase the risk of bleeding. However, 100 mg aspirin per day taken by MD patients increased the risk of minor bleeding (e.g., epistaxis, ecchymoses, or bruising) by threefold ($p = 0.001$) but not the risk of major bleeding episodes (e.g., leading to hospitalization or fatality) (69).

Multifactorial intervention may reduce the risk of adverse cardiovascular events in patients with type 2 diabetes mellitus without advanced kidney failure (70). The intervention consisted of dietary treatment (fat intake less than 30% of daily energy intake, saturated fatty acids less than 10% of daily intake), 30 minutes of light to moderate exercise three to five times per week, smoking cessation classes for smokers, daily intake of angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) irrespective of blood pressure, daily vitamin-mineral supplements providing vitamin C 250 mg, D-α-tocopherol 100 mg, folic acid 400 μg, chromium picolinate 100 μg, aspirin (unless there were contraindicators), and aggressive control of blood glucose, blood pressure, and hypercholesterolemia and hypertriglyceridemia. The patients receiving this intensive therapy had a significantly lower risk of adverse cardiovascular events, kidney disease (albuminuria greater than 300 mg/24 h in two of three consecutive urine specimens), retinopathy, and autonomic neuropathy. We treat hypertriglyceridemia by dietary modification or medicines only when fasting serum triglycerides are very high (i.e., 500 mg/dL or more), because in the general population, these triglyceride levels increase the risk of adverse cardiovascular events and pancreatitis. In this situation, dietary fat intake may be increased but not above 40% of total calories. A high proportion of dietary carbohydrates should be complex. These modifications often lower the palatability of the diet; therefore, the patient's total energy intake must be monitored closely to ensure that it does not fall to levels that are inadequate to maintain desirable body and protein mass. With high serum triglyceride levels that are unresponsive to dietary therapy, a fibrate (e.g., fenofibrate) may be tried cautiously while monitoring the patient for myopathy.

Oxidant and Carbonyl Stress

As indicated earlier, end-stage kidney disease is associated with increased levels of compounds that promote oxidant and carbonyl stress and chronic inflammation, all of which may promote atherosclerotic and proliferative vascular disease (71,72). Although there are few interventional trials evaluating the effects of reduction of these risk factors on morbidity or mortality of MD patients, the following treatments may be considered for MHD patients, particularly given their high risk of cardiovascular disease: (a) larger flux dialyzers that remove greater amounts of advanced glycation end products and other reactive carbonyl compounds; (b) antioxidants or antioxidant precursors, such as vitamins E or C (see the section "Vitamins" in the subsequent text) or selenium; supplemental selenium must be taken with caution because selenium is primarily excreted in the urine and may accumulate in kidney disease (73); (c) one glass per day of an alcoholic drink, perhaps particularly red wine; (d) statins, notwithstanding the lack of evidence for their effectiveness in MHD patients; and (e) regular exercise.

Carnitine

Carnitine, which is essential for life (74), is both ingested and synthesized *in vivo*. Carnitine facilitates the transfer of long-chain (greater than 10 carbon) fatty acids into muscle mitochondria. Since fatty acids are the major fuel source for skeletal and myocardial muscle at rest and during mild to moderate exercise, carnitine is considered necessary for normal skeletal and cardiac muscle function. MD patients and

particularly MHD patients display low serum-free carnitine and, in some but not all studies, low skeletal muscle-free and total carnitine levels (74). Also, in MHD patients, serum and sometimes muscle acylcarnitines (fatty acid-carnitine compounds) and serum total carnitines are increased (75). The low serum and skeletal muscle-free carnitine levels led some investigators to postulate that many MD patients are carnitine deficient. Clinical trials of oral or intravenous carnitine administration to MD patients have led to conflicting results. Most students of this problem believe that evidence for beneficial effects of carnitine supplements to MD patients is unconvincing.

Carbohydrates

Patients should be encouraged to eat complex rather than purified carbohydrates to reduce triglyceride synthesis and to improve glucose tolerance if it is abnormal.

Minerals and Vitamins

Sodium

Hypertension in MD patients generally is more easily controlled when they are sodium restricted, and hypertension may be accentuated by an increased sodium intake, probably because of expanded extracellular fluid volume (76) and possibly due to altered intracellular electrolyte composition within arteriolar smooth muscle cells that increase contractility. Cross-sectional studies indicate that the blood pressure that is associated with lowest mortality are increased in MHD patients. The range of prehemodialysis systolic and diastolic blood pressures associated with the lowest mortality in MHD patients is approximately 160 to 189 mm Hg and 70 to 99 mm Hg, respectively (77). However, longitudinal studies of MHD patients indicates blood pressures closer to healthy levels for the general population are associated with improved survival.

It is recommended that blood pressures for CPD patients and for MHD patients, obtained prehemodialysis, should be no higher than 140/90 mm Hg (78). If sodium and water balance are tightly controlled in MHD patients, most such individuals will require little or no antihypertensive medications to maintain a desirable blood pressure. However, this level of sodium control is difficult to attain with hemodialysis performed only thrice weekly for ≤4 hours per hemodialysis treatment. Usually, when sodium balance is well controlled, the thirst mechanism will adequately regulate water balance. In patients with diabetes mellitus, hyperglycemia may also increase thirst and enhance positive water balance. Some MD patients are at risk for overhydration from excessive water intake independent of sodium intake, and their water intake should be controlled independently of sodium. In patients undergoing MD who are not anuric and who gain excessive sodium or water despite attempts at dietary restriction, a potent loop diuretic, such as furosemide or bumetanide, may be tried to increase urinary sodium and water excretion.

Patients undergoing MHD or CPD frequently are oliguric or anuric. For MHD patients, sodium and total fluid intake generally should be restricted to 1,000 to 2,000 mg/d and 1,000 to 1,500 mL/d, respectively. Because sodium and water can be removed easily with CAPD or other forms of daily PD, a more liberal salt and water intake is usually allowed. Indeed, by maintaining a larger dietary sodium and water intake, the quantity of fluid removed from the CPD patient and hence the daily dialysate outflow volume can be increased. This may be advantageous, since with CPD, the daily clearance of small- and middle-sized molecules is directly related to the volume of dialysate outflow. Therefore, for some CPD

patients, a higher sodium and water intake (e.g., 6 to 8 g/d of sodium and 3 L/d of water) may enable the patient to use more hypertonic or hyperoncotic dialysate to increase the dialysate outflow volume, thereby increasing dialysate clearances and energy uptake from dialysate, if hypertonic glucose is used. This treatment may be undesirable for obese or severely hypertriglyceridemic patients because the greater use of hypertonic glucose exchanges will increase their glucose load. Also, there is the potential disadvantage that some patients may become habituated to high salt and water intakes; if they change to hemodialysis therapy, they may have difficulty curtailing their sodium and water intake.

Potassium

MD patients exhibit increased fecal potassium (46), which slightly increases the tolerance to dietary potassium. Loss of renal function, acidemia, catabolic stress, hypoinsulinism or insulin resistance, and catecholamine antagonists may each be associated with increased risk of hyperkalemia in MD patients (79). Hyperkalemia can usually be prevented in MD patients if they ingest no more than 70 mEq of potassium per day. Refractory hyperkalemia may require treatment with lower dialysate potassium, oral intake of potassium binders, or more frequent hemodialysis.

Magnesium

The optimal dietary magnesium allowance for MD patients has not been well defined. Experience suggests that when the magnesium content is about 1.0 mEq/L in hemodialysate or 0.50 to 0.75 mEq/L in peritoneal dialysate, a dietary magnesium intake of 200 to 300 mg/d will maintain the serum magnesium at normal or only slightly elevated levels.

Phosphorus and Phosphate Binders

The rationale for controlling dietary phosphorus and methods to prevent and treat hyperphosphatemia, a high serum calcium–phosphorus product, calcium phosphate deposition in soft tissue, hyperparathyroidism, and altered bone mineral metabolism are discussed in Chapter 24. This section considers the prescription of dietary phosphorus intake and phosphate binders. In MD patients, a large dietary phosphorus intake can lead to a high plasma calcium–phosphorus product with increased risk of calcium and phosphate deposition in soft tissues including arteries. Moreover, hyperphosphatemia, by lowering serum calcium, provides a strong stimulus to the development of hyperparathyroidism and increased serum FGF-23 levels. Hyperphosphatemia, hyperparathyroidism, and increased FGF-23 are independently associated with increased mortality in MHD patients (33,80). The NKF KDOQI Clinical Practice Guidelines recommend for MHD and CPD patients that serum phosphorus be maintained between 3.5 and 5.5 mg/dL (11). This often requires a low phosphorus intake not to exceed 1,000 to 1,200 mg/d, (i.e., about 12 to 15 mg phosphorus/kg/d), particularly when MD patients have moderate or severe hyperparathyroidism (see the subsequent text). This higher upper limit was chosen because with their greater protein intakes, dialysis patients cannot readily ingest less phosphorus without making the diet too restrictive and unattractive. Without phosphate binders, there is a net intestinal phosphate absorption (diet minus fecal phosphorus) of roughly 60% of the phosphorus intake (46). Therefore, even with this level of dietary phosphorus restriction, MHD and CPD patients almost always require phosphate binders to prevent hyperphosphatemia, unless MHD patients undergo hemodialysis more than thrice weekly. Serum phosphorus levels should be monitored monthly after starting MD, and dietary phosphorus restriction

should be employed with use of phosphate binders as necessary to ensure that serum phosphorus remains within the normal range.

The phosphate binders, aluminum carbonate and aluminum hydroxide, are uncommonly used now because of aluminum toxicity (81). Phosphate binders in current use include calcium carbonate, calcium acetate, sevelamer hydrochloride (82), sevelamer carbonate, lanthanum carbonate (83), and several iron preparations (84,85). These phosphate binders are discussed in greater detail in Chapter 24. Phosphate binders vary somewhat as to the effectiveness at binding phosphate in the intestinal tract and not uncommonly cause such mild gastrointestinal distress as anorexia, nausea, diarrhea, or constipation which may reduce compliance (86). Often, with more time taking the same binder, these symptoms will abate. Calcium binder doses should not provide more than about 600 to 1,500 mg of elemental calcium per day [total calcium intake (from diet plus binders) should not exceed 1,000 to 2,000 mg/d] to prevent excessive accumulation of calcium in soft tissues and especially arteries (11,13). Treatment with 1,25-dihydroxycholecalciferol (calcitriol) or its analogs may decrease tolerance to calcium binders by enhancing intestinal calcium absorption. Calcium binders should be taken in divided doses with meals and should not be prescribed if the serum phosphorus level is very high in order to avoid precipitation of calcium and phosphate in soft tissues. Therefore, hyperphosphatemic patients may be treated with other binders of phosphate until serum phosphorus falls to normal or near normal. At that time, the regimen may be changed to a calcium binder. Calcium comprises 40% of calcium carbonate and 25% of calcium acetate.

Noncalcium binders have the advantage that they should pose no increased risk of calcium deposition in soft tissues including arteries. Sevelamer HCl is often given in doses of two to six 800 mg capsules three or four times per day with meals. Sevelamer HCl also has the benefit of lowering serum LDL-cholesterol and increasing serum HDL-cholesterol (87). Some individuals taking this drug can become acidemic because of the large hydrochloride content of this preparation. Sevelamer carbonate, which should not induce acidemia, can be prescribed instead (88). Lanthanum carbonate appears to be one of the more effective phosphate binders and is generally well tolerated. Small quantities of lanthanum accumulate in tissues of MD patients with daily doses (89); at present, there is no evidence that this is harmful to patients. Lanthanum carbonate is often given in doses of 0.5 to 1.5 g three times daily with meals. Ferric citrate and sucroferric oxyhydroxide are currently available iron-based phosphate binders (85,90). These compounds may also provide an iron supplement and may decrease the amount of intravenous iron and the dosage of erythropoiesis-stimulating agents that MD patients may require (84,91). Bixalomer, a phosphate-binding polymer, may also be tried (92). If MD patients are intolerant to recommended doses of any of these binders or if they remain hyperphosphatemic despite maximal or maximally tolerated doses of a binder (serum phosphorus greater than greater than 5.5 mg/dL), two or more phosphate binders may be given simultaneously. Phosphate binders, in general, bind only up to 300 to 500 mg phosphorus per day, even when given in maximum doses. Since people absorb roughly 60% of ingested phosphorus, the use of phosphate binders does not substitute for the need to restrict dietary phosphorus unless patients are receiving quotidian dialysis (93).

Some studies indicate that compounds that impair phosphate transport in the intestinal tract may also decrease serum phosphorus and the body phosphate burden. This has been shown for niacin and tenapanor (94,95).

Calcium, Vitamin D, and Parathyroid Hormone

The NKF DOQI guidelines recommend the serum calcium–phosphorus product should be maintained below 55 mg^2/dL^2 (11). This product should be attained primarily by controlling serum levels of phosphorus within the target range as indicated earlier. Frequent monitoring of serum calcium is important because hypercalcemia may develop, particularly if serum phosphorus should fall to low-normal or low levels. This is especially likely to occur if the patient also has hyperparathyroidism, a common complication of CKF, or is receiving larger doses of calcitriol. The NKF DOQI guidelines recommend that serum calcium levels, corrected for any alteration in serum albumin (see the subsequent text), should be maintained within the normal range for the laboratory used but preferably toward the lower end of normal (8.4 to 9.5 mg/dL) (11). As indicated earlier, it is the authors' policy that total calcium intake from the diet and calcium-based phosphate binders combined should not exceed 1,000 to 2,000 mg/d. If the serum total corrected calcium is below the lower limit for the laboratory used (less than 8.4 mg/dL), the patient may receive a higher dose of calcitriol or other vitamin D analog, a lower intake of the calcium receptor agonist, cinacalcet, or a greater intake of calcium to increase serum calcium levels. Serum calcium corrected for serum albumin may be calculated as follows (**EQUATION 27.1**) (11):

$$\text{Corrected serum calcium (mg/dL)} = \text{Total serum calcium (mg/dL)} + 0.0704 \times [34 - \text{serum albumin (g/L)}] \quad (27.1)$$

A simpler equation, which is about as accurate, is as follows (**EQUATION 27.2**):

$$\text{Corrected serum calcium (mg/dL)} = \text{Total serum calcium (mg/dL)} + 0.8 \times [4 - \text{serum albumin (g/dL)}] \quad (27.2)$$

MD patients have an increased dietary requirement for calcium because they have vitamin D deficiency and resistance to the actions of vitamin D which may impair the intestinal absorption of calcium. The risk of calcium deficiency in these patients is enhanced because the diets prescribed for MHD patients are almost always low in calcium, because foods high in calcium are usually high in phosphorus (e.g., dairy products) and are therefore restricted for uremic patients.

On the other hand, MHD and CPD patients often have extensive calcification of their arteries including the coronary arteries (96). In the general population, the extent of coronary artery calcification is directly related to the risk of myocardial infarction (97). Therefore, for MHD or CPD patients, it may be preferable to maintain total calcium intake closer to 1,000 mg/d or even lower if serum calcium is greater than 9.4 mg/dL. It is emphasized that when patients take l,25-dihdroxycholecalciferol (calcitriol) or other vitamin D analogs that increase intestinal calcium absorption, lower calcium intake may be indicated. Serum calcium should be monitored frequently because hypercalcemia may develop with these treatments.

To reduce the total daily calcium load to the dialysis patient who is taking calcium binders of phosphate, the calcium content of dialysate is often reduced. This is a somewhat more effective method for controlling calcium balance with daily CPD than with thrice-weekly MHD. The usual dialysate calcium concentration for MHD or CPD patients is 2.5 mEq/L. Secondary hyperparathyroidism can be treated in patients with CKD with vitamin D analogs. In general, serum intact parathyroid hormone in MD patients should be maintained within a target range of 150 to 300 pg/mL. If the serum level of 25-hydroxyvitamin D is less than 30 ng/mL, supplementation with vitamin D_2 (ergocalciferol) or vitamin D_3

(cholecalciferol) should be initiated. For MD patients, therapy with an active vitamin D sterol (1,25-dihdroxycholecalciferol, alphacalcidol, paricalcitol, or doxercalciferol) should be provided if the plasma levels of intact parathyroid hormone are greater than 300 pg/mL (11). Retrospective studies indicate that MHD patients treated with calcitriol or paricalcitol had lower mortality than patients not receiving these medicines (p <0.001) (98,99). Vitamin D has many other actions in addition to its effects on calcium absorption, parathyroid hormone secretion, and bone metabolism. These effects include regulation of immune function, antiproliferative, differentiating effects (100), promotion of muscle strength, and possibly hypertrophy (101). Thus, it is not surprising if vitamin D and its congeners may affect survival rates. Moreover, another retrospective study indicates that MHD patients treated with the vitamin D analog paricalcitol had a lower mortality rate than MHD patients who received calcitriol (98). Cinacalcet increases the sensitivity of the calcium receptor in the parathyroid gland to calcium so that parathyroid hormone secretion can be suppressed or inhibited at lower serum calcium levels (102). This medicine is effective at suppressing hyperparathyroidism in MD patients.

The syndrome of aplastic or hypoplastic bone disease in MD patients is characterized by relatively low serum parathyroid hormone concentrations, decreased bone osteoblasts, and marked reduction in bone turnover. The syndrome can be caused by aluminum toxicity and probably excess iron (11,103). Large doses of calcium binders of phosphate or vitamin D with consequent suppression of parathyroid hormone also appear to cause this disorder (11,103).

Trace Elements

Many trace elements are excreted primarily in urine and may accumulate with kidney failure. Excessive uptake from dialysate or losses of trace elements into dialysate may occur during dialysis therapy depending on the relative concentrations in plasma and dialysate of the trace element and the degree of its binding to protein or red cells (104). Hemodialysance of copper, strontium, zinc, and lead, for example, which are largely bound to plasma proteins or red cells, should be minimal (105). Hemodialysis or hemodiafiltration may remove some trace elements if the dialysate concentrations are sufficiently low (e.g., bromide, iodine, lithium, rubidium, cesium, and zinc) (105,106). Zinc may be taken up and copper lost from peritoneal dialysate. Because many trace elements are avidly bound to serum proteins, they may be taken up by blood against a concentration gradient when present in even small quantities in dialysate (105,107). These observations provide part of the justification for intensive purification of dialysate. Inhalation may result in increased intake of certain trace elements. This may occur in people exposed to certain industrial processes, fertilizers, insecticides, herbicides, or burning of fossil fuels.

PEW, which can be associated with lowered serum concentrations of proteins that bind trace elements, may decrease the serum levels of a number of these elements including zinc, manganese, and nickel (108). Occupational exposure or pica may increase the burden of some trace elements. Therapeutic doses of trace elements may be administered through dialysis, as has been done for zinc (109). Reduced dietary intake of many nutrients by the uremic patient might lower body pools of trace elements, but there is little scientific evidence that bears on this hypothesis (108).

Assessment of trace element burden in kidney disease patients is difficult because the binding protein concentrations may be decreased, thereby lowering serum trace element levels, and the binding characteristics of these proteins may be altered in kidney disease as well. Also, red cell concentrations of trace elements may not reflect levels in other tissues. Trace element supplementation should be undertaken

with caution because impaired urinary excretion and poor dialysance of most trace elements, due to protein binding, increase the risk of overdosage.

Dietary requirements for trace elements have not been well defined in MD patients. Iron deficiency is common, particularly in MHD patients because intestinal iron absorption is sometimes impaired, there are often substantial blood losses; iron may bind to the dialyzer membrane, and the erythropoietin-induced rise in hemoglobin concentrations may deplete the body's iron supply (110). Not only do iron requirements increase during the time when erythropoietin therapy is initiated and hemoglobin concentrations rise, but higher serum iron levels and body iron burden are associated with a greater response to erythropoietin (111). Some researchers recommend that, in general, MHD or CPD patients should maintain serum transferrin saturation (TSAT) at 30% to 50% and serum ferritin at about 400 to 800 ng/mL (111). Although some MD patients may maintain these iron values with oral iron supplements, many such individuals will not be able to do so unless they receive parenteral iron therapy (12,111). Oral ferrous sulfate, 300 mg three times per day one-half hour after meals, may be tried. Some patients develop anorexia, nausea, constipation, or abdominal pain with ferrous sulfate; these individuals sometimes will tolerate other iron compounds better, such as ferrous fumarate, gluconate, or lactate. Patients may satisfy some of their iron requirement by taking such iron salts as ferric citrate and sucroferric oxyhydroxide that are also phosphate binders (see above). Patients who are intolerant to oral iron supplements and the preponderance of MHD or CPD patients who will not maintain TSAT at 30% to 50% and serum ferritin levels of 400 to 800 ng/mL with oral iron may be treated with intravenous iron (12,111).

As indicated earlier, MHD patients may have an increased body burden of aluminum, often from ingesting aluminum salts used as phosphate binders or from contaminated dialysate. Increased serum aluminum has been implicated as a cause of a progressive dementia syndrome, osteomalacia, weakness of the muscles of the proximal limbs, impaired immune function, and anemia (81,103). Current methods of water treatment have removed virtually all aluminum from dialysate. Increased body burden and toxicity of iron or aluminum in MHD or CPD patients may be reduced by reduction of intake or by infusion of deferoxamine, which is dialyzable (112). Care must be taken because deferoxamine may promote infection, particularly mucormycosis (113). Injections of erythropoietin with repeated phlebotomy are another method for removing excess body iron (114).

Although the zinc content of most tissues is normal in kidney disease patients, usually serum and hair zinc are reported to be low and red cell zinc increased (13,108,115). Fecal zinc is increased (115), and the dietary requirement for zinc may be increased. Further studies are needed to confirm this possibility. Some reports indicate that dysgeusia, poor food intake, and impaired sexual function, which are common problems of MD patients, may be improved by giving patients zinc supplements (13,115). Other studies, however, have not confirmed these findings (116). The finding that serum selenium is low in dialysis patients has raised the question of whether selenium supplements are indicated (117). This question is of particular importance because selenium participates in the defense against oxidative damage of tissues, which may be increased in kidney disease (118).

Vitamins

Among MD patients who do not take vitamin supplements, vitamin deficiencies are not uncommon because of reduced intake, dialysis losses and altered absorption, metabolism, or activity of some vitamins (119). The low potassium and phosphorus diets prescribed for MD patients often lead to low

intake of some vitamins. Some medicines interfere with the actions of certain vitamins. Vitamin deficiencies are particularly frequent for 25 hydroxycholecalciferol and 1,25-dihydroxycholecalciferol (calcitriol) (discussed above), folic acid, vitamin B_6 (pyridoxine), vitamin C, and, to a lesser extent, other water-soluble vitamins (119,120). Vitamin B_{12} deficiency is uncommon in MD patients, even in patients undergoing hemodiafiltration (121) because it is protein bound in plasma and therefore poorly dialyzable and because body vitamin B_{12} stores are quite large.

There is a high prevalence of vitamin C deficiency in MHD and CPD patients who do not take vitamin supplements, which is probably due to reduced vitamin C in their diets and losses into dialysate. Zhang et al. (122) reported that in 64% of 284 MHD and CPD patients who were not receiving supplements, plasma vitamin C levels were insufficient or deficient. The amount of vitamin C lost in hemodialysate is reported to range from 92 to 334 mg per treatment (123). Plasma ascorbic acid fell by 50% during an individual MHD treatment (123). Morena et al. (124) reported that with hemodiafiltration, two-thirds of dialysate vitamin C losses are due to diffusion and one-third to convection, and the convection volume in this study was substantially lower than what is currently recommended. Scurvy is seldom reported in MD patients (125), but it is not unlikely that less severe vitamin C deficiency may be unrecognized. Raimann et al. (126) found that in comparison with MD patients who had plasma vitamin C levels above the normal range, those with plasma vitamin C below the normal range had more severe periodontal disease and teeth losses, signs consistent with scurvy. Only a supplement providing the RDA for vitamin C is recommended because larger doses can increase plasma oxalate levels (127).

Vitamin B_6 is composed of three compounds: pyridoxine, pyridoxal, and pyridoxamine. Pyridoxal-5-phosphate (PLP), a key phosphorylated metabolic product of vitamin B_6, is a coenzyme for almost 100 enzymatic reactions, particularly for enzymes involved in the metabolism of amino acids and lipids. Corken and Porter (128) reported a 33% to 56% prevalence of vitamin B_6 deficiency when low plasma PLP was used as the criterion for deficiency. Removal of PLP in high-flux dialysis is significantly increased even though it is bound to albumin; PLP is often low in serum of PD patients. The dietary requirement for vitamin B_6 is increased to 10 mg/d, given as a pyridoxine HCl supplement (8.2 mg/d of free pyridoxine, **TABLE 27.5**). Some but not all studies suggest that treatment with large doses of pyridoxine HCl can decrease elevated plasma oxalate levels in MHD patients, although not to normal values (129).

TABLE 27.5 Recommended Mineral and Vitamin Intake for Patients Undergoing Maintenance Hemodialysis or Chronic Peritoneal Dialysis[a]

	Maintenance Hemodialysis	Continuous Ambulatory Peritoneal Dialysis or Automated Peritoneal Dialysis
Minerals and water (range of intake)		
Sodium (mg/d)	1,000–2,000[b]	1,000–3,000[b]
Potassium (mEq/d)	40–70[c]	40–70[c]
Phosphorus (mg/kg/d)	12–15[c] (not to exceed 1,000–1,200 mg/d)	12–15[c] (not to exceed 1,000–1,200 mg/d)
Calcium (mg/d)	500–2,000[d]	500–2,000[d]
Magnesium (mg/d)	200–300	200–300
Iron (mg/d)	See text[e]	See text[e]
Zinc (mg/d)	15[b]	15[b]
Water (mL/d)	≤1,500[f]	≤1,500[f]
Vitamins	Diets to be supplemented with these quantities	
Thiamin (mg/d)	1.5	1.5
Riboflavin (mg/d)	1.8	1.8
Pantothenic acid (mg/d)	5	5
Niacin (mg/d)	20	20
Pyridoxine HCl (mg/d)	10	10
Vitamin B_{12} (mg/d)	3	3
Vitamin C (mg/d)	75–90	75–90
Folic acid (mg/d)	0.8–1[g]	0.8–1[g]
Vitamin A	No addition	No addition
Vitamin D	See text	See text
Vitamin E (IU/d)	15	15
Vitamin K	None[h]	None[h]

[a]When recommended intake is expressed per kilogram of body weight, this refers to the adjusted edema-free body weight (see text).
[b]Can be higher in continuous ambulatory peritoneal dialysis (CAPD) patients or in hemodialysis patients who have greater urinary losses.
[c]Phosphate binders, calcium carbonate, acetate, or citrate, sevelamer carbonate or hydrochloride, lanthanum carbonate, ferric citrate, or other iron binders of phosphate are generally needed to maintain normal serum phosphorus levels. Inhibitors of intestinal phosphate transport may also reduce body phosphate burden.
[d]Prescribed dietary calcium intake will depend on the dialysate calcium concentration, the dose and type of vitamin D compound administered and the intake of any calcium-based binders of phosphate. The indicated Ca intake in this table includes any calcium-based binders of phosphate ingested.
[e]Iron needs may be increased because of the rapid rise in hemoglobin after commencing erythropoietin therapy, blood losses, possibly because of impaired intestinal absorption, and adherence of iron to dialyzer membranes. Since oral iron supplements may not maintain adequate iron stores and may cause gastrointestinal symptoms, iron is not uncommonly given intravenously. Iron-based binders of phosphate may increase serum iron and reduce the needed doses of erythropoiesis-stimulating agents.
[f]Water intake may be greater in patients with substantial daily urine volumes.
[g]Folic acid, 0.8–1 mg/d, is adequate for maintenance hemodialysis (MHD) and chronic peritoneal hemodialysis (CPD) patients (see text).
[h]Vitamin K supplements may be needed for patients who are not eating and who receive antibiotics.

Low plasma niacin concentrations are reported in some patients receiving MD therapy (119,120). Nicotinamide has been shown to inhibit the Na/Pi type IIb cotransporter (Na Pi-2b) in the intestinal brush border and the type IIa cotransporter (NaPi-2a) in the proximal renal tubular epithelial cells of the kidneys (130). Large doses of nicotinamide, 500 to 1,500 mg/d taken twice daily, can reduce serum phosphorus concentrations in hemodialysis patients by inhibiting intestinal phosphate absorption and increasing fecal phosphate excretion.

Low plasma folate levels are not uncommon in advanced CKD patients who do not take vitamin supplements. Folates losses into dialysate may be substantial because it is water soluble, not very large, and not protein bound. Because many patients eat poorly, some patients present with low serum folate levels, and some medications may interfere with folate metabolism, a daily supplement of about 0.8 to 1 mg of folic acid is recommended for MHD and CPD patients (**TABLE 27.5**). Possible mild side effects of

folate, such as nausea, headache, or vivid dreams, have been reported with folate supplements, usually with a dose of 5 mg/d or greater (131).

Despite the water solubility of riboflavin, thiamin, pantothenic acid, and biotin, plasma concentrations of these vitamins are usually not decreased in patients undergoing MHD. Nonetheless, because of their water solubility, a daily supplement equal to the RDA or average intake (for biotin) is recommended. Functional thiamin deficiency has been reported both in MHD and CPD patients even when the plasma thiamin levels are normal (132). The hemodialysis procedure induces a greater decrease in plasma thiamin levels with high-flux versus low-flux membranes (133). Plasma thiamin levels are reported to be lower but not outside the normal range in patients treated with longer MHD treatment times (134). Beriberi, a disease associated with thiamin deficiency, is rarely described in dialysis patients. Hung et al. (135) found thiamin deficiency in 10 out of 30 MHD and CPD patients presenting with mental disturbances. Half of these patients were taking vitamin supplements containing vitamin B_1. In 9 out of these 10 patients, their mental disorder improved with intravenous thiamin supplements (135). Infection, surgery, and large glucose loads may increase the nutritional needs for thiamin and may precipitate clinical manifestations of thiamin deficiency in people who have marginal thiamin levels.

Vitamin K, available as phylloquinone (vitamin K_1) and menaquinone (vitamin K_2), is a coenzyme involved in the posttranslational carboxylation of glutamate residues in several proteins. This produces gamma-carboxyglutamate (Gla) residues on proteins which can bind to calcium. Gla-proteins are found in the coagulation cascade. Several inhibitors of coagulation are also vitamin K-dependent, including proteins C, S, and Z. The anticoagulation effect of coumarin-like compounds is related to blockade of the vitamin K participation in the formation of the Gla residues. Two Gla-proteins are present in bone, osteocalcin and matrix Gla protein (MGP). Osteocalcin is the most abundant noncollagenous protein of bone and is a specific marker for osteoblast activity. *In vitro*, osteocalcin binds to hydroxyapatite in bone and regulates its formation. MGP is also expressed in smooth muscle cells of the arterial wall and regulates calcium deposition in bone and in vascular tissue. Knock-out mice for MGP develop extensive lethal vascular calcifications (136).

Vitamin K is bound to lipoproteins; hence, no losses should occur during dialysis. Reports indicate that there is an increased serum uncarboxylated fraction in vitamin K–dependent proteins in many dialysis patients (137). These proteins include prothrombin, MGP, and osteocalcin and indicate a functional deficiency of vitamin K in some patients with kidney failure. Patients with elevated plasma dephosphorylated-uncarboxylated MGP may have increased vascular calcification (137). The need for vitamin K to maintain normal levels of certain anticoagulant factors and to maintain normal levels of MGP and osteocalcin may explain why coumarin-derivatives are risk factors for calciphylaxis stimulated by bone mineral metabolism imbalance in kidney failure patients (138). It has been proposed that measuring the uncarboxylated fractions of vitamin K–dependent proteins can indicate vitamin K deficiency. In support of this, vitamin K_2 supplements were able to reduce dephosphorylated-uncarboxylated MGP (139). This raises the possibility of a therapy to prevent vascular calcification. Several trials are currently being conducted to evaluate the effectiveness of vitamin K supplements for reducing vascular calcification. Patients who do not eat (and hence do not ingest foods containing vitamin K) and who are receiving antibiotics that suppress intestinal bacteria for extended periods of time may be at particular risk for vitamin K deficiency (140).

Serum total vitamin A, retinol binding protein (RBP), RBP-bound vitamin A, and free vitamin A are increased in CKD patients (141). Moreover, even relatively small supplements of vitamin A, that is, 7,500 to 15,000 IU/d [about 2,250 to 4,500 μg retinal equivalents (RE) per day], appear to cause bone toxicity and hypercalcemia in some CKD patients (142). On the other hand, Espe et al. (143) found that the lower quartiles of plasma retinol and RBP4 were associated with increased risk of sudden death, infection-related mortality, and overall mortality. It is noteworthy that the lower quartile of plasma retinol remained above the normal range for plasma retinol. One possible interpretation is that the lower retinol level is a marker of inflammation. In dialysis patients, plasma vitamin A levels are elevated, and vitamin A deficiency is rarely observed. Moreover, even small vitamin A supplements (7,500 to 15,000 IU; i.e., 2,250 to 4,500 μg of RE) may cause vitamin A toxicity. Hence, there is a consensus that supplemental doses of vitamin A larger than the RDA for vitamin A in normal healthy adults (i.e., 700 to 900 μg of RE) should not be given (**TABLE 27.5**).

Normal, low, and increased plasma or red cell vitamin E (α-tocopherol) levels have been described in nondialyzed MHD and CPD patients (119,120). Several studies indicate that administration of 1,200 IU of vitamin E (all-racemic α-tocopherol acetate) to MHD patients may decrease oxidative stress induced by 100 mg of iron sucrose, and this antioxidant effect may be enhanced with the use of a combination of vitamins E and C (144). In the Secondary Prevention with Antioxidants of Cardiovascular Disease (SPACE) study of MHD patients with preexisting cardiovascular disease, treatment with vitamin E (α-tocopherol), 800 IU/d, is reported to significantly reduce [relative risk (RR) = 0.46] the primary composite end point (fatal and nonfatal myocardial infarction, ischemic stroke, peripheral vascular disease, and unstable angina) (145). This trial has never been confirmed. The Heart Outcomes Prevention Evaluation (HOPE) trial did not find a reduction in cancer and cardiovascular events with vitamin E supplements in patients with diabetes mellitus or a history of adverse cardiovascular events (146). When the duration of this trial was extended (HOPE-TOO trial), these initial results were confirmed; unexpectedly in the HOPE-TOO trial, an increased risk of heart failure was observed in the patients receiving vitamin E supplements. It has been suggested that vitamin E–coated dialyzer membranes might reduce oxidative stress during MHD treatment. Most clinical trials with these membranes reported an increase in plasma or red blood cell (RBC) vitamin E levels. However, currently, no trial has clearly shown improvement in important clinical outcomes with the use of these membranes (147). More research will be necessary before the routine use of daily vitamin E supplements or vitamin E–coated dialyzer membranes can be recommended for MD patients (**TABLE 27.3**).

Since a low intake of several vitamins from foods is common in patients with kidney disease, many reports continue to show that substantial numbers of patients with kidney disease not taking supplements show evidence for vitamin deficiencies. Because water-soluble vitamin supplements are generally safe, it would seem wise to use these supplements routinely (119,120). The Dialysis Outcomes and Practice Study (DOPPS) report showed a survival advantage in MD patients who were vitamin-supplemented. Analysis of the composition of the supplements, which was available only for the U.S. patients, indicated that vitamins C, B_6 and B_{12}, and folate were present in all of the multivitamin preparations used. However, it was not possible to determine the contribution of each of these vitamins to the greater survival of these patients. Recommended nutritional intakes for vitamins are shown in **TABLE 27.5**. Recommendations for vitamin D intake are given in Chapter 24.

Homocysteine

Increased plasma homocysteine is a risk factor for adverse cardiovascular events in the general population (148), and plasma homocysteine is increased in about 90% to 95% of MHD and CPD patients (15,148). Epidemiologic studies in large numbers of MHD patients indicate that a high plasma homocysteine may indicate a better prognosis, because malnutrition and/or inflammation may lower plasma homocysteine levels (149). Homocysteine is an intermediary product of sulfur amino acid metabolism. Plasma homocysteine levels are not affected by membrane flux, and dialysis treatment is not sufficiently effective to normalize plasma homocysteine levels. Three vitamins, vitamins B_6, B_{12}, and folate, are directly involved in its synthesis and metabolism. The Homocysteinemia in Kidney and End Stage Renal Disease (HOST) study indicated that megavitamin therapy that lowers hyperhomocysteinemia in advanced CKD and MHD patients is not associated with reduced cardiovascular events (150). Heinz et al. (151) reported similar findings in another randomized controlled study of vitamin therapy in ESKD patients.

Alkalinization

A high serum anion gap is associated with greater survival in MHD patients (152). This relation is considered to be due to greater appetite and protein intake, which are signs of health in patients but also lead to higher anion gaps (20,152,153). After adjustment for measures indicating protein intake, PEM, or inflammation, it turns out that individuals with lower serum anion gaps (i.e., who are less acidotic) have greater survival (20,153–155). Since the level of acidemia at which amino acid or protein loss or bone reabsorption is stimulated is not well defined, it would seem prudent to prevent any degree of chronic acidemia. Indeed, evidence indicates that CPD patients are more anabolic or less catabolic when their arterial blood pH is 7.42 to 7.45 as compared to 7.35 to 7.38 (25). Also, in nondialyzed CKD patients, both observational studies and randomized controlled clinical trials indicate that when serum bicarbonate is about ≤24 mmol/L, the rate of loss of GFR appears to be more rapid (156–159). Two National Kidney Foundation K/DOQI Practice Guidelines recommend that the serum bicarbonate should be measured once monthly in MHD and CPD patients and that the predialysis or stabilized serum bicarbonate should be maintained at or greater than 22 mmol/L in these individuals (40,160). Because of the above-mentioned potential advantages of completely eradicating acidemia and the safety of giving bicarbonate, the authors believe that these KDOQI guidelines are no longer acceptable. A normal serum bicarbonate (i.e., about 25 mEq/L) is now recommended. In nondialyzed CKD patients, urine also should be continuously maintained alkaline (urine pH >7.0) to slow progression of kidney failure. Alkali therapy probably should be initiated if the arterial blood pH is less than approximately 7.38 regardless of the serum bicarbonate level. Sodium bicarbonate tablets, Shohl's solution, or Bicitra (citric acid and sodium citrate, 1.0 mEq of alkali per milliliter of solution) may be given. For most nondialyzed CKD patients, a dose of about 1 mEq alkali/kg/d, split into at least two doses per day, will usually ensure that there is no acidemia and an alkaline urine. MD patients with large protein intakes or who have a large residual GFR and excrete substantial urinary bicarbonate may also need alkali supplements. MHD patients are often alkalemic immediately postdialysis; if they become acidemic before their next dialysis, they may need to take alkali starting 1 or 2 days postdialysis but excluding the hemodialysis day.

Fiber

In normal individuals, a high dietary fiber intake may lower the incidence of constipation, irritable bowel syndrome, diverticulitis, and neoplasia of the colon and possibly, improve glucose tolerance (161,162). It seems reasonable that the benefits of a high dietary fiber intake in normal people would also occur in MD patients. A high dietary fiber intake of 20 to 30 g/d is therefore recommended.

PRIORITIZING DIETARY GOALS

Since the number and magnitude of the changes in the dietary intake for MD patients are rather numerous, some patients could become discouraged if these recommendations were all presented to the patient at once; the patient could become demoralized and lose his motivation to comply with the diet. We therefore prioritize goals for dietary treatment. Usually, we emphasize the importance of controlling the protein, phosphorus, sodium, potassium, water, energy, and magnesium intake and the need to take vitamin supplements. Statins or fibric acid derivatives are usually better tolerated than dietary modifications, and prescription of these medicines, if lipid disorders are apparent, may enable patients to initially focus on other pressing aspects of dietary modification. If the patient has complied well with the more critical elements of dietary therapy, has a specific lipid disorder that may benefit from dietary therapy, or has expressed an interest in modifying fat, carbohydrate, or fiber intake, then the modifications of the dietary intake of these latter nutrients are explored more intensively with the patient.

ADJUSTED EDEMA-FREE BODY WEIGHT

Many recommended nutrient intakes are given in terms of the patient's body weight. Since MD patients often are underweight, obese, and/or overhydrated or frankly edematous, the NKF practice guidelines issued the following statement (40): "The body weight to be used for assessing or prescribing protein or energy intake is the aBW_{ef} [sic, adjusted edema-free body weight]. For MHD patients, this should be obtained postdialysis. For CPD patients, this should be obtained after drainage of dialysate." The adjusted edema-free body weight (aBW_{ef}) should be used for MD patients, who have an edema-free body weight that is less than 95% or greater than 115% of the median standard weight, as determined from the National Health and Nutrition Evaluation Survey II (NHANES II) data. For individuals with an edema-free body weight between 95% and 115% of the median standard weight, the actual edema-free body weight may be used. The guideline goes on to state, "For DXA measurements of total body fat and fat-free mass, the actual edema-free body weight obtained at the time of the DXA measurement should be used. For anthropometric calculations, the postdialysis (for MHD) or postdrain (for CPD) actual edema-free body weight should be used." Clinical judgment and, if desired, body composition measurements can be used to estimate the magnitude of the edema, if any. The aBW_{ef} may be calculated as follows (**EQUATION 27.3**) (40):

$$aBW_{ef} = BW_{ef} + [(SBW - BW_{ef}) \times 0.25] \qquad (27.3)$$

where aBW_{ef} is the actual edema-free body weight and SBW is the standard body weight as determined from the NHANES II data (163). If possible, the BW_{ef} should be measured after the patient has fasted for at least 8 hours. The NHANES II weights are used for SBW because Americans as a group were less fat at the time that the NHANES II data were collected than they are today.

ORAL AND ENTERAL NUTRITION

Provision of increased nutrients to chronic dialysis patients with PEW who are not eating well is best accomplished by nutritional counseling, oral nutritional supplements, or, if these maneuvers fail, enteral nutrition. In general, feeding by the gastrointestinal tract is safer, maintains the gastrointestinal tract in a healthier state, and is less expensive than parenteral nutrition (164). Intensive nutritional counseling may improve nutritional status in some chronic dialysis patients (165). When nutritional counseling is not sufficient, supplements may be tried. A number of clinical trials, usually rather small in sample size and often without randomized prospective controls, indicate that oral or enteral nutrition often improves nutritional or protein-energy status in CKD or MD patients with PEW (166,167). Some studies have examined oral nutritional supplements during the dialysis procedure. Giving nutritional supplements in this manner may increase adherence to the nutritional prescription and mitigate the marked disruption in extracellular and intracellular amino acid pools that occurs when patients undergo hemodialysis in the fasting state. Protein anabolism also increases acutely when patients receive oral nutrition containing protein during hemodialysis (168). A longer term randomized, prospective controlled clinical trial of routine feeding of a nutritional supplement during the hemodialysis procedure describes improvement in nutritional status (169). This nutritional supplement also contained compounds considered to be anti-inflammatory and antioxidant and measures of inflammation and oxidant stress also decreased in the patients who received this supplement. A retrospective analysis of a large cohort of MHD patients indicated that intradialytic provision of oral nutritional supplements in MHD patients with PEW is associated with increased survival (30). Some nephrologists are reluctant to allow feeding during hemodialysis because feeding may cause changes in hemodynamics that may promote hypotension during hemodialysis (170). Our experience indicates that intradialytic hypotension or nausea and vomiting are not common complications associated with intradialytic feeding. Possibly, feeding during hemodialysis should not be offered to patients with a history of intradialytic hemodynamic instability. Many patients tire of taking nutritional supplements, and after about 3 to 4 months, adherence rates to such supplements often decrease. One possible solution to this dilemma is to prescribe the nutritional supplements to be given in the hemodialysis unit by the nurses, like a medicinal prescription (171). Another possibility is to use enteral tube feeding, which in the opinion of the authors is an underused therapy. Finally, there is the option of IDPN, nutrition through dialysate, or, in extreme cases, total parenteral nutrition.

INTRADIALYTIC PARENTERAL NUTRITION

For patients who have marginally adequate intakes and who will not ingest more nutrients through foods or food supplements or take enteral tube feedings (166), supplemental amino acids, glucose, and lipids may be infused intravenously during hemodialysis treatment (i.e., IDPN) (28,29,172,173). The preparation is infused into the blood leaving the dialyzer to reduce dialysate losses of amino acids and glucose.

Evidence does not clearly show that IDPN is beneficial or that patients may not receive similar advantages from oral supplements or tube feeding (28,29,172,173). Large-scale prospective, randomized controlled appropriately performed clinical trials that test the clinical value or indications for use of IDPN have not been performed. Studies describe acute increases in total body and muscle protein

synthesis and positive-energy balance during IDPN (174). However, protein anabolism also increased acutely if patients received oral nutrition during hemodialysis (175). Improved serum albumin and edema-free body mass have been described in a number of studies, which often involved small numbers of patients, no randomized control group, or no strict control or monitoring of oral nutrient intake (172,176,177). Exercise on a stationary bicycle during hemodialysis in patients receiving IDPN promotes more positive protein balance (178). Reference is made to a recently published detailed review of IDPN (173).

A case control retrospective study (28) and a nonrandomized retrospective report (29) provide suggestive data that IDPN increases survival in malnourished MHD patients. In the case control study, those patients with a serum albumin of 3.3 g/dL or lower who were given IDPN had greater survival than those who were not (28). In the retrospective comparison of nonrandomized MHD patients, those individuals who received IDPN had a reduced mortality rate (29). The French Intradialytic Nutrition Evaluation (FINE) Study involved 186 MHD patients with PEW who received an oral nutritional supplement for 1 year that provided approximately 5.8 kcal/kg/d and 0.38 g protein/kg/d. During this same time, patients were randomized to receive IDPN or no IDPN with each hemodialysis (179). The recommended IDPN was designed to bring the total intake (oral plus intravenous) 30 to 35 kcal/kg/d and 1.2 g/protein/kg/d. The patients randomized to receive IDPN, in comparison to those not receiving IDPN, did not show, over 2 years, improved mortality or hospitalization rates, or reduced evidence for PEW. This lack of beneficial nutritional effect from IDPN may have been due to the fact that almost all IDPN-treated and control patients received an oral nutritional supplement as well (179).

TABLE 27.6 summarizes the potential advantages and limitations of IDPN. Some reports concerning indications for IDPN emphasize that IDPN is only indicated for malnourished MHD patients who ingest inadequate nutrients and for whom counseling, food supplements, and enteral tube feeding are not helpful or are contraindicated (173,180). IDPN is probably of value only for clinically stable or only modestly inflamed MHD patients who have a slightly or moderately suboptimal intake of nutrients (i.e., perhaps 60% to 80% or greater of the patient's recommended daily intake). This technique is probably inadequate for severely ill MHD patients because their oral or enteral intake is usually very low, their nutrient needs are high, and the nutritional supplements can be given only intermittently, when the patient undergoes hemodialysis. Of course, if the patient is hospitalized and receiving continuous venovenous hemodialysis or daily hemodialysis—particularly if the daily hemodialysis extends for more than 4 hours each day, then intravenous nutrition can provide all of the patient's nutritional needs and can be completely substituted for oral or enteral feeding.

TABLE 27.6 Advantages and Disadvantages of Intradialytic Parenteral Nutrition

Advantages

1. IDPN can be provided with each dialysis session (usually thrice weekly) through the blood tubing without the need for additional venipuncture or placement of a central catheter.
2. It provides nutritional support to patients independent of anorexia, appetite, willingness or ability to cooperate, gastrointestinal function or disease states.
3. All needed nutrients can be provided through IDPN in contrast to nutrition provided through the dialysate.
4. The quantity and nutrient composition of the nutritional intake can be regulated.
5. Excess fluid and minerals and metabolic products can be removed during the course of dialysis; therefore, undesirable positive fluid or mineral balance and probably increased accrual of potentially toxic metabolites can be prevented.
6. It is a convenient way to provide supplemental nutrition with little or no effort by the patient and does not interfere with the patient's daily activities.

Disadvantages

1. The nutritional intake is given only during hemodialysis, which typically is provided for 3–4 h thrice weekly or ~12 h/wk; therefore, IDPN is not very effective as the sole source of nutrition.
2. Nutrients given intravenously are cleared very rapidly from blood.
3. The short intense duration of intravenous feeding by IDPN is unphysiologic because normal nutrient-gut interactions are lacking and also because adult humans eating three or four meals daily spend most of their lives in the postprandial state, in contrast to the short intense duration of intravenous nourishment by IDPN.
4. It often is expensive, although theoretically it does not have to be.
5. It requires time and effort from the nursing staff.
6. Microbial contamination with ensuing infection in the patient can occur.
7. There is a risk of reactive hypoglycemia, particularly if patients are infused with large quantities of D-glucose over a short period of time.
8. Oral nutritional supplements, if tolerated, appear to be just as effective as a nutritional source (179).

IDPN, intradialytic parenteral nutrition.
This table is reproduced, with modifications. (Dukkipati R, Kalantar-Zadeh K, Kopple JD. Is there a role for intradialytic parenteral nutrition? A review of the evidence. *Am J Kidney Dis* 2010;55(2):352–364. Courtesy of the editor.)

Since most patients who need IDPN do ingest energy sources and protein/amino acids, but in suboptimal amounts, we generally give about 40 to 42 g of essential and nonessential amino acids and 200 g of D-glucose (150 g of D-glucose if the dialysate contains glucose) and usually 250 mL of a 10% or 20% lipid solution (i.e., 25 to 50 g of fat). The nutrients are administered at a constant rate throughout the dialysis procedure to minimize the decrease in plasma glucose that occurs with the use of glucose-free hemodialysate and the fall in amino acid pools in the body that normally occur with a hemodialysis treatment. In the authors' experience, about 85% to 90% of the amino acids and a large proportion of the glucose infused during hemodialysis are retained; the amino acid losses in dialysate rise by an average of only 4 to 5 g (181). The nutrients may be utilized more efficiently because they are given continuously rather than as a bolus.

Patients who have low serum concentrations of potassium or phosphorus at the start of the dialysis

treatment may need supplements of these minerals during the amino acid and glucose infusions to prevent worsening of hypokalemia or hypophosphatemia due to both intracellular movement as well as dialysis losses of these minerals. If the dialysate is glucose-free, the infusion is not stopped until the end of the hemodialysis session to prevent hypoglycemia. Also, the patient may eat a source of carbohydrates 20 to 30 minutes before the end of the IDPN infusion if there is any concern that the patient may develop reactive hypoglycemia. The infusion may be tapered or a peripheral infusion of glucose started to avoid hypoglycemia. Since lipids have been added to the IDPN solutions and the glucose dose from IDPN has been correspondingly reduced, the risk of developing postinfusion hypoglycemia appears to be reduced.

Nutritional Hemodialysis and Nutritional Peritoneal Dialysis

Amino acids may be added to the dialysate of patients undergoing CPD or MHD (182,183). With hemodialysis, additional glucose also may be added. The nutrients diffuse into the body during dialysis. These techniques have the potential advantages of consolidating nutritional and dialysis treatment into one procedure, reducing the risk of fluid and electrolyte disturbances from intravenous nutrition, and decreasing the considerable costs of intravenous feeding. When the nutrients are added to the hemodialysate, some investigators have reduced the dialysis flow rate to increase the fractional extraction of amino acids and glucose from dialysate. This has the benefit of reducing the cost of the nutrients given to the patient, but it also decreases the efficiency of dialysis; hence, these patients may require more hours of dialysis therapy, which raises nursing costs. Also, nutritional hemodialysis would have to be performed daily if it were the only or the main source of nutrition for a patient. Daily nutritional hemodialysis is probably only of benefit only for hospitalized patients, and it would have to be designed so that it was performed by intensive care unit personnel rather than by hemodialysis nurses in order to save costs. Under these conditions, it would be a variant of continuous venovenous hemodialysis (CVVHD).

Chazot et al. (5) added amino acids to hemodialysate during a standard hemodialysis using a cellulose triacetate hemodialyzer. When about 46 g of a mixture of 20 amino acids were added to the concentrate to provide a final dialysate amino acid concentration similar to fasting plasma levels, the amino acid losses into hemodialysate were prevented. When 139 g of these amino acids were added to the hemodialysate concentrate, there was a net transfer of about 39 g of amino acids from the dialysate to the patient during the hemodialysis.

Amino acids maybe added to peritoneal dialysate for protein-wasted CPD patients (182,183). By adding amino acids, the glucose load from the dialysate can be reduced. Also, for malnourished patients who are ingesting low-protein diets, the supplemental amino acids appear to increase protein synthesis, nitrogen balance, and serum levels of several proteins (182,183). In general, a mixture of both essential and nonessential amino acids are provided in about a 1.1% solution of standard peritoneal dialysate with the glucose contented deleted. One or two peritoneal dialysate exchanges of this solution are substituted each day for the patient’s usual exchanges. Dwell times should last about 4 to 6 hours to ensure an uptake of about 80% of the total dialysate amino acid content and to prevent excessive reabsorption of other compounds in dialysate by an excessively long dwell time. It is to be emphasized that the calorie load from these solutions is very small. Hence, it is preferable that these exchanges are given during the major meals of the day. Again, it should be emphasized that dietary counseling and food supplements should be attempted and tube feeding should be considered before turning to these more expensive and incomplete

nutritional supplements.

[*Note*: When the recommended nutrient intake is given in terms of body weight, the latter refers to standard body weight as determined from the NHANES data from 1976 to 1980 (40,163)].

CHAPTER 28

Disorders of Hemostasis in Dialysis Patients

Federica Mescia, Miriam Galbusera, Paola Boccardo, and Giuseppe Remuzzi

The association between bleeding and kidney disease was first described by Morgagni (1) in 1794. The advent of modern dialysis techniques and the use of erythropoietin to correct anemia definitively reduced the incidence of severe hemorrhages, but bleeding diathesis still represents a relevant problem for uremic patients. For instance, among the control group of a clinical trial, 24% of hemodialysis patients experienced clinically significant bleeding over less than 1 year (2). Compared to the general population, patients with end-stage kidney disease (ESKD) have around a 10-fold greater risk of cerebral hemorrhage (3), subdural hematoma (4), and gastrointestinal bleeding (5). Surgery and invasive procedures, such as biopsies, pose additional hemorrhagic risks.

On the other hand, abnormalities in blood coagulation and fibrinolysis may predispose uremic patients to a hypercoagulable state rather than hemorrhage, and patients undergoing hemodialysis are exposed to thrombotic complications of vascular access.

PATHOGENESIS OF UREMIC BLEEDING

The causes of uremic bleeding have been the subject of a major debate since the 1970s. Most landmark studies in the field were indeed conducted in the 1970s to 1980s, when, in the early days of dialysis, hemorrhagic issues often posed major clinical challenges. In the following decades, widespread adoption of erythropoiesis-stimulating agents substantially reduced the clinical relevance of uremic bleeding. Nonetheless, a deep understanding of the hemostatic derangements in ESKD remains pivotal to provide optimal patient care. The pathogenesis of uremic bleeding is multifactorial, and the major defects involve primary hemostasis (**FIGURE 28.1**), that is, platelet–vessel wall and platelet–platelet interactions.

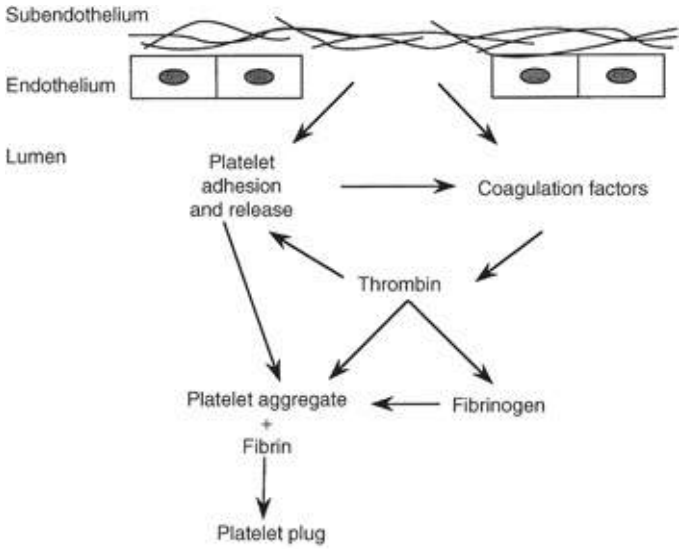

FIGURE 28.1 Schematic representation of primary hemostasis.

Platelet Abnormalities and Uremic Toxins

Moderate thrombocytopenia is commonly found in uremic patients, suggesting inadequate production or platelet overconsumption (6). Nonetheless, thrombocytopenia rarely is severe enough to cause bleeding. Numerous biochemical changes have been reported in platelets from ESKD patients. Dense granule content is altered in uremic platelets, with reduced levels of the aggregation agonists serotonin and adenosine diphosphate (ADP) (7). Granule secretion is defective too: Release of adenosine triphosphate (ATP) from dense granules (8) and of α-granule proteins, including β-thromboglobulin (9), are impaired. Calcium content is increased in platelets from uremic patients (10), and its mobilization in response to stimulation is abnormal (11), leading to functional defects. Anomalies in the platelet cytoskeleton contribute to defective hemostasis in chronic kidney disease (CKD): Cytoskeletal proteins are quantitatively reduced, and their assembly upon stimulation is qualitatively abnormal (12), hindering cellular contraction and motility. Platelets from uremic patients also display defects in two adhesion receptors, glycoprotein (Gp) Ib and the Gp IIb–IIIa complex. Gp Ib is fundamental for platelet adhesion to the subendothelium at high shear rates, like those found in the capillary circulation. Availability of Gp Ib on the platelet surface is decreased in CKD, likely because of enhanced proteolysis of the receptor (13). Platelet adhesion to subendothelial surfaces leads to activation of the Gp IIb–IIIa receptor complex, that in turn binds von Willebrand factor (vWF) and fibrinogen. The number of Gp IIb–IIIa receptors expressed on the platelet membrane of uremic patients is normal, but their function is impaired (14,15). This has been ascribed to competitive binding of the receptor by fibrinogen fragments and, possibly, other dialyzable toxic substances that accumulate in uremic plasma.

Arachidonic acid and prostaglandin metabolism is deregulated in uremia: A relative deficiency of the platelet agonist thromboxane A_2 and an excess of the potent platelet inhibitor and vasodilator prostacyclin are found, tipping the balance toward defective platelet function. Production of thromboxane A_2 by platelets in response to endogenous and exogenous stimuli is impaired (16,17). On the other hand, formation of prostacyclin is increased in uremic patients (18), and their plasma contains higher than normal amounts of a factor that stimulates vascular production of prostacyclin (19). Elevation in prostacyclin and pathologic hyperactivity of platelet adenylate cyclase (20) cooperate in increasing intracellular levels of cyclic adenosine monophosphate (cAMP) (21), which in turn contributes to impaired platelet function.

Nitric oxide (NO) is another key player in uremic bleeding (22,23) that interferes with hemostasis by inhibiting platelet aggregation and by preventing the vasoconstriction that normally follows vessel injury. Rats made uremic by extensive surgical ablation of kidney mass display bleeding time prolongation and elevated plasma levels of the stable NO metabolites nitrites and nitrates (24). In this animal model, increased expression of both inducible nitric oxide synthase (iNOS) and endothelial nitric oxide synthase (eNOS) is found in the aorta (24), consistently with enhanced vascular release of NO. Higher plasma levels of L-arginine, the substrate for NO synthesis, have been documented in uremic patients, compared with healthy volunteers. Platelets taken from CKD patients generate more NO than control platelets (25), and uremic plasma, unlike plasma from controls, potently induces *in vitro* NO production in cultured human umbilical vein or microvascular endothelial cells (26). Increased NO synthesis is likely the main mechanism by which the uremic toxins guanidinosuccinic acid and methylguanidine interfere with platelet function (26). Cytokines such as tumor necrosis factor-α (TNF-α) and interleukin-1β (IL-1β), which rise in ESKD, are also potent inducers of iNOS (27).

After mixing with plasma from healthy subjects, uremic platelets show improvement of many functional parameters, while mixing of uremic plasma with normal platelets leads to platelet dysfunction. These findings highlight the key role of soluble plasma factors in determining platelet defects. The already cited elevation in prostacyclin, fibrinogen fragments, and inducers of NO synthesis, together with reduced thromboxane A_2 in uremia, partially account for these effects. The metabolites phenol, phenolic acid (28), and guanidinosuccinic acid (29) rise in CKD and impair platelet aggregation to ADP *in vitro*. Also, parathyroid hormone (PTH) has been consistently shown to inhibit platelets *in vitro* (30). Nonetheless, a clear correlation between skin bleeding time and the serum concentrations of these substances has not been demonstrated in ESKD patients (31,32). Other uremic retention solutes, like urea, creatinine, and guanidinoacetic acid, do not significantly interfere with platelet function when added to normal plasma (33).

Chronic volume overload in dialysis patients has been proposed to be an additional factor that increases bleeding risk, in particular of spontaneous subdural hematomas. The putative pathogenic mechanism entails venous hypertension, predisposing to small venous tears of dural bridging veins (4).

Anemia

Anemia is a common finding in ESKD patients and has a multifactorial origin, encompassing shortened survival of red blood cells in the uremic milieu, reduced responsiveness of the erythroid marrow induced by uremic toxins (34), repeated blood loss during dialysis, and, most importantly, defective secretion of erythropoietin. Anemia plays a key role in uremic bleeding, mainly through rheologic factors. At a low hematocrit, platelets tend to be dispersed along the blood vessels, which impairs their interaction with the vascular walls (35). At a hematocrit above 30% instead, erythrocytes mainly localize at the center of the vessels and platelets are displaced more peripherally, closer to the endothelial surface where their efficiency in forming a plug, in case of exposure of the subendothelium, is optimized. Erythrocytes also directly enhance platelet function by releasing platelet aggregation agonists ADP and thromboxane A_2, by inactivating prostacyclin, and by scavenging NO through hemoglobin (35).

Skin bleeding time is inversely correlated with hematocrit and significantly shortened after red blood cell transfusion (36,37). Treatment with recombinant human erythropoietin also reduces bleeding time and

increases hemostatic efficiency (38). In a randomized study, erythropoietin normalized the bleeding time in all uremic patients as hematocrits rose from 27% to 32% (39).

Effects of Dialysis

Dialysis has opposing effects on hemostasis. On the one hand, it allows removal of some of the uremic toxins that induce platelet dysfunction and hemostatic derangements. As a proof of concept, for example, skin bleeding time is significantly shortened, albeit rarely normalized, in uremic patients after the first dialysis sessions (40). However, dialysis cannot effectively remove all uremic retention solutes, especially those with high molecular weight or protein-bound, and only partially corrects uremia and the associated bleeding tendency (31).

Importantly, dialysis itself can increase bleeding risk, especially in the case of hemodialysis, where blood gets in contact with the extracorporeal circuit and systemic anticoagulation is usually required (41). In patients on chronic hemodialysis, skin bleeding time is often longer right after the dialysis session than before, an effect not attributable to heparin use (42). In spite of significant advances in biocompatibility with current hemodialysis technology, exposure of blood to the dialyzer membrane, to circuit tubing, to microbubbles in the circuit, and to shear stress, particularly in the roller pump segment, inevitably leads to a certain degree of activation of platelets, inflammatory cells, coagulation, and complement system. As well documented also in the setting of cardiopulmonary bypass, continual platelet activation can bring about mild thrombocytopenia and transient functional platelet exhaustion due to reiterated degranulation and loss of Gp receptors (41).

In the course of the hemodialysis session, hemostasis is modulated also by oscillations in the plasma levels of NO, which are the result of two opposing processes. Hemodialysis removes uremic toxins that stimulate NO synthesis and, at the same time, activates inflammation pathways in the extracorporeal circuit, raising the levels of potent NO inducers like the cytokines TNF-α and IL-lβ (25,43). In particular, NO induction has been attributed to complement-activating dialyzer membranes, acetate-containing dialysate, and dialysate contamination by intact endotoxin, endotoxin fragments, and other bacterial components that may cross the dialysis membranes. The current use of synthetic, more biocompatible, membranes, the widespread availability of bicarbonate dialysis, and the adoption of more and more stringent standards of dialysate purity could hopefully tip the balance toward a net reduction in NO during hemodialysis, thus improving hemostasis.

Administration of anticoagulants to avoid circuit clotting during hemodialysis is an additional factor that can increase bleeding risk. In particular, heparin, the drug most widely used for this purpose, is known to promote platelet self-aggregation and activation through nonimmunogenic mechanisms, which can exacerbate the functional alterations generated by the extracorporeal circulation.

From the standpoint of bleeding risk, peritoneal dialysis presents clear theoretical advantages over hemodialysis by avoiding the need of intradialytic anticoagulation and the exposure of blood to the extracorporeal circuit. Along the same line, epidemiologic studies have documented a lower incidence of gastrointestinal and intracranial bleeding in peritoneal dialysis, compared to hemodialysis patients (5,44).

Medications

Dialysis patients are often prescribed anticoagulant and antiplatelet agents due to their cardiovascular conditions or to preserve vascular access. Compared to the general population, these drugs put uremic

patients at higher bleeding risk (45,46), exacerbating their hemorrhagic diathesis. Particular caution must be exercised prescribing drugs like low molecular weight heparins, which rely on a primarily kidney metabolism and tend to accumulate in ESKD (47). Bleeding risk due to bioaccumulation is significantly raised also with the new oral anticoagulants, targeting either thrombin (e.g., dabigatran) or factor Xa (e.g., apixaban), which are contraindicated in dialysis (48). The effects of aspirin on hemostasis are potentiated in the uremic milieu: In addition to the well-known irreversible blocking of platelet cyclooxygenase, aspirin also causes a cyclooxygenase-independent marked prolongation of the bleeding time in uremic patients but not in normal subjects (49). In addition, aspirin and the other nonsteroidal anti-inflammatory drugs directly hamper integrity of the gastrointestinal mucosa through inhibition of prostaglandin synthesis (50). This effect may be of particular relevance in dialysis patients, that are especially prone to gastrointestinal bleeding.

Other drugs that can contribute to uremic bleeding are β-lactam antibiotics. They accumulate in advanced kidney disease and may perturb platelet membrane, interfering with the ADP receptor and therefore inhibiting platelet aggregation (51). These effects are dose- and duration-dependent and resolve after drug discontinuation. Among the β-lactam antibiotics, third-generation cephalosporins may affect hemostasis the most, due to concomitant interference with intrahepatic vitamin K metabolism, in addition to platelet inhibition (52).

CLINICAL FINDINGS

The most common bleeding complications in uremia are petechial hemorrhages, blood blisters, and ecchymoses at the site of fistula puncture or temporary venous access insertion. Less frequent but more serious bleeding problems are discussed below.

Gastrointestinal Bleeding

The gastrointestinal tract is the most frequent site of major bleeding in ESKD patients (53). The sources of gastrointestinal hemorrhage are similar to those in patients with normal kidney function and include gastric and duodenal ulcers/erosions, vascular ectasias, esophagitis, gastritis, Mallory-Weiss tears, gastric cancer (54), hemorrhoids, colonic diverticular disease, and polyps (55).

Angiodysplasias (telangiectasias, arteriovenous malformations) are small vascular lesions of the gastrointestinal mucosa and submucosa that have been observed all along the digestive tract and may cause acute or subacute hemorrhage. They have been reported as a cause of bleeding more frequently in dialysis patients than in the general population (56). It is not clear whether this finding reflects a higher incidence of angiodysplasias in the setting of CKD and/or an increased risk for these lesions to bleed and thus to be diagnosed in uremic patients.

Ischemic colitis is another important differential diagnosis in dialysis patients with lower gastrointestinal bleeding, especially in those with widespread vascular disease and prone to intradialytic hypotension (57).

Alternative rare causes of digestive hemorrhage, like Kaposi’s sarcoma, cytomegalovirus colitis, and non–Hodgkin’s lymphoma, need to be considered in patients with concomitant severe immunodepression, such as those with HIV nephropathy or a history of long-term exposure to immunosuppressant drugs for kidney transplantation or immune-mediated systemic diseases (55).

Intracranial Hemorrhage

ESKD patients are more prone than the general population to intracranial bleedings, including subdural hematomas, intracerebral hemorrhages, and subarachnoid hemorrhages (4,58,59). Such events are often spontaneous, without recallable trauma, and are associated with higher mortality in dialysis patients. For instance, data from a large U.S. database showed that the incidence rate of subarachnoid hemorrhages was more than sixfold higher in patients on dialysis, who had a mortality of 38.4% versus 21.9% in the general population (59).

Brain magnetic resonance imaging (MRI) studies have also shown that small hemosiderin deposits, indicative of prior microscopic cerebral hemorrhage, are highly prevalent among hemodialysis patients. These alterations, known as cerebral microbleeds, are closely associated with other cerebral small-vessel diseases and likely contribute to cognitive dysfunction; age and high blood pressure are significant risk factors (60,61).

Hemorrhagic Pericarditis and Pleuritis

Limited, fibrinous pericardial and pleural effusions are common findings in patients with advanced kidney disease. Without adequate dialysis, serous effusion can undergo hemorrhagic transformation, leading to life-threatening uremic pericarditis, with possible tamponade (62), or pleuritis (63). These presentations used to be frequent in the predialysis era and are now rarely encountered. Nonetheless, they remain medical emergencies that require prompt recognition and treatment, the core of management being intensive, anticoagulant-free dialysis.

Other Hemorrhagic Presentations

Women on dialysis frequently present abnormal uterine bleedings, with a high prevalence of uncontrolled menorrhagia, contributing to symptomatic anemia (64). Kidney cysts are a common finding in dialysis-associated cystic kidney disease and occasionally give rise to unprovoked bleeding. Presentations range from asymptomatic, trivial intracystic hemorrhage to massive retroperitoneal hematomas (65).

Subcapsular liver hematoma is another serious hemorrhagic complication that has been rarely observed in uremic patients (66).

Notably, patients with CKD from autosomal dominant polycystic kidney disease may be at higher than average bleeding risk, due to predisposing anatomic abnormalities like kidney and liver cysts, an elevated frequency of colon diverticulosis and susceptibility to develop intracranial aneurysms (67).

Finally, in spite of the current improvements in standards of care, major surgery and invasive procedures still entail perioperative hemorrhagic risks that are more elevated in dialysis patients than in the general population, with subsequent higher morbidity and mortality rates (68).

LABORATORY ASSESSMENT OF THE BLEEDING RISK

The single assay that best correlates with uremic bleeding is skin bleeding time, an *in vivo* test that gives an overall assessment of primary hemostasis (69). Among the factors that influence skin bleeding time, there are platelet number and functionality, hematocrit, vascular integrity, and activity of vWF. The skin bleeding time is most commonly determined using the Ivy method. A blood pressure cuff is applied above the cubital fossa and inflated at 40 mm Hg to elevate venous pressure and increase test sensitivity. A

small cut is made on the ventral side of the subject's forearm, in an area where there are no hairs or visible veins. The cut is done quickly by an automatic device, which provides a standardized width and depth. The blood is blot away every 30 seconds by filter paper, until the platelet plug forms and the bleeding terminates. The time it takes for the bleeding to stop is measured and represents the skin bleeding time. Normal values are below 7 minutes; prolongation above 10 minutes correlates with a significantly increased risk of bleeding in uremic patients. The skin bleeding time was established as a predictor of hemorrhagic events in CKD patients in the 1970s and suffers from poor reproducibility and accuracy; nonetheless, it remains the best available test at present.

Several *in vitro* assays of platelet function have been developed, such as closure time test (also known as platelet function analyzer or PFA-100, that measures platelet aggregation in response to ADP and epinephrine), whole blood platelet aggregation (WBPA), thromboelastography (TEG), and cone platelet analyzer (CPA) (70). However, none of these tests has been validated in clinical practice in the setting of uremic bleeding, and their use remains investigational.

PREVENTION AND TREATMENT

We will focus on the following key points that should be systematically addressed in all dialysis patients in order to prevent bleeding and optimize treatment of active hemorrhage (**TABLE 28.1**): the dialysis prescription, correction of anemia, appropriateness of concomitant antiplatelet/anticoagulant therapies, and use of specific agents to improve hemostasis.

TABLE 28.1 Guidelines for the Prevention and Management of Hemorrhagic Complications of Uremia

- For all patients with hemorrhagic complications or undergoing major surgery, the dialysis prescription should be carefully reviewed, ensuring adequacy and personalizing intradialytic anticoagulation.
- Correction of anemia by red blood cell transfusion and/or erythropoiesis-stimulating agents is the first key step in the prevention and treatment of uremic bleeding. The hematocrit should be kept above 30% in order to improve hemostasis.
- Indications for prescription of antiplatelet/anticoagulant agents in dialysis patients should be regularly reassessed, focusing on risk/benefit profile.
- Desmopressin acetate can be useful to improve hemostasis during acute bleeding episodes. It can be administered intravenously (0.3 μg/kg added to 50 mL of saline over 30 min), subcutaneously (0.3 μg/kg) or intranasally (3 μg/kg). The effect of desmopressin acetate has a fast onset but lasts only a few hours and loses efficacy after repeated administrations.
- Tranexamic acid can be used as a second-line agent in acute bleeding, paying attention to the risk of bioaccumulation in dialysis patients.
- Conjugated estrogens, given by intravenous infusion in a cumulative dose of 3 mg/kg as a daily divided dose (i.e., 0.6 mg/kg for 5 consecutive days), can help to achieve long-lasting hemostasis in case of persistent chronic bleeding.
- Because the favorable effect of cryoprecipitate on bleeding time has not been uniformly observed, we do not recommend its use.

In case of ongoing hemorrhage, first-line management is not specific for dialysis patients and includes hemodynamic support; identification of the hemorrhagic source and, possibly, subsequent treatment by surgical, endovascular, or endoscopic techniques. ESKD should be accounted for in the risk

assessment of bleeding patients and in the subsequent planning of therapeutic interventions. For example, markedly higher rebleeding rates from endoscopically treated peptic ulcers have been documented in dialysis patients, even when these patients had low-risk ulcer stigmata on endoscopy (71). While awaiting more comprehensive data, it could thus be reasonable to manage all dialysis patients with peptic ulcer bleeding, and maybe other hemorrhagic disorders as well, as high-risk patients.

Dialysis Prescription

Adequate dialysis is a mainstay in the prevention of uremic bleeding. However, as already discussed, current dialysis technologies allow only partial correction of the bleeding diathesis associated with uremia, and hemodialysis in particular interferes with hemostasis. For these reasons, in the absence of other contraindications, peritoneal dialysis is a reasonable choice for patients at particularly high hemorrhagic risk.

In the hemodialysis prescription, intradialytic anticoagulation needs to be personalized, balancing individual thrombotic and hemorrhagic risks. The minimum dose of heparin effective in preventing circuit clotting should be determined for each patient. Reduced-intensity intradialytic anticoagulation is a sensible option in patients treated with oral anticoagulants: In many of such cases, even complete avoidance of intradialytic anticoagulation is feasible, provided that the international normalized ratio (INR) is within the target range, there is minimal inflammation, a native vascular access with adequate blood-flow rate is available, and synthetic high-flux membranes are used (72). As detailed elsewhere in this book, use of minimum-dose heparin or no-heparin hemodialysis is possible in patients at high bleeding risk or with ongoing hemorrhage, at the cost of increasing the possibilities of circuit clotting. Regional citrate anticoagulation is a valid alternative. In case of life-threatening bleeding, like intracranial hemorrhages, complete avoidance of anticoagulants is advised, usually for a period of at least 2 weeks.

Dialytic adequacy must be carefully considered, especially in patients presenting with uremic or dialysis-associated pericarditis. In this setting, it is mandatory to make a trial of intensive dialysis, usually defined, in the case of hemodialysis, as daily sessions for 10 to 15 days, preferably without heparin to minimize the risk of hemopericardium and cardiac tamponade (62).

In case central venous catheters are used as hemodialysis access, heparin lock is an often under recognized factor possibly concurring to bleeding risk. In fact, a certain degree of spillage of lock solution in the systemic circulation is practically inevitable, and if high-concentration heparin (5,000 to 10,000 U/mL) is employed, this can occasionally contribute to clinical bleeding. Use of 4% citrate or low-dose heparin (1,000 U/mL) is safe and effective alternative as lock solution (73,74).

Correction of Anemia

Management of anemia is pivotal in the prevention and treatment of uremic bleeding. Use of recombinant human erythropoietin has largely replaced transfusions and significantly lowered hemorrhagic risk. A randomized study established that a threshold hematocrit between 27% and 32% effectively normalized bleeding time in uremic patients on erythropoietin (**FIGURE 28.2**) (39). Treatment of anemia likely improves hemostasis by displacing platelets from a midstream position toward the vessel wall, thus encouraging platelet–endothelium interactions. In addition, recombinant human erythropoietin affects hemostasis also independently of amelioration of anemia. For instance, it increases the number of

reticulated platelets, which are more metabolically active (75), improves platelet calcium signaling (76), and enhances thrombin-induced phosphorylation of platelet proteins (77).

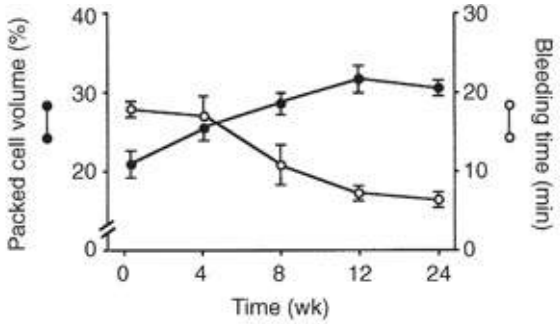

FIGURE 28.2 Effect of recombinant human erythropoietin therapy on packed cell volume and bleeding time in uremic patients.

In case of ongoing hemorrhage, correction of anemia should be prompt, applying a lower transfusion trigger than in nonuremic patients, in order to steadily keep the hematocrit above 30%. Erythropoiesis-stimulating agents need a long time—at least 7 days—to significantly increase the red blood cell mass; nonetheless, it is reasonable to start their administration or increase dosing also in the acute setting, due to the direct effects on platelet activation and to limit the need for future transfusions.

Appropriateness of Concomitant Antiplatelet/Anticoagulant Therapies

Dialysis patients frequently take antiplatelet and anticoagulant medications for primary or secondary cardiovascular prevention. These drugs often result in a relatively higher increase in bleeding risk in ESKD patients than in those with preserved kidney function. For instance, absolute risk of major bleeding in dialysis patients on warfarin ranged from 0.10 to 0.54 events per patient-year, which was 10 times higher than rates in the general population (46). Antiplatelet agents, especially when taken in combination, also significantly raise hemorrhagic risk in patients on hemodialysis. For example, major hemorrhage was noted in 7.6% of hemodialysis patients on a trial of aspirin and clopidogrel (2), compared with 3.7% of nonuremic patients enrolled in the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial, despite the use of the same two drugs (78).

To further complicate decision making, we must consider that the indications for antiplatelet and anticoagulant medications derive from clinical trials that excluded patients with advanced CKD. It is therefore unknown whether the risk/benefit profile demonstrated for these therapies in the general population can be reliably extrapolated to dialysis patients. For instance, based on retrospective case series, efficacy of warfarin to prevent stroke in dialysis patients with atrial fibrillation has not been consistently demonstrated, while increased hemorrhagic risk clearly emerged (79).

Anticoagulant/antiplatelet agents are frequently prescribed also for preservation of hemodialysis access patency, despite the lack of clinical studies demonstrating clear-cut evidence of benefit for this indication (46). Prescription appropriateness needs to be carefully evaluated on a case-by-case basis.

Ongoing bleeding should prompt assessment of the opportunity to discontinue any medication that interferes with hemostasis. Treatments to quickly reverse the effects of anticoagulant medications are available too, such as protamine for heparin and vitamin K, alone or in association with prothrombin complex concentrates, for warfarin.

Use of Specific Agents to Improve Hemostasis

In selected cases, it is possible to use medications that directly affect the hemostatic system and ameliorate uremic bleeding, like desmopressin acetate, cryoprecipitate, estrogens, or tranexamic acid.

Desmopressin and Cryoprecipitate

Even if quantitative or qualitative defects in vWF have not been consistently demonstrated in uremia, therapies that increase vWF plasma levels, such as desmopressin acetate and cryoprecipitate, improve platelet–vWF interaction and significantly shorten bleeding time in patients with advanced CKD.

Desmopressin acetate [1-deamino-8-D-arginine vasopressin (DDAVP)] is a synthetic derivative of the antidiuretic hormone with fewer vasopressor effects. It induces the release of autologous vWF from storage sites and may also increase platelet membrane Gp expression. In two randomized, double-blind, crossover trials in uremic patients, DDAVP was effective in shortening bleeding time at the dose of 0.3 μg/kg, administered either intravenously (added to 50 mL of saline over 30 minutes) or subcutaneously (80,81). Peak responses are achieved 1 hour after intravenous administration or 1.5 to 2 hours after subcutaneous dosing. The effect lasts 6 to 8 hours, and bleeding time subsequently returns to basal values. Desmopressin can also be given by the intranasal route, which is well tolerated and safe, at 10 to 20 times the intravenous dose (3 to 6 μg/kg) (82). Desmopressin loses its efficacy when repeatedly administered, probably due to a progressive depletion of vWF stores in endothelial cells (83). Adverse effects include mild to moderate decreases in platelet count, facial flushing, transient headache, nausea, abdominal cramps, and tachycardia. Thrombotic events following DDAVP administration have been rarely reported, particularly in patients with underlying advanced cardiovascular disease. Contraction of urinary volume and hyponatremia may also seldom occur if residual diuresis is present. Thanks to its rapid onset of action, DDAVP is commonly used as the first-line hemostatic agent in patients with active severe bleeding or those who are about to undergo surgery (84).

Cryoprecipitate is a transfusional product obtained when plasma is frozen and thawed, enriched with factor VIII/vWF multimers and fibrinogen. It shortens bleeding time, enhances resolution of hemorrhages in uremic patients, and reduces blood losses in ESKD patients undergoing major surgery (85). The effect of cryoprecipitate on bleeding time is detectable by 1 hour after infusion, maximal after 4 to 12 hours (on average 8 hours) and vanishes by 24 to 36 hours. The usual dose is 10 units given intravenously over 30 minutes. Cryoprecipitate has important drawbacks: As many as 50% of patients fail to respond to it, and being a blood product, it carries a minimum, yet not negligible, risk of transmission of infectious agents. Rare but severe reactions are possible, including anaphylaxis, pulmonary edema, and intravascular hemolysis. For these reasons, the use of cryoprecipitate for uremic bleeding has been largely abandoned.

Conjugated Estrogens

The anecdotal observation of reduced gastrointestinal bleeding in uremic patients treated with conjugated estrogens and of improved hemostasis in von Willebrand disease during pregnancy led to investigations of the effect of estrogens on the bleeding tendency in uremia (86,87). Estrogens mainly ameliorate uremic bleeding by decreasing the production of L-arginine, which is a precursor of NO. Although none of the studies in this specific setting have looked into the effects of estrogens on coagulation, it is plausible that the well-documented capacity of these hormones to decrease the levels of antithrombin III and protein S and to increase factor VII concentrations play a role as well.

The minimum dose of conjugated estrogens to reduce bleeding time is 0.6 mg/kg, administered

intravenously over 30 to 40 minutes. Dosing is the same in women and men. Four or five daily infusions are needed to shorten bleeding time by at least 50% (88). The effect manifests only after several hours, becomes maximum over 5 to 7 days, and lasts up to 14 to 21 days. More data exist to support the use of intravenous estrogens, but the oral and transdermal routes have been shown to be effective as well. One oral dose of 25 mg of conjugated estrogens (Premarin) normalizes bleeding time for 3 to 10 days (88). Courses of 25 to 50 mg/day, for an average of 5 to 7 days, have been used with success in clinical studies (89). Low-dose transdermal estrogens (estradiol 50 to 100 μg/24 h), applied as a patch twice a week, effectively reduced bleeding time and lowered the risk of recurrent gastrointestinal bleeding (90). In all the clinical trials on estrogens in uremic bleeding, the hormones were administered only for a few days. With such short courses of treatment, no significant adverse effects were reported, other than hot flashes. The clinical use of estrogens in uremic bleeding is mainly reserved for selected cases where long-lasting effects are needed, for example, in the preparation of elective surgery at high hemorrhagic risk.

Tranexamic Acid

Tranexamic acid (TXA) is a potent inhibitor of the fibrinolytic system that stabilizes clots by preventing the binding of plasminogen to fibrin and the activation of plasminogen to plasmin. TXA rapidly decreases bleeding time in uremia (91). Case reports showed that TXA was effective in controlling chronic bleeding from colonic angiodysplasias (92) and spontaneous subdural and cerebral hematomas in dialysis patients (93). In a pilot study, adjunctive therapy with TXA effectively reduced rates of rebleeding in dialysis patients with major upper gastrointestinal hemorrhage. The dosage used was 20 mg intravenously, followed by 10 mg/kg/48 h orally for the next 4 weeks (94). TXA may accumulate in kidney insufficiency, and there is no evidence that it is more effective than desmopressin. Severe side effects, such as seizures (95) and visual impairment (96), have been linked to TXA overdose in dialysis patients. Intravenous TXA should therefore be considered only in the acute setting and as a second-line agent.

ABNORMALITIES OF COAGULATION AND FIBRINOLYSIS

Paradoxically, despite the hemorrhagic diathesis, uremic patients also run an increased risk of thrombosis, in particular thrombosis of the hemodialysis access and cardiovascular events.

PATHOGENESIS

Several prothrombotic alterations have been reported in uremia. Plasma levels of coagulation cascade proteins, like fibrinogen, factor VII, factor VIII (97), and tissue factor (98), rise in the setting of CKD. On the other hand, uremic patients display a downregulation in anticoagulant pathways, such as protein C activity (99) and antithrombin III activity (100). Contrasting results have been obtained regarding fibrinolysis. Seminal studies documented a decrease in fibrinolytic activity in uremia, concurring to the hypercoagulable state (101,102). Instead, later reports found evidence of enhanced activation of fibrinolysis in uremia, consistent with increases in plasmin–antiplasmin complexes and fibrinogen\fibrin degradation products, together with reduced plasminogen activator inhibitor activity (103). These findings probably reflect fibrinolytic responses secondary to fibrin deposition, taking place even if the

overall fibrinolytic activity is depressed.

Chronic endothelial injury and activation (104), with subsequent loss of thromboresistance, contribute to the prothrombotic environment. CKD patients display increased plasma levels of markers of thrombosis, like thrombin–antithrombin III complex, D-dimer (105), activated factor XII, and activated factor VII (106). Activation of coagulation parallels the low-grade inflammation of uremia that is reflected, for instance, by the rise in C-reactive protein and interleukin-6 and the decrease in albumin levels (97,107). Inflammation in turn has been increasingly recognized as a key player in the pathogenesis of atherosclerosis and cardiovascular diseases, also independently of kidney insufficiency (108). Hyperhomocysteinemia, a common finding in dialysis patients, has also been associated with endothelial dysfunction and cardiovascular events (109,110).

In the case of vascular access thrombosis, local factors, such as surgical trauma, hemodynamic shear stress, and vessel wall injury, play a prominent pathogenetic role too (111).

Additional conditions that may further increase thrombotic risk in specific subsets of dialysis patients include nephrotic syndrome, heparin-induced thrombocytopenia type 2 (HIT-II), and antiphospholipid antibodies.

Nephrotic syndrome significantly raises the risk of deep venous thrombosis and renal vein thrombosis. The latter has been reported in as many as 37% of adult patients with membranous nephropathy, who are—for unknown reasons—the group of nephrotic subjects at highest risk of thrombotic complications. Some of the best defined pathophysiologic mechanisms of thrombophilia in nephrotic syndrome include urinary loss of antithrombin III and increased synthesis of fibrinogen and coagulation factors V and VIII by the liver (112).

HIT-II is an acquired prothrombotic state due to the formation of platelet-activating antibodies following exposure to heparin. Typical manifestations include thrombocytopenia, venous or arterial thrombosis, skin necrosis at heparin injection sites, and acute systemic reactions after an intravenous bolus of heparin. In spite of frequent exposure of hemodialysis patients to heparin, full-blown HIT-II syndrome is rare. On the other hand, HIT antibodies are frequently detected in ESKD patients; for example, they were documented in 8.1% of 1,450 patients exposed to unfractionated heparin and in 1.8% of 218 patients dialyzed with low molecular weight heparin (113). The clinical significance of these findings is unclear. Several studies have reported absence of clinical sequelae despite positive antibody tests (114–116). Other authors instead have proposed that isolated thrombocytopenia, frequent clotting of the extracorporeal circuit, and higher risk of vascular access thrombosis are putative manifestations of HIT-II peculiar to dialysis patients (117,118).

Like HIT-II antibodies, antiphospholipid antibodies can be frequently detected in hemodialysis patients but in most cases are not associated with the typical syndrome of recurrent arterial/venous thrombosis and pregnancy-related adverse events. Their clinical significance in the dialysis setting has not been clearly established. An increased risk of vascular access thrombosis has been reported (119) but has not been confirmed in all settings (120).

CLINICAL FINDINGS AND TREATMENT

The most frequent thrombotic complications in dialysis patients are related to the vascular access and

include thrombosis of native arteriovenous fistulae, arteriovenous grafts, and central venous catheters. Vascular access–related thromboses account for a substantial percentage of hospital admission of dialysis patients and have a multifactorial pathogenesis. Local hemodynamic factors play a prominent role and are probably more relevant than hemostatic alterations in most cases. In particular, stenosis in the anastomosis region or the draining veins of arteriovenous fistulae and grafts, due to neointimal hyperplasia, are the usual harbinger of thrombosis (121). In the case of central venous catheters, thrombosis stems from a variable combination of the Virchow triad, including endothelial damage (initial insertion of the catheter leading to disruption in vessel walls), coagulability, and stasis (intraluminal stasis of blood in the interdialytic period) (122). Central vein thrombosis and right atrial thrombus can be serious complications.

No intervention, including administration of anticoagulant and antiplatelet agents, has been demonstrated to consistently improve vascular access patency with a favorable risk/benefit profile. Management is based on clinical monitoring of the vascular access and multidisciplinary approach in case of thrombosis, including personalized prescription of antithrombotic therapy and surgical/interventional radiology maneuvers.

Cardiovascular events are the predominant cause of morbidity and mortality in uremic patients and include acute coronary syndromes, heart failure, cerebrovascular events, and peripheral artery diseases. Even after adjustment for other risk factors, cardiovascular mortality is 10 to 20 times higher in dialysis patients than in the general population (123). Pathogenesis is complex, and hemostatic alterations alone likely play only a marginal role. An intricate, only partially understood interaction between traditional cardiovascular risk factors and elements peculiar to the uremic milieu, like uremic toxins and derangements in mineral metabolism, probably takes place.

There have not been major clinical trials directly addressing the management of cardiovascular events in dialysis patients. The therapeutic approach is therefore not significantly different from that adopted in the general population and includes a combination of pharmacologic, endovascular, and surgical treatments.

CHAPTER 29

Treatment of Anemia in Patients with End-Stage Kidney Disease

Yaakov Liss and Jeffrey S. Berns

ANEMIA AND END-STAGE KIDNEY DISEASE: THE MAGNITUDE OF THE PROBLEM

Anemia, or reduced erythrocyte mass, is one of the most clinically significant complications of chronic kidney disease (CKD) and is associated with increased mortality and decreased quality of life. Although there is no universal definition of anemia, recent guidelines recommend diagnosing anemia in adult men with a hemoglobin (Hb) <13.0 g/dL and in adult females with an Hb <12.0 g/dL (1). Anemia is highly prevalent among patients with CKD and end-stage kidney disease (ESKD), with an increase in the rate and severity of anemia associated with a decrease in glomerular filtration rate (GFR) and the near universal prevalence of anemia in patients on chronic dialysis (2,3). Recent data from the National Health and Nutrition Examination Survey (NHANES) demonstrated a prevalence of anemia in predialysis patients with CKD stage 5 of 53.4%. The prevalence of anemia increases as patients initiate chronic dialysis therapy, with 85% of patients on chronic dialysis reported to have an Hb <12.0 g/dL by the 2014 United States Renal Data System (USRDS) annual report (4).

Numerous observational studies have shown that the presence and severity of anemia correlate with numerous adverse outcomes including increased mortality (5–7), left ventricular hypertrophy (LVH) (8,9), and decreased health-related quality of life (10,11). However, randomized control trials have not demonstrated a mortality benefit for the treatment of anemia with the use of erythropoiesis-stimulating agents (ESAs) in patients with CKD or ESKD, and some studies even suggest harm.

Despite the overwhelming prevalence of anemia in patients with ESKD and the clear association of anemia with significant morbidity and mortality, the degree to which anemia should be corrected and the optimal strategy for doing so is controversial. This chapter focuses on the treatment of anemia in patients with ESKD. We first review normal erythrocyte production and the normal response to anemia followed

by a discussion of the various pathophysiological processes which lead to anemia in patients with ESKD before discussing treatment directly, as an understanding of the former topics are vital to successfully employing the latter.

NORMAL ERYTHROCYTE PRODUCTION

Under normal conditions, approximately 1% of circulating erythrocytes are replaced daily. Erythrocyte production occurs in the bone marrow and depends on erythropoietin (EPO), a hormone which is mainly produced in the kidneys, and regulates erythropoiesis via binding to EPO receptors on erythroid precursor cells located in the bone marrow. The proper functioning of this process requires additional cofactors including iron, vitamin B_{12}, and folic acid.

EPO is the major regulatory hormone of erythropoiesis and is produced primarily in peritubular interstitial cells of the kidney with lesser production in the liver postnatally (12,13). EPO production is modulated by the delivery of oxygen from circulating erythrocytes; in the presence of tissue hypoxia, EPO production is increased. On a cellular level, this process occurs due to the presence of hypoxia-inducible factors (HIFs) in EPO-producing cells, specifically HIFα and HIFβ (14). Under normoxic conditions, HIFα is constitutively produced and subsequently degraded by the ubiquitin-proteasome system. This degradation is dependent on the hydroxylation of HIFα via specific hydroxylase enzymes, which allow for the binding of HIFα to the tumor suppressor protein von Hippel-Lindau (VHL). This leads to the HIFα molecule being tagged for proteasomal degradation. Under hypoxic conditions, HIFα degradation is inhibited, allowing for the successful production of EPO. EPO is then secreted into the systemic circulation where it binds with EPO receptors on erythroid precursor cells in the bone marrow, leading to increased production of erythrocytes by preventing erythroid cell apoptosis (15).

In order for successful erythropoiesis to occur, an adequate supply of iron, B_{12}, and folate are necessary. Iron balance is a highly regulated process, and iron deficiency, either absolute or functional, significantly contributes to anemia of CKD. The successful production of erythrocytes depends on both adequate nutritional iron stores and the mobilization of these stores for use by the bone marrow. The master regulator of this process is hepcidin (16,17). Elevated hepcidin levels inhibit duodenal iron absorption and iron release from macrophages, whereas decreased hepcidin levels promote gastrointestinal (GI) absorption and mobilization from macrophages. Hepcidin production is stimulated by total body iron overload and infection (18).

UNDERLYING ETIOLOGIES OF ANEMIA OF CHRONIC KIDNEY DISEASE

Anemia in patients with CKD is, as a rule, a multifactorial process. While EPO deficiency is usually the primary pathophysiological process (19), iron deficiency anemia related to chronic blood loss and anemia of chronic disease related to comorbidity burden and the malnutrition–inflammation complex syndrome (20) both play significant contributory roles. Other causes for anemia found in the general population can also be superimposed on the above processes and should be considered when evaluating a patient with CKD and anemia.

In healthy patients, EPO levels increase in response to anemia. In patients with CKD, there is an inadequate response, and EPO levels are inappropriately low relative to the degree of anemia (21,22). While patients with CKD and ESKD (including anephric patients) continue to produce EPO and have been shown to increase EPO production (23), the response in EPO production is blunted and inadequate to sufficiently correct the anemia. The explanation for inadequate EPO production has historically implicated reduced nephron mass and loss of EPO-producing peritubular interstitial cells. However, recent evidence including clinical trials that have demonstrated that EPO production can be increased in patients with ESKD via pharmacological stabilization of HIF using prolyl hydroxylase inhibitors (24) raises the possibility that a disturbed oxygen-sensing mechanism rather than a lack of capacity for EPO production may be the primary cause of anemia.

ESKD and chronic hemodialysis (HD) inevitably lead to negative iron balance, primarily as a result of chronic blood loss through several different mechanisms. Patients with ESKD are more likely to have both overt and occult GI bleeding (25,26). Additionally, significant blood loss occurs both due to frequent phlebotomy as well as due to the HD procedure itself (27). In addition to absolute iron deficiency, patients with ESKD have a frequently impaired ability to absorb iron or utilize their existent iron stores due to ongoing inflammation (20).

There are several other processes that may contribute to anemia in patients with CKD that are worth mentioning. It has been known for some time that patients with CKD have a shortened erythrocyte survival time (28). Neither the precise pathophysiological cause of this phenomenon nor the degree to which this shortened survival contributes to anemia is entirely clear. However, it is unlikely that dialysis modality plays a significant role, as studies have shown no significant difference in the decrease in erythrocyte survival time between peritoneal dialysis, conventional thrice-weekly HD, nocturnal HD, or short daily HD (29,30). Furthermore, while the toxic uremic milieu is frequently cited as the probable cause for shortened erythrocyte survival, more frequent HD has shown no benefit in improving anemia (31).

Folate and vitamin B_{12} deficiency, while not common, are both readily reversible causes of anemia. These diagnoses should be tested for, particularly in the setting of macrocytosis. While there is loss of folate with dialysis, normal dietary intake should exceed such losses (32).

Historically, aluminum toxicity was a significant cause of anemia in patients with ESKD on dialysis, both due to the use of aluminum-containing phosphate binders and due to the presence of aluminum in water used for dialysis (33). Its incidence has waned significantly due to the now routine removal of aluminum from dialysis water and due to the wide availability of non–aluminum-containing phosphate binders. Aluminum toxicity–related anemia presents as a microcytic anemia in the presence of adequate iron stores (34).

Given the universal polypharmacy of patients with ESKD, it is important to consider medications and their potentially contributory role to anemia. The myelosuppressive effects of immunosuppressants, commonly used in the setting of solid organ transplants or systemic autoimmune conditions, are well known and well described. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) have also been causally implicated in CKD-related anemia, although the evidence is primarily composed of case reports and small case series (35–37). Experimental data in rats demonstrates that angiotensin plays a role in EPO production (38), and it is therefore plausible that angiotensin blockade would impair EPO production and lead to anemia. While observational studies in

patients on chronic dialysis have shown mixed results regarding the relationship between ACE inhibitor and ARB use with ESA dose (39,40), several uncontrolled studies did show the need for increased ESA dosing in patients receiving ACE inhibitors or ARBs (41,42).

TREATMENT OF ANEMIA OF CHRONIC KIDNEY DISEASE

The initial step in the treatment of anemia in patients with ESKD involves a basic diagnostic workup to identify the numerous processes that may be contributing to the anemia. Recent Kidney Disease Improving Global Outcomes (KDIGO) guidelines recommend that initial testing for patients with CKD and anemia includes complete blood count (CBC), absolute reticulocyte count, serum ferritin level, serum transferrin saturation (TSAT), and serum vitamin B_{12} and folate levels (1).

While tests for serum EPO levels are commercially available, these tests are not recommended since they are unlikely to affect clinical care given the lack of correlation between absolute EPO levels and the degree of anemia in patients with a creatinine clearance of less than 40 mL/min (43). As such, it can be assumed that all patients with advanced CKD and ESKD have EPO deficiency; however, it is recommended to first treat any correctable causes of anemia prior to initiating treatment with ESAs (1). This recommendation is predicated upon the fact that ESA responsiveness is unlikely in patients with additional causes of hypoproliferative anemia such as iron, vitamin B_{12}, or folate deficiency. Furthermore, correction of these underlying issues can significantly reduce the dose of or need for ESA use. In particular, iron deficiency is exceedingly common in patients with CKD and ESKD, and numerous randomized studies have demonstrated that iron supplementation reduces ESA requirements (44–48).

DETERMINATION OF IRON STATUS

In healthy patients with an isolated finding of anemia, the diagnosis of iron deficiency anemia is generally clinically obvious and determined by the presence of numerous consonant factors including a low-reticulocyte index, low mean corpuscular volume (MCV), decreased iron stores based on decreased serum ferritin levels, and decreased iron availability based on decreased serum TSAT. In patients with anemia of CKD, straightforward determination of iron status is generally the exception rather than the rule. Iron stores may be present but not available for erythropoiesis, and serum ferritin levels are frequently normal or even increased without a concomitant increase in serum TSAT or even a decreased TSAT. Despite this laboratory discrepancy in iron status, studies have demonstrated that the administration of supplemental iron to patients with elevated ferritin levels can still improve the anemia (48,49), rendering serum ferritin a rather poor marker of ESA response. Given the complexity with accurately determining the iron status of patients with CKD, numerous additional serologic tests have been explored, including erythrocyte zinc protoporphyrin (50), percentage of hypochromic red blood cells (51), reticulocyte Hb content (52), and serum hepcidin (53). Thus far, none of these tests have been incorporated into routine clinical practice due to a lack of consistent results over numerous studies, lack of commercial availability, or lack of utility in meaningfully impacting current clinical practice. For now, guidelines recommend determining iron status by serum ferritin and TSAT alone; ultimately, when uncertainty still remains, iron status is determined by the administration of supplemental iron and the

presence or absence of an erythropoietic response.

TREATMENT OF IRON DEFICIENCY

Therapeutic Targets

The treatment of anemia in patients with ESKD almost always involves both the use of intravenous (IV) iron and the use of ESAs, and an increased dose in the first of these agents generally allows for a reduced dose in the last. Safety concerns related to ESA use, shifting market pressures, and small studies demonstrating the ability to decrease ESA use by targeting higher levels of ferritin and TSAT have led to changing serum iron marker targets over time. The 2006 Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines recommended administering IV iron to achieve a serum ferritin greater than 200 ng/mL and a TSAT greater 20% (54). The 2012 KDIGO guidelines recommend the administration of IV iron if serum ferritin is less than 500 ng/mL or TSAT is less than 30% and an increase in Hb or decrease in ESA dose is desired (1). Routine administration of iron to patients with serum ferritin levels greater than 500 ng/mL or TSAT greater than 30% is recommended against due to a lack of data demonstrating the safety of this approach, but this may be considered on an individual patient basis, particularly when a reduction in ESA dose is desired.

Two randomized control studies specifically evaluated the use of IV iron to achieve different iron targets and its effect on anemia parameters. A study by Besarab et al. (48) randomized 43 patients to receive maintenance IV iron dextran to maintain TSAT 20% to 30% versus increased doses of IV iron dextran to achieve TSAT 30% to 50% over 6 months and demonstrated comparable Hb levels in both groups with increased ferritin levels and a 40% decrease in ESA dosing in the increased IV iron group. The Dialysis Patients' Response to IV Iron with Elevated Ferritin (DRIVE) study by Coyne et al. (49) randomized 134 patients with a serum ferritin of 500 to 1,200 ng/mL, and a TSAT <25% over a 6-week period to 1 g of IV ferric gluconate administered with HD over eight doses versus placebo while receiving EPO at a 25% increased dose from baseline with further titration prohibited over the duration of the study. Results demonstrated a 0.5 g/dL increase in Hb in the IV ferric gluconate group versus the placebo group.

While the above studies demonstrate that iron supplementation can improve anemia parameters even in patients with significantly elevated iron stores, there are no studies adequately powered with long enough follow-up to demonstrate long-term benefit or harm related to employing a strategy that favors the administration of iron over the use of ESAs (55).

Route of Administration

There is general agreement that IV iron is the preferred route of iron administration to patients with ESKD and that oral iron is inadequate to replete deficient iron stores. A recent meta-analysis of 28 studies involving 2,098 subjects demonstrated increased ferritin, increased TSAT, increased Hb, and decreased ESA dose with the use of IV versus oral iron (56). The accepted explanation for reduced effectiveness of oral iron has implicated elevated hepcidin levels from chronic inflammation leading to poor GI absorption. Interestingly, recent trials involving ferric citrate, an oral iron-containing phosphate binder, have demonstrated a decreased need for IV iron and ESA doses (57). It remains to be seen how the use of oral iron-containing phosphate binders will impact the overall management of anemia in patients with

CKD.

Parenteral Iron Preparations

Sixty-two percent of patients with ESKD on HD regularly received IV iron in 2012 according to data from the USRDS (4). There are currently several parenteral iron preparations available for use in the United States: iron dextran, iron sucrose, ferric gluconate, ferric carboxymaltose, and ferumoxytol. Iron isomaltoside is available for use in Europe but is not currently U.S. Food and Drug Administration (FDA) approved. Data from Dialysis Outcomes and Practice Pattern Study (DOPPS) demonstrate that approximately 90% of IV iron administered in the United States in 2015 was an iron sucrose formulation, with the remainder consisting almost entirely of ferric gluconate (58).

Most IV iron preparations consist of iron associated with a carbohydrate shell. The infusion of IV iron and the release of free iron can lead to a range of anaphylactoid and other reactions including myalgias, arthralgias, facial flushing, and hypotension, although there is a relatively low risk for the occurrence of serious adverse events (59), with a predicted absolute risk of life-threatening events ranging from 0.6 to 11.3 events per million depending on the IV iron preparation used (60). Details of the various IV iron preparations are discussed below (**TABLE 29.1**).

TABLE 29.1 Intravenous Iron Preparations

Generic Drug	Trade Name	Commonly Used Single Dose	Elemental Iron Concentration (mg/mL)	Test Dose?
Iron dextran (high molecular weight)	Dexferrum	100 mg	50	Yes
Iron dextran (low molecular weight)	INFeD	100 mg	50	Yes
Iron sucrose	Venofer	200–300 mg	20	No
Ferric gluconate	Ferrlecit	125 mg	12.5	No
Ferumoxytol	Feraheme	510 mg	30	No
Ferric carboxymaltose	Ferinject	20 mg/kg (maximum 1,000 mg)	50	No
Iron isomaltoside	Monofer (not available in United States)	20 mg/kg	100	No

Iron Dextran

Iron dextran is available in the United States in both a high molecular weight formulation (Dexferrum) and a low molecular weight formulation (INFeD). While KDIGO guidelines strongly recommend close monitoring of all patients during their initial dose of iron dextran (1) due to an increased risk of severe anaphylactic reactions, several studies suggest that the increased risk of severe anaphylactic reactions is limited largely to the use of high molecular weight formulations (61,62). The use of low molecular weight iron dextran appears to have an equivalent risk of adverse reactions to other commonly used IV iron preparations (63). Iron dextran is available in 1- or 2-mL solutions of 50 mg/mL. The package insert recommends administration of a test dose of 25 mg prior to the administration of a full dose. Furthermore, KDIGO guidelines recommend that patients be monitored for 60 minutes after their initial infusion of iron dextran and that resuscitative personnel be available at the time of infusion. While the package insert recommends a maximum dose of 100 mg daily, the administration of 1,000 mg of iron dextran over 1 hour has been shown to be safe and effective (64).

Iron Sucrose

Iron sucrose (Venofer) is widely used in the United States and worldwide for the treatment of CKD-associated anemia. It appears to have a superior safety profile to iron dextran and an equivalent safety and efficacy profile to other IV iron preparations (65,66). It is available in 2.5-, 5-, or 10-mL solutions of 20 mg/mL. The package insert states that there is no need for a test dose in product-naive patients. KDIGO guidelines suggest monitoring patients for 60 minutes after the initial infusion of iron sucrose but mention that the data to support this suggestion is not strong. The package insert states that a dose of up to 200 mg can be given over a 2- to 5-minute IV infusion. Doses of 300 mg should be given over 1.5 hours. It is not recommended to administer doses above 300 mg, as this has been associated with a significant rate of adverse reactions including dizziness, nausea, and hypotension (67).

Ferric Gluconate

Ferric gluconate (Ferrlecit) was available for use in Europe for many decades before being FDA approved in 1999. It is safer than iron dextran with comparable safety and efficacy to other IV iron preparations (68,69). It is available in 5-mL solutions of 12.5 mg/mL. The package insert states that prior labeling recommended a test dose of 2 mL, but a test dose is no longer recommended. KDIGO guidelines suggest monitoring patients for 60 minutes after the initial infusion of ferric gluconate but mention that the data to support this suggestion is not strong. The package insert recommends a maximum dose of 125 mg which can be infused over 1 hour, although the infusion of 250 mg over 1 hour appears to be safe (70). There is little data available to support the safety of administering larger one-time doses.

Ferumoxytol

Ferumoxytol (Feraheme) was FDA approved for the treatment of anemia in patients with CKD in 2009. It possess supermagnetic properties and can affect magnetic resonance imaging (MRI) for days to months after its administration (71). Randomized trials have demonstrated ferumoxytol to have comparable efficacy and safety to other IV iron preparations (65,72). It is available in 17-mL solutions of 510 mg/17 mL. The package insert does not indicate the need for a test dose but recommends patient monitoring for at least 30 minutes after infusion in a setting where proper personnel and therapies are immediately available. While ferumoxytol was initially recommended to be administered as a rapid injection of 510 mg over 17 to 60 seconds, this was suggested to lead to an increased rate of anaphylactic reactions (73); subsequent recommendations suggest administering ferumoxytol in a diluted form over a slow infusion of at least 15 minutes. Although the maximum recommended dose is 510 mg, administering 1,020 mg as a one-time dose has been shown to be safe and efficacious (74).

Ferric Carboxymaltose

Ferric carboxymaltose (Injectafer) was FDA approved for anemia in non–dialysis-dependent CKD in 2013. Several randomized trials demonstrated superior efficacy with comparable safety of ferric carboxymaltose versus oral iron in patients with anemia not related to CKD (75–77). Additionally, one randomized trial demonstrated superior efficacy with comparable safety of ferric carboxymaltose versus oral iron in patients with non–dialysis-dependent CKD (78), and one randomized trial demonstrated comparable efficacy and safety between two injections of 750 mg of ferric carboxymaltose given over 1

week versus five injections of 200 mg of iron sucrose given over 2 weeks in patients with non–dialysis-dependent CKD (79). There is very little published data available at this time evaluating the safety and efficacy of ferric carboxymaltose in patients with ESKD. Ferric carboxymaltose is available in 15-mL solutions of 750 mg/15 mL. There is no mention of requiring a test dose in the package insert, and there is no specific recommendation by the FDA to monitor patients after their initial infusion. Of note, ferric carboxymaltose infusion was associated with transient hypertensive episodes (79).

Iron Isomaltoside

Iron isomaltoside (Monofer) is currently not FDA approved and is only in use outside of the United States. It can be administered as a 15-minute infusion with doses of >1,000 mg given at one time.

Iron Loading and Maintenance Therapy

There are generally two phases in the treatment of iron deficiency in anemic patients with ESKD: iron loading and maintenance therapy. Iron loading is the use of IV iron to correct iron deficiency. Maintenance therapy is the ongoing administration of IV iron in iron-replete patients who are usually receiving concurrent ESA therapy. As discussed earlier, current guidelines (1) recommend administering IV iron to patients with a TSAT <30% and a ferritin <500 ng/dL when an increase in Hb is desired. Most iron loading regimens recommend the intensive administration of approximately 1,000 mg of IV iron over a relatively short time period. This can be done over relatively few treatments with the use of iron dextran, ferumoxytol, or ferric carboxymaltose but would require more treatments with the use of iron sucrose and ferric gluconate. During the iron loading phase, it is recommended to check the CBC, TSAT, and ferritin frequently to ensure that the treatment is achieving its goals. It is recommended to ensure that iron stores are replete prior to initiating ESA therapy, as the administration of an ESA to an iron deficient patient has a high probability of failure. Once iron stores are replete and Hb and iron indices are stable, laboratory test results can be checked every 3 months (1).

Once iron stores are replete, there are two possible strategies regarding maintenance therapy: intermittent dosing of IV iron when iron indices fall below target or continuous dosing of IV iron to maintain iron indices above target. Theoretically, continuous dosing of IV iron is more likely to ensure that iron stores remain adequate, allowing for the possibility of continued, effective erythropoiesis (80). Several randomized trials evaluated the use of continuous IV iron versus intermittent administration in iron-replete patients and demonstrated superiority of a continuous dosing regimen with either a higher Hb achieved or an equivalent Hb with a reduced ESA dose (81,82).

Maintenance Therapy via Iron-Containing Dialysate

A newly tested method of maintenance administration of IV iron to patients with ESKD who are iron replete involves the addition of ferric pyrophosphate citrate (FPC) (Triferic), a water-soluble iron salt, to the dialysis solution, allowing for routine administration of low doses of IV iron with each dialysis treatment. Two identical randomized trials, Continuous Replacement Using Iron Soluble Equivalents (CRUISE) 1 and 2 (83), evaluated the effects of the use of dialysate containing 2 μmol/L of FPC iron versus standard dialysate in 599 patients on a fixed dose of ESA with prohibited supplemental iron use and demonstrated that FPC-containing dialysate maintained steady Hb levels with less of a decrease in ferritin levels versus the placebo group. An additional randomized trial, Physiological Replenishment

Iron Maintenance Equivalency (PRIME) (84), evaluated the use of dialysate containing 2 μmol/L FPC iron versus standard dialysate in 103 patients on adjustable doses of ESAs and IV iron to be administered when serum ferritin levels decreased below 200 μg/L and demonstrated a decrease in ESA dose and decrease in IV iron need versus placebo. FPC (Triferic) was FDA approved as an iron replacement product to maintain Hb in adult patients with HD-dependent CKD in January 2015.

Adverse Effects of Intravenous Iron

As discussed earlier, all IV iron preparations are associated with anaphylactic-type reactions which at times can be life threatening. Excluding high molecular weight iron dextran which carries an increased risk, the absolute risk of a life-threatening serious adverse event has been estimated to be approximately 1 in 200,000 with commonly used IV iron preparations (60).

Theoretically, an iron-rich environment can promote bacterial growth, and the administration of IV iron to patients with active infection is contraindicated (1). Despite this recommendation, the evidence linking the administration of IV iron to an increased infection risk is mixed and of low quality. A retrospective study of 32,566 patients (85) showed no association between IV iron dose and infection-related mortality; a prospective, observational study of 985 patients (86) showed no association between IV iron use and infection risk; a retrospective study of 117,050 patients (87) demonstrated an increased risk of infection-related hospitalization in patients receiving higher dose intermittent versus lower dose maintenance IV iron therapy; a meta-analysis of 72 randomized controlled trials involving 10,605 patients (88) demonstrated an increased risk of infection with the use of IV versus oral or no iron; a retrospective study of 14,078 patients (89) showed no significant increased risk of infection-related mortality with IV iron dose but did demonstrate a nonsignificant trend of increased infection-related mortality in patients receiving >1,050 mg of IV iron over 3 months or >2,100 mg IV iron over 6 months; and a retrospective study of 22,820 patients on chronic HD (90) demonstrated that IV iron administration in the setting of hospitalization for infection was not associated with an increased risk of readmission for infection, increased length of stay, or mortality. A recent trial by Agarwal et al. (91) randomized 136 patients with CKD stage 3 or CKD stage 4 to IV versus oral iron and demonstrated no significant difference in serious adverse events between the two groups. However, there was incomplete randomization, and adjustment after randomization did demonstrate a significant increase in the adjusted risk of serious adverse events including infection-related adverse events in patients receiving IV iron versus oral iron. Given the incomplete randomization, the findings of this study are difficult to interpret.

The relationship between IV iron use and overall mortality is not entirely clear at this time. A retrospective study of 32,566 patients (85) showed no association between IV iron dose and overall mortality; a retrospective study of 32,435 patients (92) demonstrated an increased risk of mortality in those receiving >300 mg/mo of IV iron; a prospective study of 58,058 patients (93) demonstrated a decreased risk of overall mortality with the use of up to 400 mg/mo of IV iron versus no iron but an increased risk of mortality with a dose of >400 mg/mo of IV iron; and a retrospective study of 14,078 patients (89) showed a decreased risk of overall mortality with the use of 150 to 350 mg/mo or >350 mg/mo of IV iron compared to 0 to150 mg/mo.

A paucity of adequately powered randomized trials of sufficient duration makes it difficult to evaluate the long-term risks and benefits of IV iron use at this time.

ERYTHROPOIESIS-STIMULATING AGENTS

Historically, anemia was an inevitable consequence of ESKD and was only treatable by regular blood transfusions, presenting a significant source of morbidity in patients with ESKD. With the advent of recombinant human erythropoietin (rHuEPO) in the 1980s, anemia became a treatable problem, with the potential of improving Hb to normal levels. Over time, additional drugs have been developed which are either derivatives of the EPO molecule or are different molecules which can directly or indirectly stimulate the EPO receptor. These medications are all grouped under the class of drugs commonly referred to as ESAs.

Epoetin

Epoetin is a term generally applied to rHuEPO preparations produced using recombinant technology via the overexpression of the human EPO gene in mammalian cell lines. Epoetin-α and epoetin-β were the first two of these compounds developed, and both are produced in Chinese hamster ovary cells. Epoetin-α is the only epoetin currently available in the United States. Several nonrandomized trials in the late 1980s demonstrated the ability of rHuEPO to increase Hb levels in patients with ESKD (94–97), leading to FDA approval of epoetin-α (Epogen; Procrit).

A number of additional epoetin preparations have been developed and are available for use outside of the United States. In particular, epoetin biosimilars, which are drugs designed as copies of either epoetin-α or epoetin-β, have been available in Europe since 2007 (98). Due to the high molecular complexity of biological medications, small changes can have a significant impact on clinical outcomes. Therefore, the FDA and other international drug-related authorities have a rigorous approval process for biosimilar medications. The potential effects of changing the formulation process of epoetins was demonstrated by the global increase in cases of pure red cell aplasia (PRCA) that occurred after subcutaneous (SC) Eprex, an epoetin-α product, was changed to an albumin-free formulation (99). There are currently no biosimilar epoetins available for use in the United States, but these drugs are expected to become available within the next few years. Details of the various epoetins are discussed below (**TABLE 29.2**).

TABLE 29.2 Epoetins

Generic Drug	Trade Name	Recommended Single Dose	Recommended Dosing Frequency	Route of Administration
Epoetin-α	Epogen; Procrit	50–100 U/kg	Three times per week	IV or SC
Epoetin-β	NeoRecormon (not available in United States)	40–100 U/kg	Three times per week	IV or SC
Darbepoetin-α	Aranesp	0.45 μg/kg weekly or 0.75 μg/kg every 2 weeks	Weekly or every 2 weeks	IV or SC
Methoxy polyethylene glycol-epoetin β	Mircera (limited United States availability)	0.6 μg/kg	Once every 2 weeks	IV or SC

IV, intravenous; SC, subcutaneous.

Epoetin Route of Administration

Several routes of epoetin administration have been studied including IV, SC, and intraperitoneal. Intraperitoneal epoetin was found to have a bioavailability of only 3% to 8% (100) with a requirement

for significantly higher doses compared to the SC route (101); it is therefore not commonly used in clinical practice. IV epoetin has a half-life of approximately 4 to 12 hours, and levels return to baseline after 2 to 3 days (100). SC epoetin has 20% to 30% bioavailability with a peak concentration at 18 hours, which is only 5% to 10% of the level that would be detected with an equivalent dose of IV epoetin; however, the levels decay much more slowly with SC administration and are still detectable 4 days later. The pharmacokinetic profile of SC epoetin appears to possess advantages over the IV route, and it has been shown that SC epoetin can maintain the same levels of Hb as IV epoetin with a 30% decrease in dose (102). Additionally, given the slower rate of decay, weekly administration of SC epoetin appears to be as effective as IV epoetin (103), whereas IV epoetin is recommended to be given thrice weekly.

The 2012 KDIGO guidelines (1) suggest that for patients with ESKD on HD, either the IV or SC route is acceptable for ESA administration, and data from DOPPS demonstrates that over 90% of patients on HD in the United States receive ESA therapy intravenously (58). A retrospective study of 62,710 patients on HD (104) demonstrated a small but significant increase in a composite outcome of death and/or cardiovascular hospitalizations among patients receiving IV versus SC epoetin-α. The study authors attributed this increased risk to the 25% increased dose of ESA used in the IV group, although they acknowledge that any conclusion from this study must be further qualified given its retrospective nature.

Darbepoetin-α

Darbepoetin-α is an EPO derivative with additional glycosylation sites which allows for an increased plasma half-life. The half-life for IV use is 25.3 hours versus 8.5 hours for epoetin (105), and SC administration has a bioavailability of 37% with a half-life of 48.8 hours. Darbepoetin appears to have comparable safety and efficacy to epoetin at a reduced dosing interval of weekly or every other week (106,107). As opposed to epoetin, there appears to be similar efficacy between IV and SC dosing (108). The conversion factor of epoetin to darbepoetin is approximately 200 U of epoetin to 1 μg of darbepoetin-α.

Methoxypolyethylene Glycol Epoetin-β

Methoxypolyethylene glycol-epoetin β, also called continuous EPO receptor activator (CERA), is a pegylated epoetin-β derivative with a half-life of approximately 130 hours when administered intravenously or subcutaneously (109). Numerous studies have shown that CERA has comparable safety and efficacy to EPO when given either once every 2 weeks or every 4 weeks (110). CERA is currently FDA approved for use in the United States under the brand name Mircera but is not commonly available for use at this time.

A meta-analysis comparing the safety and efficacy of epoetin-α, epoetin-β, darbepoetin-α, methoxypolyethylene glycol-epoetin β, and biosimilar ESAs concluded that there is insufficient evidence to suggest the superiority of any ESA formulation over another and suggested that consideration of drug cost, availability, and dosing frequency should be used to determine choice of specific ESA therapy (111).

Peginesatide

Peginesatide is an EPO-mimetic peptide that binds to the EPO receptor and increases Hb by stimulating EPO production (112). It has an amino acid sequence unrelated to that of rHuEPO and was specifically

recommended for use in patients with antibody-mediated red cell aplasia (1). Peginesatide was FDA approved for use in 2012, but the product was subsequently removed from the market due to a high rate of hypersensitivity reactions occurring in 0.2% of patients and fatal reactions occurring in 0.02% of patients. Peginesatide is no longer available for use.

Hypoxia-Inducible Factor Stabilizers

The HIF stabilizers are a class of oral medications that are currently undergoing clinical trials to assess their efficacy and safety in the treatment of anemia in patients with CKD and ESKD. They increase endogenous EPO production by inhibiting prolyl hydroxylase, which subsequently prevents degradation of HIFα, leading to increased endogenous EPO production by renal peritubular cells and hepatocytes (14). In addition to stimulating endogenous EPO production, HIF also plays a role in iron metabolism, and HIF stabilizers may also improve anemia by enhancing iron absorption and iron mobilization. A randomized trial of 4 weeks of oral roxadustat (FG-4592), a first-in-class prolyl hydroxylase inhibitor, versus placebo in patients with non–dialysis-dependent CKD demonstrated an average of a 1.7-g/dL increase in Hb with a concurrent decrease in serum hepcidin levels with roxadustat use (113). There are currently six different drugs in the HIF stabilizer class undergoing phase I to III clinical trials testing their overall safety and efficacy, with numerous trials comparing various HIF stabilizers to epoetin-α or darbepoetin-α. Given their success thus far in early trials, there is a strong possibility that in the next several years, HIF stabilizers will provide an additional option to the nephrologist managing anemia in patients with CKD and ESKD.

CLINICAL TRIALS: RISKS, BENEFITS, AND TARGET HEMOGLOBIN

With the advent of rHuEPO, the management of anemia in patients with ESKD dramatically improved, with a significant decrease in transfusion requirements, a decrease in iron overload caused by frequent transfusions, and the ability to achieve an almost normal Hb value in the overwhelming majority of patients with ESKD with relative ease. However, despite these apparent benefits, initial studies that first lead to FDA approval of rHuEPO in 1989 were generally nonrandomized studies involving relatively small numbers of patients being monitored for a relatively short duration. As such, the long-term safety and overall benefit of ESAs were never established initially. Since that time, several large-scale randomized controlled trials have been done in several different patient populations including patients with malignancy-associated anemia, patients with CKD not on dialysis, and patients with ESKD on dialysis. As will be discussed in greater detail, in each of these populations, these trials have raised concerns with the overall safety of ESAs.

Erythropoiesis-Stimulating Agent Use in Patients with Malignancy-Associated Anemia

Epoetin-α and darbepoetin-α are both FDA approved for the treatment of malignancy-associated anemia. While studies have consistently shown that ESAs are effective in raising Hb levels, decreasing transfusion requirements, and improving quality of life, several meta-analyses have raised concerns with

the long-term safety of ESAs in this patient population. A meta-analysis from 2012 of 91 trials involving 20,102 patients being treated with ESAs for malignancy-associated anemia demonstrated a decrease in transfusions and an improvement in quality of life but an increase in mortality during the active study period and an increase in thromboembolic events (114). A randomized trial of epoetin-β versus placebo in 351 patients with head and neck cancer demonstrated increased tumor progression with ESA use (115), but an adverse relationship of ESA use and tumor growth has not been consistently shown, with no relationship between ESA use and tumor growth seen in the aforementioned meta-analysis and several other randomized trials (116,117). Given the safety concerns of ESA use in patients with malignancy, with a possible increase in tumor growth, thromboembolic events, and death, current guidelines recommend against the use of ESAs in patients receiving myelosuppressive chemotherapy when the anticipated outcome is cure and recommend a target Hb level of 10 to 12 g/dL when using ESAs for malignancy-associated anemia.

Erythropoiesis-Stimulating Agents Use in Patients with End-Stage Kidney Disease

Several large randomized trials have been done comparing various Hb targets in patients with ESKD which have raised concerns with the overall safety of ESAs. The largest trial done in patients with ESKD was the U.S. Normal Hematocrit (HCT) Trial (118) which randomized 1,233 patients with ESKD on HD and evidence of congestive heart failure (CHF) or ischemic heart disease to receive increasing doses of epoetin to achieve a hematocrit target of 42% versus a hematocrit target of 30%. The trial was halted early due to an increase in both deaths and nonfatal myocardial infarctions in the normal hematocrit group, although this result did not achieve statistical significance since the trial was stopped prior to the possibility of this occurring. The normal hematocrit group required significantly fewer transfusions and had a significant improvement in their physical function score but also had a significant increase in the incidence of thrombosis of the vascular access site. While numerous past studies have demonstrated that ESA use increases blood pressure and the rate of hypertension (95,119), there was no significant difference in blood pressure between the two groups in the Normal HCT Trial. Given that the Normal HCT Trial included only ESKD patients with underlying cardiac disease, an additional trial was conducted in patients with ESKD on HD with an absence of symptomatic cardiac disease and a lack of left ventricular dilatation on cardiac imaging to determine if normalization of the Hb in this subpopulation of patients with ESKD had a beneficial effect on cardiac remodeling and ultimately cardiovascular events. The trial done by Parfrey et al. (120) randomized 596 patients with ESKD who had recently initiated HD to increasing doses of epoetin to achieve a target Hb of 13.5 to 14.5 g/dL versus a target of Hb of 9.5 to 11.5 g/dL and assessed left ventricular volume index (LVVI) as a primary outcome measure. The results demonstrated that despite an achieved Hb of 13.3 g/dL versus 10.9 g/dL in the higher versus lower Hb groups, there was no difference in LVVI or left ventricular mass index (LVMI). The higher Hb group had improved quality of life as demonstrated by an improved SF-36 vitality score. There was no overall difference in adverse events including death, cardiac events, and vascular access thrombosis, but there was a small but statistically significant increase in stroke in the higher Hb group.

Erythropoiesis-Stimulating Agent Use in Patients with Chronic Kidney Disease Not on Dialysis

Although initial trials in patients with ESKD demonstrated no long-term benefit to achieving a normal Hb

value and even raised concerns for possible harm, given that patients with CKD are a distinct patient population with improved prognosis and decreased comorbidity burden, several randomized trials were done to evaluate the risks and benefits of targeting a normal Hb in this patient population.

The Cardiovascular Reduction Early Anemia Treatment Epoetin β (CREATE) trial (121) randomized 603 patients with an estimated glomerular filtration rate (eGFR) of 15.0 to 35.0 mL/min to SC epoetin-β treatment to an Hb target of 13.0 to 15.0 g/dL versus an Hb target of 10.5 to 11.5 g/dL. Results demonstrated no significant difference between the groups in the incidence of cardiovascular events, death, or LVMI. The higher Hb group had improved quality of life scores. There was no change in overall eGFR or eGFR decline between the two groups, although the higher Hb group had a significant increase in number of patients initiating dialysis, a finding that the study investigators found difficult to interpret. There was a higher rate of hypertension in the higher Hb group, but no change in overall adverse events and no change in AV fistula thromboses.

The Correction of Hemoglobin and Outcomes in Renal Insufficiency (CHOIR) trial (122) randomized 1,432 patients with an eGFR of 15 to 50 mL/min to SC epoetin-α to a target Hb of 13.5 g/dL versus a target Hb of 11.3 g/dL. The trial was stopped early due to a statistically significant increase in the primary end point of a composite of death, myocardial infarction, hospitalization for CHF, and stroke in the higher Hb group. None of the composite end points individually achieved statistical significance, but a near-significant increase in both deaths and CHF hospitalizations led to a statistically significant increase in the overall primary end point. Additionally, there was no improvement in quality of life scores in the higher Hb group, nor was there a significant difference in progression to ESKD. There was also an increase in serious adverse events in the higher Hb group.

The Time to Reconsider Evidence for Anaemia Treatment (TREAT) trial (123) is the largest trial to date of an ESA and randomized 4,038 patients with diabetes and an eGFR of 20 to 60 mL/min to SC darbepoetin-α to a target Hb of 13 g/dL versus placebo with the availability of darbepoetin-α rescue therapy only when the Hb decreased below 9.0 g/dL. There was no significant difference between the two groups in the incidence of death or cardiovascular events, although there was a significant increase in stroke, arterial thromboembolic events, and venous thromboembolic events in the higher Hb group. The higher Hb group also had a significant decrease in transfusions and a modest improvement in patient-reported fatigue scores. There was no difference in the incidence of progression to ESKD between the two groups, but the higher Hb group did have a significant decrease in cardiac revascularization procedures. Although not a prespecified outcome, among patients with a baseline history of cancer, there was a nonsignificant increase in deaths and a significant increase in cancer-related deaths in the higher Hb group.

Summarizing the Data

The aforementioned randomized trials of ESA use in patients with CKD and ESKD (**TABLE 29.3**) have demonstrated that achieving normal Hb values provides modest benefits including decreased transfusion requirements and improved physical functioning and quality of life, but there are consistently no significant long-term benefits such as a decrease in mortality or cardiac events. Furthermore, all of the studies showed increased risks, although the precise risks were inconsistent from study to study. For example, the Parfrey et al. study (120) and the TREAT trial (123) showed a significant increase in stroke,

but this finding was absent in the CREATE (121) and CHOIR (122) trials. The Normal HCT trial (118) and the CHOIR trial (122) both demonstrated an increase in mortality, but this finding was absent in CREATE (121) and TREAT (123) trials. The CREATE trial showed a significant increase in the rate of progression to ESKD, and the Normal HCT Trial demonstrated an increased rate of vascular access thrombosis, but neither of those findings were consistently seen throughout the other trials.

TABLE 29.3

Summary of Randomized Controlled Trials of Erythropoiesis-Stimulating Agent Use in Patients with Chronic Kidney Disease and End-Stage Kidney Disease

Randomized Controlled Trials	Number of Patients	Intervention	Inclusion Criteria	Exclusion Criteria	Primary Outcome	Results	Adverse Events
U.S. Normal HCT Trial (118)	1,233	Epoetin-α administration to target HCT of 42% versus 30%	Patients with CHF or ischemic heart disease on chronic hemodialysis	DBP >100 mm Hg; severe cardiac disability; MI, PTCA, CABG in prior 3 mo	Time to death or nonfatal MI	Nonsignificant increase in primary outcome (CI 0.9–1.9)	Significant increase in vascular access thrombosis; nonsignificant increase in deaths
Canadian Normal HCT Trial (120)	596	Epoetin-α administration to target Hb range of 13.5–14.5 g/dL versus 9.5–11.5 g/dL	Patients who initiated hemodialysis during the prior 3–18 months with an LVVI <100 mL/m^2	Symptomatic ischemic heart disease or heart failure; angiographic critical CAD	Difference in change in LVVI	No difference between groups in LVVI or LVMI change	Significant increase in strokes
CREATE (121)	603	Epoetin-β administration to a target Hb of 13.0–15.0 g/dL versus 10.5–11.5 g/dL	Patients with an eGFR 15–35 mL/min, Hb 11.0–12.5 g/dL, and a BP less than 170/95 mm Hg	Anticipated need for RRT in the next 6 mo; advanced cardiovascular disease; nonrenal cause of anemia	Time to first cardiovascular event	No significant difference between groups in cardiovascular events, death, or LVMI	Significant increase in progression to ESKD
CHOIR (122)	1,432	Epoetin-α administration to a target Hb of 13.5 g/dL versus 11.3 g/dL	Patients with an eGFR 15–50 mL/min, Hb <11.0 g/dL	Uncontrolled HTN; active GI bleeding; iron overload state; active cancer; prior ESA use	Time to composite of death, MI, hospitalization for CHF, or stroke	Significant increase in the composite outcome, primarily driven by a near significant increase in both deaths and hospitalization for CHF	Increased risk of serious adverse events overall, including a significant increase in CHF episodes
TREAT (123)	4,038	Darbepoetin-α administration to a target Hb of 13 g/dL versus placebo with darbepoetin-α rescue therapy available only when the Hb decreased below 9.0 g/dL	Patients with type 2 DM, eGFR 20–60 mL/min, Hb <11.0 g/dL, and TSAT >15%	Uncontrolled HTN; prior receipt of or planning for upcoming kidney transplant; current use of IV antibiotics, chemotherapy, or radiation therapy; cancer; HIV; active bleeding; hematologic disease	Time to composite of death or cardiovascular event; time to composite of death or ESKD	No significant difference between groups in both composite outcomes of death and cardiovascular events or death and ESKD; significant increase in fatal and nonfatal strokes	Significant increase in fatal and nonfatal strokes; significant increase in venous and arterial thromboembolic events; significant decrease in cardiac revascularization procedures

HCT, hematocrit; CHF, congestive heart failure; DBP, diastolic blood pressure; MI, myocardial infarction; PTCA, percutaneous transluminal coronary angioplasty; CABG, coronary artery bypass grafting; CI, confidence interval; Hb, hemoglobin; LVVI, left ventricular volume index; CAD, coronary artery disease; LVMI, left ventricular mass index; CREATE, Cardiovascular Reduction Early Anemia Treatment Epoetin β; eGFR, estimated glomerular filtration rate; BP, blood pressure; RRT, renal replacement therapy; ESKD, end-stage kidney disease; CHOIR, Correction of Hemoglobin and Outcomes in Renal Insufficiency; HTN, hypertension; GI, gastrointestinal; ESA, erythropoiesis-stimulating agent; TREAT, Time to Reconsider Evidence for Anaemia Treatment; DM, diabetes mellitus; TSAT, transferrin saturation; IV, intravenous.

The results of the aforementioned trials which have demonstrated very modest benefits with a concern for significant harm has led to recommendations for judicious use of ESAs in patients with CKD and ESKD, with current guidelines recommending great caution when considering ESA use in patients with active malignancy, a history of malignancy, or a history of stroke (1). Furthermore, the epoetin-α package insert recommends using the lowest dose sufficient to reduce the need for blood transfusions.

Target Hemoglobin

All of the aforementioned trials randomized patients to a normal Hb target versus an Hb target of 9 to 11.3 g/dL depending on the trial. While it is generally accepted that the risks of achieving a normal Hb level outweigh the benefits, there is little data to determine what the ideal Hb target should be. As such, the most optimal approach at this time is an individualized one which takes into account the patient's particular risks as related to his comorbidities and his particular benefits as related to his transfusion needs and anemia symptom burden. KDIGO guidelines recommend initiating the use of ESAs in patients with ESKD when the Hb level decreases below 10 g/dL with a goal of maintaining the Hb up to 11.5 g/dL (1); however, the guidelines state that one can consider initiating ESA use when the Hb is above 10.0 g/dL and maintaining an Hb level greater than 11.5 g/dL for individual patients who may have an improvement in quality of life with higher Hb levels and are prepared to accept the added risks of treatment. Intentionally maintaining an Hb level above 13.0 g/dL is recommended against under all circumstances. In addition to maintaining higher Hb levels for specific individual patients, there are specific patient populations for whom a lower Hb target may be indicated such as patients with sickle cell anemia or cirrhosis, as studies in these patient populations have demonstrated increased risk even with Hb levels above 10 g/dL (124,125).

Erythropoiesis-Stimulating Agent Dosing

The initial dose of ESA used should be individualized based on the patient's initial Hb, body weight, and clinical circumstances (1). Generally speaking, it is recommended to start with a lower dose of ESA to minimize ESA-related cardiovascular risks, and it is recommended to avoid raising the Hb by more than 2.0 g/dL per month. If the Hb level is increasing by more than 2.0 g/dL per month, the dose should be held or reduced by 50%. While initiating ESA therapy, Hb levels should be checked at least monthly and up to weekly, and a time period of 2 to 4 weeks should generally be allowed to assess the full effect of the ESA dose prior to making dose adjustments. If the Hb value increases above the target, the ESA dose can be held or continued at a reduced dose, the latter being recommended by KDIGO (1). Once a stable Hb level is achieved on a steady dose of ESA, Hb levels need not be monitored more frequently than monthly.

Erythropoiesis-Stimulating Agent Hyporesponsiveness

Lack of an appropriate response in erythropoiesis despite appropriate weight-based ESA dosing is a commonly encountered problem while managing anemia in patients with ESKD and has been shown to correlate to poor outcomes including increased cardiovascular events and death (126). Poor response to ESA therapy may portend a poor prognosis as a result of representing a significant disease marker or by leading to escalating doses of ESA therapy which itself may lead to an increased risk of cardiovascular events and death. For this reason, ESA hyporesponsiveness should be managed by initiating a search for reversible causes of ESA hyporesponsiveness and, if no reversible cause can be identified, the

acceptance of a lower Hb target with a limited increase in ESA dose and the possible need for regular blood transfusions; it should not be managed through ever escalating doses of ESA therapy.

KDIGO defines initial ESA hyporesponsiveness as a lack of increase in Hb level after 1 month of treatment with appropriate weight-based dosing and acquired ESA hyporesponsiveness as the need to increase the ESA dose twice up to an increase of 50% of the prior dose to maintain a stable Hb value from prior. In the setting of initial or acquired ESA hyporesponsiveness, the ESA dose should not be increased by more than two times the initial weight-based dose or the prior dose on which the patient had achieved a target Hb level (1).

Workup for ESA hyporesponsiveness should include evaluation for iron, vitamin B_{12}, and folate deficiency. Medications should be carefully reviewed, and discontinuation of ACE inhibitors and ARBs should be considered. Secondary hyperparathyroidism has been associated with ESA hyporesponsiveness (127), and parathyroid hormone levels should be optimized. Underlying causes of ongoing inflammation such as infection, chronic rejection of a prior failed transplant, or malnutrition should be considered. Additional causes of ESA hyporesponsiveness include primary marrow disorders such hemoglobinopathies, aluminum toxicity, occult malignancy, and antibody-mediated PRCA and should be evaluated for when appropriate. PRCA should be suspected in the setting of a decreasing Hb level or new transfusion requirements on a steady dose of ESA and an absolute reticulocyte count of less than 10,000/μL.

Often, despite an exhaustive search, no reversible cause of ESA hyporesponsiveness is identified, and management needs to be adjusted toward a lower Hb target with the possible need for regular blood transfusions.

CONCLUSION

Anemia is a nearly universal complication of ESKD and contributes significantly to the morbidity of patients with ESKD. It is usually multifactorial due to relative EPO deficiency, negative iron balance, and chronic inflammation leading to poor iron absorption and utilization, and its treatment consists of ESA administration, iron supplementation, and ongoing surveillance for underlying causes of chronic inflammation. Despite significant advances in the treatment of anemia in patients with ESKD over the last several decades, the long-term benefits of Hb correction have never been rigorously demonstrated, concerns abound related to the safety of ESA use, and the ideal balance of iron supplementation and ESA use have not been rigorously tested. Several new medications are either now FDA approved or in the process of being tested for the management of anemia in patients with ESKD including iron-containing oral phosphate binders and HIF stabilizers, and only time will tell how these new options will affect the treatment of anemia in patients with ESKD.

CHAPTER 30

Neurologic Complications Associated with Dialysis and Chronic Kidney Disease

Imran I. Ali and Noor A. Pirzada

Chronic kidney disease (CKD) is associated with neurologic derangements that involve both the central and the peripheral nervous system (1–4). Several of these neurologic syndromes are well defined, and their clinical characteristics are protean and nonspecific (2,3). The diagnosis of these disorders is sometimes straightforward, although a high index of suspicion is required to exclude other potentially serious and possibly reversible causes. Moreover, it is important to remember that some systemic disorders that result in kidney disease may also cause neurologic symptoms. For example, polyarteritis nodosa may present with kidney disease and mononeuritis multiplex or central nervous system involvement requiring a more detailed evaluation for prompt diagnosis.

The clinician must distinguish the neurologic symptoms and signs associated with the primary disease from those associated with uremia. This requires familiarity not only with the neurologic features of renal insufficiency but also with those of disorders that may present with neurologic and renal involvement (**TABLE 30.1**). A comprehensive neurologic evaluation is necessary for precise diagnosis and subsequent management of these disorders. The spectrum of neurologic disorders seen in association with CKD is listed in **TABLE 30.2**.

TABLE 30.1 Systemic Disorders with Renal and Nervous System Involvement

Disease	Clinical Presentation
Polyarteritis nodosa	Mononeuritis multiplex, CNS vasculitis
Systemic lupus erythematosus	Neuropsychiatric disease, cerebral infarction, myelitis, neuropathy
Wegener's granulomatosis	Midline granulomatous inflammation, peripheral neuropathy
Thrombotic thrombocytopenic purpura	Cerebral edema, seizures, fluctuating focal deficits
Rheumatoid arthritis	CNS vasculitis, cervical myelopathy, neuropathy
Hypertensive encephalopathy	Headaches, seizures, altered sensorium, coma
Autosomal dominant polycystic kidney disease	Intracranial aneurysms

CNS, central nervous system.

TABLE 30.2 Neurologic Disorders Associated with Kidney Disease and Dialysis

Central nervous system disorders
Uremic encephalopathy
Dialysis dysequilibrium syndrome
Dialysis dementia
Cerebrovascular disease
Peripheral nervous system disorders
Uremic neuropathy
Autonomic and cranial neuropathy
Mononeuropathies
Carpal tunnel syndrome
Ischemic monomelic neuropathy
Compressive neuropathies

This chapter is divided into two sections. The first discusses central nervous system disorders in patients with CKD and dialysis patients, and the second addresses the peripheral nervous system in patients with CKD and in dialysis patients.

CENTRAL NERVOUS SYSTEM ABNORMALITIES

Uremic Encephalopathy

CKD may result in cognitive impairment associated with clouding of consciousness, especially when the glomerular filtration rate (GFR) falls below 10 mL/min (4). The clinical features of uremic encephalopathy are nonspecific and include confusion, psychomotor agitation, alteration of sleep–wake cycle, disorientation, impaired memory, inattention, paranoid ideation, impaired abstraction, visual hallucinations, myoclonus, and seizures (4–8). The clinical course is usually insidious in onset with waxing and waning of intellectual function, a typical feature of most metabolic encephalopathies.

Progression of renal insufficiency may subsequently result in gradual obtundation followed by coma unless dialysis is performed. Dialysis initiation usually results in gradual clinical improvement (4).

There is no absolute correlation between neurologic impairment and the blood urea nitrogen level, although it has been suggested that the rate of rise of urea and creatinine may be related to the development of neurologic symptoms (6,8). Neurologic examination is usually nonlateralizing; impaired

higher cortical functions, hyperreflexia, and asterixis may be present.

Asterixis, a sudden loss of muscle tone that results in a “flapping” tremor, is best assessed by having the patient hyperextend at the elbow and wrist with the fingers spread apart; the asterixis is then best seen at the metacarpophalangeal joints and the wrist. This phenomenon is also seen in hepatic and other metabolic encephalopathies, and, although a nonspecific finding, it may be useful in assessment of a patient with declining renal function (2).

Patients with uremic encephalopathy characteristically may also manifest multifocal myoclonus. Myoclonus is a sudden rhythmic movement of muscle groups; it is asymmetric and usually not related to seizures. In addition, focal neurologic findings such as extensor plantar response and grasp or snout reflexes have been described. Myoclonus may also occur in kidney disease patients associated with medications such as but not limited to serotonin reuptake inhibitors and narcotic analgesics.

The presence of focal neurologic findings should be fully investigated to look for other causes of altered mentation. Neuroimaging studies such as computed tomography (CT) or magnetic resonance imaging (MRI) typically show cortical atrophy (9,10). Rarely, changes suggestive of edema are seen involving the basal ganglia, cerebral cortex, and centrum semiovale (10). Interestingly, these changes are similar to those seen in hypertensive encephalopathy. The cause and significance of these changes are unknown in the absence of marked hypertension, but they are thought to be related to transient ischemia or cerebral edema. The possibility that these changes are related to uremic toxins or other metabolic derangement cannot be excluded because these changes usually resolve after dialysis (10).

Posterior reversible leukoencephalopathy syndrome (PRLS) is a well-defined syndrome seen in associated with severe hypertension and acute renal insufficiency (11). Clinical features include headaches, altered mentation, visual changes, and even cortical blindness related to the predilection for involvement of the occipital lobes (12). These findings have also been described in patients with organ transplantation and with use of certain immunosuppressant medications such as cyclosporine and tacrolimus (13,14). Typically, this condition is reversible with complete resolution of symptoms, clinical and radiologic changes with control of blood pressure and/or discontinuation of offending agents (**FIGURE 30.1**).

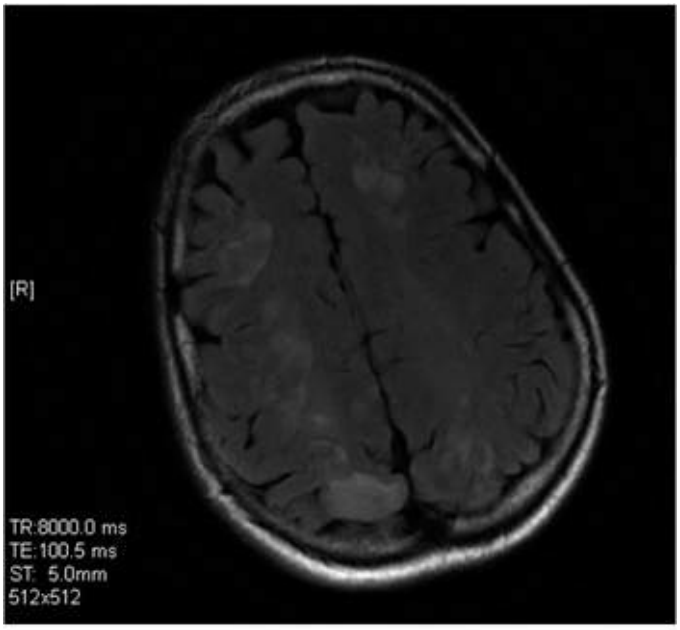

FIGURE 30.1 Magnetic resonance imaging of brain showing evidence of T2 white matter hyperintensities in a patient with posterior reversible leukoencephalopathy. These resolved completely on a repeat scan a month later.

Cerebrospinal fluid (CSF) examination usually is normal, although mildly elevated protein is seen in more than half of the patients with uremia and lymphocytic pleocytosis may be seen in up to 10% of patients (2,15). It is of critical importance that encephalitis, meningitis, and other causes of CSF abnormalities be excluded before attributing the CSF changes to uremia alone.

One of the most interesting questions in uremia relates to the pathogenesis of uremic encephalopathy. The substance responsible for the encephalopathy is not known. There is no direct relationship between urea or creatinine levels and the level of encephalopathy (5–7). Most likely, uremic encephalopathy is a result of a combination of factors, including accumulation of various organic acids and substances such as urea guanidine (16–17), myoinositol, purines, organic phosphates, oxalate, ascorbic acid, amino acid peptides, parathyroid hormone (PTH), β_2-microglobulin, methylguanidine, guanidinosuccinic acid, hippuric acid, polyamines, phenols, and indoles, in addition to urea and creatinine (6,7,18–20). In animal models, a number of these compounds of different molecular weights produce toxicity similar to that seen in uremic syndrome.

Urea and creatinine are considered low molecular weight compounds (less than 300 Da), whereas myoglobulin is considered high molecular weight (greater than 12,000 Da). Similarly, compounds with molecular weight between 300 and 12,000 Da such as β_2-microglobulins are considered “middle molecules.” Because the middle molecules are removed less efficiently than urea and creatinine during hemodialysis, these are considered likely candidates that contribute to uremic encephalopathy. These compounds include PTH, peptides, glucuronated conjugates, and β_2-microglobulin. Compounds such as methylguanidine, hippuric acid, polyamines, phenols, and indoles have lower molecular weight, but their kinetics of removal during dialysis are similar to the “classic” middle molecules (19).

As stated previously, PTH has been implicated in the pathogenesis of uremic encephalopathy (20–22) because of secondary hyperparathyroidism and effect of PTH on neuronal function (21). Even in the absence of renal insufficiency, elevated levels of PTH can result in confusion and altered mental status. In animal models of uremia, there is a marked increase in intracellular calcium (7,20), suggesting a possible link between PTH and neuronal dysfunction. In these animals, blockade of PTH function reverses the

symptoms associated with uremic encephalopathy. Increased intracellular calcium results in impairment of energy metabolism with reduced adenosine triphosphate (ATP) levels because of abnormal mitochondrial function. There is also evidence to suggest abnormal phospholipid metabolism related to the previously mentioned events causes membrane instability and further neuronal injury (3,15–20).

Accumulation of various organic acids and the middle molecules described previously (6,7,18,19), either from increased permeability of the blood–brain barrier or from impaired cellular transport mechanisms, may further compromise neuronal function. Biasioli et al. (8) describe an alteration in amino acid profile in serum and CSF of uremic patients, which indicates an increase in glycine, dopamine, and serotonin and a decrease in γ aminobutyric acid (GABA). Increased dopamine, serotonin, and glycine accumulation may result in increased irritability, sensorial clouding, tremors, and unsteadiness. Low GABA levels may lead to seizures and myoclonus and may exacerbate other uremic symptoms (8,20). However, no single abnormality fulfills all the criteria for being the putative neurotoxin, and uremic encephalopathy is most likely the result of derangements of neuronal function at multiple levels. Positron emission tomography (PET) scans in patients with CKD show reduced brain metabolism that correlates well with cognitive dysfunction and may be explained by the molecular events discussed previously (23). Additional metabolic derangements such as hyponatremia and hypernatremia have been associated with CKD and dialysis, these may result in altered mental status, encephalopathy, and seizures and addressed elsewhere in this text.

Seizures

Seizures may occur during the course of uremic encephalopathy in as many as 10% to 20% of patients and are usually generalized tonic clonic, although simple or complex partial seizures may also be seen (2,6). It is important to exclude drug toxicity as a reversible cause of seizures, because a number of commonly used drugs are associated with seizures in kidney disease. Drugs such as quinolones, penicillins, cephalosporins, acyclovir, and erythropoietin lower the seizure threshold and can lead to clinical seizure activity (24,25). The diagnosis is one of exclusion, and withdrawal of the presumed offending agent is enough to control the seizure activity.

Electroencephalography (EEG) in patients with seizures usually shows marked slowing of the background with increased θ (4 to 7 Hz) and δ (1 to 3 Hz) activity, as well as bilateral frontal paroxysmal slowing and occasional frontal epileptiform activity in the form of spikes and sharp waves (**FIGURE 30.2**) (6–8,26). It is important to note that these epileptiform abnormalities may be seen in patients with uremia and without a history of seizures as well. This finding in patients without seizures most likely represents evidence of cortical irritability and by themselves do not require any treatment. A characteristic EEG finding in patients with uremic encephalopathy is triphasic waves, which are seen with advanced stages (**FIGURE 30.3**). However, this pattern may also be seen in other metabolic disorders such as hepatic encephalopathy, severe hyponatremia, and certain drug intoxications (e.g., lithium) (26).

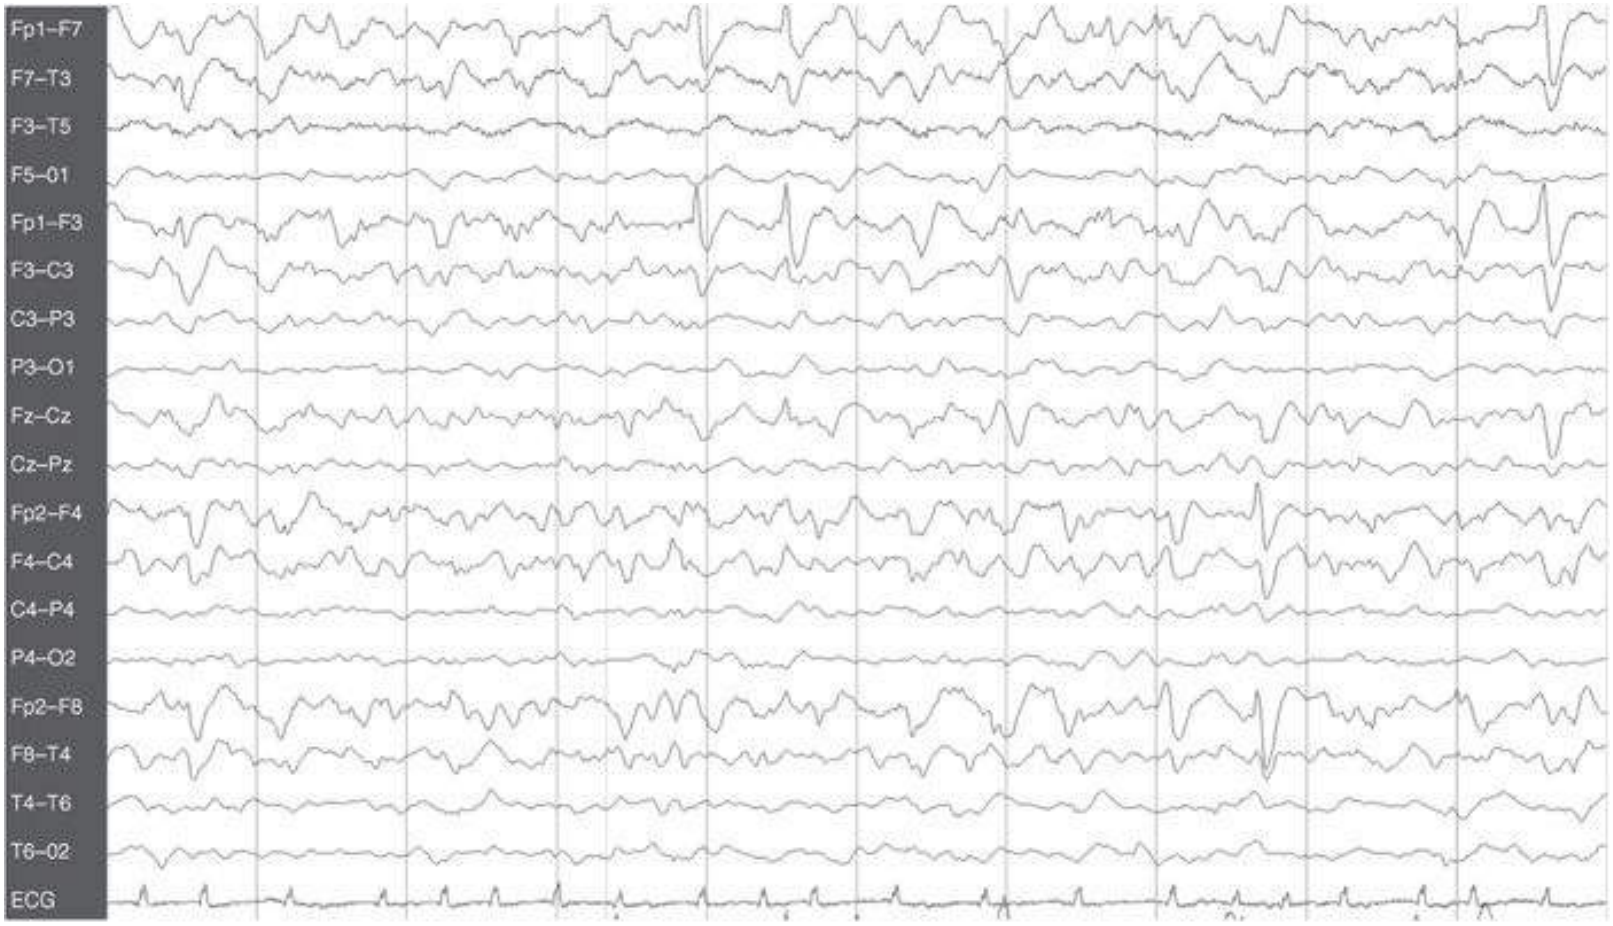

FIGURE 30.2 An electroencephalography showing bilateral frontal epileptiform discharges in a patient with uremic encephalopathy. ECG, electrocardiogram.

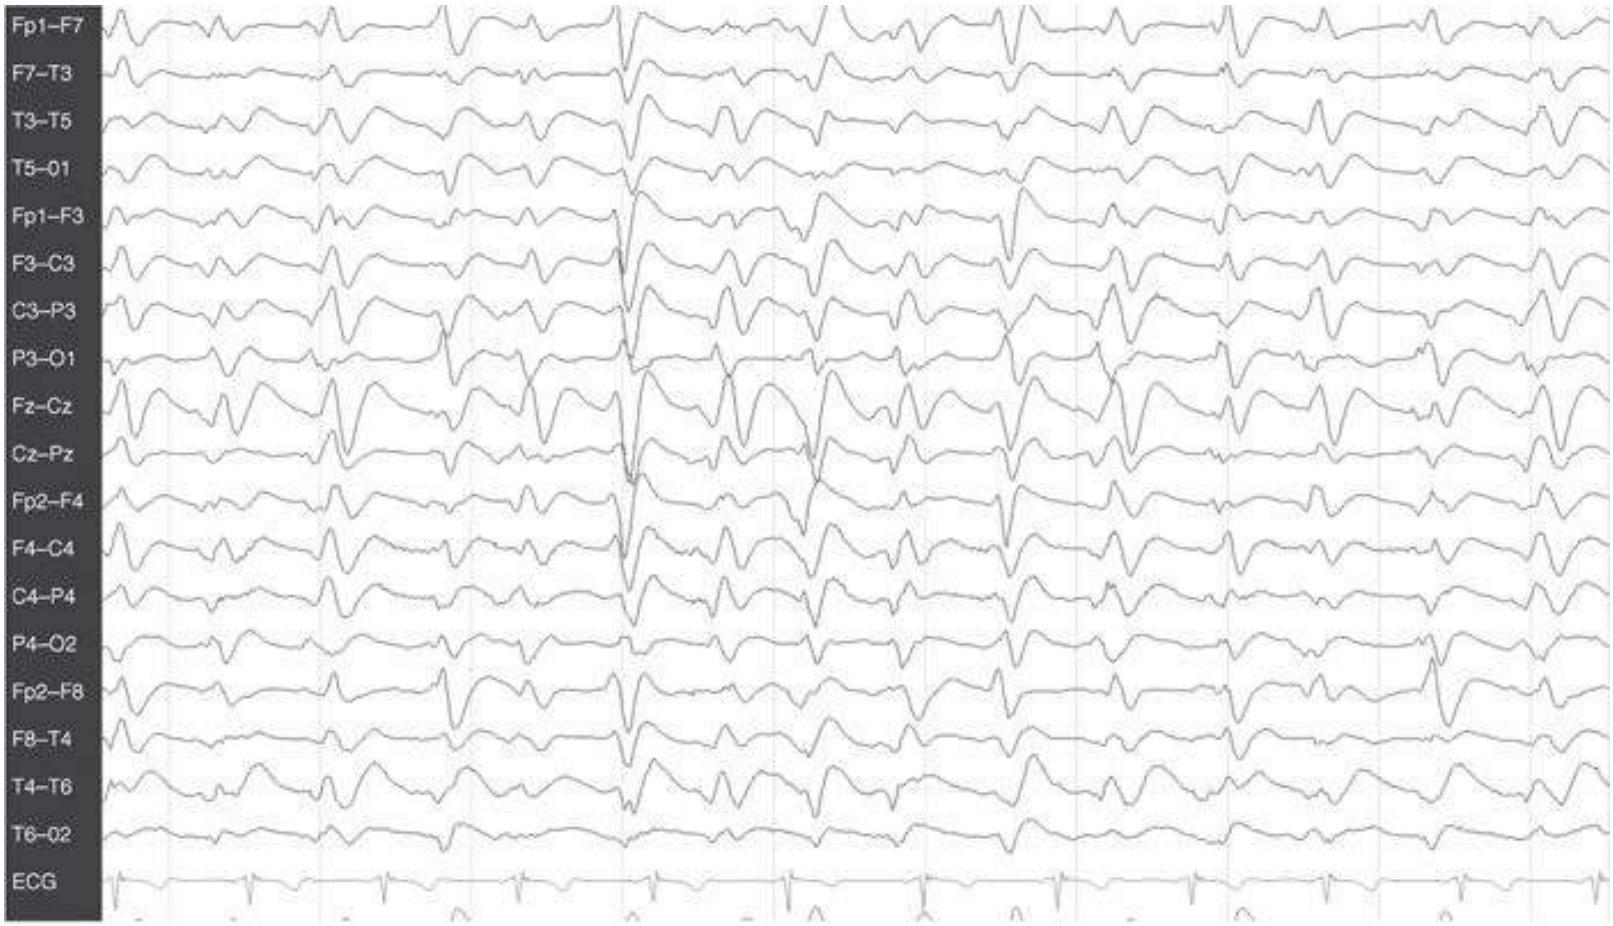

FIGURE 30.3 An electroencephalography showing classical triphasic waves in a patient with uremic encephalopathy. ECG, electrocardiogram.

The seizures should be treated the same as in other patients with metabolic encephalopathies. Long-term antiepileptic drug (AED) therapy is only required in patients with a high risk of recurrence, such as those with multiple seizures, history of recent status epilepticus, focal neurologic deficits, focal abnormality involving the cerebral cortex on imaging, and seizures in the absence of any specific metabolic derangement. If long-term antiepileptic medication is indicated, the impact of renal insufficiency and dialysis on drug metabolism should be taken into account (**TABLE 30.3**) (27–30). Phenytoin, carbamazepine, and valproic acid are all reasonable first-line agents for the treatment of seizures, although the newer agents have less systemic toxicity associated with them and are preferred by most neurologists. Phenytoin, levetiracetam, lacosamide, and valproate have the advantage of being available in intravenous (IV) form and can be given rapidly in an emergency. Because phenytoin is one of the most commonly used antiepileptic medications and its metabolism is affected by uremia (2,31,32) the pharmacokinetics in kidney disease must be well understood before using them in these medically complex patients. Because of expanded volume of distribution there is a reduction in total level, although this is offset by a marked increase of the free fraction of the drug from 10% to 25% (31,32). This may result in clinical toxicity, even though the total level may be low; therefore, free phenytoin levels, which are easily available in most centers, should be used as a guide to dosing. The half-life of phenytoin is also reduced from 13 hours to approximately 8 hours; therefore, three times a day dosing is recommended.

TABLE 30.3 Selected Antiepileptic Drug Therapy in Kidney Disease

AED	Typical Daily Dose Range with Normal Renal Function (mg/d)	Plasma Concentration in CRF	Plasma Half-Life	Dose Adjustment	Removal by Dialysis	Post-HD Supplementation
Phenytoin	300–600	Total ↓, free ↑	Decreased	Based on free levels	Negligible	No
Carbamazepine	600–1,600	No change	No change	None	None	No
Oxcarbazepine	600–2,400	Increased	Increased	Yes	Insignificant	No
Phenobarbital	60–200	No change	Increased or no change	Slight reduction: avoid in most cases	Significant	Possibly
Lacosamide	200–400	Increased	Increased	Yes	Significant	Yes
Gabapentin	1,200–3,600	Increased	Increased	Yes	Significant	Yes
Pregabalin	150–600	Increased	Increased	Yes	Significant	Yes
Lamotrigine	100–600	Increased	Increased	Yes	Significant	Yes
Valproic acid	1000–3,000	Decreased	No change	No	Negligible	No
Topiramate	100–400	Increased	Increased	Yes: avoid if possible	Significant	Yes
Zonisamide	100–400	Increased	Increased	Yes: unknown	Unknown	Unknown

AED, antiepileptic drug; CRF, chronic renal failure; HD, hemodialysis.
Data related to other less commonly prescribed AEDs such as clobazam, perampanel, eslicarbazepine, rufinamide, ezogabine, and felbamate can be found elsewhere (79).

Valproic acid is now also available in IV formulation as is levetiracetam and lacosamide, although there is very little confirmatory data regarding its use in management of status epilepticus. We prefer to use these agents for seizures initially, and it requires careful monitoring for toxicity due to the impact of renal insufficiency on their respective serum levels (as noted in **TABLE 30.3**). Drugs that are metabolized by the cytochrome P-450 such as phenytoin, carbamazepine, oxcarbazepine, and phenobarbital are enzyme inducers and may interfere with metabolism of a number of other drugs including tacrolimus, a commonly used antirejection drug; therefore, caution is advised when using these antiepileptic agents in medically

complex patients. We typically tend to avoid use of phenobarbital in most patients due to numerous other options available and its significant toxicity. A number of new antiepileptic agents have been approved by the U.S. Food and Drug Administration (FDA) over the last few years and may be a reasonable alternative for these patients (**TABLE 30.3**). The choice of AED is based on the need for rapid dosing (phenytoin, valproic acid, levetiracetam, lacosamide), side effect profile (potential renal toxicity with topiramate and zonisamide), and significant dosing adjustment of the drug (gabapentin, levetiracetam, lacosamide, oxcarbazepine). Phenytoin is still preferentially used for rapid IV dosing in a patient with acute repetitive seizures or status epilepticus. However, in a patient with focal seizures who does not have status epilepticus one may choose a drug like carbamazepine as dosing adjustments are not necessary in patients with renal insufficiency. AEDs such as lamotrigine and levetiracetam are additional exceedingly effective and safe options for add-on therapy if a single drug is ineffective at its maximally tolerable dose. However, these drugs are renally excreted and substantial dose adjustments are required especially with hemodialysis. A neurologic consultation may also be helpful in choosing the most appropriate AED.

Cerebrovascular Disease in Chronic Kidney Disease

Patients on chronic hemodialysis have a fivefold higher risk of cerebrovascular disease compared with the normal population (33–36). This may be related to the high prevalence of hypertension (33), underlying diabetes, hyperhomocysteinemia, dyslipidemia, and atherosclerosis in hemodialysis patients (34). There are considerable data that suggest hyperhomocysteinemia is an important risk factor in patients with ischemic cerebrovascular disease and chronic renal insufficiency (34). It is important to identify the cause of hyperhomocysteinemia, which may be related to folate, cobalamin, or pyridoxine deficiency or because of a mutation of methylene tetrahydrofolate reductase (MTHFR) enzyme. Folic acid at 1 to 5 mg is recommended for most patients with MTHFR mutation, for folate deficiency, or when no other cause of hyperhomocysteinemia is identified.

The stroke risk is increased in patients with CKD and those undergoing dialysis. In a paper published recently (35), stroke occurred at a rate of 49.2/1,000 patient-years with a greater risk of ischemic stroke in patients undergoing hemodialysis compared to peritoneal dialysis. However, the risk of hemorrhagic stroke did not appear to show such an association. The management of ischemic cerebrovascular disease is the same as in patients without kidney disease. Addressing associated risk factors such as hypertension, hypercholesterolemia, and other modifiable risk factors is critically important. Antiplatelet agents such as aspirin and clopidogrel are recommended for atherothrombotic disease, whereas patients with embolic infarction may need to be anticoagulated with warfarin. The decision to anticoagulate is based on the size of the infarct, the risk of recurrence, and the risk of systemic or intracranial bleeding in a particular patient.

In another older study intracerebral hemorrhage was seen more commonly than cerebral infarct as the cause of stroke and most likely is related to hypertension (36). The actual incidence of intracerebral hemorrhage was noted to be *12.3 per 1,000 patient-years, and that of cerebral infarct is 3.9 per 1,000 patient-years* (32). This was also associated with an overall 30-day stroke mortality that is 74.4%, compared with 12.3% in the general population. This high mortality could be partly related to the disproportionately high incidence of intracerebral hemorrhage and associated systemic disease that was

noted in this particular study. However, a more recent study has shown a higher incidence of ischemic infarction compared to intracerebral hemorrhage in patients with CKD who are receiving hemodialysis (35).

Patients with autosomal dominant polycystic kidney disease (ADPKD) have a higher prevalence of intracranial aneurysms (35). These aneurysms are usually small, involve the anterior circulation, and are frequently multiple. The prevalence of these aneurysms is approximately 5% to 12%, depending on the screening method used. Cerebral angiography is the gold standard diagnostic method for locating these aneurysms (**FIGURE 30.4**) (11); however, magnetic resonance angiography (MRA) is sometimes a useful screening tool. It is safe in patients with kidney disease when no contrast is needed.

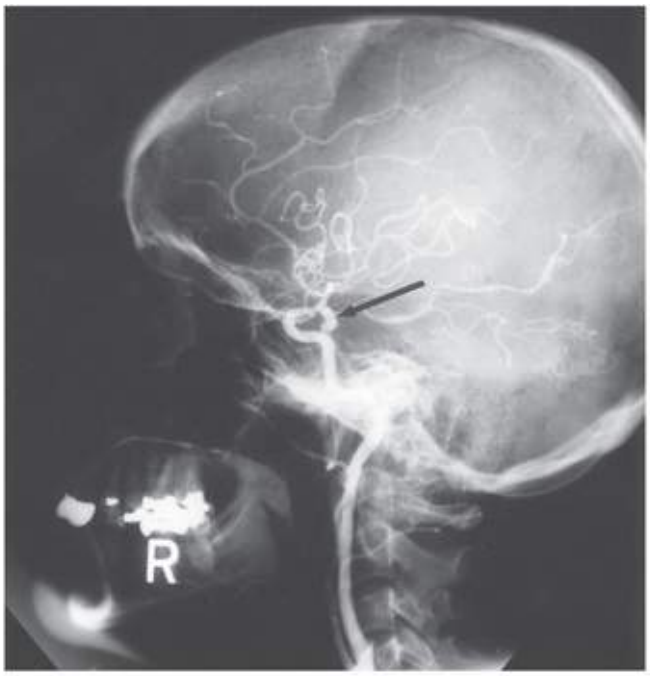

FIGURE 30.4 A cerebral angiogram showing a posterior communicating artery aneurysm (*arrow*). (Courtesy Brinker RA, MD, Department of Radiology, formerly Medical College of Ohio, Toledo, Ohio.)

Screening is recommended for patients above the age of 20 as aneurysms are typically not noted in individuals younger than that. Risk factors for aneurysms include a family history of aneurysms, a previous history of aneurysm or subarachnoid hemorrhage, polycystic kidney disease, as well as certain connective tissue disorders such as Marfan or Ehler-Danlos syndrome type IV (35).

Clinical features may be related to mass effect in the case of a large aneurysm or because of a sudden rupture. Patients with subarachnoid hemorrhage usually present with sudden explosive headache that is frequently described as the “worst headache of their life.” Nuchal rigidity and third cranial nerve (CN) palsy may also be present but are not seen in all patients. The initial evaluation must be rapid in patients with suspected subarachnoid hemorrhage, and urgent admission to an intensive care unit is warranted. The overall mortality of a ruptured aneurysm is approximately 30% to 50% in patients with or without ADPKD. Timely intervention can be lifesaving, and most of interventions are now planned and done before development of vasospasm, which usually occurs 3 to 4 days after rupture. In addition to open craniotomy, endovascular procedures are being more commonly utilized in these medically challenging patients (37).

Management of asymptomatic aneurysms guidelines have previously been published (38). Patients with ADPKD should undergo screening every 5 years due to a high prevalence of intracranial aneurysms

(39). There is a strong correlation between size of the aneurysm, location (posterior circulation > anterior circulation), family history, and risk of rupture. Aneurysm location does also affect management because those located in the posterior circulation such as the basilar artery or posterior communicating arteries are more likely to rupture irrespective of size. Other factors that may have an impact on management of unruptured aneurysms include previous subarachnoid hemorrhage; age; family history; coexisting medical conditions; aneurysm characteristics such as size, location, and morphology; and neurosurgical expertise. In the authors' opinion, surgical decisions in an asymptomatic patient with intracranial aneurysms should be individualized after an informed discussion between the neurosurgeon, endovascular neurologist, nephrologist (in case of associated renal disease), and the patient.

Approach to a Patient with Confusion and Kidney Disease

In a patient who develops confusion associated with renal insufficiency, it is imperative to exclude other causes that may mimic uremic encephalopathy. A complete history and physical including a careful neurologic examination is mandatory. A systematic approach should be adopted to evaluate these patients. In these medically complex patients, systemic infections may result in profound confusion and should be looked for in addition to a complete neurologic evaluation. The differential diagnosis and the diagnostic workup for some of the neurologic diseases are listed in **TABLE 30.4**. It is important to exclude nonconvulsive status epilepticus as a cause of confusion in a patient with uremia. It is a potentially life-threatening disorder that can be easily diagnosed by EEG and responds to antiepileptic therapy. If unrecognized and untreated, nonconvulsive status epilepticus can lead to irreversible neurologic injury.

TABLE 30.4 Approach to a Patient with Confusion in Kidney Disease

Clinical Features	Diagnosis	Diagnostic Tests
Head trauma, headaches, falls	Subdural hematoma	CT or MRI
Focal neurologic findings (hemiparesis, homonymous hemianopsia, aphasia, etc.)	Infarct or intracerebral hemorrhage	CT or MRI
Fever, headaches, nuchal rigidity, seizures	Meningitis (bacterial, fungal, or mycobacterial)	CSF examination
Worst-ever headache, nuchal rigidity, subhyaloid hemorrhage on funduscopy	Subarachnoid hemorrhage	CT, cerebral angiography, neurosurgical evaluation
Altered sensorium, nonlateralizing examination	Hepatic encephalopathy, hyponatremia, hypoxia, hypercarbia gases	Liver function chemistries, arterial blood
Intermittent confusion, stereotypical behavior, automatisms	Nonconvulsive status epilepticus	EEG
Seizures with or without any other symptoms	Drug toxicity (penicillins, cephalosporins, carbapenems acyclovir, erythropoietin	History, drug withdrawal

CT, computed tomography; MRI, magnetic resonance imaging; CSF, cerebrospinal fluid; EEG, electroencephalogram.

Dialysis Disequilibrium Syndrome

The dialysis disequilibrium syndrome is an unusual complication in current dialysis practice. It presents with a variety of constitutional and neurologic symptoms that include headache, fatigue, nausea, vomiting, hypertension, tremors, seizures, agitation, delirium, and subsequent coma (1–3,5,40–43). These symptoms usually appear within 24 hours of dialysis completion and last for a few hours (1). The syndrome is usually seen in patients who are severely uremic and are dialyzed aggressively. The EEG may show generalized and paroxysmal slowing during this period (3,26).

With regard to cause, some patients develop elevated intracranial pressure (ICP) during dialysis

(19,43). This increase may be explained on the basis of reverse urea effect (40). Reverse urea effect results from more efficient removal of urea from plasma, as compared with the brain, with development of a reverse osmotic gradient. This intracellular accumulation of solutes such as urea favors movement of water to the intracellular space, leading to cerebral edema and the increase in ICP. The finding of more efficient removal of urea from the plasma compared with the brain during hemodialysis is disputed by some, but it is a plausible explanation for much of the clinical symptomatology seen.

Urea is, however, not the only compound responsible for the osmotic gradient, and other compounds such as idiogenic osmoles may also be involved (1,40). Idiogenic osmoles are thought to be organic acids that are formed intracellularly in the brain and also contribute to the increased brain osmolality. Support for this comes from studies that show that the urea concentration in the brain can only account for 50% to 60% of the increase in brain osmolality; the rest is presumably related to these idiogenic osmoles (8).

Another somewhat controversial explanation for the development of cerebral edema is paradoxical intracellular acidosis (7,20), which may also be related to accumulation of organic acids. A fall in CSF pH is noted during dialysis in patients and in experimental animal models. This increase in the intracellular H^+ ion concentration in the brain results in increased osmolar content with a secondary increase in brain water. This would then result in cerebral edema and the symptoms of dialysis disequilibrium syndrome. This finding has, however, been refuted by other studies (8), which have not been able to demonstrate acidosis within the central nervous system. Similarly, the possible association of hemodynamic alterations and electrolyte shifts to the genesis of this syndrome is also unclear.

Dialysis Dementia or Dialysis Encephalopathy

Patients with CKD on hemodialysis undergoing neuropsychologic testing show impaired performance on tests of short-term memory, attention, concentration span, and sequential information processing (4,44). This cognitive decline may or may not improve with therapy and is associated with diffuse cerebral atrophy, which may be seen on routine studies such as CT or MRI (9). Pathologically, there is neuronal cell loss and other nonspecific changes. The pathophysiology of these changes are unknown but are thought to be related to a combination of chronic aluminum toxicity, impaired cerebrovascular autoregulation, and breakdown of blood–brain barrier (9). Interestingly, patients undergoing peritoneal dialysis perform better on cognitive testing than those patients receiving hemodialysis (44).

Unlike the benign course described previously, some patients on hemodialysis for a period of greater than 2 years may develop a progressive dementia that is irreversible and invariably fatal (45–51). This form of dementia is exceedingly rare now; because of *the reduction in the use of aluminum-containing phosphate binders* and improved screening for aluminum in dialysate water (see also Chapter 25) (20). However, rare cases have been described in association with contamination of the dialysate water supply, such as when well water high in aluminum was used for home dialysis. The clinical features include aphasia, apraxia, myoclonus, seizures, progressive intellectual decline, confusion, auditory or visual hallucinations, and dysarthria (1–4). The symptoms are initially intermittent and may worsen immediately after dialysis (47).

As the disease progresses, there is persistent cognitive impairment, and an increase in seizures may also occur. These seizures are poorly responsive to AED therapy but may initially respond to benzodiazepines. EEG may initially show paroxysmal slowing with predominant frontal spikes and sharp waves intermixed with normal background. As the disease progresses, the EEG may also show more

severe background abnormalities (7,26,52). There is evidence that EEG changes may precede the clinical picture by months (4). Neuroimaging is usually unremarkable but may be useful in excluding tumors, subdural hematoma, or chronic infections.

The occurrence of dialysis dementia has been linked by a number of epidemiologic studies to aluminum intoxication (45–52). These patients have a high serum aluminum level and may also show increased brain levels, especially in the gray matter (1,51). Removing aluminum from the dialysate and reducing intake of phosphate-binding gels that have a high aluminum content have resulted in a dramatic decline in the incidence of this disease (2–4). However, there are patients who develop this disease with no evidence of exposure or evidence of aluminum intoxication (49). Children with CKD may develop this syndrome without ever undergoing dialysis or being exposed to aluminum. In such cases, it is hypothesized that uremia may result in development of this syndrome through its effect on the developing brain (7).

Aluminum is normally absorbed in the gastrointestinal tract and is excreted through the kidneys. Increased absorption is probably the effect of PTH (21) on the gastrointestinal tract; in combination with reduced excretion, patients on dialysis have plasma levels that are six to eight times higher than normal (normal, 0 to 20 mg/L). At levels above 200 mg/L, chelating agents such as deferoxamine are recommended (2). To prevent the development of this complication, dialysate aluminum is kept below 20 mg/L by deionization (4,7). This process also removes other compounds such as cadmium, mercury, lead, manganese, copper, nickel, thallium, boron, and tin. The relationship of other substances including trace elements to dialysis dementia is not known (see Chapter 3) (7).

PERIPHERAL NERVOUS SYSTEM INVOLVEMENT IN UREMIA

Involvement of the peripheral nervous system in CKD was described initially in the 19th century. Kussmaul (1864), Charcot (1870), and Osler (1892) wrote on various aspects of this condition. However, in the first half of the 20th century descriptions of peripheral neuropathy in CKD were uncommon in the medical literature, which was instead dominated by central nervous system manifestations such as coma and seizures. After hemodialysis was introduced and patients began to live longer, peripheral neuropathy was reported more frequently and now is considered an integral part of the uremic syndrome.

Uremic Polyneuropathy

Uremic polyneuropathy is the most common type of peripheral nerve involvement, and typically occurs when the creatinine clearance is less than 10 mL/min. As determined by electrophysiologic studies and careful clinical examination, evidence of peripheral neuropathy is seen in 50% to 60% of patients with ESKD who require hemodialysis (53). It is more common in men than in women.

Usually the neuropathy has an insidious onset. Muscle cramps have been thought to herald peripheral nerve involvement, but many patients with similar complaints have no other manifestation of neuropathy. In such cases, the cramps probably are a nonspecific manifestation of uremia. Patients experience distal dysesthesias which are described as painful tingling, aberrant sensation of swelling of fingers and toes, and a constrictive feeling around the feet and ankles. These prominent sensory manifestations may be

accompanied by slowly progressive distal weakness and atrophy. Restless legs syndrome is seen in 20% of patients with CKD (54). Contributing factors in such patients include peripheral neuropathy and iron deficiency anemia. The syndrome of restless legs consists of creeping, crawling, prickling, and pruritic sensations deep within the legs that worsen during periods of inactivity and become particularly bothersome before the onset of sleep. The sensations disappear temporarily when the legs are moved, only to recur within a few seconds. The symptoms last from minutes to hours; they can significantly delay sleep onset and result in sleep deprivation.

The earliest signs on examination are impaired vibration sense in the lower extremities associated with loss of deep tendon reflexes—first the Achilles reflex, then the patellar responses. Advanced cases display distal decrease in touch and position sense and may also show weakness and atrophy of distal muscles.

When fully developed, uremic polyneuropathy is a distal symmetric mixed motor and sensory polyneuropathy involving the legs more than the arms. The major factors correlating with the appearance of neuropathy are the degree and duration of CKD. No correlation has been demonstrated with other factors such as age, race, levels of specific uremic metabolites, or type of underlying renal disease. Although most commonly uremic polyneuropathy evolves over many months, there have been reports of severe fulminant motor neuropathies, sometimes associated with sepsis (55).

CSF protein levels are usually normal but may be elevated up to 100 to 200 mg/dL (normal 15 to 45 mg/dL) in patients with severe uremic polyneuropathy.

The most significant abnormality on electrophysiologic study is a reduction in the amplitude of the compound muscle and sensory action potential, a finding typical of axonal neuropathy. Both motor and sensory conduction velocities are mildly reduced and the late reflexes (H reflex and F wave) become abnormally prolonged, more commonly in the lower extremities. There is a high correlation between declining creatinine clearance and reduction in conduction velocities (56). Specific predictors that herald the appearance of clinical symptoms and signs have not been identified. Quantitative sensory testing, especially the vibratory threshold, is a sensitive indicator of peripheral neuropathy in CKD and correlates well with severity (57). An early and unusual sign is the perception of heat in response to low temperature stimuli. This paradoxical heat sensation to cold can precede other signs of neuropathy (58).

Pathologically, uremic polyneuropathy represents a primary axonal disease with secondary segmental demyelination. All fiber sizes, both myelinated and unmyelinated, are affected, although the largest and the most distal are especially vulnerable. The pathologic findings are not specific for uremia and cannot be distinguished from other causes of axonal degeneration such as alcoholic neuropathy.

The fact that the appearance of peripheral neuropathy correlates with reduction in GFR and the neuropathy improves after dialysis or transplantation implies that a uremic toxin impairs peripheral nerve function. However, in spite of intensive research no specific substance has been shown to correlate with the development or severity of peripheral neuropathy in CKD. Initially attention centered on the so-called middle molecules, substances of molecular weight between 500 and 5,000 as the cause. However, this has not been substantiated. Many other agents including PTH, myoinositol, calcium, magnesium, and methylguanidine have been investigated and discarded as possible culprits in the development of neuropathy in CKD. Some studies indicate that hyperkalemia may contribute to the development of neuropathy in CKD (59).

In most patients on long-term dialysis, the neuropathy will stabilize, but improvement is less consistent (60,61). Progressive neuropathy is an indication for starting dialysis therapy and is also an indicator of insufficient dialysis. Earlier reports indicated that patients on peritoneal dialysis do not develop uremic polyneuropathy with the same frequency as patients on hemodialysis, but these observations have not been substantiated (62).

Successful renal transplantation has a more predictable and clear-cut beneficial effect on uremic polyneuropathy and remains the only cure. Provided that the transplant is successful, progressive improvement has been the rule, with substantial clinical recovery. Recovery often occurs in two phases, initial rapid improvement over days to weeks and then more protracted improvement over a period of months (63,64). Even in severe cases, walking is possible within 2 to 3 months, although some residual clinical signs such as absent ankle reflexes may persist. Serial electrophysiologic studies following transplantation have demonstrated rapid improvement in nerve conduction velocities (65). Patients with neuropathic pain can benefit from treatment with tricyclic antidepressants like amitriptyline or anticonvulsants medications such as gabapentin. Neuropathic symptoms may also improve after supplementation with biotin, pyridoxine, thiamine, and cobalamin (66). The restless legs syndrome responds poorly to dialysis. Symptomatic relief can be provided by a number of medications, including dopamine agonists, levodopa, gabapentin, and opioids. Treatment of the iron deficiency anemia can reduce symptom severity. Substantial improvement of restless legs symptoms can occur after kidney transplantation (67).

Autonomic and Cranial Neuropathies

Uremic neuropathy is not confined to motor and sensory nerves. Autonomic dysfunction is a well-known complication (see Chapter 19) (68,69). Patients with CKD demonstrate abnormal responses to the Valsalva maneuver, abnormal heart rate responses to atropine, and reduced baroreceptor sensitivity. Symptoms that indicate disordered autonomic function include orthostatic hypotension, impotence, diarrhea, and excessive perspiration. Reduced baroreceptor activity may be an important factor in producing hemodialysis-induced hypotension (see Chapter 19) (70). However, overt signs of autonomic dysfunction may be uncommon during the course of CKD. Renal transplantation can lead to considerable improvement of autonomic function while dialysis is not associated with any significant change.

Increased incidence of eighth cranial nerve (CN VIII) dysfunction, both auditory and vestibular, has been noted (71). The pathogenesis is obscure and is most likely multifactorial, potentially related to uremic toxins and prior exposure to ototoxic drugs such as aminoglycosides. There have been reports of esophageal dysfunction in patients with CRF, and uremic neuropathy of the vagus nerve (CN X) has been postulated (72).

Diabetes mellitus can also involve peripheral, cranial, and autonomic nerves. Because 40% to 45% of all patients with ESKD have diabetes, it is important to distinguish diabetic from uremic neuropathy. The clinical picture in diabetic and uremic neuropathy can be similar, but there are some differences. In diabetic neuropathy overt autonomic dysfunction, cranial nerve involvement, and compressive neuropathies are more common. Diabetic neuropathy can be asymmetric and could present with a distinctive clinical picture, as in diabetic amyotrophy that manifests with painful proximal leg weakness. Electrophysiologic studies and nerve biopsy are not helpful in making this distinction, with both disorders showing evidence of axonal disease. Importantly, diabetic polyneuropathy will not respond to

hemodialysis or transplantation.

Mononeuropathies

Carpal Tunnel Syndrome

Carpal tunnel syndrome is the most common mononeuropathy in patients with CKD, just as it is in patients without renal insufficiency. However, in certain situations, kidney disease patients are especially liable to develop median nerve entrapment. In patients with CKD, carpal tunnel syndrome has been associated with arteriovenous fistulas between the radial artery and the cephalic vein in the forearm (73). The symptoms of tingling dysesthesias in the median nerve distribution with nocturnal exacerbation are similar to those reported by nonuremic patients, although in uremic patients, these symptoms may get worse during dialysis. This exacerbation is most likely related to a combination of compression and median nerve ischemia within the carpal tunnel because of venous congestion and edema. In refractory cases, treatment may ultimately require closure of the fistula.

Amyloidosis will develop in some patients on chronic hemodialysis because of β_2-microglobulin deposition and may produce carpal tunnel syndrome (this is discussed in detail in Chapter 23).

Ischemic Monomelic Neuropathy

Rarely, an arteriovenous fistula placed in the proximal upper arm can induce severe ischemia involving the median, ulnar, or radial nerve (see Chapter 4) (74,75). Pathologically, the shunting of blood in the arm and transient loss of blood flow produces acute multiple mononeuropathies, with axon loss that is most marked distally. Clinical manifestations consist of acute onset of limb pain associated with distal weakness and sensory loss. Nerve conduction studies demonstrate abnormalities in multiple distal nerves in the affected limb, and electromyography (EMG) also shows distal greater than proximal abnormalities in muscles consistent with the clinical picture. Ischemic monomelic neuropathy is considered a medical emergency and requires prompt surgical closure of the fistula or shunt. Severe or permanent neurologic sequelae may occur even after the fistula or shunt has been closed.

Compressive Neuropathies

Compressive neuropathies involving the ulnar nerve at the elbow and the peroneal nerve at the fibular head occasionally occur during ESKD, particularly if the patient is malnourished and bedridden for any length of time. Uremic toxins make the nerves more susceptible to damage from focal compression. Successful renal transplantation restores the function of these nerves.

Myopathy

Myopathy can occur in CKD and usually appears when the GFR falls under 25 mL/min and can affect up to 50% of patients on dialysis. The clinical features include proximal muscle weakness, muscle wasting, bone pain, increased fatigability, and reduced exercise tolerance. EMG and creatine kinase levels are often normal while muscle biopsy may show type 2 muscle fiber atrophy. Possible etiologic factors for myopathy include accumulation of uremic toxins, abnormalities of vitamin D metabolism, insulin resistance, malnutrition, and carnitine deficiency (76). The myopathy of CKD may respond to high doses of vitamin D while supplementation with L-carnitine has produced mixed results. Successful renal transplantation can cause significant improvement of symptoms but may not fully restore muscle function

to normal (77). Rarely CKD may be associated with widespread arterial calcification in small subcutaneous and intramuscular arteries with skin necrosis, painful myopathy, and myoglobinuria. The incidence of this complication has been greatly reduced by improvement in dialysis techniques (78). The differential diagnosis of chronic myopathy also includes the nonspecific cachexia associated with CKD. Acute myopathy can be caused by abnormalities of potassium metabolism, and muscle weakness resulting from defective transmission at the neuromuscular junction occurs as a complication of aminoglycoside antibiotics.

CHAPTER 31

Diabetes Management in a Patient with End-Stage Kidney Disease

Andrew Kowalski, Ruchita Patel, Armand Krikorian, and Edgar V. Lerma

EPIDEMIOLOGY

For some time, diabetes mellitus (DM) has been known to be the leading cause of chronic kidney disease (CKD) in the world. Diabetic kidney disease (DKD) is a well-known complication hastened by uncontrolled diabetes, and unfortunately, it is a condition that affects millions around the world. Estimations in the United States demonstrate that diabetes is responsible for approximately 50% of all end-stage kidney disease (ESKD) in the developed world (1). Although the number of ESKD patients due to diabetes continues to rise, with nearly 50,000 new cases in 2011, the incidence has seemed to have plateaued over the last decade (2). This plateau may be attributed, in part, to an increase in education and awareness, easy accessibility to supportive medications, and due diligence in screening on the part of primary care providers. Despite this trend, the prevalence of DKD is increasing in the United States with an increase from 7.4% to 9.6% in adults over the age of 20 years from 1998 to 2006 (3). Differences remain among socioeconomic classes and ethnic subgroups such as African Americans, Hispanics, and Native Americans having a higher rate of ESKD (4). This is likely in response to the increase in incidence of type 2 diabetes and obesity that is plaguing younger generations allowing the expansion of diabetes at younger ages (4).

Current advances in renal replacement therapy, especially dialytic modalities, have slowly decreased mortality rates over the past years. According the United States Renal Data System, mortality rates have declined 26% since 1985 and 21% since 2000 in patients receiving hemodialysis (1). Additionally, 52% and 61% of patients receiving hemodialysis and peritoneal dialysis, respectively, are still alive after 3 years of therapy. Despite these advances, the all-cause mortality rate still remains high in patients receiving dialysis, 6.5 to 7.9 times greater than in the general population (1). Moreover, diabetic dialysis patients have a worse survival than those with other ESKD etiologies with a survival of 34% at 5 years

(2). It can be inferred that if this trend continues, then two probable paths will emerge, either the incidence will continue to increase proportionally with an increase in DKD and progression to ESKD or there will be a maintained plateau or even fall in ESKD prevalence with continued focus of prevention of DKD (3). That is why it is imperative that continued education, perseverance of screening, and appropriate pharmacotherapy be implemented.

IMPACT ON PATIENTS AND RESOURCES

DKD continues to have a large impact on patient morbidity and financial institutions. Kidney disease, notably albuminuria, and declining glomerular filtration rates are independent risk factors for cardiovascular disease and noncardiovascular mortality (4). These consequences are related to the micro- and macrovascular sequelae that arise from repeated insults of oxidative stresses and inflammatory mediators as a result of chronic diabetes. Furthermore, ESKD confers a risk of cardiovascular disease about 40 to 50 times greater than the general population (5).

The financial burden of ESKD is high and has been steadily increasing. In 2012, Medicare's expenses for ESKD had risen 3.2% from the previous year, the highest in the last 20 years, accounting for a total of $28.6 billion and 5.6% of the total Medicare expenditure (1). These expenses cover 5,525,481 ESKD patients in the prevalent Medicare population, along with 111,418 non-Medicare patients, with the latter adding an additional estimated $14.93 billion (1). The total fee-for-service in the hemodialysis population in per person per year (PPPY) were $87,945 in 2011 and for peritoneal dialysis patients $71,630 PPPY (1). These costs have led to significant economic strain on the U.S. health care system especially in light of budget cuts in recent years.

MORTALITY IN PATIENTS WITH DIABETES AND END-STAGE KIDNEY DISEASE

Although there is an increased risk of mortality related to end-stage microvascular events such as progressive nephropathy and retinopathy, cardiovascular events have escalated rates of morbidity and mortality in patients with DM (6). Multiple studies have been conducted to evaluate cardiovascular and all-cause mortality in diabetic patients with comparison between intensive versus conventional/standard glycemic control therapy.

In patients with type 1 DM, Diabetes Control and Complications Trial (DCCT) demonstrated that intensive glycemic control [targeting a glycated hemoglobin (Hb_{A1c}) level of less than 7% vs. 9%] delayed the onset of microvascular complications and nephropathy with a 34% and 56% reduction in microalbuminuria and macroalbuminuria over a mean follow-up period of 6.5 years (7). In Epidemiology of Diabetes Interventions and Complications (EDIC), a follow-up study was completed to evaluate cardiovascular outcomes in this population. DCCT could not assess such results because of the younger population demography (ages 13 to 39 years). EDIC monitored patients for an 11-year period and found that intensive glycemic control lowered the risk of a cardiovascular event by 42% and by 57% for a severe cardiovascular event. It was extrapolated that those patients with cardiovascular events also had some level of retinopathy or nephropathy concurrently. Thus, EDIC demonstrated that intensive glycemic

control contributed to a decrease in end organ damage, including nephropathy (7).

There are four significant trials that examined cardiovascular events in patients with type 2 DM, in comparing intensive versus conventional glucose control. In the United Kingdom Prospective Diabetes Study (UKPDS), intensive glycemic control (fasting glucose <108 mg/dL, median Hb_{A1c} 7.0%) led to a 25% reduction in microvascular complications (mainly retinopathy requiring photocoagulation) in patients with newly diagnosed with type 2 DM. There was also a reduction in myocardial infarctions and all-cause mortality that was ascertained during a 10-year follow-up period (8). This amount of extended follow-up could not be replicated in the other studies analyzing similar variables (8).

Afterward, in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial, the initial goal aimed to see if the results from DCCT crossed over to patients with type 2 DM. In ACCORD trial, the intensive glycemic control group had an average Hb_{A1c} <6%, while the standard glycemic control group had an average Hb_{A1c} of 7% to 7.9%. Diverging from similar studies, ACCORD trial found that patients in the intensive therapy group had increased mortality, with no improvement in cardiovascular risk reduction. The original study was prematurely halted due to this statistically significant and surprising finding. A follow-up of the study illustrated a reduction in nonfatal cardiovascular events (9).

Concurrently, in the Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation (ADVANCE) trial, patients with onset of DM after age 30 years were examined. There was a 23% reduction of microvascular events such as nephropathy in the intensive glycemic control (Hb_{A1c} less than or equal to 6.5%) study group compared to the standard one at a mean 5-year follow-up period. In contrast to the ACCORD trial, there was not an increased risk of mortality in the intensive glycemic control study group. An additional 5-year follow-up demonstrated similar findings as well (9).

In Glucose Control and Vascular Complications in Veterans with Type 2 Diabetes [Veterans Affairs Diabetes Trial (VADT)], a similar group of patients was found to have no significant improvement in cardiovascular event rate after randomization to intensive versus standard glycemic control study groups. After a 5.6-year follow-up, the constricted group (average Hb_{A1c} 6.5%) had a decreased occurrence of microvascular events, in mainly the incidence of nephropathy. However, the number of deaths did not significantly differ between the two study groups (10).

In review of these trials, it is concluded that long-term intensive glucose control (Hb_{A1c} around 7%) corresponds to the delay in developing kidney disease secondary to DM. The question of whether CKD itself presents a risk factor for cardiovascular mortality is not addressed in these studies, as most of the selected patients did not have preexisting CKD from another known etiology. Unfortunately, there have been no randomized controlled trials assessing mortality in patients with diabetes and ESKD. Therefore, the clinician’s goal is to aim for optimal glycemic control in patients, with the hope to prevent DKD or delay the progression.

GLUCOSE HOMEOSTASIS IN RENAL DYSFUNCTION

Insulin utilization in muscle and adipose tissue is the rate-limiting step that sets into action specific transporter proteins to translocate glucose into cells (11). These actions are precipitated by the phosphorylation of the insulin receptor substrate 1 (IRS-1), thereby leading to the activation of other

downstream proteins, namely, protein kinase C, glycogen synthase, and endothelial nitric oxide synthase, and ultimately leading to the uptake of glucose (11).

In light of renal dysfunction, glucose homeostasis experiences altered functions, with episodes of sustained or periodic hyper- or hypoglycemia (12). Abnormal glucose control has been a known manifestation of renal dysfunction, notably ESKD, for many decades (13). Although diabetes plays a key role, patients with ESKD from other etiologies have also been noted to experience altered glucose metabolism leading to a mild fasting hyperglycemia and episodes of spontaneous hypoglycemia (14).

Insulin Clearance

One of the key abnormal factors that surround glucose homeostasis in ESKD is the clearance of insulin by the kidneys. Insulin clearance is mediated by its uptake and degradation in the peritubular and endothelial cells of the kidney (13). Glomerular filtration has little effect on insulin clearance until the filtration rate drops below 40 mL/min. The uptake and degradation of insulin is increased as the filtration rate decreased, until the filtration rate reaches 15 to 20 mL/min, and then the rate of insulin clearance declines proportionally (13). The rate of insulin uptake and degradation is also affected by other factors that lead to a prolonged half-life of the compound. As kidney function begins to decline, other toxins begin to accumulate and sites of nonrenal insulin degradation such as muscle and liver begin to experience impaired function contributing to a longer circulating time (13).

Hyperglycemia

In the advanced stages of CKD, hyperglycemia and glucose intolerance continue to progress until a decline in insulin secretion and insulin resistance is observed (13). Hyperglycemia, as a manifestation of insulin resistance and glucose intolerance, has also been observed in nondiabetic patients. This suggests that one of the presenting features of ESKD is insulin dysregulation and that it possibly plays a role in the alteration of glucose regulation (13). Studies have looked at insulin receptor sites in uremic patients and through the investigation of muscle biopsies rendered normal insulin binding and activation of downstream proteins (15). This suggests that in uremic patients, the mechanisms are not related to alterations in the protein complexes themselves but may be related to an outside influence. One suggestion is the possibility of oxidative and nonoxidative pathways augmenting insulin resistance (16). Although the exact pathogenesis is not known, it is speculated that accumulation of uremic toxins, such as pseudouridine and asymmetric dimethyl arginine (ADMA), may play a role in insulin resistance, as improvements in sensitivity has been observed when patients began dialysis (17). Additionally, urea, which was never given weight in terms of toxicity, has been shown in animal models to induce reactive oxygen species and lead to insulin resistance (18). Long-standing metabolic acidosis may also play a role in insulin resistance as it has been associated with progressive inflammation and protein-energy malnutrition due to its influence on catabolic effects at the cellular level (19). Administration of bicarbonate has been shown to mitigate its effects with improved insulin sensitivity and insulin secretion in uremic patients (20).

Chronic inflammation, as in ESKD, also leads to impaired glucose uptake due to the release of inflammatory mediators such as interleukin 6 (IL-6), C-reactive protein (CRP), interleukin 1 beta (IL-1-β), and tumor necrosis factor alpha (TNF-α) (21). TNF-α appears to play a major role in insulin resistance through multiple mechanisms. Downstream effects of TNF-α mediation have been shown to

induce the phosphorylation of muscle cell IRS-1 that is linked to two main pathways: phosphatidylinositol 3-kinase and protein kinase B (18). These two pathways are metabolically responsible for the majority of glucose transport. With the phosphorylation of IRS-1, downstream effects are activated in the insulin receptor that ultimately leads to a failure of the signaling pathway and disrupts glucose transporter type 4 (GLUT4) translocation, thereby interfering with glucose uptake (22). This was observed after the infusion of TNF-α in healthy humans, where downstream effects lead to the dysfunction in the GLUT4 transporter (23). TNF-α is also responsible for the induction of lipolysis and accumulation of free fatty acids that contribute to insulin resistance through the induction of additional inflammatory markers in the hepatic system (24). IL-6 contributes to insulin resistance by the induction of suppressors of cytokine signaling (SOCS) proteins responsible for feedback regulation (25). These proteins directly affect the insulin receptor and IRS-1 resulting in an inhibition of glucose translocation into muscle and adipose tissue (25).

Other factors have also emerged that lead to the suggestion that alterations in metabolism, primarily adipose tissue, have played a role in insulin resistance. Adipose tissue, accounting for less than 2% of glucose load usage, is now acknowledged as an active organ that secretes numerous enzymes, hormones, and cytokines (26). The tissue is rich in macrophages and adipocytes, and it is speculated that these cells release TNF-α and IL-6 among other cytokines, commonly referred to as adipokines (26). Data suggests that in uremic patient's adipose tissue, primarily visceral fat, is an important source of these inflammatory molecules (27). The progressive reduction in renal function contributes to the imbalance of these adipokines, along with decreased clearance of proinflammatory cytokines leading to a state of chronic inflammation (26).

Many adipokines play a role in the augmentation of insulin sensitivity. Leptin is a small peptide responsible for energy expenditure and the feeling of satiety that is commonly filtered by the kidney and degraded in the renal tubules (28). This peptide appears to have a correlation with CRP and has been suggested that elevation in its plasma concentration may be a major contributor in uremic cachexia (29). Interestingly, additional studies in animal models have proposed that hyperleptinemia may lead to increased expression of TGF-β and therefore contribute to the development of tubulointerstitial fibrosis and nephron destruction further decreasing renal clearance (30). Although chronic plasma elevations of leptin may contribute to worsening kidney disease, its association with insulin resistance is not quite understood. It has been observed that elevated plasma concentrations of leptin appear to be associated with elevated insulin levels leading to the speculation that resistance is present (31).

Adiponectin is another small adipokine peptide that is predominantly secreted by adipocytes. Unlike other cytokines, adiponectin has many protective biologic roles as it appears to have anti-inflammatory and antiatherogenic properties along with an insulin sensitizing effect by inducing GLUT4 (32). Its actions are primarily responsible for assisting in the production on nitric oxide in the endothelial cells, fatty acid oxidation, and inhibition of hepatic gluconeogenesis (33). Although adiponectin is a desirable peptide, lower levels are a result of chronic inflammation and have been implicated in increasing the risk for cardiovascular disease and the development of insulin resistance (34). Although lower concentrations are associated with resistance, patients undergoing hemodialysis were found to have exceptionally high levels of adiponectin (35). The elevation is likely related to the decrease in renal function; however, there is some minor evidence that there might be an upregulation in adiponectin synthesis in response to the uremic inflammatory state (36). Despite ESKD patients having elevations in adiponectin, it is currently

unknown as to how this relates to insulin resistance.

Recent evidence has pointed to the role of vitamin D deficiency and secondary hyperparathyroidism in insulin resistance, suggesting that there is an inverse relationship between serum 25-hydroxyvitamin D and insulin resistance (13). One of the nonclassical effects of vitamin D is the effect on the islet cells in the pancreas and the stimulation of insulin secretion (37). Vitamin D repletion has been shown to increase insulin secretion and improve glucose tolerance in hemodialysis patients without changes in parathyroid hormone concentration (37).

Finally, a major contribution to hyperglycemia in patients undergoing dialysis is the use of larger glucose concentrations in peritoneal dialysis. Glucose concentrations in dialysate can range from 1,360 to 3,860 mg/dL and can contribute to as much as 10% to 30% of a patient's total caloric intake (38).

Hypoglycemia

Alterations in renal physiology compounded with dialytic therapy have been observed to change the natural course of diabetes, leaving the patient with variability in glucose homeostasis (39). The uremic milieu has been thought to contribute to poor glucose tolerance and a decrease in insulin sensitivity leaving the patient with episodes of hyperglycemia (2). Despite these observations, spontaneous resolution of hyperglycemia, along with an impressive normalization of Hb_{A1c}, has been seen in patients undergoing dialysis, regardless of other treatment modalities (39). This phenomenon has been described as "burnt-out" diabetes, where in many diabetic patients undergoing dialysis, the occurrence of glucose normalization with spontaneous hypoglycemia results in the cessation of antidiabetic therapy in hopes of mitigating the potentially fatal episodes (40).

This condition appears to be multifactorial, with numerous factors contributing to glucose normalization. As progression to ESKD occurs, there is an observed reduction in the nephron mass (41). This reduction, likely related to nephron scarring and an attenuation of function, may lead to the reduced renal gluconeogenesis (42). Additionally, the uremic milieu asserts its deleterious effect on hepatic functions by disrupting the mechanisms of insulin clearance, thus contributing to an increase in the half-life of circulating insulin (13). The process of insulin clearance and degradation is affected once the filtration rate declines to below 15 to 20 m/min (39).

Along this thought, the decline in filtration rate leads to the accumulation of multiple uremic toxins (39). Guanidine solutes contribute to a large variety of compounds that make up the uremic milieu (43). Several have been implicated in vascular disease acceleration and have been identified as players in neuronal, cardiovascular, leukocyte, erythrocyte, and platelet dysfunction (43). Biguanides are frequently used to treat type 2 diabetes, and interestingly, their structure is composed of a simple marriage between two guanidine with the loss of an ammonia group (2). It has been suggested that the accumulation of these guanidine groups may contribute to the stabilization of blood glucose and the normalization of Hb_{A1c} (2).

These metabolic instabilities have been observed to extend beyond the context of glucose homeostasis. Physical fitness has long been advised a method of glucose control (13). Observations have been made with dialysis patients who participate in a long-term fitness program resulting in improved glucose tolerance, normalizations of glycemic, and exercise capacity (44).

Existing evidence has shown that uremia contributes to muscle protein catabolism and likely other metabolic defects (12). Nondiabetic and nonobese patients undergoing dialysis have also been observed

to undergo similar muscle protein catabolism (12). This breakdown has been implicated through the ubiquitin–proteasome pathway due to the suppression of phosphatidylinositol-3 kinase (39).

Glucose utilization may also be improved by the influence of diabetes in the mechanics of gut motility. Diabetic gastroparesis leads to slowing of gut motility leading to early satiety and contributes to poor oral intake and malnutrition (13). Along that thought, distention of the abdominal cavity caused by peritoneal dialysate may also contribute to the delayed gastric emptying and interfere with food intake and utilizations (45). Additionally, there is evidence that suggests that hemodialysis may also lead to dysfunction of myenteric activity, thereby contributing to the gastric dysfunction in ESKD patients (46). Long durations of poor glycemic control has been associated with a higher incidence of gastroparesis; fortunately, prokinetic agents have been shown to ameliorate the effects and lead to improved absorption in this population (47).

MONITORING

Management of diabetic patients undergoing dialysis has numerous challenges as previously stated. The question arises as to how to monitor such a patient to mitigate the complications associated with attempting to achieve glucose homeostasis. Guidelines have proposed the use of Hb_{A1c} as a tool with a goal of <7% and a slightly less stringent goal for the elderly (48). Dialysis patients pose a challenge as their comorbidities and metabolic derangements often lead to inaccuracies in laboratory methods. These inaccuracies have led to the investigation of other laboratory modalities, namely, fructosamine and glycated albumin (2).

Fructosamine

Fructosamine is a measurement of nonenzymatically glycated serum proteins that have stable ketoamines (49). This measurement has become increasingly popular as a metric for short-term glucose monitoring in ESKD patients, with an assessment period of about 7 to 14 days (12). Fructosamine has been of interest because of its ability to more accurately predict glycemic control in states of chronic anemia regardless of the use of erythrocyte-stimulating agents (40). Despite these accuracies in altered hemoglobin levels, fructosamine has been observed to underestimate glucose control in states of dysproteinemias, such as malnutrition, protein-energy wasting, hepatic disease, steroid use, and in peritoneal dialysis (50). Although fructosamine's accuracy offers diminishing returns in states of hypoproteinemia, studies have shown that its use may be beneficial as a predictor of increased hospitalization and infection (51). Additionally, fructosamine has been observed as a marker of cardiovascular mortality, with evidence supporting a doubling of fructosamine correlating with a twofold increase in cardiovascular disease (52).

Glycated Albumin

Similar to the formation of fructosamine, glycated albumin is a nonenzymatic reaction of glucose with albumin that is able to measure glucose control within a similar time frame of 7 to 14 days (53). Studies have proposed that glycated albumin is a better measure of glycemic control in patients with diabetes and CKD, although few studies have looked into its impact on ESKD (12). As with fructosamine, glycated albumin is not influenced by erythrocyte lifespan, anemia, or erythropoietin stimulants but is influenced by abnormal protein turnover, peritoneal dialysis, infections, malnutrition, and steroids (2). Although

fructosamine and glycated albumin have many similarities, improved assays have allowed glycated albumin greater accuracy in settings of hypoalbuminemia (54). Glycated albumin has also been noted to be superior to Hb_{A1c} as large studies discovered lower values of Hb_{A1c} when compared to direct glucose measurements and glycated albumin suggesting a better representation of overall glucose control (54). Additionally, increasing concentrations of glycated hemoglobin were believed to be a strong predictor of hospitalization and overall mortality as compared to glucose levels and Hb_{A1c} (55). Despite the limitations of fructosamine and glycated albumin, further research and deeper investigation is warranted into these novel metrics as interest has shown a specific niche and predictive value in patients with ESKD.

Hemoglobin A1c

Hb_{A1c} is typically described as a nonenzymatic reaction between hemoglobin β chains and glucose and is typically illustrated as a percentage of the total hemoglobin exposed to glucose over time (39). This measurement offers a rough 120-day timeline of a patient's average blood glucose concentration. The value is influenced by numerous factors: glucose concentration, anemia, length of glucose exposure, serum pH, and temperature; therefore, it is not unreasonable to expect alterations in Hb_{A1c} in dialysis patients with their prevalence of metabolic derangements (50). Exposures to elevated urea concentrations have been shown to lead to the formation of carbamylated hemoglobin, which is indistinguishable from Hb_{A1c} in certain assays (2). Furthermore, Hb_{A1c} appears to normalize in the dialysis population, and this can be attributed to a number of factors. With progression to ESKD, erythropoietin production diminishes leading to a state of chronic anemia. The uremic milieu also contributes to a decreased erythrocyte lifespan by leading to hemoglobinopathies and an increase in erythrocyte fragility (12). Erythropoietin has thus been frequently utilized as a stimulating agent to increase the production of erythrocytes (56). All of these factors have led to the phenomena of Hb_{A1c} normalization. Additionally, chronic anemia and a decreased erythrocyte lifespan have led to an underestimation of Hb_{A1c}, compounded by the utilization of erythrocyte-stimulating agents, which lead to the production of new, nonglycated erythrocytes and thus leading to a further decrease in Hb_{A1c} (56).

Despite the evidence of uremia and anemia affecting the value of Hb_{A1c}, guidelines from the Kidney Disease Improving Global Outcomes (KDIGO) and the Kidney Disease Outcomes Quality Initiative (KDOQI) recommend long-term and routine Hb_{A1c} measurements along with home blood glucose monitoring as a staple in the management of diabetes in patients with ESKD (57).

OPTIMUM GLUCOSE CONTROL

Appropriate glucose control in ESKD patients has long been a concern and struggle for health care professionals. Large trials have demonstrated that uncontrolled blood glucose predisposes patients to micro- and macrovascular disease and have stressed the importance of targeting Hb_{A1c} to <7% (39). More recent landmark trials such as ADVANCE trial, the VADT, and ACCORD trial pointed out that intensive glycemic control may have no benefit on cardiovascular outcomes and in patients with preexisting cardiovascular disease may even increase the risk of mortality (58). This has led to some

concerns as normalization of blood glucose in patients with underlying cardiovascular disease may potentially lead to an increase in mortality (59).

As previously mentioned, ESKD patients are at risk for hypoglycemia and have been observed to normalize their Hb_{A1c} over time, with one study suggesting that about 33% of diabetic dialysis patients have an Hb_{A1c} of <6% (60). This leads to the uncertainty of an optimal glycemic target in dialysis patients (2). In an attempt to answer this question, there was a small study that showed no correlation between Hb_{A1c} and mortality. It was quickly criticized due to the lack of repeated Hb_{A1c} measurements and multiple confounders (61). A subsequent study with a longer duration of follow-up initially suggested an increase in mortality with lower Hb_{A1c} levels. This study was also criticized when adjusted for other confounders such as malnutrition and inflammation: Higher Hb_{A1c} levels correlated with mortality (60). Building on these two studies, subsequent research has pointed out that Hb_{A1c} exhibits a J-shaped curve with mortality being prevalent at <6.5% and >11% (62). More recent work has suggested that Hb_{A1c} values of <6% and >8% were associated with an increase in mortality (63). Additionally, analysis has also suggested that a lower Hb_{A1c} may be a marker for malnutrition and worsening illness (2). Currently, KDIGO and KDOQI recommend that Hb_{A1c} in dialysis patients be maintained >7% in those with comorbidities and decreased life expectancy to minimize the risk of hypoglycemia and death (57).

Although no studies have looked at a comparison of hemodialysis to peritoneal dialysis, observational data supports that both modalities might be equally efficacious (12). When diving deeper into recent literature, suggestions have arisen that hemodialysis might have a slightly better advantage in survival, but this appears to be short lived with disadvantages emerging after 2 years of use (64). Further differences appear between the two modalities in regard to diabetic patients with abnormal glucose homeostasis. Patients undergoing peritoneal dialysis, especially diabetic patients, are at risk of developing peritoneal fibrosis at a faster rate and ultimately compromising ultrafiltration (12). Additional challenges in glucose management stem from the high glucose concentration in the peritoneal dialysate. This large glucose load often contributes to the patient's morbidity and offers additional challenges in achieving glucose control (12). Glucose control may be achieved with the substitution of dextrose with icodextrin. This polymer is advantageous in that it is minimally absorbed across the peritoneal membrane, although lymphatic absorption does occur (65). While safe, its use may lead to confusion and difficulty with glucose management by the development of spurious hyperglycemia. After being absorbed by the lymphatic system, icodextrin is metabolized to maltose metabolites, which some on glucometers will register as significant hyperglycemia and if not educated properly may lead the patient to receive a larger insulin load (65).

THERAPEUTIC MANAGEMENT OF DIABETICS IN END-STAGE KIDNEY DISEASE POPULATION

There is a continuing challenge in treating patients with progressive diabetic nephropathy and specifically ESKD. Not only is mortality linked to medication side effects, namely, hypoglycemia, but cardiovascular risk of death is heightened in this population as well (57). Insulin therapy is mainstay therapy in diabetic patients with ESKD, largely due to contraindication of most oral hypoglycemic agents in severe renal

impairment. In general, oral medications are not indicated in this group because of increased drug accumulation with decreased renal clearance leads to adverse drug effects such has hypoglycemia. Dose adjustments are required in CKD and ESKD in those medications that can be used in diabetic patients in ESKD (**TABLE 31.1**) (66).

TABLE 31.1 Summary of Antidiabetic Medications and Their Use in End-Stage Kidney Disease

Drug Class	Drug	Mechanism of Action/Pharmacokinetics		Adverse Side Effects	Use in HD	Use in PD	Dose Adjustment (if Used in PD/HD)	Dialyzable?
Sulfonylureas: First generation	Acetohexamide	Closes potassium channel on pancreatic β cell membrane, promoting insulin secretion; longer half-lives than second generation	Excreted in urine	Hypoglycemia, nausea, affects liver enzymes, hypersensitivity in patients with sulfa allergies, weight gain	No	No		
	Chlorpropamide				No	No		
	Tolazamide				No	No		
	Tolbutamide				No	No		
Sulfonylureas: Second generation	Glipizide	Closes potassium channel on pancreatic β cell membrane, promoting insulin secretion	Excreted in urine	Hypoglycemia, nausea, affects liver enzymes, hypersensitivity in patients with sulfa allergies, weight gain	Yes	Yes	None	
	Gliclazide		20% excreted in urine		Yes	Yes	None	
	Glyburide		50% excreted in urine		No	No		
	Glimepiride		Excreted in urine		No	No		
Meglitinides (can be used as monotherapy in some ESKD patients)	Repaglinide	Insulin secretagogue; act at ATP-dependent potassium channels on pancreatic β cells (different site than sulfonylureas)	Excreted in feces	Hypoglycemia	Yes, with caution	Yes, with caution	Initiate 0.5 mg before each meal (not done in United States)	
	Nateglinide	Decreases postprandial glucose levels	Excreted in urine		Yes, with caution	Yes, with caution	Initiate dose of 120 mg daily	
	Mitiglinide (only approved in Japan)							
Biguanides	Metformin	Inhibits hepatic gluconeogenesis, increases peripheral sensitivity to insulin	Excreted in urine	Nausea, diarrhea, metallic taste, lactic acidosis (0.03 cases per 1,000 patient-years), weight loss	No	No		Yes
Thiazolidinediones	Rosiglitazone	Decreases hepatic gluconeogenesis; increases peripheral sensitivity to insulin by acting on PPAR-γ receptor	Primarily excreted in urine	Increase LDL-C, increased cardiovascular related mortality, volume expansion	Avoid	Avoid		
	Pioglitazone		Excreted in urine and feces	Bladder cancer, volume expansion	Avoid	Avoid		
Incretin-based: dipeptidyl peptidase 4 (DPP4) inhibitors	Sitagliptin	Increase GLP-1 activity by blocking DPP4	Excreted in urine	Hepatotoxicity, acute pancreatitis (both rare)	Yes	Yes	Initiate 25 mg/d	<15% dialyzable
	Saxagliptin		Excreted in feces		Yes	Yes	Initiate 2.5 mg/d	25% dialyzable
	Vildagliptin				Yes	Yes	Initiate low dose	
	Alogliptin				Yes	Yes	Initiate 6.25 mg/d	
	Linagliptin				Yes	Yes	None	

(*Continued*)

TABLE 31.1 **Continued**

Drug Class	Drug	Mechanism of Action/Pharmacokinetics		Adverse Side Effects	Use in HD	Use in PD	Dose Adjustment (if Used in PD/HD)	Dialyzable?
Incretin-based: glucagon-like peptide-1 (GLP-1) agonists	Exenatide	Resistant to metabolism by DPP4; increase insulin secretion and suppress glucagon secretion in a glucose-dependent manner	Excreted in urine	Nausea, vomiting, weight loss, pancreatitis, thyroid C-cell hyperplasia, and tumors (liraglutide and weekly exenatide)	No	No		
	Liraglutide		Excreted in urine and feces		Avoid	Avoid		
	Albiglutide				No	No		
α-Glucosidase inhibitors	Acarbose	Inhibits gastrointestinal α-glucosidases and pancreatic α-amylases, affecting gastrointestinal glucose absorption	Excreted in urine and feces	Flatulence, diarrhea, abdominal pain	No	No		
	Miglitol		Excreted in urine		No	No		
	Voglibose				No	No		
Sodium-glucose cotransporter 2 (SGLT2) inhibitors	Canagliflozin	Inhibits glucose absorption at the SGLT2 receptor in the renal proximal tubule, promoting glucosuria	Excreted in urine	Genitourinary tract infections, hypotension, diabetic ketoacidosis, dehydration	No	No		
	Dapagliflozin				No	No		
	Empagliflozin				No	No		
Amylin analogs	Pramlintide	Stimulates glucose dependent insulin release from pancreatic β cells, inhibits glucagon release, decreases appetite, delays gastric emptying	Excreted in urine	Nausea, hypoglycemia	Avoid	Avoid		
Dopamine 2 agonists	Bromocriptine	Unknown mechanism, may reset hypothalamic circadian activities which have been altered by obesity	Excreted in feces	Dizziness, headache, fatigue, constipation, low efficacy	No data	No data		
Bile acid sequestrant	Colesevelam	Binds with bile acids in intestine to form insoluble complex, eliminated in feces	Excreted in feces	Constipation, lowers LDL	No data	No data		
Insulin	Aspart, lispro, glulisine	Supplements endogenous insulin	Excreted in urine	Hypoglycemia, weight gain	Yes	Yes (can use intraperitoneal vs. subcutaneous)	Initiate 50% dose reduction; those on PD may require increase in dosage due to absorption of glucose from the dialysate through the peritoneal cavity	No
	Regular							
	Neutral protamine hagedorn (NPH)							
	Detemir							
	Glargine							

HD, hemodialysis; PD, peritoneal dialysis; ESKD, end-stage kidney disease; ATP, adenosine triphosphate; PPAR, peroxisome proliferator-activated receptor; LDL-C, low-density lipoprotein cholesterol; LDL, low-density lipoprotein.
Avoid = limited data on use in patients with estimated glomerular filtration rate less than 30 mL/min/1.73 m^2.

Biguanides

Metformin has been the most widely studied oral antidiabetic agent. By decreasing hepatic gluconeogenesis, its prevalent use stems from the mostly tolerable side effects. Most commonly, gastrointestinal disturbance is experienced with initial therapy that is titrated up in a stepwise manner. A benefit of the medication is the lack of weight gain observed (8). In addition, monitoring of vitamin B_{12} and folate levels is required with long-term therapy. Historically, metformin has been contraindicated in patients with renal impairment [plasma creatinine >1.5 mg/dL for men and >1.4 mg/dL in women, estimated glomerular filtration rate (eGFR) <40 mL/min/1.73 m^2]. Lactic acidosis is the rare complication most concerning with metformin use and occurs at a rate of less than 0.01 to 0.08 cases per 1,000 patient-years. Renal impairment is the greatest risk factor for the development of lactic acidosis (67). However, through review of observational and retrospective studies, metformin will not likely increase the risk of lactic acidosis in patients with CKD stage 3 (eGFR 30 to 60 mL/min/1.73 m^2), but no randomized controlled trials exist as of yet (68). About 90% of metformin is excreted through the kidneys, and thus, there is decreased elimination of the drug in patients with reduced kidney function. It is recommended the dose be halved in patients with eGFR <60 mL/min/1.73 m^2 and completely avoided in patients on dialysis (69).

Sulfonylureas

Sulfonylureas stimulate insulin secretion by binding to sulfonylurea receptors, leading to closure of adenosine triphosphate (ATP)-sensitive potassium channels on pancreatic β cells and then insulin release (69). Because of their mechanism, the most common side effects are hypoglycemia and weight gain, and its effectiveness decreases with prolonged history of DM and reduction in β cell function. The United Kingdom Prospective Diabetes Study and ADVANCE trial demonstrated sulfonylureas' success in achieving tight glycemic control (8). They are excreted mainly in the urine. First-generation sulfonylureas (acetohexamide, chlorpropamide, tolazamide, and tolbutamide) were known to have longer duration of action and so, contraindicated in dialysis patients (66). They have since fallen out of clinical practice. The second-generation medications (glipizide, gliclazide, glyburide, glimepiride) are shorter acting and subsequently have a safer side effect profile. In patients on dialysis, the only available medications are glipizide and gliclazide (not available in United States) (69). The major metabolites of glipizide, through aromatic hydroxylation, have no hypoglycemic activity. These two agents do not require dose adjustments in dialysis patients; however, initial doses are low with titration every 1 to 4 weeks (69).

Meglitinides

Similar to sulfonylureas, meglitinides are also insulin secretagogues. Their mechanism of action relies upon closure of ATP-dependent potassium channels on pancreatic β cells at a different site than sulfonylureas. Their role is utilized in lowering postprandial blood glucose levels. With its recommended use to be taken before meals, basal insulin levels are achieved 2 hours after ingestion of the drug (70). The meglitinides (repaglinide, nateglinide, and mitiglinide) are approved for use in dialysis patients. Mitiglinide is only available in Japan. Repaglinide is preferred in dialysis patients because 80% of the drug is metabolized by the liver and about 8% is excreted unchanged in the urine, so there is a lower risk of hypoglycemia (71). Initial dose is 0.5 mg taken prior to meals in dialysis patients (69). Nateglinide has

renally excreted metabolites that cause a higher risk of hypoglycemia (72). In ESKD patients, meglitinides can be used as monotherapy agents (73).

Thiazolidinediones

The thiazolidinediones (TZDs), rosiglitazone and pioglitazone, are medications that activate peroxisome proliferator-activated receptors (PPARs). They lower blood glucose levels by increasing peripheral sensitivity to insulin, in addition to decreasing hepatic gluconeogenesis (70). The side effect profiles of both of these medications have led to its infrequent use in recent years. Rosiglitazone was initially thought to lead to increased myocardial infarctions, but a large randomized controlled trial did not show similar results (74). That same randomized controlled trial did show increased risk of heart failure and fractures with rosiglitazone, compared with standard glucose-lowering agents such as metformin and sulfonylureas. However, there was no increased risk of overall cardiovascular morbidity and mortality with its use compared with standard therapy (74). Rosiglitazone can be administered in dialysis patients because less than 1% of its active metabolites are excreted unchanged in the urine. There is no dose adjustment required. Pioglitazone has been linked to increased bladder cancer risk in a large randomized controlled trial (75). Both medications are shown to cause weight gain, along with fluid retention, and thus are generally avoided in ESKD patients (66).

Incretin-Based Therapies

Among the newer antidiabetic agents, the incretin-based therapies have provided an addition to the list of possible medications appropriate for use in dialysis patients. Glucagon-like peptide-1 (GLP-1) is an intestinal hormone that is secreted in response to food, triggering insulin secretion, along with a decrease in glucagon secretion, gut motility, and increase in satiety (70). Dipeptidyl peptidase 4 (DPP4) is an enzyme that breaks down GLP-1.

Glucagon-Like Peptide-1 Agonists

GLP-1 agonists include exenatide, liraglutide, and albiglutide. In contrast to previously mentioned antidiabetic agents, GLP-1 agonists are administered subcutaneously and, in addition, only recommended for adjunct therapy (70). Exenatide is not recommended for use in dialysis patients, and ingestion leads to intolerable nausea, diarrhea, and headache (57). In studies with rats, liraglutide use has led to C-cell hyperplasia, raising concerns for risks of medullary thyroid carcinoma. A randomized controlled trial with 24 patients with type 2 DM and ESKD and 23 control subjects with just type 2 DM demonstrated statistically significant increased plasma through levels of liraglutide in ESKD patients compared to the control group, with increased temporary nausea and vomiting as well (76). Therefore, liraglutide use is not advised in ESKD patients. There is limited data with albiglutide use in severe renal impairment, and thus, its use is not advised.

Dipeptidyl Peptidase 4 Inhibitors

DPP4 inhibitors include sitagliptin, saxagliptin, linagliptin, alogliptin, and vildagliptin (not approved for use in the United States). By increasing GLP-1 activity, these agents work by decreasing postprandial hyperglycemia. Aside from linagliptin, all other members of this class are excreted by the kidneys and require dose adjustments in ESKD patients. The main side effects include weight neutrality and possible

hepatotoxicity (70). Sitagliptin dosing is initiated at 25 mg daily in ESKD patients (77). Saxagliptin had similar results in an open-label study with severe renal impairment patients, and recommended initial dose is 2.5 mg daily (78). In addition, about 23% of the drug will be removed with a 4-hour hemodialysis session, so an additional dose may need to be given after it is completed (79,80). Alogliptin dose is adjusted to 6.25 mg daily in ESKD patients, but caution is advised (69). Vildagliptin use in patients with moderate or severe CKD had similar adverse event profiles in the placebo and vildagliptin groups and also labeled with the same warnings as the alogliptin (81). Linagliptin is not renally excreted and therefore does not require dose adjustment; however, its safety has not been extensively studied in the dialysis population (66).

α-Glucosidase Inhibitors

The α-glucosidase inhibitors include acarbose, miglitol, and voglibose (not available in the United States). This class of medications inhibits the enzyme α-glucosidase from metabolizing polysaccharides to monosaccharides (70). Glycemic control is achieved through maintaining homeostatic glucose levels postprandially. The side effect profile limits its use, mainly gastrointestinal: abdominal discomfort, diarrhea, flatulence (2). These medications are not advised in ESKD because of the accumulation of metabolites in severe renal impairment, along with lack of clinical trials, on its use in diabetic patients with ESKD (69).

Sodium-Glucose Cotransporter 2 Inhibitors

The sodium-glucose cotransporter 2 (SGLT2) receptor is found in the proximal renal tubule and responsible for about 90% of glucose reabsorption. Currently, there are three medications in this class: canagliflozin, dapagliflozin, and empagliflozin. The main side effects of these medications include glucosuria, dehydration, and natriuresis. As being the only antidiabetic agent to exhibit its effects on the kidney itself, this class of medications is contraindicated in ESKD patients (82). Canagliflozin is the only SGLT2 inhibitor that can be used in patients with eGFR of 45 mL/min/1.73 m^2 and greater (83). Recent data from four randomized placebo controlled phase 3 studies indicated that canagliflozin dosed at 100 mg daily will lead to a 0.47% reduction in Hb_{A1c} with a greater number of patients reaching target Hb_{A1c} of <7.0%, compared to placebo. This effect was largely seen in patients with stage 3a CKD (eGFR 45 to <60 mL/min/1.73 m^2), as opposed to stage 3b CKD (83). Even though there was a slight decrease in eGFR (10% to 15%) after initiation of therapy, kidney function trended toward baseline after 6 weeks of therapy. This transient decline in kidney function is secondary to intravascular hemodynamic changes after initial therapy and does not suggest progression of CKD (83).

Amylin Analogs

Another medication available to assist in lowering postprandial hyperglycemia is pramlintide, an amylin analog. This medication is appropriate for use in both type 1 and 2 DM. It is an endogenous hormone secreted by pancreatic β cells in response to postprandial hyperglycemia. As an adjunct therapy to mealtime insulin, its use enhances satiety, delays gastric emptying, increases hepatic glycogen synthesis, and subdues postprandial glucagon secretion. Pramlintide has not been studied well in dialysis patients, and therefore, its use in this population is not advised (84).

Bile Acid Sequestrants and Dopamine-2 Agonists

Colesevelam is an antihyperglycemic agent used in type 2 DM with a poorly understood mechanism of action. Its use has been beneficial in diabetic patients with elevated low-density lipoprotein cholesterol levels (85). For dopamine agonists, the antihyperglycemic effect is theorized around the proposed reset of the circadian rhythm in the hypothalamus, leading to less insulin resistance (86). No clinical studies have been conducted for either class on diabetic patients with CKD and ESKD.

Insulin

Insulin therapy is recommended for most patients with ESKD. However, even though it is the most commonly used medication in diabetics with ESKD, it carries a significant risk of hypoglycemia. Insulin's half-life is prolonged since the diseased kidney cannot metabolize it effectively. In addition, there is decreased first-pass hepatic metabolism in ESKD with exogenous use. The improved insulin sensitivity that occurs with the start of hemodialysis contributes to an increased risk of hypoglycemia as well (17). In general, there is basal (glargine, detemir, neutral protamine hagedorn) and mealtime or correction (aspart, regular, lispro, glulisine) insulin therapies. It is recommended to decrease the insulin dose by 50% in patients with ESKD (87). The approach for insulin dosing in ESKD patients is individualized because of variable meal schedules, and thus, no superior treatment, basal, or mealtime has demonstrated a reduction in Hb_{A1c} or other clinical outcomes (88). There are no studies conducted regarding insulin pump use in patients with CKD (12).

In peritoneal dialysis, insulin can be administered subcutaneously or intraperitoneally. In a meta-analysis performed on intraperitoneal insulin use in diabetic patients on peritoneal dialysis, three studies showed that optimal glycemic control was achieved with intraperitoneal insulin versus standard subcutaneous insulin use. However, insulin use was twofold higher in the intraperitoneal group and showed worsening lipid profiles (89,90). Also, there is an increased risk of bacterial contamination with injection into the dialysate bag, possible peritoneal fibroblastic proliferation, and can cause hepatic subcapsular steatonecrosis (91–93).

CHAPTER 32

Pregnancy in the Chronic Dialysis Patient

Lakshmi Kannan and Janani Rangaswami

Confortini et al. (1) reported the first successful pregnancy in a dialysis patient in 1971. Despite improving results with pregnancy outcomes, 44 years after this initial success, pregnancy in a long-term dialysis patient is still a challenging situation (2). In 1980, the European Dialysis and Transplant Association reported that only 23% of 115 pregnancies in dialysis ended with surviving infants (3). Since then, fetal survival rate in pregnant dialysis patients has increased by approximately 25% per decade, and recent estimate of live birth rates in pregnant dialysis patients touched an all-time high of 86.4%, as reported from the Toronto Pregnancy and Kidney Disease Clinic Registry (4). With prolonged waiting times for transplantation, the need to optimize maternal and fetal outcomes with pregnancy and dialysis is more relevant than ever. This chapter discusses the diagnosis and management of pregnancy in the setting of maintenance dialysis and summarizes maternal and fetal outcomes.

INCIDENCE AND DIAGNOSIS

Infertility is common in dialysis patients, with the incidence of pregnancy in end-stage kidney disease (ESKD) being approximately 2.2% per year in the United States (5).The luteal hormone surge and the estradiol peak that occurs mid to late menstruation with ovulation are absent in uremia, possibly due to the hyperprolactinemic state found in ESKD (6,7). While transplantation is the most effective way to restore fertility in these patients, intensification of the dialysis prescription by switching from intermittent dialysis to nocturnal hemodialysis increased the conception rate to 16.5% in a small series (8). The preponderance of anovulatory cycles with dialysis makes amenorrhea difficult to interpret in women with suspected pregnancy. While this should be investigated with β-human chorionic gonadotropin (β-hCG) serum testing, caution should be exercised when interpreting hCG test results in ESKD owing to high number of false-positive results (7). The half-life of circulating hCG is increased in these patients, making the test unreliable for calculation of gestational age as well. Obstetric ultrasound is favored for estimation of gestational age in pregnant women with ESKD, with the mean gestational age at which the diagnosis of pregnancy is made being 16.5 weeks (9).

DIALYSIS PRESCRIPTION IN THE PREGNANT PATIENT

Poor outcomes for pregnancy in ESKD have been attributed to uremia-induced disturbances in hormonal homeostasis and the ensuing effects on placentation and fetal growth. The increasing success with fetal and maternal outcomes with dialysis over the last decade are largely due to intensification of the dialysis prescription, with the best results coming from long, nocturnal dialysis–based regimens (8,10,11). Nocturnal dialysis with a mean dialysis duration of 36 hours preconception and 48 hours during pregnancy in a cohort of seven pregnancies resulted in a mean gestational age of 36.2 weeks and a mean birth weight of 2,417.5 ± 657 g (8). In a study by Hladunewich et al. (4) that compared outcomes between a Canadian and American cohort of pregnant dialysis women, the live birth rates were 86.4% and 61.4%, respectively (p= 0.03), and the mean gestational ages was 36.2 weeks and 27 weeks, respectively (p= 0.002) (4). Notably, the Canadian cohort received a mean of 43 hours of dialysis compared to the 17 hours provided in the United States (4). Intense dialysis regimens of five to seven times a week, with each session lasting 8 to 10 hours, are associated with improved outcomes leading to improved live birth rates, decrease in prematurity, and improved blood pressure (BP) control. Intensive dialysis improves urea clearance, lowers peripheral vascular resistance, and ameliorates fluctuations in volume status (12,13). Daily dialysis offers the advantage of decreased risk of hypotension owing to decreased fluid removal per session and allows for high protein intake to meet caloric needs of the fetus and mother. It is also hypothesized that increased solute clearance with daily dialysis reduces placental urea and thus reduces fetal osmotic diuresis and resulting complications such as polyhydramnios (12).

While maternal and fetal outcomes do not significantly differ between hemodialysis and peritoneal dialysis (9), intensification of the dialysis prescription is easier on hemodialysis. As with hemodialysis, a patient's treatment requirements will increase with peritoneal dialysis especially during the latter half of gestation (14). A switch to continuous cyclical peritoneal dialysis (CCPD) with an increased frequency of small volume exchanges, with supplemental manual exchanges, is often required in late pregnancy to achieve adequate clearance (14). Using tidal peritoneal dialysis to successfully optimize solute clearance in pregnancy with restricted abdominal volumes has been reported (15). There are no changes in peritoneal dialysis efficacy in pregnancy as measured by a standard peritoneal equilibration test (PET) of glucose and creatinine and ultrafiltration efficacy (14). Rarely, complications such as lacerations of the gravid uterine veins from trauma to the peritoneal dialysis catheter and preterm delivery from peritonitis during pregnancy have been reported (14).

Dialyzers used during pregnancy range from standard high-flux dialyzers to nonreusable biocompatible dialyzers with blood flows ranging from 200 to 400 mL/min (4). There is little data reported on vascular access for maintenance hemodialysis in pregnancy influencing the outcome. In patients dialyzing with arteriovenous fistulae, the risk of aneurysmal dilation of the fistula due to histologic changes in the vessel wall associated with the hormonal changes in pregnancy and altered pregnancy-related hemodynamics must be factored into the routine examination of the pregnant dialysis patient (16). Heparin does not cross the placental barrier and can be used safely with hemodialysis in pregnancy, without necessitating a dose reduction.

The physiologic weight gain associated with pregnancy, which is recommended to be 1 to 1.5 kg within the first trimester and thereafter 0.3 to 0.5 kg/wk (9), should be factored into dry weight assessment. With daily dialysis, fluid gains should be minimal, and BP goals of <140/90 mm Hg should

be achievable with minimal antihypertensives (9). Persistent elevations in BP despite optimal fluid removal should raise the suspicion of preeclampsia.

Target values of the main laboratory parameters suggested for pregnant women on dialysis are similar to those advised in nonpregnant dialysis patients. The pregnant patient is predisposed to respiratory alkalosis as a result of progesterone-induced hyperventilation. Hence, a bicarbonate solution concentration as low as 25 mM is preferred to standard higher concentrations to avoid superimposed metabolic alkalosis (9). With a standard 2.5 mEq/L calcium dialysate solution, the mother will need 2 g of oral calcium per day to keep a positive calcium balance and ensure the fetal calcium requirement of 25 to 30 g during pregnancy (17). The placenta secretes calcitriol which also aids in positive calcium balance.

Intensive dialysis regimens during pregnancy can result in hypophosphatemia. Most patients often do not require any phosphate binders, and at times, addition of phosphorus to the dialysate may be necessary (18). In patients with hyperphosphatemia, calcium-containing binders are preferred due to their safety profile (9). There is no experience with sevelamer or lanthanum in pregnancy (9). There is limited data currently on the effects of pregnancy on dialysis-associated metabolic bone disease profiles. Activated vitamin D analogs such as paricalcitol (pregnancy category C) and calcitriol (pregnancy category B) are dosed based on the individual nephrologist's discretion (**TABLE 32.1**).

TABLE 32.1 Commonly Used Drugs in Hemodialysis and Their Use in Pregnancy

Drug	Safety Data	Dosing and Pharmacology
Erythropoietin	FDA category C	Dosing similar to nonpregnant state, typical pregnancy requirement is double the baseline dose, placental kinetics unknown
Paricalcitol	FDA category C	Similar to nonpregnant state
Calcitriol	FDA category B	Similar to nonpregnant state
Calcium acetate	FDA category C	Similar to nonpregnant state
Sevelamer/lanthanum	FDA category C	No safety data/guidelines available
Intravenous iron	FDA category B	Similar to nonpregnant state
Heparin	FDA category C	Similar to nonpregnant state, does not cross the placental barrier

FDA, U.S. Food and Drug Administration.

MANAGEMENT OF ANEMIA

Anemia is common in pregnancy due to volume expansion. Daily iron losses are also frequent in pregnancy. In pregnant patients with ESKD, this physiologic anemia is exaggerated, and most patients will require erythropoietin and iron supplementation. Accentuated anemia and increased erythropoiesis-stimulating agent (ESA) requirements are attributed to cytokine-induced erythropoietin resistance and the effect of plasma volume expansion leading to hemodilution (19). ESA is not associated with fetal congenital anomalies at usual doses, and if patients are on ESA when they become pregnant, the dose is typically doubled for the length of the pregnancy (9). Intravenous iron supplementation can be given in pregnant dialysis patients, given the expected physiologic need for an extra 700 to 1,150 mg of elemental iron during pregnancy. The U.S. Food and Drug Administration has labeled intravenous iron as category B for pregnancy.

NUTRITION

Protein intake should be increased to meet the metabolic needs of the mother and the growing fetus. For this, a daily protein intake of 1.8 g/kg is recommended (9). Folate supplementation at higher than usual doses (around 4 mg/d) is recommended for the pregnant mother on dialysis to compensate for losses from intensification of dialysis and prevention of neural tube defects (9).

PREGNANCY OUTCOMES

Fetal Outcomes

With intensification of dialysis dose, the rate of live births has escalated from 23% in the 1970s (3) to a high of 87% (20). In the Canadian cohort (4) and in the nocturnal hemodialysis cohort reported by Barua et al. (8), the mean duration of the pregnancy was 36 weeks compared to 32 weeks on previous reports (20). Enhanced solute clearance with these regimens appears directly related to fetal outcomes with a significant negative correlation noted between blood urea nitrogen (BUN) and birth weight/gestational age (21). In a large registry performed in the United States (5), there was a nonsignificant trend toward better survival and decreased prematurity in patients who received >20 hours of dialysis per week. The ability to maintain maternal BP throughout pregnancy with minimal to no antihypertensives also offers improved fetal perfusion, in regimens such as described by Barua et al. (8).

The Australian and New Zealand Dialysis and Transplantation (ANZDATA) registry compiled all pregnancy data in dialysis patients between 1996 and 2008 (22). This registry noted superior live birth rates among women who conceived prior to dialysis initiation compared with those on dialysis at the time of conception (91% vs. 63%, p= 0.03). This study further noted that this significant difference in live birth rate was secondary to early pregnancy losses (<20 weeks of gestation) in established dialysis patients. However, beyond 20 weeks, these pregnancies were similar with no significant difference in gestational age or birth weight.

MATERNAL COMPLICATIONS

Hypertension is the major clinical concern with regard to the pregnant mother on dialysis. This could manifest as gestational hypertension, preeclampsia, or eclampsia. High placental urea leads to increased fetal solute diuresis resulting in complications such as polyhydramnios (23). Other frequently reported complications include gestational diabetes mellitus, premature rupture of membranes, chorioamnionitis, placental abruption, and hemorrhage postpartum (8).

MANAGEMENT OF HYPERTENSION IN PREGNANCY

Hypertension is notable for earlier onset (<24 weeks) in pregnant dialysis patients compared to pregnant women without ESKD. About 80% of all pregnant women on dialysis have a BP of 140/90 mm Hg or above, and 40% have severe hypertension as defined by systolic BP >200 mm Hg and/or diastolic BP >110 mm Hg (9). Improved surveillance measures that include weekly weight change assessments and daily BP measurements at home are therefore recommended. Fluid status is first determined when the mother is found to be hypertensive. Once euvolemia is established, persistent elevations in BP are managed with medications. Safe options include methyldopa (class B), labetalol (class C; selective β-

blockers are associated with intrauterine growth restriction), and calcium channel blockers (class C). Hypertensive crises are treated with intravenous labetalol or hydralazine (class C), and magnesium loading for seizure prophylaxis should be cautious with careful monitoring of serum levels (9). Recently, endothelial dysfunction and cardiovascular outcomes in chronic kidney disease (CKD) and ESKD patients have been linked to an increase in soluble fms-related tyrosine kinase 1 (sFlt1), an inhibitor of the vascular endothelial growth factor (VEGF) (24). The "antiangiogenic" milieu created by a relative VEGF deficiency with preeclampsia is reflected with persistent elevations of sFlt1 in this population at baseline (25), making it a possible nontraditional cardiovascular risk marker in these women, in addition to serving as a marker for superimposed preeclampsia.

LABOR AND DELIVERY

Pregnant women on dialysis are considered high-risk pregnancies and need close coordination care between the nephrologist and obstetrician. Biweekly antenatal monitoring to screen for fetal well-being, biometry, amniotic fluid index, cervical length, and umbilical artery pulsatility should begin at 26 weeks of gestation and increased to weekly profiles near term (4). Combinations of calcium channel blockers and magnesium should be avoided due to profound maternal hypotension. Cesarean sections are performed for obstetric indications and can be performed in patients on peritoneal dialysis if indicated (9). Newborns should be monitored in high-risk neonatal care units. The baby's BUN and creatinine will initially be elevated. This leads to solute diuresis necessitating careful monitoring of volume status and electrolytes. A snapshot of key concepts during and after the course of the pregnancy is summarized in **TABLE 32.2**.

TABLE 32.2 Highlights of Hemodialysis Management during Pregnancy

Prepregnancy	During Pregnancy	After Delivery
• High risk for fetal loss (<20 weeks) • Stop ACEI and ARB before or right after conception. • Confirm pregnancy with obstetric ultrasound in addition to β-hCG results. • Preconception counseling about higher risks of early pregnancy losses, stillbirth, fetal prematurity, and preeclampsia	• Best results with intense dialysis regimens of 5–7 times/wk of 8–10 h/session • Expected weight gain 1–1.5 kg in first trimester and 0.3–0.5 kg/wk thereafter • Oral calcium and phosphate supplements may be needed. • ESA dose is typically doubled for the length of pregnancy. • Intravenous iron to supplement the extra 700–1,100 mg of elemental iron needed • Protein intake of 1.8 g/kg/d and folate dose of 4–5 mg/d • Close surveillance for preeclampsia	• Readjust dry weight and antihypertensives. • Watch for postpartum preeclampsia.

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; β-hCG, β-human chorionic gonadotropin; ESA, erythropoiesis-stimulating agent.

SUMMARY AND RECOMMENDATIONS

In summary, while the management of pregnancy in a patient on dialysis remains complex and challenging, huge strides have been made over the last decade in terms of gestational age, live birth rate, and minimizing maternal complications with intensification of the dialysis prescription. Having an international registry for pregnancy outcomes in dialysis patients will help pool experience with the complex interface of pregnancy-related physiologic needs and the absence of the optimal renal adaptive response to this state. Close multispecialty monitoring and communication is the key to successful

maternal and fetal outcomes, which will hopefully be the standard of care with pregnancy in this population.

CHAPTER 33

Acquired Cystic Kidney Diseases in Dialysis Patients

Judy K. Tan, Jonathan Silverman, and Edgar V. Lerma

In 1977, Dunnill et al. (1) first described the presence of acquired cystic kidney disease (ACKD) in patients with end-stage kidney disease (ESKD) on hemodialysis examined on autopsy. Since then, there have been a number of reports that have been published on the association of ACKD and kidney disease.

ACKD is characterized by the development of multiple fluid-filled cysts in the kidneys of patients who do not have a hereditary cause of cystic kidney disease. A diagnosis requires the involvement of both kidneys, four or more cysts being present, and that the cysts are confined in the kidney. ESKD is frequently associated with ACKD. It occurs in patients on long-term renal replacement therapy either in the form of hemodialysis or peritoneal dialysis. During the past years, ACKD has become more prevalent with the widespread use of dialysis and as patients with ESKD tend to live longer and undergo more diagnostic imaging studies.

EPIDEMIOLOGY

The incidence of acquired cystic disease increases progressively with the duration of renal replacement therapy—hemodialysis or peritoneal dialysis. However, ACKD can occur in some patients even before dialysis is initiated. In one study of 130 patients with advanced kidney disease or ESKD, the incidence of multiple cysts was noted to be 7% in those with chronic kidney disease (CKD) and 22% in those on maintenance dialysis (2). The duration of dialysis was 15 months in patients with no cysts, 28 months in those with one to three cysts, and 49 months in those with acquired cystic disease (2). Fifty percent to 80% of patients are affected after 10 or more years on dialysis (3–5). In a similar study of 48 patients with ESKD on continuous ambulatory peritoneal dialysis (CAPD), the incidence of both solitary and multiple renal cysts was noted to be 52% in patients on CAPD for 23 ± 16 months (6). The frequency however may be underestimated on the basis of imaging studies alone. In a single-center study in which most renal transplant patients undergo ipsilateral native nephrectomy at the time of transplant surgery, the prevalence of ACKD was reported to be at 33% based on strict pathologic criteria, which may still be lower than the true incidence given that only one kidney was removed (7) (**FIGURE 33.1**).

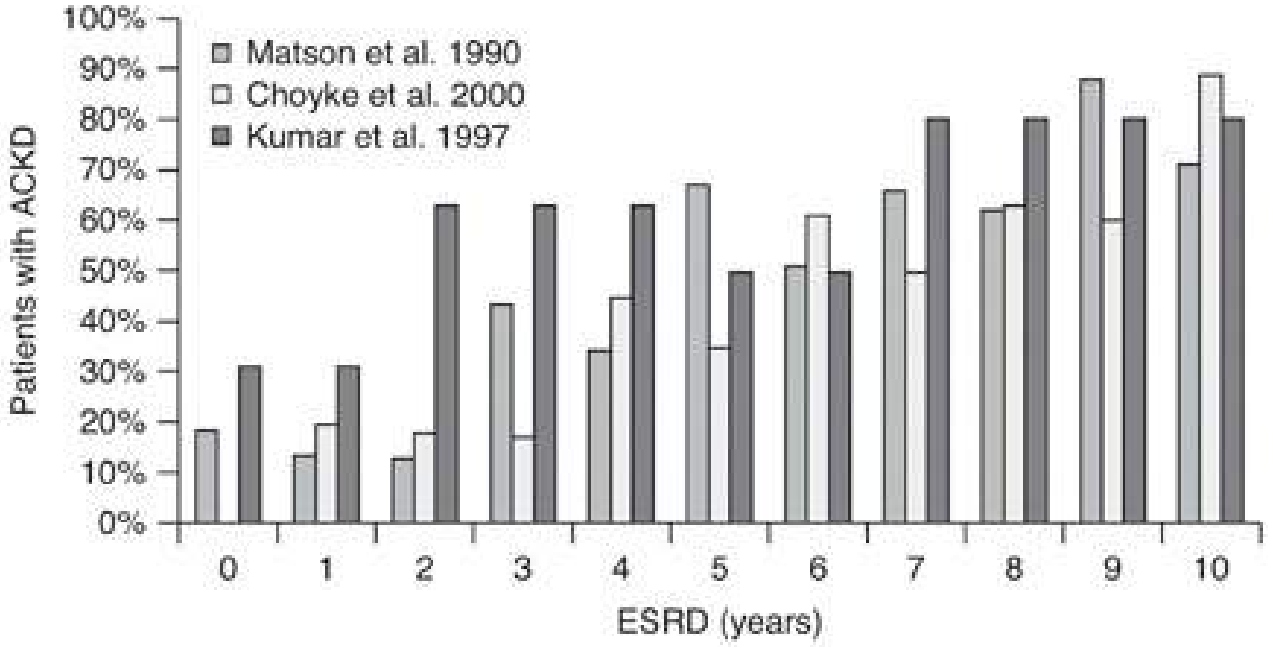

FIGURE 33.1 Prevalence of acquired cystic kidney disease (ACKD) in hemodialysis patients in relation to their duration of hemodialysis treatment.

RISK FACTORS

Researchers have shown that time spent on hemodialysis was the most important risk factor for the development of ACKD (8). Men and African Americans have been reported to be at much higher risk than women or Caucasians (8,9).

PATHOGENESIS

The exact pathogenesis of ACKD in humans is not known, but its understanding has been aided by available *in vivo* and *in vitro* animal models. The slow progressive loss of functioning renal tissue in ESKD promotes initial compensatory hypertrophy and later hyperplasia of the residual nephrons (3,9). The cysts being confined to the kidneys suggest that local intrarenal events are of primary importance (9). Analysis of the cyst fluid, which is thought to derive from ultrafiltrate secreted into the cyst, typically has a composition similar to that in the plasma; this finding plus the presence of a brush border on the luminal membrane on microdissection studies suggests that the cysts arise primarily from proliferation of proximal tubular epithelial cells (3,9).

Compensatory renal hypertrophy is influenced by many factors, the most important of which is activation of oncogenes and release of growth factors, which, over a prolonged period of time, promote progressive tubular hyperplasia and cyst formation (10,11). Alternatively, other provoking factors might emerge, such as environmental chemicals, transforming viruses, or male sex hormones, that lead to the transition of the proliferative process into malignant growth.

CLINICAL MANIFESTATIONS

ACKD is usually asymptomatic and discovered incidentally during imaging studies. In one review, for example, only 14% of patients developed symptoms, with hematuria being most common, followed by

pain and urinary tract infection. Some may manifest with potential complications of ACKD such as cystic hemorrhage that may present with or without hematuria, cyst rupture with consequent perinephric or retroperitoneal hemorrhage, and cyst infection or abscess formation or erythrocytosis.

COMPLICATIONS

Renal Cell Carcinoma

As with ACKD, the incidence of renal cell carcinoma (RCC) as a complication of ACKD varies in different reports (8,12,13). Two prospective studies found an incidence of 4% (2 of 57) and 7% (2 of 30) over a 7- to 10-year period. A review of published reports estimated an incidence of 0.18% per year, compared with 0.008% in the general population in the United States.

Most reports, however, may misrepresent the true prevalence of RCC because they primarily rely upon screening radiography for detection. A single-center study in which most renal transplant patients underwent ipsilateral native nephrectomy at the time of transplant surgery showed that RCC was found in 4.2% of 260 nephrectomies, which may still be lower than the true incidence given that only one kidney was removed (7).

There are important differences between the renal cell cancer development in the setting of ACKD and in the general population. ACKD patients with renal cancer are younger, predominantly male compared with the general population. The carcinomas as a complication of ACKD are usually limited to the kidney and, in approximately 25% to 50% of cases, are multiple and bilateral (3,9,12). Whereas sporadic tumors are mostly composed of clear cell or granular carcinomas (90%), papillary cell types represent approximately 5% to 7%, in ACKD the proportion of clear-cell carcinomas to papillary carcinoma is approximately 1:1 (14). The reason for the difference is uncertain. There seems to be a lower metastatic rate in the ACKD group compared with that in the general population, but mortality rate was similar in both groups. The similar mortality rate may partly explained by the higher prevalence of comorbid conditions associated in the ACKD group.

Men (male-to-female ratio 7:1) and patients with large cysts and an increased kidney size are at increased risk for malignant transformation (12,15).

Cystic Hemorrhage

Bleeding is usually confined within the cyst but occasionally extend into the renal collecting system causing gross or microscopic hematuria or into the perinephric or retroperitoneal space causing flank pain. Rarely, bleeding may evolve into cyst rupture severe enough to require surgical intervention or transcatheter embolization.

Other Complications

Other important complications of ACKD include cyst infection, abscess formation, erythrocytosis, and calcification in or around the cyst.

DIAGNOSIS AND SCREENING

By itself, acquired renal cysts are of limited clinical significance. However, some cysts transform into

malignant lesions. In an attempt at early detection of these premalignant or malignant lesions, some investigators have suggested that periodic imaging of the native kidneys be performed in patients on long-term dialysis (3,9). However, the basis for these recommendations nor their potential consequences have been elaborated. Moreover, the relatively low incidence of RCC in addition to the high mortality of patients with ESKD from other causes and the need for computed tomography (CT) or magnetic resonance imaging for effective screening in this population has prompted others to suggest that routine imaging is not cost-effective (16). A decision analysis model performed to more precisely determine the cause of screening showed that screening could lead to a 1.6 year in life expectancy over a 25-year period provided that only young (20-year-old) patients with a long life span were screened (17). When the screening tests are applied to the young ESKD patients, the benefit ACKD screening programs appears to be comparable to the benefit of established interventions such as breast cancer screening, colon cancer screening, and cervical cancer screening. However, the benefit of screening depends critically on life expectancy. For middle-aged patients beginning dialysis treatments with a life expectancy of 5 years, screening by CT or ultrasound prolong average life expectancy by 4 or 5 days. For yet older patients, the gains are even smaller. Since the median age of patients beginning dialysis in the United States is about 62 years old, this analysis implies that more than half of the incident ESKD population screening of asymptomatic individuals for ACKD is unlikely to be of benefit.

Given the aforementioned data, some investigators have suggested that radiologic studies be performed only in patients with concerning symptoms such as new hematuria or flank pain, or in young patients with risk factors such as long duration of dialysis and large kidneys due to acquired cystic disease (16,18). An individualized approach to cancer screening is also recommended based on the patient's cancer expected survival and transplant status.

The optimal imaging modality for screening is uncertain. Contrast-enhanced CT scanning is more sensitive than ultrasonography in detecting and characterizing cysts but may not be superior in detecting solid tumors (2,4,19). Moreover, CT scanning has the added benefit of defining the extent of disease.

Magnetic resonance imaging (MRI) with injection of gadolinium is the best modality to explore complex renal cysts, but there is a concern of the development of nephrogenic systemic fibrosis (NSF) in patients with CKD stages 4 and 5 and in patients on dialysis.

Some experts recommend initiating screening by ultrasonography in at-risk patients. Once the ultrasonogram becomes positive for cysts, the more sensitive contrast-enhanced CT scan or MRI is performed at recommended intervals to screen for the possible occurrence of carcinoma. A classification of renal cysts, based on their appearance in CT scans, introduced by Bosniak, is now widely accepted and is also applied to ultrasound and MRI.

TREATMENT

The treatment for ACKD is supportive unless complications arise.

The treatment for renal cancer is a radical nephrectomy. The challenge is to determine if this surgical procedure is indicated in any patient with a renal mass as in some cases, it is difficult to definitively differentiate benign from malignant lesions on the basis of an imaging study. It is generally agreed that a tumor larger than 3 cm in diameter, a rapidly growing mass, or one that is associated with suspicious symptoms such as hematuria warrants a nephrectomy.

PROGNOSIS

The cysts may stabilize or regress following successful renal transplantation, a setting in which the level of growth factors is reduced due to the restoration of normal renal function. In one prospective study of patients with ESKD and patients with renal transplant, the incidence of cystic disease was lower and the native kidneys were smaller and had lower cyst grades in transplant recipients when compared with patients treated with maintenance hemodialysis (20). This benefit was limited to patients not receiving cyclosporine. Those treated with cyclosporine had an incidence of cystic disease similar to the dialyzed patients.

CHAPTER 34

Quality of Life and Rehabilitation in Dialysis Patients

Daniel Jay Salzberg and Fathima Konari

DEFINITION OF QUALITY OF LIFE

The *American Heritage Dictionary* defines life as the physical, mental, and spiritual experiences that constitute existence (1). This chapter explores how we have come to define quality of life (QOL) and various methods by which QOL is assessed in patients with chronic kidney disease (CKD) stage 5 requiring dialysis [previously called *end-stage kidney disease* (ESKD), now abbreviated CKD stage 5D]. The World Health Organization defines QOL as "an individual's perception of their position in life in the context of the culture and value system where they live, and in relation to their goals, expectations, standards, and concerns" (2). The measurement of QOL should incorporate the many factors that effect a subject's existence and satisfaction. It should include not just the physical aspect but also the emotional, intellectual, social, cultural, and ethnic components that comprise daily life.

Terms that are sometimes equated with QOL include functional status, sense of well-being, life satisfaction, and health status. Although health status is not synonymous with QOL, the two are interrelated with health affecting QOL and QOL affecting health. Illustrative of this point is that survival appears to be greater in subjects with a higher measured QOL (3–5).

Given this foundation, one can define an aspect of QOL as being health related. This health-related quality of life (HRQOL) represents the "physical, psychological, and social domains of health that are influenced by a person's experience, beliefs, expectations, and perceptions" (6). Within this context, health is defined as not only the absence of disease and infirmity but also the presence of physical, mental, and social well-being (2). HRQOL includes both an objective assessment of functional status and a subjective perception of one's health (6).

When dealing with a chronic illness like CKD, it is essential to take a multidisciplinary approach.

Given the number and complexity of stressors faced by patients with CKD stage 5D, it would be naive to draw conclusions about their global health based solely on a single metric such as Kt/V or normalized protein catabolic rate (nPCR). Similarly, methodologic studies that evaluate only one primary endpoint, such as blood pressure control, may miss other significant aspects that effect health. It is with this global concept of health that HRQOL tools have been developed. The use of HRQOL instruments is even more important in subjects with CKD stage 5D, as compared with other chronic disease states, because of the associated high prevalence and severity of their comorbid conditions.

An important concept that underscores the study of QOL is that a new procedure or drug may decrease mortality but may not necessarily improve QOL and, therefore, may not be of overall benefit to the patient. To further illustrate this paradigm, take the example of two patients with virtually identical medical conditions. Despite similar care and objective disease states, they may have vastly different perceived QOL based on their social support systems, psychological outlook, and coping mechanisms. HRQOL measurements allow for the assessment of these factors contributing to QOL.

Some of the practical applications of measuring HRQOL include assessment of therapeutic interventions and their impact on QOL, effect of different modalities of renal replacement therapy and effect on QOL, determination of change in QOL within the same population over the course of the disease, and assessment of the impact of interventions on cost and/or morbidity with relation to QOL.

MEASUREMENT OF QUALITY OF LIFE

Optimal HRQOL measurement instruments capture all the nuances that disease and its treatment have on the physical, emotional, social, and mental dimensions of an individual (7). Ideally, instruments should be comprehensive, valid, have test–retest reliability, and be responsive to change and yet be brief enough to allow for quick administration. They should allow for comparisons between groups of subjects with different illnesses and be sensitive enough to pick up subtle differences within a specific group. Lastly, for an HRQOL measure to be of value, subjects' life experiences must be converted into a quantitative, numerical value.

Unfortunately, there is no one ideal tool that measures HRQOL, and therefore, multiple different instruments have been developed (**TABLE 34.1**). Most of these instruments use a psychometric approach, which is based on the item measure theory (8). This theory postulates that true QOL cannot be directly measured but can be assessed indirectly through a series of questions. These questions are defined as "items" (9). Each item is then given a numerical value based on a predetermined scale. For example, in the RAND 36-Item Health Survey 1.0 Questionnaire (10), a subject is asked to rate his or her health on a scale from 1 (excellent) to 5 (poor).

When items are rated in this way, they are often referred to as *Likert-type items*. This rating presumes the existence of an underlying continuous variable whose value characterizes the respondents' attitudes and opinions. Each Likert-type item provides a discrete approximation of the variable being assessed (11). The advantage of this ordinal scale is its ability to rank order subjective responses that are otherwise difficult to quantify. When using these Likert-type items, there is no assumption that the difference between the possible responses is of the same magnitude. Said another way, the difference between responses 2 and 4 may not have the same meaning as the difference between responses 3 and 5.

The numerical score of each Likert-type item is then added together to obtain a sum score that represents the overall global HRQOL score. It is the ability of these instruments to quantify QOL and produce a meaningful numerical score that allows for intragroup and intergroup comparisons.

HRQOL instruments can be subdivided into categories based on whether the tool is global or domain specific. Three major domains comprise global HRQOL: the physical domain, the social domain, and the psychosocial or mental domain (**FIGURE 34.1**) (12). Certain HRQOL instruments examine only one domain of HRQOL such as the Karnofsky Performance Status (KPS) scale, which primarily assesses the dimension of physical health. Other instruments, such as the Sickness Impact Profile (SIP), not only examine the physical domain but also give a global, overall measurement of HRQOL.

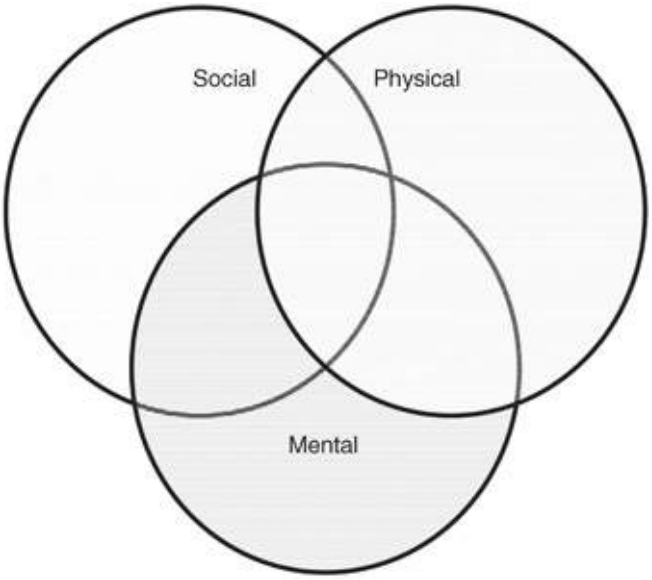

FIGURE 34.1 Domains of health-related quality of life.

The types of HRQOL instruments can be further grouped into disease-targeted versus generic disease nonspecific tools (**TABLE 34.1**). The major advantage of disease-targeted tools is their ability to focus on the unique aspects and treatments of the disease being studied. However, extrapolation to other disease populations is severely limited. On the other hand, generic tools allow for comparisons of HRQOL across different populations and disease states but may not be specific or sensitive for subtle changes within a specific disease.

Generic Instruments

Generic instruments are designed to be applicable to a wide variety of populations. The major advantage of using a generic measure of HRQOL is that one can compare groups of subjects across different health and disease states. A number of these HRQOL instruments, however, have not been validated in the CKD stage 5D population, and these include Spitzer QL-index, Nottingham Health Profiles, Campbell Index of Well-Being (IWB), Cantril's Self-Anchoring Scale, and the Life Satisfaction Scale (12,13). Others have been demonstrated to be valid and will, therefore, be examined further.

Generic measures of HRQOL can be further subdivided into those that give a global assessment of HRQOL and those that focus on a specific domain, that is, physical health, mental health, or social health.

Generic, global assessment instruments are designed to provide a comprehensive overview of the three domains included in HRQOL. The potential advantages of using a global assessment tool include the ability to use a single instrument instead of many domain-specific ones and the ability to combine the global tool with either a disease-specific tool or a domain-specific tool.

A classic example of these generic, global assessment tools is the SIP, which was developed by Bergner et al. (14,15). As its name implies, the SIP was designed to assess the impact of sickness on QOL. The SIP contains 136 behavior-based items that are either interviewer- or self-administered questionnaires. These 136 items are divided into 12 health-related categories, including ambulation, mobility, body care and movement (these three categories comprise the physical dimension of the SIP), social interaction, alertness, emotional behavior, communication (these four categories comprise the psychosocial dimension), sleep and rest, eating, work, home management, and recreation and pastimes. Combining the score of all the items gives a global QOL score that ranges from 0 to 100 points. A lower score indicates better QOL. The SIP has been proved to be reliable and valid in the CKD stage 5D

population (7,12).

The Medical Outcomes Study Short Form 36-Item Health Survey (MOS SF-36, also abbreviated as SF-36) (16) is another widely used generic HRQOL measurement instrument. It was designed specifically to be a more time-efficient questionnaire allowing comparisons of HRQOL across different groups. As with the SIP, the SF-36 Health Survey can be either interviewer- or self-administered. Unlike the SIP, which contains 136 items, the SF-36 only contains 36 items, through which it evaluates eight health concepts of HRQOL. The eight health concepts are physical functioning (10 items), role limitations resulting from physical problems (4 items), role limitations caused by emotional or personal problems (3 items), social functioning (2 items), bodily pain (2 items), energy/fatigue (4 items), emotional well-being (5 items), and general health perceptions (5 items). In addition, there is one single item that provides an indication of perceived change, now versus 1 year ago. For example, the questions that are used to assess social functioning are "During the last 4 weeks, to what extent has your physical health or emotional problems interfered with your normal social activities with family, friends, neighbors, or groups?" ranked from 1 (not at all) to 5 (extremely) and "During the last 4 weeks, how much of the time has your physical health or emotional problems interfered with your social activities (such as visiting with friends, relatives, etc.)?" ranked from 1 (all of the time) to 5 (none of the time) (10). Two additional components can be calculated from the SF-36, and they are the Physical Component Summary (PCS) and the Mental Component Summary (MCS). There are different methods for determining an overall score within each health concept, but the overall concept is that a higher score represents a more favorable health state. The SF-36 Health Survey has been proved to be both reliable and valid in the CKD stage 5D population (7,12).

Unlike the SIP and the SF-36, the Time Trade-Off (TTO) technique of assessing HRQOL employs a preference-based approach rather than using a psychometric item-based instrument. The TTO technique employs modern utility theory, which postulates that, if presented with two alternatives with full disclosure of the risks and benefits involved, a person will choose the option that serves them best (17). In this model of decision making, subjects are first given a fixed amount of time that they will live in their current chronic disease state, defined as time (t). Next, they are presented with the theoretical question: "How many years of life would you be willing to give up in order to live the remaining years of your life in perfect health?" The utility theory postulates that everyone would choose to live in perfect health. By subtracting the subject's answer from the predefined t, this technique establishes the amount of time that the subject would live in perfect health, defined as variable x. The subject is then asked, "If the amount of time you were to live in perfect health (x) was decreased, would you still choose perfect health?" In this technique, t is a fixed number and x is varied to achieve a point of indifference. This indifference point (hi) is defined as the point at which there is no preference between shorter life with perfect health and longer life with chronic disease. Mathematically, this is expressed as $hi = x / t$, with a resultant single value, ranging between 0.0 and 1.0. For example, a subject who is willing to trade no more than 2 years of his or her life to achieve perfect health, when given 10 years to live with CKD stage 5D, has a hi score of 0.8. In this example, t equals 10 years and x equals 8 years. The higher the hi score, the better the estimated HRQOL (7). Although the TTO approach appears to be reliable in the setting of CKD stage 5D (18), its validity has been questioned (19–22).

Generic domain-specific instruments are less comprehensive for measuring overall HRQOL when

compared with generic global tools. However, the domain-specific instruments may have the advantage of being more sensitive to changes within the assessed particular domain (**FIGURE 34.1**).

The physical health domain encompasses the concept of performance status, which can be defined as the functional capacity of an individual. These instruments were originally tested in patients with cancer and demonstrated a significant positive correlation with survival (23,24). The prototypical example of a measure of performance status is the KPS scale, also known as the *Karnofsky Index* (*KI*). The KPS scale has been used extensively in CKD stage 5D studies (7). Unlike the SIP and SF-36, it is clinician assessed, and it cannot be self-administered. There are 11 descriptive statements that rank performance status on an ordinate scale from normal (score of 100) to death (score of 0) (**TABLE 34.2**). In the CKD stage 5D population, as with cancer patients, the KPS appears to be a predictor of mortality (12).

TABLE 34.2 The Karnofsky Performance Status Scale

Description	Scale (%)
Normal, no complaints	100
Able to carry on normal activities; minor signs or symptoms of disease	90
Normal activity with effort	80
Cares for self; able to carry on normal activity or do active work	70
Requires occasional assistance but able to care for most needs	60
Requires considerable assistance and frequent medical care	50
Disabled; requires special care and assistance	40
Severely disabled; hospitalization indicated although death not imminent	30
Very sick: hospitalization necessary; active supportive treatment necessary	20
Moribund	10
Dead	0

The checklist of symptoms and sexual functioning scales are two other techniques used to assess physical health. These HRQOL instruments are exemplified by a list of physical symptoms that are rated on a numerical scale. Examples of these surveys include the Index of Comorbidity (25), the Sexual Dysfunction Scale (26), the Index of Sexual Function (27), and the checklist created by Parfrey et al. (28). Unfortunately, most of these measures have not been established to be reliable and/or valid in the CKD stage 5D population (7).

HRQOL tools that measure the mental health domain primarily assess for depression, anxiety, and psychological well-being. In CKD stage 5D, the most frequently used measures include Campbell's Indices of General Affect, Well-Being, and Life Satisfaction; the Affect Balance Scale (ABS); the Beck Depression Inventory (BDI); the Self-Esteem Inventory; and locus of control scales (7).

Campbell's indices combine the Index of Life Satisfaction (ILS) and the Index of General Affect (IGA) to determine the IWB (29,30). The ILS, as the name implies, explores the concept of life satisfaction. It consists of one global item, "How satisfied are you with your life as a whole these days?" rated on a 7-point scale from completely dissatisfied to completely satisfied (29). The IGA consists of eight pairs of diametrically opposed items. These items are presented at either end of a 7-point scale. For example, in the pair of adjectives "discouraging to hopeful," discouraging would be 1 and hopeful would be 7. Respondents are asked to rank how they feel about their present life for each item. This technique is

called a *semantic differential scale* and was developed by Osgood. The items that comprise the IGA are "boring versus interesting," "miserable versus enjoyable," "useless versus worthwhile," "lonely versus friendly," "empty versus full," "discouraging versus hopeful," "disappointing versus rewarding," and "does not give me much chance versus brings out the best in me" (29). The IGA score is obtained by averaging all eight items and ranges from 1 to 7. The IWB is then calculated from the ILS and the IGA. Mathematically, IWB = (ILS × 1.1) + IGA, with a resultant range of scores between 2.1 and 14.7, and a higher score indicating a better level of well-being. Campbell's indices are reliable and valid in the CKD stage 5D population (7) and can be either interviewer- or self-administered.

Like Campbell's indices, the ABS is also a composite of two scales, the Positive Feeling Scale (PFS) and the Negative Feeling Scale (NFS), each consisting of five items (**TABLE 34.3**) (31). The questions are presented in a yes or no format, where yes = 1 and no = 0. A composite score is calculated using the following formula: ABS = (PFS + 5) − NFS. Scores range from 0 to 10, with 10 representing a better affect. It can be either interviewer- or self-administered. The ABS is both reliable and valid in subjects with CKD stage 5D (7).

TABLE 34.3 The Affect Balance Scale

During the past few weeks, did you ever feel . . .
- Positive feelings: yes/no
  - Pleased about having accomplished something?
  - That things were going your way?
  - Proud because someone complimented you on something you had done?
  - Particularly excited or interested in something?
  - On top of the world?
- Negative feelings: yes/no
  - So restless that you could not sit long in a chair?
  - Bored?
  - Depressed or very unhappy?
  - Very lonely or remote from other people?
  - Upset because someone criticized you?

Adapted from Bradburn N. *The Structure of Psychological Well-Being. Two Dimensions of Psychological Well-Being: Positive and Negative Affect.* Chicago, IL: Aldine, 1967, with permission.

Unlike the ABS and Campbell's indices, the BDI is used to measure the presence and intensity of depression (32,33). It consists of 21 items that deal with a specific behavioral manifestation of depression, ranked from 0 to 3. Overall scores range from 0 to 63, with higher scores correlating with more severe depression. When compared with the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-III*) criteria for depression, the BDI was found to be valid in the CKD stage 5D population (31). Of note, there is a new edition of the BDI, the BDI-II, which revised the BDI to match the revamped criteria for depression in the DSM-IV. Both the BDI and the BDI-II take less than 10 minutes to complete and can be either interviewer or self-administered.

An additional tool validated in patients on dialysis is the nine-question Patient Health Questionnaire (PHQ-9) (34). Scores of 5, 10, 15, and 20, on the PHQ-9, represent mild, moderate, moderately severe, and severe depression, respectively (35). Importantly, a number of electronic health records have the PHQ-9 already built into the system.

Other HRQOL instruments relating to mental health attempt to quantify one's self-esteem. Self-esteem, in this setting, is defined as an overall evaluation of one's worth or value (36). The most widely used tool for measuring self-esteem is the Rosenberg Self Esteem Inventory (SEI) scale. The SEI scale uses 10 Likert-like items, such as "On whole, I am satisfied with myself" and "At times I think I am no

good at all," that are answered on a scale from strongly agree to strongly disagree. A higher score indicates a higher self-esteem (32). With regard to the CKD stage 5D population, the Rosenberg SEI scale has not been established as valid and reliable (7). These instruments are often used as a component of a battery of tests used to assess the mental domain of HRQOL.

Another type of mental health HRQOL instrument that has been used in patients with CKD stage 5D is the locus of control scales. These tools attempt to measure the extent to which a subject believes that health is or is not determined by his or her own behavior; that is, the outcomes are the result of his or her own actions (internal) or the result of external forces (external). Examples of locus of control scales include the Health Locus of Control (HLC) scale developed by Wallston et al. (37), the Internal External Locus of Control (IELC) scale developed by Rotter (38,39), and the Locus of Control of Behaviour (LCB) scale developed by Craig et al. (40). The LCB consists of 17 items, rated in a Likert-type response scale from 0 (strongly agree) to 5 (strongly disagree). One example from Craig's scale is "People are victims of circumstance beyond their control." A higher score corresponds to a stronger external locus of control. Both of the IELC and the LCB have not been established as reliable or valid in the CKD stage 5D population (7). As with the tools to assess one's self-esteem, these tools are often used as a component of a battery of tests used to assess the mental domain of HRQOL. However, it seems the field is moving away from using locus of control scales.

The social health domain of HRQOL is the least well characterized, and tools used to measure this domain focus mainly on illness intrusiveness and employment status. HRQOL tools that measure illness intrusiveness attempt to quantify the degree to which a chronic illness or treatment disrupts a patient's life. The Illness Intrusiveness Rating Scale (IIRS) was developed by Devins et al. (41) to assess perceived intrusiveness of CKD stage 5D on HRQOL. The IIRS is a self-administered scale that rates perceived intrusiveness on 11 to 13 life domains, including work, recreation, family and marital relations, sex, and diet. Each item is rated in a Likert-type response scale ranging from not very much (1) to very much (7). The IIRS is valid and reliable in the CKD stage 5D population (42–44).

Various approaches have been attempted to quantify vocational rehabilitation ranging from objective measure of working status (yes and no), to subjective determination of ability to work, to detailed self-reports such as the Psychosocial Adjustment to Illness Scale (PAIS) (45). Despite the apparent ease of determining this variable, it appears that this measure may not be a valid measure of the social domain of HRQOL (46).

The other major category of HRQOL instruments is the disease-targeted instruments, which are applicable to a defined population of subjects. Examples of these tools include Parfrey's Health Questionnaire Specific for CKD stage 5D (28), Laupacis's Kidney Disease Questionnaire (KDQ) (47), Hays's Kidney Disease QOL Instrument (48), and Wu's Choice for Health Outcomes in Caring for End-Stage Renal Disease (CHOICE) Health Experience Questionnaire (49).

Parfrey et al. (28) developed the first published ESKD-targeted HRQOL instrument in 1989. The "Health Questionnaire Specific for ESRD" goal was to measure the effect of specific ESKD therapy on QOL. They constructed two unique scales for the CKD stage 5D population exploring physical symptoms (the symptom scale) and emotional symptoms (the affect scale). The symptom scale consists of 12 items (tiredness, headache, sleep disturbance, joint pain, cramps, pruritus, dyspnea, angina, nausea/vomiting, abdominal pain, muscle weakness, and other) rated from 1 (very severe) to 5 (absent). Like the symptom

scale, the affect scale also consists of 12 items (determination*, faith*, confused, different, angry, scared, helpless, alone, fed up, sad, desperate, and other) [*faith and determination are actually rated from 1 (absent) to 5 (very strong)] again rated from 1 to 5. They then combined these two indices with two subjective measures of HRQOL (Campbell's Indices of General Affect, Well-Being, and Life Satisfaction and the Spitzer Subjective QOL Index) and two objective measures of HRQOL (KPS scale and the Spitzer Concise QL-Index). Overall, this questionnaire has good reproducibility (except for the Spitzer Subjective QOL Index), is responsive to change, has construct validity, and allows for comparisons between CKD stage 5D and other disease states. The questionnaire takes between 15 and 20 minutes to complete but does require a trained interviewer to administer it.

In 1992, Laupacis et al. (47) developed the KDQ, a disease-specific HRQOL tool particularly for patients on chronic hemodialysis (HD) therapy. The KDQ contains 26 items in the following five dimensions: physical symptoms (6 items), fatigue (6 items), depression (5 items), relationships (6 items), and frustration (3 items) (47). Unlike other HRQOL questionnaires, the physical symptoms dimension of the KDQ is patient specific. The six physical symptoms that are most important to each subject are identified and used to assess that dimension. Items are ranked from 1 (all of the time) to 7 (none of the time). The KDQ has construct validity and reliability (47) and is more responsive to change than the SIP or TTO (47,50). The two major limitations of the KDQ are that it is designed for use only in subjects with CKD stage 5D undergoing HD and that there is no single overall health rating.

Like the KDQ, Hays's Kidney Disease Quality of Life (KDQOL) instrument was also developed for use in subjects with CKD stage 5D on HD. Unlike the KDQ, the KDQOL uses the SF-36 as its core and supplements this with 19 additional multi-item scales (48). The incorporation of the SF-36, a global generic assessment tool, allows for comparisons of HRQOL across disease states. Major advantages of the KDQOL are its comprehensive scope and the inclusion of a single-item overall health rating. The major limitation of the KDQOL is its length, 134 items, which takes approximately 30 minutes to complete. Rao et al. (51) have subsequently developed an 11 multi-item subscale from the KDQOL's Symptoms/Problems and Effects of Kidney Disease scales, which correlates with the SF-36 Health Survey and number of disability days.

Because of the length of the KDQOL, the KDQOL short form (KDQOL-SF) was created. It includes the core SF-36 scale, 43 kidney disease-targeted items from the original KDQOL, and a single overall health-rating item, thereby containing only 80 items. Both the KDQOL and its short form are self-administered, but the KDQOL-SF takes about half as long to complete. The KDQOL-SF can be used to determine the three components of HRQOL: PCS, MCS, and the Kidney Disease Component Summary (KDCS). Both the short and long forms appear to be reliable and have construct validity (48,52). In addition to the KDQOL-SF, there is the KDQOL-36 that only contains 36 items.

Like the KDQOL, the CHOICE Health Experience Questionnaire (CHEQ) also incorporates the SF-36 as its core (49). It consists of 83 items divided into 21 domains. It can be used for subjects on either peritoneal dialysis (PD) or HD and appears to be reliable and have construct validity (49).

We recommend the 80-item KDQOL-SF for routine clinical practice for the following reasons: It allows comparisons across diseases (by incorporation of the SF-36 Health Survey), it has proven kidney disease-targeted items, it takes a relatively short amount of time to administer, and it has a single overall health-rating item. The KDQOL-SF version 1.3 instrument and scoring programs can be downloaded at

the following website: http://www.rand.org/health/surveys_tools/kdqol.html.

Although not a direct measure of QOL, there have been a number of studies looking at the quality of dying in dialysis patients. CKD stage 5D offers a unique opportunity to quantify this process because dialysis is the only life-support therapy that is frequently discontinued. An estimated 17.8% of dialysis patients between 1990 and 1995 withdrew from dialysis before death (53). To better understand this aspect of QOL, Cohen et al. (54) developed a prototype tool to assess the quality of dying, the Dialysis Discontinuation Quality of Dying (DDQOD) instrument. The DDQOD is composed of three domains: duration (of dying), pain and suffering, and psychosocial. Each domain is scored on a scale from 1 to 5. A summed score can range from 3 to 15 and is divided into three types of death: a very good death defined as a score greater than 12, a good death greater than 8 to 12, and a bad death less than or equal to 8. Using the DDQOD instrument in 131 adults discontinuing dialysis, 38% of the subjects were judged as having had very good deaths, 47% good deaths, and 15% bad deaths (54). The major drawback of this tool is that it is not applicable to death in subjects with CKD stage 5D that are not preceded termination of dialysis therapy (54,55).

The Dialysis Quality of Dying Apgar (QODA) is another tool that attempts to quantify quality of dying. It is modeled after the original pediatric Apgar assessment and consists of five domains (pain, nonpain symptoms, advanced care planning, peace, and time). Each domain is scored from 0 to 2, with a range of scores between 0 and 10. It is currently being field tested in six New England dialysis clinics, but it still requires testing for reliability and validity [see reference (56)]. At this time, QODA scores correlating to the three types of deaths (as in the DDQOD) have not been established (55).

QUALITY OF LIFE IN END-STAGE KIDNEY DISEASE

As more and more people develop advanced CKD requiring renal replacement therapy, the understanding of HRQOL becomes more pertinent, as mortality and outcome measures alone do not provide a comprehensive understanding of patient dynamics. However, there is consistent data that subjects with CKD and CKD stage 5D have impaired HRQOL. In a landmark study by Evans et al. (25), the National Kidney Dialysis and Transplant Study rigorously examined the HRQOL of 859 subjects undergoing dialysis or transplantation to determine major variables that affect patient outcomes. Using Campbell's indices (IGA, ILS, and IWB), Evans reported that 79% of the transplant recipients were able to function at nearly normal levels compared with only 59%, 44.7%, and 47.5% of subjects on home HD, in-center HD, and PD, respectively.

Overall, subjects receiving renal replacement therapy had significantly lower functional scores than the general population. Nonetheless, the study suggested that patients with CKD stage 5D are able to adapt to very adverse life circumstances.

Other studies have also demonstrated improved QOL with transplantation when compared with dialysis. In a meta-analysis of 61 published articles, kidney transplantation was associated with greater well-being and lower distress when compared with other forms of renal replacement therapy (57). Bremer et al. (58) found similar results using Campbell's Indices of General Affect, Well-Being, and Life Satisfaction. In this trial, 489 of 903 eligible subjects returned valid questionnaires (54% response rate). Regarding QOL, subjects with functioning allografts fared the best, consistent with the National Kidney Dialysis and Transplant Study. Unlike Evans's study, however, that group of subjects whose allograft

failed and required reinitiation of dialysis had the greatest measured loss of HRQOL. Using the SF-36 Health Survey, DeOreo (3) demonstrated that the PCS was a significant predictor of mortality, which is equal to measured Kt/V. In the Italian "Dialysis-Quality of Life" (DIAQOL) project, 246 of 304 subjects on center dialysis completed the SF-36 questionnaire (59). Factors that effected HRQOL included the presence of diabetes and the subjects' age, whereas there was no association with Kt/V, hemoglobin (Hb) concentration, body mass index, or parathyroid level. There was, however, a strong association between the serum albumin level and the SF-36 Health Survey measurement of physical functioning.

In the Spanish Cooperative Renal Patients QOL study, HRQOL was assessed using the KI and SIP in more than 1,000 subjects, the majority on HD (60). All study participants reported a reduced HRQOL, with the most severely affected dimensions being work, activities, and sleep. There was no significant effect predicted by mode of dialysis, dialysis membrane, delivered Kt/V, or PCR. Higher Hb concentration and greater education and socioeconomic levels predicted positive measures of HRQOL. Subjects with diabetes, peripheral vascular disease (PVD), multiple comorbidities, and female gender scored lower. Unfortunately, there were variations in QOL between the different centers, thereby increasing the complexity and applicability of these results (61).

There may also be perceptual differences between a subject's HRQOL and that of health care providers. Molzahn et al. (62) explored this issue in a cross-sectional, descriptive comparative study of 215 subjects with CKD stage 5D who were administered measures of HRQOL: the Self-Anchoring Striving Scale, the IWB, and TTO. Of note, when compared to the subjects' own rated HRQOL, nurses tended to have a lower, and physicians a higher, perception of the subjects' HRQOL.

IMPACT OF QUALITY OF LIFE

The importance of assessing the HRQOL cannot be overemphasized because it not only reflects patients' satisfaction but also has been independently correlated with morbidity, hospital utilization, and survival (63). The PCS score on the SF-36 Health Survey appears to be as significant a predictor of mortality as PCR and delivered Kt/V (3). Specifically, for each 5-point increment in the PCS score the survival rate increased by 10%. In a prospective, international, observational study, the Dialysis Outcomes and Practice Patterns Study (DOPPS) used the KDQOL-SF (version 1.3) to measure HRQOL in 9,526 subjects on dialysis (64). Lower PCS and lower MCS scores were associated with significant increased risk of death (relative risk of 1.29 and 1.13, respectively, $p < 0.001$) and hospitalization (relative risk of 1.15 and 1.05, respectively, $p < 0.01$) (63).

In a longitudinal observational study by Parkerson and Gutman (65), 103 subjects on dialysis were given five questionnaires, which included the KDQOL-SF. HRQOL was measured at baseline and then after 6 months and 1 year. After adjusting for hypertension and demographic factors, a higher physical functioning dimension on the KDQOL-SF correlated with 1-year survival (odds ratio 1.050, $p = 0.008$).

A multicenter, prospective study using the SF-36 Health Survey in 226 subjects with new CKD stage 5D starting dialysis demonstrated that HRQOL was substantially impaired compared to the general population (66). Physical and mental scores greater than two standard deviations lower than the general population were predictors of poor outcomes (malnutrition, prolonged hospitalization, and death), as were baseline comorbidities and low serum albumin.

EARLY REFERRAL

Because of the substantial effect that kidney disease can have on a subject's functional status, social functioning, and overall well-being, it is important to consider HRQOL measures early in the course of kidney disease. Numerous studies have demonstrated the importance of early referral to a nephrologist (**TABLE 34.4**) (67,68). The National Institutes of Health recommends that patients with CKD be referred to a multidisciplinary predialysis team to minimize morbidity and ease the transition to renal replacement therapy (69). Early referral affords (a) the benefit of improved patient involvement and compliance; (b) greater participation in the selection and initiation of a dialysis modality; (c) better patient education; (d) time for access maturation and avoidance of unnecessary central catheters; (e) broader employment opportunities; (f) improved ability to delay the progression of CKD stage 5D; (g) delayed development of associated comorbidities such as anemia and malnourishment; (h) improved QOL with less frustration, dissatisfaction, and depression; and (i) improved mortality rate (**TABLE 34.5**) (67,70–75). Patients with established predialysis care also require fewer emergency starts and in-hospital days compared with standard care (76). Although Dialysis Outcomes Quality Initiative (DOQI) guidelines advocate an early start of dialysis, the evidence is not convincing (see Chapter 6 for discussion) (77). To further assess the DOQI guidelines, the multicenter, prospective Netherlands Cooperative Study on the Adequacy of Dialysis (NECOSAD) (78) used the KDQOL-SF in 237 subjects with new CKD stage 5D starting dialysis. In this cohort, 90 subjects (38%) were classified as starting "too late," according to the DOQI guidelines. This study demonstrated that subjects starting HD "too late" uniformly had lower perceived HRQOL versus those that were not late starters. However, this effect was not significant after 12 months. Additionally, all subjects treated with HD demonstrated marked improvement in HRQOL when reassessed at 3 and 6 months.

TABLE 34.4 Prognostic Factors Associated with the Quality of Life (QOL) in Dialysis Patients

Improved QOL	Reduced QOL
Early referral to nephrologist	Younger age
Higher hematocrit	Diabetes
Black race	Intermittent claudication
Socioeconomic level	Female sex
Educational level	Depression
Adequate dialysis	Multiple comorbidities
Exercise	Malnutrition
Social support	Sleep disorders

TABLE 34.5 Potential Benefits of Early Nephrology Referral

Better patient involvement
Improved compliance
Greater participation in one's care
Time for access maturation
Avoidance of unnecessary catheters
Better patient education
Improved employment opportunities
Delayed progression to ESKD
Delayed development of anemia
Delayed development of malnutrition
Improved quality of life
Improved mortality

ESKD, end-stage kidney disease (chronic kidney disease stage 5D).

A retrospective study by White et al. (67) used the SF-36 Health Survey to compare 71 incident dialysis subjects who had attended predialysis clinics with 46 who had not. Adjusting for age, sex, residual kidney function, and other comorbidities, predialysis clinic attendance was an independent predictor of higher HRQOL scores for physical function, emotional role limitation, social function, and general health. Such patients generally show improved compliance and less depression and difficulties with interpersonal relationships. These findings are exaggerated in the elderly population who may require more intensive medical education and support in the setting of already compromised physical function. The finding that subjects initiated on continuous ambulatory PD therapy have a greater HRQOL as compared with HD may be related to the fact that they often receive more intensive, individualized predialysis training (79).

Insofar as early initiation of dialysis is accompanied by increased monetary costs and earlier personal restrictions, the advantage of early initiation must be individualized. A multidisciplinary approach coupled with predialysis care should help to optimize this decision and improve overall HRQOL.

SLEEP DISTURBANCES

Sleep disturbances are one of the most common problems encountered by subjects on dialysis. The prevalence of primary dyssomnias, defined as disturbances in the amount, quality, or timing of sleep, is estimated to exceed 60% in subjects on dialysis compared to between 15% and 25% in the general population (80). In one study, subjects with diabetes on maintenance HD had a prevalence of sleep disturbances of 68% (81). Many individuals experience significant distress or impairment resulting in a compromised HRQOL as measured by physical and emotional problems, reduced general health and vitality, increased pain and social isolation, and possibly increased mortality (81).

The most commonly encountered sleep disorders in subjects on dialysis include insomnia, sleep apnea and related breathing disorders, and the restless legs syndrome. In the Kidney Outcomes Prediction and Evaluation (KOPE) study, significant number of patients report waking during the night (57%), waking too early (55%), difficulty falling asleep (41%), and excessive daytime sleepiness (31%) (82). Risk factors for sleep disturbances in subjects with diabetes on HD include advanced age, depression, and compromised nutritional status (81). Increased perception of pain and greater depressive symptoms

are more likely to be related to difficulty falling asleep and excessive daytime sleepiness. Patients with reduced functional status are more likely to wake during the night or too early. Women are more than twice as likely to wake too early and experience restless sleep. Patients encounter more frequent sleep disturbances if they have bone pain, pruritus, or inadequate dialysis; if they smoke; or if they have been on dialysis for a long time (80,83–85). Interestingly, nutritional status and the dose of dialysis as measured by Kt/V do not correlate with sleep disturbances; the effect of increasing Hb concentration is controversial (82,84,86–88).

Measures to improve successful sleep habits include limitation of smoking and alcohol, relaxation and biofeedback techniques, avoiding daytime and intradialytic naps, and changes in the sleep environment. Pharmacotherapy should be avoided, and first-line therapy should include cognitive behavioral therapy (89). In a randomized control trial of cognitive behavioral therapy versus sleep hygiene education in subjects on HD, cognitive behavioral therapy significantly improved all measures (Pittsburgh Sleep Quality Index, Fatigue Severity Scale, BDI, and Beck Anxiety Inventory) when compared to controls (90). When absolutely necessary, benzodiazepines that are converted into inactive metabolites, such as clonazepam, lorazepam, oxazepam, and temazepam, or the hypnotic agent, zolpidem, can be used for sedation with appropriate dose adjustments for kidney disease (91). Initial doses should be reduced by 25% to 50%.

Sleep-related breathing disorders and pathologic breathing patterns affect up to 70% of subjects on dialysis and frequently present as excessive sleepiness (92). In addition to impairing normal cognitive function, subjects with sleep-related breathing disorders are at greater risk for cardiovascular morbidity and mortality (93). Sanner et al. (94) reported clinically significant increases in the number of apnea and hypopnea episodes that exceeded 13 per hour in most subjects on dialysis, with normal defined as less than 10 per hour. These abnormalities were associated with a median oxygen saturation of 92.5%. The severity of the breathing disorder correlated with impairments in physical functioning, social functioning, role limitation, and general health and vitality, as measured on the SF-36 Health Survey. It was also correlated with pain, sleep, social isolation, and emotional reactions. The etiology of sleep apnea remains unclear but may be related to alterations in acid–base balance, thereby favoring periodic hyperventilation/hypoventilation cycles (95,96). Because of the high prevalence of sleep apnea, clinicians should maintain a high clinical suspicion and have a low threshold to obtain polysomnography in subjects on dialysis who are hypersomnolent.

Another common cause of sleep disturbances in subjects on dialysis is the periodic limb movement/restless legs syndrome. Twenty percent to 30% of subjects with CKD stage 5D report lower extremity symptoms of ascending and migratory paresthesias or cramps so severe as to interfere with sleep (83,97). Patients typically experience prolonged muscle contractions preceded by sensory discomfort (98). These are associated with sudden jerking movements that occur two to three times per minute and can lead to sudden waking. Although fluid and electrolyte imbalances may contribute to the pathophysiology, many subjects have hyperactivity of the motor neurons (99). Anecdotal reports of improvement in cramping symptoms have been reported with quinine sulfate, which appears to interfere with the excitability of the motor end plate and subsequent contractility of the muscles. However, the U.S. Food and Drug Administration has withdrawn its use for cramps because of hypersensitivity and adverse reactions. Other agents, including levodopa (100 to 200 mg/d), gabapentin (300 mg thrice weekly), or

moderate doses of carbamazepine, have been used with widely variable efficacy (100–102).

SOCIAL SUPPORT AND THE QUALITY OF LIFE FOR CAREGIVERS

The interplay between patients and their social support is multidimensional. In subjects on dialysis, social support scores correlate with depression, psychosocial measures, and compliance (103,104). Their perceptions of increased social support correlate with lower depression scores, lower perceptions of illness burden, and higher marital and life satisfaction scores independent of age and severity of illness. Higher socioeconomic, education, and employment levels generally are associated with a greater QOL, except perhaps in African Americans (60,105). Perception of social support and living with family in CKD stage 5D are predictors of survival (65,103,106,107).

Loss of employment also affects HRQOL. Unemployed subjects with CKD stage 5D score significantly lower in the SF-36 Health Survey as compared with those employed (in physical function, role physical, bodily pain, general health, vitality, and emotional scales) (108). Multiple comorbidities, a physical occupation before the onset of significant CKD, and poor physical function are independent predictors of unemployment in CKD stage 5D. Subjects who are employed or do housework tend to be more compliant with their medical regimen (109). Stack (110) attempted to better define determinants of modality selection (HD vs. PD) among incident dialysis patients in the United States. Subjects were more likely to choose PD if they were employed, married, educationally accomplished, more autonomous, and/or living with someone, as compared to HD. In addition, the selection of PD significantly associated with younger age, white race, fewer comorbid conditions, and lower serum albumin.

An important but frequently overlooked component of a subject's well-being is the QOL of their caregivers. Healthy, well-balanced relationships can provide the support many subjects on dialysis need to maintain compliance with medications, diet, and treatments; reduce the severity or occurrence of depression; and improve the overall care that they receive. Social support from family members improves compliance with interdialytic fluid restrictions (111). It is well documented that families who live with chronically ill members have a greater frequency of physical and mental disturbances (112,113). The burden and QOL of the caregivers for subjects on HD can be substantial. In a study in Brazil by Belasco and Sesso (114), most caregivers were female (84%), married (66%), and had a low socioeconomic level. The health and vitality of the caregivers, as measured by the SF-36 Health Survey, were the most frequently effected variables and inversely correlated with the burden of the caregiver, the illness of the patient, and perceived pain of the caregiver. Other studies support this finding. In a study in Sweden, Lindqvist et al. (115) demonstrated that optimistic and palliative coping strategies and less confrontational and emotional behaviors resulted in improved HRQOL of the caregivers. Spouses who were female more frequently used these skills (115). In a study from the United States, caregiver ethnicity and mode of dialysis did not significantly affect dialysis subjects perceived QOL (116). Highly functioning patients and families report the least burden and best coping strategies. To circumvent the stress associated with the ubiquitous uncertainty about the patient's health and life expectancy, frequent dialytic treatments, and potential for transplantation, families and caregivers rely heavily on their support groups and religious beliefs, living one day at a time (117). Such family and interpersonal dynamics

should be explored for all subjects with CKD to help optimize their overall well-being.

ANEMIA

The impact of anemia on the HRQOL is well described and spans the continuum from early stage CKD through ESKD (see Chapter 29). Symptoms associated with uncorrected anemia in subjects with CKD include fatigue, sexual function, cognitive dysfunction, cold intolerance, angina, dyspnea, and an impaired HRQOL. The introduction of human recombinant erythropoietin (rHuEPO) therapy into clinical practice to increase the Hb has had a dramatic effect on these parameters, particularly HRQOL measures. In subjects on HD or PD, correction of anemia consistently results in improvement in functional status, exercise ability, cognitive function, sexual function, and somatic complaints (50,118–122). In the Spanish Cooperative Study, Hb concentrations correlated significantly with physical and global scores on the SIP (60). Other large clinical studies confirm improvements in fatigue, perceived strength, and global scores on the SIP, KI, and SF-36 Health Survey, even with only modest increases in hematocrit (Hct) to 30.1% (123,124). In these trials, subjects on HD who were not receiving rHuEPO had significantly lower scores on the SF-36 than those who were receiving rHuEPO. The gap in the scores progressively diminished as the patients were initiated on rHuEPO therapy. In a similar trial, Moreno et al. (125) observed significant improvement in all three dimensions of the SIP when subjects on dialysis were started on rHuEPO. HRQOL had a positive correlation with Hct between the levels of 29% and 35%, as assessed using the KI and SIP. Using the KI and objective measures of employment status, Evans (118) demonstrated that the perceived HRQOL of subjects on dialysis treated with rHuEPO for 10 months actually exceeded that of untreated subjects with kidney transplantation.

Anemic predialysis subjects also gain substantial improvements in HRQOL when started on rHuEPO (126,127). In a randomized prospective trial, Revicki et al. (72) compared pre-ESKD subjects treated with rHuEPO to achieve an Hct of 35% with comparable untreated cohort whose mean Hct was 26.8%. HRQOL was measured using components of the SIP (three scales), SF-36 (four scales), and Campbell's ILS. Treated subjects reported improvements in physical function, energy, health distress, sexual dysfunction, depression, and satisfaction; results correlated with the improvement in Hct (72). It has also been suggested that early correction of anemia may prevent some of the complications of CKD. Correction of anemia may lead to regression of left ventricular hypertrophy, improve myocardial contractility, and increase left ventricular ejection fraction. Early treatment of anemia, instituted when the Hct falls below 35%, may prevent cardiovascular deterioration, reduce overall morbidity and mortality, and is essential in maintaining HRQOL (128–131).

Unfortunately, the target Hg/Hct that optimizes HRQOL remains controversial. Initial National Kidney Foundation (NKF)-DOQI guidelines for the management of anemia recommended targeting Hb concentrations between 11 and 12 g/dL (132). Whether HRQOL measures are improved by further increasing the Hg remains uncertain. In the Canadian Erythropoietin Study, the increase in HRQOL effects plateaued at an Hb concentration of 11.7 g/dL (21,50). The KI and SIP scores obtained by Moreno et al. (133) showed a positive correlation with Hct between 29% and 35%; the benefits are most evident at higher Hct concentrations. Eschbach et al. (134) demonstrated continued improvement in HRQOL with increasing Hct up to 42%. In another trial by Moreno et al. (135), the Hct of subjects on dialysis was increased 5 points above their baseline Hct. Baseline Hct ranged between 28% and 35%. The increase in

Hct was associated with a significant improvement in HRQOL as assessed by both the KI and SIP. Although this trial was not associated with other problems, it should be noted that the cohort tested did not have significant comorbidities.

In contrast, in subjects on HD with ischemic heart disease or congestive heart failure, normalization of the Hct may be detrimental. In the North American Multicenter Study, Besarab et al. (136) prospectively randomized 1,233 subjects with known heart disease to target Hct levels of either 42% or 30%. Given concerns regarding increased risk of morbidity and mortality in normalized Hct group, an independent data monitoring committee terminated the study early. After 29 months, there were 183 deaths and 19 nonfatal myocardial infarctions (MIs) in the normal Hct group as compared with 150 deaths and 14 MIs in the low Hct group. Of note, the mortality of both groups decreased with increasing Hct, and HRQOL, as measured by the SF-36, increased 0.6 points for each percentage increase in the Hct. Other studies have demonstrated that patients with higher Hct experience less morbidity (135). The Correction of Hemoglobin and Outcomes in Renal Insufficiency (CHOIR) study was a randomized trial in subjects with CKD not on dialysis randomized to either high-Hb group (target Hg 13.5 g/dL) or low-Hb group (target Hg 11.3 g/dL) (137). HRQOL was assessed using the following three metrics: the KDQ, SF-36 Health Survey, and the Linear Analogue Self-Assessment (LASA). The CHOIR study was terminated early due to concerns that the conditional power for demonstrating benefit for the high-Hb group was going to be less than 5%. Data from the 1,432 subjects demonstrated that both groups demonstrated improvement in HRQOL scores when anemia was treated. When comparing improvement from baseline HRQOL using the LASA and KDQ, there was no significant difference between the two groups. However, the lower Hb group had more improvement in role limitations caused by emotional or personal problems as determined by the SF-36 (137). Issues with the CHOIR study include target Hb of the high-Hb group was not achieved (median Hb 12.8 g/dL), unclear time frame when the QOL tools administered, and use of high doses of rHuEPO, which have been hypothesized as having vascular effects.

The 2006 Kidney DOQI guidelines recommend that Hb levels be maintained at or above 11 g/dL in all subjects with CKD and that Hb levels not be routinely maintained above 13 g/dL (138). However, because the HRQOL may improve more the closer the Hb is to 13 g/dL, emphasis must be placed on at least achieving currently recommended levels of Hb. The KDIGO's 2012 guidelines stated that individualization of anemia therapy will be necessary, as some patients may have improvements in QOL at Hb concentration above 11.5 g/dL, although this recommendation was not graded (139).

DEPRESSION

Depression appears to be the most common psychological problem experienced by subjects on HD, effecting anywhere from 20% to 70% of patients (12,140,141). Estimates of the prevalence of depression vary widely based on the instruments used to detect it and differing diagnostic criteria. In subjects on dialysis, depression clearly correlates with a compromised HRQOL (142), is more common in women, is unrelated to satisfaction with the dialysis staff or the nephrologist, and is most common in HD as compared with PD and transplantation (143,144). The etiology of depression in dialysis patients is multifactorial. Impaired physical status; complex medical regimens; and the loss of time, finances, sexual function, and control contribute to depressive symptoms. As in other chronic illnesses, the extent of depression over time in subjects with CKD stage 5D predicts mortality (141,143,145). Kovac et al. (143)

investigated whether the risk of mortality and rate of hospitalization can be predicted from physician-diagnosed depression and patients' self-reports of depressive symptoms. In their cohort of more than 5,000 HD patients, the prevalence of depression was 20%. The relative risk of mortality and hospitalization among depressed patients, as measured by medical records and the KDQOL-SF, was 23% higher than in nondepressed patients. Consequently, subjects should be evaluated periodically for depression, using sensitive tools such as the BDI, BDI-II, or PHQ9, and if found, treated accordingly (33). In a few small studies in subjects on HD, cognitive behavioral therapy has been associated with improvement in BDI-II (self-reported, $p = 0.03$) and Hamilton Depression Rating Scale (clinician-reported, $p < 0.001$) scores after intervention (146–148).

DEMOGRAPHIC VARIABLES

Age

As the age of the dialysis and transplant population increases, it is critical to explore the impact of age on the HRQOL. Early studies indicated that advanced age has a negative impact on the HRQOL (25,66,149). These studies compared the HRQOL of subjects with CKD younger than 65 years with those older than 65 years and found that HRQOL was worse in the older cohort. In the Spanish QOL study, deterioration in the physical dimension of the SIP was strongly correlated to increased age (12,60,133). However, using the SIP and SF-36, Rebollo et al. (150) studied 485 subjects who were either on HD or posttransplant; the scores of the elderly subjects were significantly higher than those of the younger subset. Elderly renal transplant subjects had even higher scores than the reference general population. This data suggest that CKD stage 5D has less of an impact in the elderly and that transplantation in this group offers a reasonable alternative to dialysis.

A study done on nursing home residents who were initiated on HD compared functional status prior to and 3 months after initiation on HD. Functional status was measured by assessing the degree of dependence using the Minimum Data Set–Activities of Daily Living scale. After 3 months of HD, functional status was maintained in only 39% of the subjects, and after 12 months, only 13% had maintenance of their functional status, 58% of the subjects had died by 12 months (151). Using a random-effects model, the initiation of dialysis was associated with a marked decline in functional status; this decline was independent of age, sex, race, and functional-status trajectory before the initiation of dialysis.

In contrast to elderly patients living in nursing homes, as assessed by the SF-36 Health Survey, elderly subjects on dialysis living in London had better physical functioning, lower levels of pain, and better general health perceptions than their younger counterparts. Interestingly, these elderly subjects were also less likely to be hospitalized and, when they were, had shorter lengths of stay. Higher economic level, educational level, KI score, and lower number of comorbid conditions were associated with higher HRQOL (152). Elderly subjects tend to be more satisfied with their life while on dialysis and appear to accept their limitations better than younger subjects. This may be due, in part, to the fact that older individuals expect some degree of deterioration in their HRQOL and are more grateful for the extension of life provided by renal replacement therapy (4,153,154). In DOPPS, older age was not significantly associated with reduced scores in MCS, social function scales, or general health but was associated with lower scores in the PCS (64).

Among elderly subjects on PD, despite having worse appetites and moods than their younger counterparts, there is no significant difference in their overall HRQOL (155). In addition, clinical outcomes and HRQOL, as measured by the SF-36 and KDQOL, do not differ significantly among elderly subjects treated with PD or HD (156). Therefore, based on HRQOL alone, subjects should not be excluded from a treatment modality simply on the basis of age.

Gender

Studies consistently demonstrate that women have a lower HRQOL than men, regardless of the type of renal replacement modality, and this exists even among CKD subjects predialysis (60,152,157,158). It has been suggested that much of the measured decrement in HRQOL may be related more to social factors and depression, particularly the change in women's social role, rather than because of physical factors (12). However, in a study done in Sweden, women appeared to be less effective at coping with the physical aspects of CKD stage 5D as compared with their male counterparts (159). Additionally, women treated with PD had lower scores on the Swedish Health-Related Quality of Life (SWED-QUAL) questionnaire (developed from the SF-36 Health Survey) as compared with woman on HD (159). DOPPS also demonstrated that women had significantly lower scores in physical functioning, bodily pain, and vitality compared to men (64).

Ethnicity

Despite the overrepresentation of racial and ethnic minorities among subjects on dialysis and underrepresentation among transplant patients, the adjusted mortality and HRQOL for minority participants in the CKD stage 5D program are better than for the majority population (160). Using the Wisconsin QOL Index, Welch and Austin (161) evaluated the HRQOL in 79 black subjects on dialysis at two urban dialysis units. Their HRQOL was fairly high and similar to that of a non–African American cohort. In the black cohort, psychological and spiritual health ranked higher than physical functioning. Worse HRQOL was associated with more education and younger age. In a prospective, observational trial in the state of Georgia, elderly black subjects on dialysis had better perceived HRQOL than elderly white subjects (105). In this study, the elderly white subjects more frequently complained of nausea, fatigue, and postdialysis inertia. They were also more likely to perceive dialysis as an intrusion to their health and diets and to be dissatisfied with their health and life, despite a lower incidence of diabetes (105). The largest data set examining differences in HRQOL comes from the DOPPS, whose cohort was broken down into: white (n = 3,143), African American (n = 2,102), Asian (n = 183), Native American (n = 50), Hispanic (n = 587), and Other (n = 86). Compared with the non-Hispanic white group, the African American group had significantly higher mean adjusted HRQOL scores for all three components of the KDQOL-SF (162). Specifically, their mean difference was +1.3, +1.1, and +1.8 (PCS, MCS, and KDCS, respectively). However, the African American group had significantly lower score (mean difference, −3.2) in the item "patient satisfaction" (162).

When compared with whites, Asian subjects in England reported significantly lower HRQOL both while on dialysis and after successful transplantation, using the KDQOL-SF survey (163). Asian subjects, in particular, were noted to perceive kidney disease as a social burden. In DOPPS, the Asian group had a significantly higher score than whites for the PCS (mean difference, +2.4), but no significant difference was observed for the MCS and KDCS (162).

When compared with the white group, the Hispanic group from DOPPS had significantly higher adjusted scores for the PCS (mean difference, +1.6) but lower scores for the MCS and KDCS (mean difference, −1.4 and −1.7, respectively) (164).

Of concern, minorities in the United States typically have longer waiting times for transplantation, limited referral for home dialysis, fewer native fistulas placed, and higher rate of inadequate dialysis prescriptions. Correction of these inequities may have a positive effect on HRQOL.

HEALTH-RELATED QUALITY OF LIFE

Comorbid Conditions

As renal function declines, many subjects experience fatigue, lethargy, muscle cramps, loss of appetite, and a sense of loss of control. This physical deterioration is accompanied by a decline in the HRQOL. In the Modification of Diet in Renal Disease (MDRD) study, the severity of physical symptoms correlated with a decline in HRQOL that paralleled the loss of kidney function (157). Some subjects experience an improvement in HRQOL after the initiation of dialysis, but the improvement was variable and depended on coexisting medical problems. In subjects both before and after initiation of dialysis, the number of comorbid conditions strongly correlates with lower physical function and worse scores on the SIP (12,60). Specifically, the presence of intermittent claudication (as a manifestation of PVD), uncontrolled hypertension, and physical symptoms has been shown to be important determinants of a poor HRQOL (59,164). Not surprisingly, diabetes is also strongly associated with a worse HRQOL (149). Subjects with diabetes mellitus (DM) consistently score lower in all variables of HRQOL measures, independent of age. This may be related to the multisystem involvement of DM and in particular, the associated neuropathy (165). Importantly, intensive education seems to improve the HRQOL in these subjects. McMurray et al. (166) randomized 83 subjects with DM on dialysis to either standard or intensive education. The control group’s risk of foot disease and amputation increased over the course of a year but was unchanged in the intensive education group. The treatment group reported significant improvement in HRQOL indices when compared with the controls, highlighting the important benefits of intensive education and support. In the Hemodialysis (HEMO) study, factors that were associated with more fatigue included the presence of diabetes, a lower serum albumin, a higher index of coexistent diseases (ICED) score, non–African American race, use of medications for sleep, and poor sleep quality (167). In this study, older subjects and dialysis vintage was also associated with a higher rate of worsening fatigue, whereas a high serum albumin was associated with improvement in fatigue.

DIALYSIS-RELATED FACTORS

Dialysis Modality

The effect of dialysis modality on HRQOL remains controversial. Some studies demonstrated better satisfaction in subjects on HD as compared with PD (25,57,58). In a prospective, observational study, the PCS and MCS components of the SF-36 Health Survey were used to compare HRQOL in 177 subjects over 15 months (168). Subjects on PD had a significantly lower PCS score than subjects on HD, despite having similar MCS scores and prevalence of depression. However, when corrected for the serum

albumin level, this difference was eliminated. Other investigators have found that although patients on PD have a greater degree of independence, they appear to be more anxious and insecure than patients on HD (12,169). Using the KDQOL-SF, the NECOSAD study demonstrated that subjects on PD had a greater decrease in the physical dimension of HRQOL compared with subjects on HD (170). Bakewell et al. (171) found similar results in subjects on PD using the KDQOL-SF.

Other studies have yielded the opposite results. In a meta-analysis of 61 studies comparing differences in HRQOL across renal replacement therapies demonstrated that subjects on PD enjoyed a greater sense of well-being and were less distressed than subjects on HD (57).

To determine if increased frequency of dialysis would improve HRQOL, the Frequent Hemodialysis Network randomized trials compared the effects of six versus three times per week HD on physical health (172). Subjects randomized to frequent HD had a significant increase in their physical health composite scores but no significant change in their short physical performance battery, when compared with the convention thrice-weekly dialysis group. Frequent HD was associated with favorable results with respect to the composite outcomes of death or change in left ventricular mass and the composite outcome of death or change in a physical health composite score.

Adequacy of Dialysis Clearance

Other studies have evaluated the impact of Kt/V and innovative approaches to dialysis on the HRQOL. Using the KDQOL-SF, SF-36, and EuroQol EQ-5D, Manns et al. (173) found that subjects on HD with an average Kt/V greater than or equal to 1.3 had better HRQOL. In the HEMO study, the IWB and the KDQOL (long-form) questionnaires were used to assess HRQOL. The high dose of delivered dialysis (eKt/V of 1.45) was associated with higher PCS scores and significantly less pain when compared with standard dose of delivered dialysis (eKt/V of 1.05) (174). Using the SF-36 Health Survey, Chen et al. (175) demonstrated that subjects on PD with adequate total urea clearance had a better HRQOL than those with inadequate clearance, as determined by Kt/V urea. Support of the notion that improved clearance improves HRQOL comes from a study which demonstrated that uremic subjects on PD showed increased HRQOL with the addition of once-weekly HD (176).

No long-term studies have demonstrated the effect of dialysate buffer on an individual's HRQOL. Other methods to improve the dose of delivered dialysis have been studied. The use of high-flux membranes was not associated with improved HRQOL in the HEMO study compared to low-flux membranes (174). However, both daily dialysis and nightly home HD have been reported to positively impact HRQOL, as they show promise in reducing dialysis-related symptoms and hospitalizations and in improving well-being (177–179). Because of substantial cost and the technical support needed for these interventions, further cost-benefit analysis is needed.

NUTRITION AND PHYSICAL ACTIVITY

The importance of maintaining adequate nutrition in CKD stage 5D has been well established (see Chapter 27 for discussion). Multiple studies, although not examining nutrition directly, report an association between low albumin levels and a low HRQOL. In general, there is a significant inverse relationship between SF-36 scores and serum albumin and anemia, and a negative correlation with obesity (180,181). Low albumin levels are independently associated with decreased physical function,

social function, and burden of kidney disease as assessed by the SF-36. Low PCR is associated with decreased physical function scores and disability, as measured by the KPS (182).

Many authors describe advantages of physical exercise in improving the HRQOL. This appears to be true both at the initiation of dialysis, when muscle deterioration begins, and throughout the course of dialytic therapy (183,184). Exercise activity independently predicts performance measures of gait speed and chair rising and perceived physical functioning (185). Interventions to improve exercise may include in-center cycling, home regimens, and rehabilitation (186,187) and should be explored for all patients.

CONCLUSION

Recognition that HRQOL is an important predictor of morbidity and mortality has been an important advancement in caring for subjects with CKD. Measurement of HRQOL is helpful in assessing the impact of interventions, increasing patients' participation in their own care, and increasing patient satisfaction (188). Improvement of anemia, malnutrition, inactivity, predialysis care, and social support systems enhance the HRQOL and are associated with improved survival. Strategies aimed at these components and in controlling blood pressure, preserving residual kidney function, and assuring adequacy of dialysis should further reduce the risk of poor outcomes. In the future, telemedicine and other technologic advances may provide additional mechanisms to improve the HRQOL (189). Presently, health care providers should focus on HRQOL issues and measure their patients' perceptions at periodic intervals using a validated tool like the KDQOL-SF.

CHAPTER 35

Prescribing Drugs for Dialysis Patients

Ali J. Olyaei and William M. Bennett

Acute and chronic kidney disease affects the pharmacokinetic and pharmacodynamics of most pharmacologic agents (1–3). The effect of uremia and kidney disease on individual agents varies. Clearly, uremia affects every organ system in the body. Therefore, alteration of drug absorption, distribution, metabolism, and excretion and their active or toxic metabolites must be considered when prescribing pharmacologic agents for patients with kidney disease, in particular for patients on renal replacement therapy (hemodialysis or peritoneal dialysis). In addition, most patients with kidney disease have many comorbid conditions, which often compound the complexity of drug management in this setting (4).

Health care providers who prescribe drug therapy for patients with chronic kidney disease must be familiar with basic pharmacokinetic and pharmacologic principles. Dosage adjustment is required for the drug excreted renally in patients with chronic kidney disease to ensure long-term efficacy and prevent short- and long-term toxicity. Often, a drug with a narrow therapeutic concentration or critical dosage schedule is necessary to treat a serious disease. For drugs with a narrow therapeutic window, therapeutic drug monitoring (TDM) is required to prevent both drug accumulation and subtherapeutic dosing. Many pharmacologic agents also have active metabolites that undergo renal excretion. The metabolism and elimination of these agents depend on normal renal function. Pharmacologic agents that do not undergo renal elimination may be altered and, therefore, cause adverse effects in this patient population.

The kidney plays an important role in the regulation of extracellular and intracellular fluid homeostasis. Renal dysfunction has profound effects on the volume distribution and pharmacology of many drugs. Improvements in the clinical management of patients with kidney disease, coupled with the development of new and more efficient methods of renal replacement therapy, have created a large patient population with a special need for drug management. One study indicated that 40% of patients with chronic kidney disease received excessive dose of medications. Another study observed a positive association with the number of medications administered and the mortality rate in patients with chronic kidney disease (5). These data highlight the importance of identifying patients with chronic kidney disease, estimating renal function, and adjusting the drug dosage appropriately according to renal function (6).

This chapter covers information about drug disposition in patients with chronic kidney disease and how to effectively approach pharmacotherapy in patients undergoing dialytic therapies to optimize drug efficacy while minimizing toxicity.

INITIAL PATIENT ASSESSMENT

Patient assessment begins with a complete past medical history and physical examination. Taking a thorough past medication history, drug allergy, adverse drug reactions, and concurrent medicines are vital in the initial evaluation of patients with chronic kidney disease. Patients with kidney disease receive on average 11 different medications for the treatment of cardiovascular diseases, metabolic disorders, infectious complications, and other comorbid conditions. In addition, patients with kidney disease experience a threefold higher incidence of adverse drug reactions compared to the general population with normal renal function (7–9). Pharmacotherapy should be individualized and minimized to reduce the risk of adverse drug reactions and potential drug–drug interactions.

Principles of Altered Pharmacokinetics in Kidney Disease

Several pharmacokinetic factors are altered when renal function is impaired. These factors include bioavailability, volume of distribution, protein binding, and biotransformation. Pharmacologic agents may pass through several body compartments before reaching receptor site or being eliminated from the body (**FIGURE 35.1**).

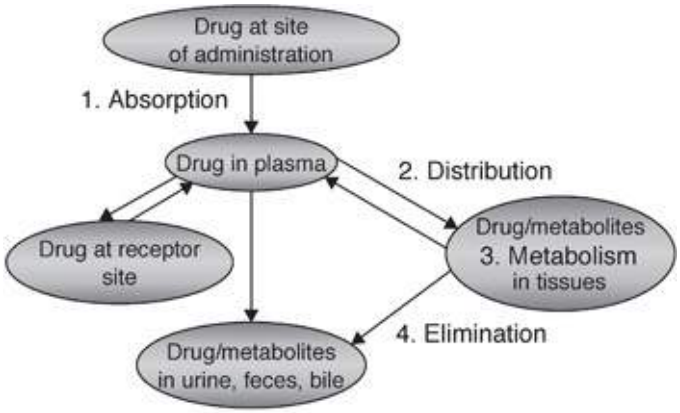

FIGURE 35.1 Pharmacologic agents may pass through several body compartments before reaching receptor site or being eliminated from body.

Bioavailability

The bioavailability of a drug refers to the fraction (expressed as a percentage) of a given dose that reaches the systemic circulation. The rate and route of administration are the primary factors which determine bioavailability. An agent that is not completely absorbed or is eliminated by the liver in its first pass has low bioavailability. Drugs administered intravenously are generally 100% bioavailable because the entire dosage reaches the systemic circulation. When given orally, subcutaneously, or intramuscularly, bioavailability decreases. For example, given intravenously, furosemide is 100% bioavailable but only approximately 50% bioavailable when given orally. In patients with right-sided heart failure or liver disease, the absorption rate may drop to 10%. For this reason, many clinicians double or triple the furosemide dose when switching a patient from IV to oral furosemide (10).

Drug absorption determines bioavailability and may be altered in patients with renal insufficiency.

Many factors may account for this phenomenon. Neuropathic changes resulting from diabetes mellitus and/or aging may cause gastroparesis or uremia-induced vomiting. Patients with cirrhosis, nephrosis, or congestive heart failure (CHF) commonly have edematous gastrointestinal mucosa, causing a reduction in drug absorption. Drugs which increase gastric pH such as phosphate binders and H_2 receptor blockers may impair absorption of concomitantly administered drugs. Concomitant administration of some drugs (such as aluminum- or calcium-containing phosphate binders) with antibiotics or iron-containing supplements may result in the formation of insoluble complexes which can both decrease absorption and slow gut motility.

Volume of Distribution

The volume of distribution (Vd) of a pharmacologic agent is derived by dividing the total amount of drug in the body by the concentration of the drug in the blood. The Vd does not refer to a specific anatomic compartment, but it is useful for calculating the dose required to achieve a desired systemic drug level. An inverse correlation exists between the serum concentration and the Vd (11,12).

After a drug reaches the systemic circulation or is completely absorbed, it is distributed throughout the body. Initially, drugs are distributed to high-flow organs such as the heart, liver, kidney, and brain. In the next phase, drugs are distributed to areas with a lower extraction ratio such as fat, bone, and skin. The rate and extent of distribution of a drug throughout the body determine how much of the drug will be available to exert the pharmacologic actions and how rapidly the drug will be eliminated. Kidney disease affects both drug distribution and protein binding. Edema and ascites increase the distribution volume of many drugs, whereas volume depletion contracts this space. Fluid-volume status of patients should be assessed before administering drugs that require dose adjustment for body weight. For most drugs, ideal body weight (IBW) should be calculated. For men, IBW is 50 kg plus 2.3 kg for each inches more than 5 ft. For women, IBW is 45.5 kg plus 2.3 kg for each inches more than 5 ft.

Therefore, alterations in the extracellular fluid volume can affect the Vd. Volume contraction decreases the Vd while serum drug concentration rises. This is particularly true for hydrophilic compounds such as aminoglycosides or drugs with low Vd (less than 0.7 mL/kg). A rise in extracellular fluid volume due to edema or ascites increases the Vd, resulting in a lower serum drug concentration.

Protein Binding

Plasma contains many proteins which bind drugs. Plasma protein binding is often altered in kidney disease (**TABLE 35.1**). Most drug molecules are circulating in both bound and unbound (free) forms. It is the unbound drug which is distributed and is biologically active (13). The concentration of a given agent which is bound to plasma proteins may be considered a storage pool for that agent. The effects of diseases on drug–protein binding are complex; however, kidney disease tends to decrease protein binding for most agents and increases the free fraction. This is, in part, true because circulating organic wastes bind to carrier proteins, thereby displacing the pharmacologic agent. As a result, a larger concentration of the agent circulates in its free, active form. Most drug assays measure total drug concentration that contains both bound and free drug levels. In some cases (such as in a patient receiving phenytoin), it may be prudent to specifically monitor unbound drug when a narrow therapeutic window exists.

TABLE 35.1 Compounds with Decreased Protein Binding in Uremic Patients

Cephalosporins	Phenytoin
Clofibrate	Primidone
Diazepam	Salicylate
Diazoxide	Sulfonamide
Furosemide	Theophylline
Morphine	Valproic acid
Penicillins	Warfarin
Phenobarbital	

Biotransformation

Metabolism or biotransformation refers to the biochemical conversion of a drug from one chemical form to another (10,14). Most biotransformation occurs in the liver through hepatic metabolic pathways including oxidation, reduction, acetylation, or hydrolysis. The result is a more polar, hydrophilic metabolite which is more readily excreted. Many drug metabolites are pharmacologically active and depend on renal excretion for elimination from the body. Kidney disease affects both renal and nonrenal pathways. There is some clinical evidence of slow hydrolysis and faster oxidation rates in patients with kidney disease. Toxic metabolites dependent upon renal excretion may also form (**TABLE 35.2**).

TABLE 35.2 Drugs with Active or Toxic Metabolites Excreted by the Kidney

Acebutolol	Imipramine
Allopurinol	Meperidine
Cephalosporins	Methyldopa
Chlorpropamide	Nitrofurantoin
Clofibrate	Prednisone
Daunorubicin	Procainamide
Diazepam	Propoxyphene
Digoxin	Rifampin
Doxorubicin	Sodium nitroprusside
Enalapril	Succinylcholine
Flurazepam	Sulfonamides

Elimination

The glomerular filtration rate (GFR) is closely correlated with renal drug elimination and is useful in determining dosage adjustments. If the total renal clearance of a drug or active metabolite is greater than 30%, a dosage adjustment is needed.

To obtain metabolic balance in patients with reduced renal function, several agents should be avoided. Some drugs increase the metabolic load by increasing creatinine production and/or urea production (glucocorticoids and androgens). Other drugs may overwhelm the kidney's capacity by increasing the metabolic load of excess acid, alkali magnesium, potassium, or sodium. Nonsteroidal anti-inflammatory agents may impair the kidney's ability to excrete free water.

Various pharmacologic agents can interfere with laboratory markers of renal function (**TABLE 35.3**). Elevated serum creatinine (Scr) from direct drug interference with the chromogen assay or by inhibition of renal tubular creatinine secretion can cause confusion to the inexperienced clinician. Similarly, a number of agents can also cause a rise in the blood urea nitrogen (BUN) through interference with the

assay utilized. Temporary discontinuation of the offending medication may be necessary when the Scr or BUN rises unexpectedly. The Cockcroft-Gault (CG) formula is widely used to calculate the creatinine clearance (Clcr) and has traditionally been used to approximate the GFR (15). BUN and Scr are, at best, crude markers of kidney function. The CG formula includes the variables of age (years), IBW (kg), and Scr (mg/dL) and calculates the Scr (mL/min) (**EQUATION 35.1**):

$$*\text{Clcr} = \frac{(140 - \text{age}) \times \text{IBW}}{72 \times \text{Scr}} \qquad (35.1)$$

*Multiply result by 0.85 in women

TABLE 35.3 Drug Interference with Kidney Function Testing

	Drug	Test and Mechanisms of Interference
Increased serum creatinine	Ascorbic acid	Elevates total chromogen
	Levodopa	Interferes with autoanalyzer method
	Methyldopa	–
	Aspirin	–

BUN, blood urea nitrogen.

Patients with acute kidney injury should have an assumed Clcr of less than 10 mL/min, and it should be remembered that CG Clcr overestimates the GFR in these setting and should be avoided for assessment of kidney function in acute kidney injury. There are a number of new method to estimate renal function in chronic kidney disease: Modification of Diet in Renal Disease (MDRD) and Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI). These new markers of GFR are currently being utilized in both the research and clinical setting to more accurately measure renal function without exposing the patient to radiolabeled material. It is important to mention that these formulas approximate GFR rather than Clcr and, therefore, may be a more accurate estimate of renal function. It has been shown to be more accurate than other formulas for predicting GFR. The formula uses a creatinine assay (the kinetic alkaline picrate reaction), which is the least subject to artifact interference. GFR was predicted over a wide range of values including variables for ethnicity and serum albumin concentration and did not rely on timed urine collections. The MDRD study equation (16) is as follows (**EQUATION 35.2**):

$$\text{GFR} = 170_{[\text{ml}]} \times [\text{Scr}]^{-0.999} \times [\text{Age}]^{-0.176} \times [0.762 \text{ if female}] \times [1.180 \text{ if patient is black}] \times [\text{BUN}]^{-0.170} \times [\text{Albumin}]^{-0.318} \qquad (35.2)$$

Appropriate application of the MDRD equation requires calibration of the measured Scr. In addition, this equation has not been rigorously validated in some patient populations, such as those with a GFR greater than 60 mL/min, renal transplant recipients, some ethnic groups, and patients with extreme body

weights.

The CG, MDRD, and CKD-EPI equations (**TABLE 35.4**) have been shown to have statistically significant differences in estimating GFR in various populations. It has been further improved with the MDRD, and CKD-EPI equations included more specific variable of race in addition to age, gender, and Scr. Although accuracy in GFR assessment has improved, one equation has yet to be developed to be the most accurate in all populations. Therefore, drug dosing adjustments based on the various equations may differ. However, without clinical outcome data, it is yet to be determined whether these differences are clinically significant.

TABLE 35.4 Commonly Used Method for Estimation of Glomerular Filtration Rate (GFR) Using Serum Creatinine

Cockroft-Gault
$Clcr\ (mL/min) = ([140 - age] \times weight) / (Scr \times 72)\ (\times 0.85\ in\ women)$
MDRD
$GFR\ (mL/min/1.73\ m^2) = 186 \times Scr^{-1.154} \times Age^{-0.203}\ (\times 0.742\ if\ female)\ (\times 1.212\ if\ black)$
MDRD using standard creatinine value
$GFR\ (mL/min/1.73\ m^2) = 175 \times Scr^{-1.154} \times Age^{-0.203}\ (\times 0.742\ if\ female)\ (\times 1.212\ if\ black)$
CKD-EPI
Women:
$GFR\ (mL/min/1.73\ m^2) = 144 \times (Scr/0.7)^{-0.329} \times 0.993^{Age}\ (\times 1.15\ if\ black)\ if\ Scr \leq 0.7\ mg/dL$
$GFR\ (mL/min/1.73\ m^2) = 144 \times (Scr/0.7)^{-1.209} \times 0.993^{Age}\ (\times 1.15\ if\ black)\ if\ Scr > 0.7\ mg/dL$
Men:
$GFR\ (mL/min/1.73\ m^2) = 141 \times (Scr/0.9)^{-0.411} \times 0.993^{Age}\ (\times 1.16\ if\ black)\ if\ Scr \leq 0.9\ mg/dL$
$GFR\ (mL/min/1.73\ m^2) = 141 \times (Scr/0.9)^{-1.209} \times 0.993^{Age}\ (\times 1.16\ if\ black)\ if\ Scr > 0.9\ mg/dL$

Clcr, creatinine clearance; Scr, serum creatinine in mg/dL; MDRD, Modification of Diet in Renal Disease; CKD-EPI, Chronic Kidney Disease Epidemiology Collaboration.

Loading Dose Determination

The half-life of many drugs may be significantly prolonged in patients with kidney disease. In patients with normal renal function, steady-state drug concentrations are achieved after approximately 3.3 half-lives. In patients with kidney disease, achievement of steady-state drug levels, which ensures therapeutic efficacy, may be greatly delayed if a loading dose (LD) is not given. Patients with renal insufficiency should, in general, receive the same LD as patients with normal renal function in order to achieve a rapid therapeutic dose. Patients with kidney disease receiving digoxin, however, should receive only 50% to 75% of the usual LD as its Vd is greatly reduced in kidney disease.

The following formula can be used to calculate the LD with Vd in L/kg, IBW in kg, Cp being the desired plasma concentration in mg/L (**EQUATION 35.3**):

$$LD = Vd \times IBW \times [Cp] \qquad (35.3)$$

Maintenance Dose Determination

Before adjusting the maintenance dose, the route of excretion should be established. The maintenance dose should be adjusted only for drugs with greater than 50% renal excretion, low rate of protein binding, and small Vd. The maintenance dosage in patients with renal insufficiency can be adjusted in three ways: dosing interval prolongation, dosage reduction, or both. Increasing the dosage interval to correspond to the degree of renal dysfunction can be calculated from the following formula (**EQUATION 35.4**):

$$\text{Dosing interval} = \frac{\text{normal Clcr} \times \text{normal interval}}{\text{patients Clcr}} \qquad (35.4)$$

Dosage reduction without changing the dosing interval can be calculated from the following formula (**EQUATION 35.5**):

$$\text{Maintenance dose} = \frac{\text{patients Clcr} \times \text{normal dose}}{\text{normal Clcr}} \qquad (35.5)$$

Dosage interval extension allows for adequate peak concentrations but may risk subtherapeutic trough levels. Dosing reduction may provide for more constant drug levels but increases the risk of toxicity from higher plasma trough concentrations. Appendix A summarizes recommendations for most drugs in patients with renal dysfunction.

Drug Level Monitoring

Dosage and interval modifications do not necessarily protect against drug toxicity in particular for drugs with a narrow therapeutic window. For such pharmacologic agents, plasma drug monitoring is important in the patient with kidney disease to avoid drug toxicity. To correctly interpret drug concentrations, it is important to know the exact dose given, the route of administration, time since the last dose, and the particular drug's half-life. Peak drug levels represent the highest drug concentration achieved after initial rapid distribution and predict drug efficacy. Trough drug levels are obtained immediately before the next dose, represent the lowest serum concentration, and predict drug toxicity. Drug level monitoring can be expensive, is not always available, and does not always reduce the incidence of toxicity. Aminoglycoside antibiotics, for instance, can concentrate in tissues such as the inner ear and renal cortex, and toxicity is not always correlated with high blood levels. Ongoing clinical assessment is important even when drug levels are within the established therapeutic range. In the presence of metabolic acidosis or hypokalemia, digoxin toxicity may occur despite therapeutic levels. Most assays do not distinguish between free and protein-bound drug in the plasma. An increase in unbound drug is common in patients with kidney disease. **TABLE 35.5** summarizes recommendations for TDM in patients with renal dysfunction (3,4,17).

TABLE 35.5 Drugs with Narrow Therapeutic Index Which Require Routine Monitoring

Drug Name	Therapeutic Range	When to Draw Sample	How Often to Draw Levels
Aminoglycosides (Conventional dosing) Gentamicin, tobramycin, and amikacin	Gentamicin and tobramycin: Trough: 0.5–2 mg/L Peak: 5–8 mg/L Amikacin: Peak: 20–30 mg/L Trough: <10 mg/L 0.5–3 mg/L	Trough: immediately prior to dose Peak: 30 min after a 30- to 45-min infusion	Check peak and trough with third dose For therapy less than 72 h, levels not necessary; repeat drug levels weekly or if renal function changes
Aminoglycosides (24-h dosing) Gentamicin, tobramycin, and amikacin		Obtain random drug level 12 h after dose	After initial dose; repeat drug level in 1 wk or if renal function changes
Carbamazepine	4–12 μg/mL	Trough: immediately prior to dosing	Check 2–4 d after first dose or change in dose
Cyclosporin	150–400 ng/mL	Trough: immediately prior to dosing	Daily for first week and then weekly
Digoxin	0.8–2.0 ng/mL	12 h after maintenance dose	5–7 d after first dose for patients with normal renal and hepatic function; 15–20 d in anephric patients
Lidocaine	1–5 μg/mL	8 h after IV infusion started or changed	
Lithium	Acute: 0.8–1.2 mmol/L Chronic: 0.6–0.8 mmol/L	Trough: before morning dose at least 12 h since last dose	
Phenobarbital	15–40 μg/mL	Trough: immediately prior to dosing	Check 2 wk after first dose or change in dose; follow-up level in 1–2 mo
Phenytoin	10–20 μg/mL	Trough: immediately prior to dosing	5–7 d after first dose or after change in dose
Free phenytoin	1–2 μg/mL		
Procainamide	4–10 μg/mL	Trough: immediately prior to next dose or 12–18 h after starting or changing an infusion	
NAPA (*N*-acetyl procainamide) a procainamide metabolite	Trough: 4 μg/mL Peak: 8 μg/mL 10–30 μg/mL	Draw with procainamide sample	
Quinidine	1–5 μg/mL	Trough: immediately prior to next dose	
Sirolimus	10–20 ng/dL	Trough: immediately prior to next dose	
Tacrolimus (FK-506)	10–15 ng/mL	Trough: immediately prior to next dose	Daily for first week, and then weekly
Theophylline PO or aminophylline IV	15–20 μg/mL	Trough: immediately prior to next dose	
Valproic acid (divalproex sodium)	40–100 μg/mL	Trough: immediately prior to next dose	Check 2–4 d after first dose or change in dose
Vancomycin	Trough: 5–15 mg/L Peak: 25–40 mg/L	Trough: immediately prior to dose Peak: 60 min after a 60-min infusion	With third dose (when initially starting therapy, or after each dosage adjustment); for therapy less than 72 h, levels not necessary; repeat drug levels if renal function changes

IV, intravenous; PO, by mouth.

Drug Removal by Dialysis

Intermittent hemodialysis necessitates high blood and dialysate flow rates, which enhances drug removal primarily by the process of diffusion down a concentration gradient from blood to dialysate, across the

dialysis membrane (18). Small molecular weight drugs (less than 500 Da) cross the dialysis membrane readily and are removed from the plasma with most dialysis membranes. With the advent of high-flux membranes, drugs with higher molecular weights are also removed very effectively. For instance, vancomycin (molecular weight approximately 1,400 Da) can be significantly removed during high-flux dialysis, especially with continuous renal replacement therapy (CRRT) (19). Drugs with large volumes of distribution are less likely to be removed by dialysis than those with a small Vd (Vd less than 0.7 mL/kg). Pharmacologic agents with large Vd are disseminated into adipose tissue or have extensive tissue binding. In conventional hemodialysis, drug removal by diffusion is based on concentration gradients, and drug removal more closely relates to the blood and dialysate flow rates (20). High-flux dialyzers are impermeable to drugs with molecular weight up to 20,000 Da and allow most drugs to be removed during the dialysis. In this setting, drug removal is more dependent on Vd and percentage of protein binding.

In peritoneal dialysis, the peritoneal membrane functions as the dialyzing membrane. It is much less effective than hemodialysis membranes with regard to drug clearance. In peritoneal dialysis, drug removal occurs as a result of diffusion and is dependent on the blood to dialysate concentration gradient. A smaller molecular weight, a lower protein binding, and a smaller Vd facilitate drug removal, similar to low-flux hemodialysis. Some high molecular weight drugs can be removed because of secretion into peritoneal lymphatic fluid. The most important factor in determining the percentage of drug removal during peritoneal dialysis is the rate of dialysate flow. Increasing the number of peritoneal exchanges facilitates removal of low molecular weight drugs, whereas extending the duration of the peritoneal dwell time enhances large molecular weight drug clearance (20–22).

CRRTs most often are used for the management of critically ill patients who are not able to tolerate conventional intermittent hemodialysis (23–25). There is very limited information about how CRRT affects the clearance of individual pharmacologic agents. During CRRT, most drugs can be safely dosed for a GFR of 10 to 30 mL/min. However, for some drugs, the diffusion process significantly increases drug clearance during CRRT due to high-flux dialysis. Similar to high-flux hemodialysis, molecular weight and blood and dialysate flow rates determine the rate and extent of drug removal during CRRT. However, because most drugs have a smaller molecular weight than 1,500 Da, the molecular weight *per se* does not significantly affect the extent of drug removal during CRRT. Like peritoneal dialysis, the Vd and duration of therapy are the most critical factors in influencing drug removal during CRRT (26,27).

There are number of alternative, hybrid method of renal replacement therapies that might alter drug dosing in patient with chronic kidney disease. A short 2 hours or slow over 6 to 8 hours of nocturnal dialysis have been become popular to improve the quality of life and avoid some of the complications of hemodialysis. In addition, patient residual renal function should be considered in dosage recommendations. Unfortunately, there is very limited information about drug dosing in either of these modalities. Due to lack of data in this area, for each drug, health care providers should assess risk versus benefits of each treatment closely to avoid toxicity while enhance efficacy. The limited data from number of antibiotics indicate that a more aggressive dosing schedule is needed compared to conventional hemodialysis. It is reasonable to consider dosing for Clcr 30 to 50 mL/min for patients on 6 to 8 hours nocturnal hemodialysis.

CONCLUSION

Due to epidemic of obesity and diabetes, the number of patients with chronic kidney disease has increased significantly in the last 10 years. Most of these patients have number of comorbid conditions that require pharmacotherapeutic agents. Health care must be aware of changes in basic pharmacokinetic and pharmacologic principles in patients with chronic kidney disease. For most drugs that excreted renally in patients with chronic kidney disease, a dosage adjustment is required to ensure long-term efficacy and prevent short- and long-term toxicity.

APPENDIX A

APPENDIX A

Antimicrobial Dosing in Kidney Disease

Drugs	Normal Dosage	% of Renal Excretion	Dosage Adjustment in Kidney Disease			Dosage Adjustment in CRRT	Comments
			GFR >50	GFR 10–50	GFR <10		
Aminoglycoside antibiotics							Nephrotoxic; ototoxic; toxicity worse when hyperbilirubinemic; measure serum levels for efficacy and toxicity; peritoneal absorption increases with presence of inflammation; Vd increases with edema, obesity, and ascites
Streptomycin	7.5 mg/kg q12h (1.0 g q24h for TB)	60	q24h	q24–72h	q72–96h	Unknown	For the treatment of TB; may be less nephrotoxic than other members of class
Kanamycin	7.5 mg/kg q8h	50–90	60%–90% q12h or 100% q12–24h	30%–70% q12–18h or 100% q24–48h	20%–30% q24–48h or 100% q48–72h	Unknown	Nephrotoxic; ototoxic; toxicity worse when hyperbilirubinemic; Vd increases with edema, obesity, and ascites; do not use once-daily dosing in patients with creatinine clearance <30–40 mL/min or in patients with acute kidney injury or uncertain level of kidney function
Gentamicin	1.7 mg/kg q8h	95	60%–90% q8–12h or 100% q12–24h	30%–70% q12h or 100% q24–48h	20%–30% q24–48h or 100% q48–72h	**Monitor levels very closely,** 1 mg/kg/d	Concurrent penicillins may result in subtherapeutic aminoglycoside levels; peak 6–8, trough <2
Tobramycin	1.7 mg/kg q8h	95	60%–90% q8–12h or 100% q12–24h	30%–70% q12h or 100% q24–48h	20%–30% q24–48h or 100% q48–72h	**Monitor levels very closely,** 1 mg/kg/d	Concurrent penicillins may result in subtherapeutic aminoglycoside levels; peak 6–8, trough <2
Netilmicin	2 mg/kg q8h	95	50%–90% q8–12h or 100% q12–24h	20%–60% q12h or 100% q24–48h	10%–20% q24–48h or 100% q48–72h		May be less ototoxic than other members of class; peak 6–8, trough <2
Amikacin	7.5 mg/kg q12h	95	60%–90% q12h or 100% q12–24h	30%–70% q12–18h or 100% q24–48h	20%–30% q24–48h or 100% q48–72h	7.5 mg/kg	Monitor levels; peak 20–30, trough <5
Cephalosporin							Coagulation abnormalities, transitory elevation of BUN, rash, and serum sickness-like syndrome
Oral cephalosporin							
Cefaclor	250–500 mg tid	70	100%	100%	50%	50%	
Cefadroxil	500–1,000 mg bid	80	100%	100%	50%	50%	
Cefixime	200–400 mg q12h	85	100%	100%	50%	50%

Drugs	Normal Dosage	% of Renal Excretion	Dosage Adjustment in Kidney Disease			Dosage Adjustment in CRRT	Comments
			GFR >50	GFR 10–50	GFR <10		
Ceftibuten	400 mg q24h	70	100%	100%	50%	50%	
Cefuroxime axetil	250–500 mg tid	90	100%	100%	50%	50%	Malabsorbed in presence of H_2-blockers; absorbed better with food
Cephalexin	250–500 mg tid	95	100%	100%	50%	50%	Rare allergic interstitial nephritis; absorbed well when given intraperitoneally; may cause bleeding from impaired prothrombin biosynthesis
Cephradine	250–500 mg tid	100	100%	100%	50%	50%	Rare allergic interstitial nephritis; absorbed well when given intraperitoneally; may cause bleeding from impaired prothrombin biosynthesis
IV cephalosporin						100%	
Cefamandole	1–2 g IV q6–8h	100	q6h	q8h	q12h	50%	
Cefazolin	1–2 g IV q8h	80	q8h	q12h	q12–24h	50%	
Cefepime	1–2 g IV q8h	85	q8–12h	q12h	q24h	50%	
Cefmetazole	1–2 g IV q8h	85	q8h	q12h	q24h	50%	
Cefoperazone	1–2 g IV q12h	20	No renal adjustment is required			50%	Displaced from protein by bilirubin; reduce dose by 50% for jaundice; may prolong prothrombin time
Cefotaxime	1–2 g IV q6–8h	60	q8h	50%	q12–24h	50%	Active metabolite in ESKD; reduce dose further for combined hepatic and kidney disease
Cefotetan	1–2 g IV q12h	75	q12h	50%	q24h	50%	
Cefoxitin	1–2 g IV q6h	80	q6h	100%	q12h	50%	May produce false increase in serum creatinine by interference with assay
Ceftazidime	1–2 g IV q8h	70	q8h	50%	q24h	50%	
Ceftriaxone	1–2 g IV q24h	50	No renal adjustment is required				
Cefuroxime sodium	0.75–1.5 g IV q8h	90	q8h	q8–12h	q12–24h	50%	Rare allergic interstitial nephritis; absorbed well when given intraperitoneally; may cause bleeding from impaired prothrombin biosynthesis
Penicillin							Bleeding abnormalities, hypersensitivity; seizures

Oral penicillin							
Amoxicillin	500 mg po tid	60	100%	100%	50%–75%	70%	
Ampicillin	500 mg po q6h	60	100%	100%	50%–75%	50%	
Dicloxacillin	250–500 mg po q6h	50	100%	100%	50%–75%	50%	
Penicillin V	250–500 mg po q6h	70	100%	100%	50%–75%	50%	
IV penicillin						50%	
Ampicillin	1–2 g IV q6h	60	q6h	q8h	q12h	50%	
Nafcillin	1–2 g IV q4h	35	No renal adjustment is required			100%	
Penicillin G	2–3 million U IV q4h	70	q4–6h	q6h	q8h	50%	Seizures; false-positive urine protein reactions; 6 million U/D upper limit dose in ESKD
Piperacillin	3–4 g IV q4–6h		No renal adjustment is required			100%	Specific toxicity: sodium, 1.9 mEq/g
Ticarcillin/ clavulanate	3.1 g IV q4–6h	85	1–2 g q4h	1–2 g q8h	1–2 g q12h	50%	Specific toxicity: sodium, 5.2 mEq/g
Piperacillin/ tazobactam	3.375 g IV q6–8h	75–90	q4–6h	q6–8h	q8h		Specific toxicity: sodium, 1.9 mEq/g
Quinolones							Photosensitivity, food, dairy products, tube feeding and Al $(OH)_3$ may decrease the absorption of quinolones
Cinoxacin	500 mg q12h	55	100%	50%	Avoid	Avoid	
Fleroxacin	400 mg q12h	70	100%	50%–75%	50%	50%	
Ciprofloxacin	200–400 mg IV q24h	60	q12h	q12–24h	q24h	q24h	Poorly absorbed with antacids, sucralfate, and phosphate binders; IV dose 1/3 of oral dose; decreases phenytoin levels
Lomefloxacin	400 mg q24h	76	100%	200–400 mg q48h	50%	50%	Agents in this group are malabsorbed in the presence of magnesium, calcium, aluminum, and iron; theophylline metabolism is impaired; higher oral doses may be needed to treat CAPD peritonitis.
Levofloxacin	500 mg po qd	70	q12h	250 q12h	250 q12h	250 q12h	L-Isomer of ofloxacin: appears to have similar pharmacokinetics and toxicities
Moxifloxacin	400 mg qd	20	No renal adjustment is required				
Nalidixic acid	1.0 g q6h	High	100%	Avoid	Avoid	Avoid	Agents in this group are malabsorbed in the presence of magnesium, calcium, aluminum, and iron; theophylline metabolism is impaired; higher oral doses may be needed to treat CAPD peritonitis.

Drugs	Normal Dosage	% of Renal Excretion	Dosage Adjustment in Kidney Disease			Dosage Adjustment in CRRT	Comments
			GFR >50	GFR 10–50	GFR <10		
Norfloxacin	400 mg po q12h	30	q12h	q12–24h	q24h	q24h	Agents in this group are malabsorbed in the presence of magnesium, calcium, aluminum, and iron
Ofloxacin	200–400 mg po q12h	70	q12h	q12–24h	q24h	q24h	Agents in this group are malabsorbed in the presence of magnesium, calcium, aluminum, and iron
Pefloxacin	400 mg q24h	11	100%	100%	100%	100%	Excellent bidirectional transperitoneal movement
Sparfloxacin	400 mg q24h	10	100%	50%–75%	50% q48h	50% q48h	
Miscellaneous agents							
Azithromycin	250–500 mg po qd	6	No renal adjustment is required				No drug–drug interaction with CsA/FK
Clarithromycin	500 mg po bid		No renal adjustment is required				
Clindamycin	150–450 mg po tid	10	No renal adjustment is required				Increase CsA/FK level
Dirithromycin	500 mg po qd		No renal adjustment is required				Nonenzymatically hydrolyzed to active compound erythomycylamine
Erythromycin	250–500 mg po qid	15	No renal adjustment is required				Increase CsA/FK level; avoid in transplant patients.
Imipenem/cilastatin	250–500 mg IV q6h	50	500 mg q8h	250–500 q8–12h	250 mg q12h	50%	Seizures in ESKD; nonrenal clearance in acute kidney injury is less than in chronic kidney disease; administered with cilastin to prevent nephrotoxicity of renal metabolite
Meropenem	1 g IV q8h	65	1 g q8h	0.5–1g q12h	0.5–1 g q24h	50%	
Metronidazole	500 mg IV q6h	20	No renal adjustment is required				Peripheral neuropathy, increase LFTs, disulfiram reaction with alcoholic beverages
Pentamidine	4 mg/kg/d	5	q24h	q24h	q48h	50%	Inhalation may cause bronchospasm; IV administration may cause hypotension, hypoglycemia, and nephrotoxicity.
Trimethoprim/sulfamethoxazole	800/160 mg po bid	70	q12h	q18h	q24h	25%	Increase serum creatinine; can cause hyperkalemia
Vancomycin	1 g IV q12h	90	q12h	q24–36h	q48–72h	Monitor levels, redoes at level <20	Nephrotoxic, ototoxic, may prolong the neuromuscular blockade effect of muscle relaxants; peak 30, trough 5–10
Vancomycin	125–250 mg po qid	0	100%	100%	100%	100%	Oral vancomycin is indicated only for the treatment of *Clostridium difficile.*

Antituberculosis antibiotics							
Rifampin	300–600 mg po qd	20		No renal adjustment is required			Decrease CSA/FK level; many drug interactions
Antifungal agents							
Amphotericin B	0.5 mg–1.5 mg/kg/d	<1		No renal adjustment is required			Nephrotoxic, infusion-related reactions, give 250 mL NS before each dose
Amphotec	4–6 mg/kg/d	<1		No renal adjustment is required			
Abelcet	5 mg/kg/d	<1		No renal adjustment is required			
AmBisome	3–5 mg/kg/d	<1		No renal adjustment is required			
Azoles and other antifungals							Increase CsA/FK level
Fluconazole	200–800 mg IV qd/bid	70	100%	100%	50%	100%	
Flucytosine	37.5 mg/kg	90	q12h	q16h	q24h	50%	Hepatic dysfunction; marrow suppression more common in azotemic patients
Griseofulvin	125–250 mg q6h	1	100%	100%	100%	100%	
Itraconazole	200 mg q12h	35	100%	100%	50%	50%	Poor oral absorption
Ketoconazole	200–400 mg po qd	15	100%	100%	100%	100%	Hepatotoxic
Miconazole	1,200–3,600 mg/d	1	100%	100%	100%	100%	
Terbinafine	250 mg po qd	>1	100%	100%	100%	100%	
Voriconazole	4 mg/kg q12h	>1	100%	100%	100%	100%	IV use should be limited for only few doses in patients with Clcr less than 30 mL/min.
Antiviral agents							
Acyclovir	200–800 mg po 5×/d	50	100%	100%	50%	25%	Poor absorption; neurotoxicity in ESKD; IV preparation can cause kidney disease injected rapidly.
Adefovir	10 mg	45	100%	10 mg q48h	10 mg q72h	10 mg q72h	Nephrotoxic
Amantadine	100–200 mg q12h	90	100%	50%	25%	25%	
Cidofovir	5 mg/kg weekly × 2 (induction) –5 mg/kg every 2 wk	90	No data: avoid	No data: avoid	No data: avoid	No data	Dose-limiting nephrotoxicity with proteinuria, glycosuria, renal insufficiency; nephrotoxicity and renal clearance reduced with coadministration of probenecid
Delavirdine	400 mg q8h	5	No data: 100%	No data: 100%	No data: 100%	No data	
Didanosine	200 mg q12h (125 mg if <60 kg)	40–69	q12h	q24h	50% q24h	50% q24h	Pancreatitis
Famciclovir	250–500 mg po bid to tid	60	q8h	q12h	q24h	q24h	VZV: 500 mg po tid HSV: 250 po bid; metabolized to active compound penciclovir

Drugs	Normal Dosage	% of Renal Excretion	Dosage Adjustment in Kidney Disease			Dosage Adjustment in CRRT	Comments
			GFR >50	GFR 10–50	GFR <10		
Foscarnet	40–80 mg IV q8h	85	20–40 mg q8–24h according to Clcr			No data	Nephrotoxic, neurotoxic, hypocalcemia, hypophosphatemia, hypomagnesemia, and hypokalemia
Ganciclovir IV	5 mg/kg q12h	95	q12h	q24h	2.5 mg/kg qd	2.5 mg/kg qd	Granulocytopenia and thrombocytopenia
Ganciclovir po	1,000 mg po tid	95	1,000 mg tid	1,000 mg bid	1,000 mg qd	1,000 mg qd	Oral ganciclovir should be used *only* for prevention of CMV infection; always use IV ganciclovir for the treatment of CMV infection.
Indinavir	800 mg q8h	10	No data: 100%	**No data:** 100%	No data: 100%	No data: 100%	Nephrolithiasis; acute kidney injury due to crystalluria, tubulointerstitial nephritis
Lamivudine	150 mg po bid	80	q12h	q24h	50 mg q24h	50 mg q24h	For hepatitis B
Nelfinavir	750 mg q8h	No data	No data	No data	No data	No data	
Nevirapine	200 mg q24h × 14 d	<3	No data: 100%	No data: 100%	No data: 100%	No data: 100%	May be partially cleared by hemodialysis and peritoneal dialysis
Ribavirin	500–600 mg q12h	30	100%	100%	50%	25%	Hemolytic uremic syndrome
Rifabutin	300 mg q24h	5–10	100%	100%	100%	100%	
Rimantadine	100 mg po bid	25	100%	100%	50%	50%	
Ritonavir	600 mg q12h	3.50	No data: 100%	No data: 100%	No data: 100%	No data: 100%	Many drug interactions
Saquinavir	600 mg q8h	<4	No data: 100%	No data: 100%	No data: 100%	No data: 100%	
Stavudine	30–40 mg q12h	35–40	100%	50% q12–24h	50% q24h	50% q24h	
Valacyclovir	500–1,000 mg q8h	50	100%	50%	25%	25%	Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome
Vidarabine	15 mg/kg infusion q24h	50	100%	100%	75%	75%	
Zanamivir	2 puffs bid × 5 d	1	100%	100%	100%	100%	Bioavailability from inhalation and systemic exposure to drug is low.
Zalcitabine	0.75 mg q8h	75	100%	q12h	q24h	q24h	
Zidovudine	200 mg q8h, 300 mg q12h	8–25	100%	100%	100 mg q8h	100 mg q8h	Enormous interpatient variation; metabolite renally excreted

GFR, glomerular filtration rate; CRRT, continuous renal replacement therapy; Vd, volume of distribution; TB, tuberculosis; BUN, blood urea nitrogen; ESKD, end-stage kidney disease; CAPD, continuous ambulatory peritoneal disease; CsA, Cyclosporine; FK, tacrolimus; LFT, liver function test; NS, normal saline; Clcr, creatinine clearance; VZV, varicella zoster virus; HSV, herpes simplex virus; CMV, cytomegalovirus.

Analgesic Drug Dosing in Kidney Disease

Analgesics	Normal Dosage	% of Renal Excretion	Dosage Adjustment in Kidney Disease				Comments
			GFR >50	GFR 10–50	GFR <10	CRRT	
Narcotics and narcotic antagonists							
Alfentanil	Anesthetic induction 8–40 μg/kg	Hepatic	100%	100%	100%	100%	Titrate the dose regimen
Butorphanol	2 mg q3–4h	Hepatic	100%	75%	50%	50%	
Codeine	30–60 mg q4–6h	Hepatic	100%	75%	50%	50%	
Fentanyl	Anesthetic induction (individualized)	Hepatic	100%	75%	50%	50%	CRRT—titrate
Meperidine	50–100 mg q3–4h	Hepatic	100%	Avoid	Avoid	Avoid	Normeperidine, an active metabolite, accumulates in ESKD and may cause seizures; protein binding is reduced in ESKD; 20%–25% excreted unchanged in acidic urine
Methadone	2.5–5 mg q6–8h	Hepatic	100%	100%	50%–75%	50%–75%	Should not be used for acute pain
Morphine	20–25 mg q4h	Hepatic	100%	75%	50%	50%	Increased sensitivity to drug effect in ESKD; active metabolites
Naloxone	2 mg IV	Hepatic	100%	100%	100%	100%	
Pentazocine	50 mg q4h	Hepatic	100%	75%	75%	75%	
Propoxyphene	65 mg po q6–8h	Hepatic	100%	100%	Avoid	Avoid	Active metabolite norpropoxyphene accumulates in ESKD; cardiotoxic
Sufentanil	Anesthetic induction	Hepatic	100%	100%	100%	100%	CRRT—titrate
Nonnarcotics							
Acetaminophen	650 mg q4h	Hepatic	q4h	q6h	q8h	q8h	Overdose may be nephrotoxic; drug is major metabolite of phenacetin.
Acetylsalicylic acid	650 mg q4h	Hepatic (renal)	q4h	q4–6h	Avoid	Avoid	Nephrotoxic in high doses; may decrease GFR when renal blood flow is prostaglandin dependent; may add to uremic GI and hematologic symptoms; protein binding reduced in ESKD

GFR, glomerular filtration rate; CRRT, continuous renal replacement therapy; ESKD, end-stage kidney disease; GI, gastrointestinal.

Antihypertensive and Cardiovascular Agent Dosing in Kidney Disease

Antihypertensive and Cardiovascular Agents	Normal Dosage		% of Renal Excretion	Dosage Adjustment in Kidney Disease			Dosage in CRRT	Comments
				GFR >50	GFR 10–50	GFR <10		
ACE inhibitors								Hyperkalemia, acute kidney injury, angioedema, rash, cough, anemia, and liver toxicity
Benazepril	10 mg qd	80 mg qd	20	100%	75%	25%–50%	25%–50%	
Captopril	6.25–25 mg po tid	100 mg tid	35	100%	75%	50%	50%	Rare proteinuria, nephrotic syndrome, dysgeusia, granulocytopenia; increases serum digoxin levels
Enalapril	5 mg qd	20 mg bid	45	100%	75%	50%	50%	Enalaprilat, the active moiety formed in liver
Fosinopril	10 mg po qd	40 mg bid	20	100%	100%	75%	75%	Fosinoprilat, the active moiety formed in liver; drug less likely than other ACE inhibitors to accumulate in kidney disease
Lisinopril	2.5 mg qd	20 mg bid	80	100%	50%–75%	25%–50%	25%–50%	Lysine analog of a pharmacologically active enalapril metabolite
Pentopril	125 mg q24h		80–90	100%	50%–75%	50%	50%	50%
Perindopril	2 mg q24h		<10	100%	75%	50%	50%	50%
Quinapril	10 mg qd	20 mg qd	30	100%	75%–100%	75%		Active metabolite is quinaprilat; 96% of quinaprilat is excreted renally.
Ramipril	2.5 mg qd	10 bid	15	100%	50%–75%	25%–50%		Active metabolite is ramiprilat; data are for ramiprilat.
Trandolapril	1–2 mg qd	4 mg qd	33	100%	50%–100%	50%	50%	
Angiotensin-II receptor antagonists								Hyperkalemia, angioedema (less common than ACE inhibitors
Candesartan	16 mg qd	32 mg qd	33	100%	100%	50%	50%	Candesartan cilexetil is rapidly and completely bioactivated by ester hydrolysis during absorption from the gastrointestinal tract to candesartan.
Eprosartan	600 mg qd	400–800 mg qd	25	100%	100%	100%	100%	Eprosartan pharmacokinetics more variable ESKD; decreased protein binding in uremia
Irbesartan	150 mg qd	300 mg qd	20	100%	100%	100%	100%	

Losartan	50 mg qd	100 mg qd	13	100%	100%	100%	100%	
Valsartan	80 mg qd	160 mg bid	7	100%	100%	100%	100%	
Telmisartan	20–80 mg qd		<5	100%	100%	100%	100%	
β-Blockers								Decrease HDL, mask symptoms of hypoglycemia, bronchospasm, fatigue, insomnia, depression, and sexual dysfunction
Acebutolol	400 mg q24h or bid	600 mg q24h or bid	55	100%	50%	30%–50%	30%–50%	Active metabolites with long half-life
Atenolol	25 mg qd	100 mg qd	90	100%	75%	50%	50%	Accumulates in ESKD
Betaxolol	20 mg q24h	80%–90%	100	100%	50%	50%	50%	
Bopindolol	1 mg q24h	4 mg q24h	<10	100%	100%	100%	100%	
Carteolol	0.5 mg q24h	10 mg q24h	<50	100%	50%	25%	25%	
Carvedilol	3.125 mg po tid	25 mg tid	2	100%	100%	100%	100%	Kinetics are dose dependent; plasma concentrations of carvedilol have been reported to be increased in patients with renal impairment.
Celiprolol	200 mg q24h		10	100%	100%	75%		75%
Dilevalol	200 mg bid	400 mg bid	<5	100%	100%	100%	100%	
Esmolol (IV only)	50 μg/kg/min	300 μg/kg/min	10	100%	100%	100%	100%	Active metabolite retained in kidney disease
Labetalol	50 mg po bid	400 mg bid	5	100%	100%	100%	100%	For IV use: 20 mg slow IV injection over a 2-min period; additional injections of 40 mg or 80 mg can be given at 10-min intervals until a total of 300 mg or continuous infusion of 2 mg/min.
Metoprolol	50 mg bid		100 mg bid	<5%	100%	100%		100%
Nadolol	80 mg qd	160 mg bid	90	100%	50%	25%	25%	Start with prolonged interval and titrate.
Penbutolol	10 mg q24h	40 mg q24h	<10	100%	100%	100%	100%	
Pindolol	10 mg bid	40 mg bid	40	100%	100%	100%	100%	
Propranolol	40–160 mg tid	320 mg/d	<5	100%	100%	100%	100%	Bioavailability may increase in ESKD; metabolites may cause increased bilirubin by assay interference in ESKD; hypoglycemia reported in ESKD

Continued

Antihypertensive and Cardiovascular Agents	Normal Dosage		% of Renal Excretion	Dosage Adjustment in Kidney Disease			Dosage in CRRT	Comments
				GFR >50	GFR 10–50	GFR <10		
Sotalol	80 mg bid	160 mg bid	70	100%	50%	25%–50%	25%–50%	Extreme caution should be exercised in the use of sotalol in patients with kidney disease undergoing hemodialysis; to minimize the risk of induced arrhythmia, patients initiated or reinitiated on Betapace should be placed for a minimum of 3 days (on their maintenance dose) in a facility that can provide cardiac resuscitation and continuous electrocardiographic monitoring.
Timolol	10 mg bid	20 mg bid	15	100%	100%	100%	100%	
Calcium channel blockers								Dihydropyridine: headache, ankle edema, gingival hyperplasia, and flushing Nondihydropyridine: bradycardia, constipation, gingival hyperplasia, and AV block
Amlodipine	2.5 po qd	10 mg qd	10	100%	100%	100%	100%	May increase digoxin and cyclosporine levels
Bepridil	No data	<1%	No data	No data	No data	Weak vasodilator and antihypertensive		
Diltiazem	30 mg tid	90 mg tid	10	100%	100%	100%	100%	Acute renal dysfunction; may exacerbate hyperkalemia; may increase digoxin and cyclosporine levels
Felodipine	5 mg po bid	20 mg qd	1	100%	100%	100%	100%	May increase digoxin levels
Isradipine	5 mg po bid	10 mg bid	<5	100%	100%	100%	100%	May increase digoxin levels
Nicardipine	20 mg po tid		30 mg po tid	<1%	100%	100%		100%
Nifedipine XL	30 qd	90 mg bid	10	100%	100%	100%	100%	Avoid short-acting nifedipine formulation
Nimodipine	30 mg q8h		10	100%	100%	100%	100%	100%
Nisoldipine	20 mg qd	30 mg bid	10	100%	100%	100%	100%	May increase digoxin levels
Verapamil	40 mg tid	240 mg/d	10	100%	100%	100%	100%	Acute renal dysfunction; active metabolites accumulate particularly with sustained-release forms

Diuretics								Hypokalemia/hyperkalemia (potassium-sparing agents), hyperuricemia, hyperglycemia, hypomagnesemia, increase serum cholesterol
Acetazolamide	125 mg po tid	500 mg po tid	90	100%	50%	Avoid		May potentiate acidosis; ineffective as diuretic in ESKD; may cause neurologic side effects in dialysis patients
Amiloride	5 mg po qd	10 mg po qd	50	100%	100%	Avoid		Hyperkalemia with GFR <30 mL/min, especially in diabetics; hyperchloremic metabolic acidosis
Bumetanide	1–2 mg po qd	2–4 mg po qd	35	100%	100%	100%		Ototoxicity increased in ESKD in combination with aminoglycosides; high doses effective in ESKD; muscle pain, gynecomastia
Chlorthalidone	25 mg q24h	50%	q24h	q24h	Avoid	Ineffective with low GFR		
Ethacrynic acid	50 mg po qd	100 mg po bid	20	100%	100%	100%		Ototoxicity increased in ESKD in combination with aminoglycosides
Furosemide	40–80 mg po qd	120 mg po tid	70	100%	100%	100%		Ototoxicity increased in ESKD, especially in combination with aminoglycosides; high doses effective in ESKD
Indapamide	2.5 mg q24h	<5%	100	100%	Avoid	Ineffective in ESKD		
Metolazone	2.5 mg po qd		10 mg po bid	70%	100%	100%	100%	High doses effective in ESKD; gynecomastia, impotence
Piretanide	6 mg q24h	12 mg q24h	40–60	100%	100%	100%	100%	High doses effective in ESKD; ototoxicity
Spironolactone	100 mg po qd	300 mg po qd	25	100%	100%	Avoid	Avoid	Active metabolites with long half-life; hyperkalemia common when GFR <30, especially in diabetics; gynecomastia, hyperchloremic acidosis; increases serum by immunoassay interference
Thiazides	25 mg bid		50 mg bid	>95%	100%	Avoid	Avoid	Avoid
Torasemide	5 mg po bid	20 mg qd	25	100%	100%	100%	100%	High doses effective in ESKD; ototoxicity

Dobutamine	2.5 μg/kg/min	15 μg/kg/min	10	100%	100%	100%	100%	
Milrinone	0.375 μg/kg/min	0.75 μg/kg/min		100%	100%	100%	100%	

GFR, glomerular filtration rate; CRRT, continuous renal replacement therapy; ACE, angiotensin-converting enzyme; ESKD, end-stage kidney disease; HDL, high-density lipoprotein; AV, arteriovenous; Vd, volume distribution.

Endocrine and Metabolic Agent Dosing in Kidney Disease

	Normal Dosage		% of Renal Excretion	Dosage Adjustment in Kidney Disease			Dosage in CRRT	Comments
				GFR >50	GFR 10–50	GFR <10		
Hypoglycemic agents								Avoid all oral hypoglycemic agents on CRRT
Acarbose	25 mg tid	100 mg tid	35	100%	50%	Avoid	Avoid	Abdominal pain, N/V, and flatulence
Acetohexamide	250 mg q24h	1,500 mg q24h	None	Avoid	Avoid	Avoid	Avoid	Diuretic effect; may falsely elevate serum creatinine; active metabolite has $T_{1/2}$ of 5–8 h in healthy subjects and is eliminated by the kidney; prolonged hypoglycemia in azotemic patients
Chlorpropamide	100 mg q24h	500 mg q24h	47	50%	Avoid	Avoid	Avoid	Impairs water excretion; prolonged hypoglycemia in azotemic patients
Glibornuride	12.5 mg q24h	100 mg q14h	No data	No data	No data	No data	No data	
Gliclazide	80 mg q24h	320 mg q24h	<20	50%–100%	Avoid	Avoid	Avoid	
Glipizide	5 mg qd	20 mg bid	5	100%	50%	50%	Avoid	
Glyburide	2.5 mg qd	10 mg bid	50	100%	50%	Avoid	Avoid	
Metformin	500 mg bid	2,550 mg/d (bid or tid)	95	100%	Avoid	Avoid	Avoid	Lactic acidosis
Repaglinide	0.5–1 mg	4 mg tid						
Tolazamide	100 mg q24h	250 mg q24h	7	100%	100%	Avoid	Avoid	Diuretic effects
Tolbutamide	1 g q24h	2 g q24h	None	100%	100%	Avoid	Avoid	May impair water excretion
Troglitazone	200 mg qd	600 mg qd	3	100%	Avoid	Avoid	Avoid	Decrease CsA level; hepatotoxic
Parenteral agents								Dosage guided by blood glucose levels
Insulin	Variable		None	100%	75%	50%	50%	Renal metabolism of insulin decreases with azotemia.
Lispro insulin	Variable		No data	100%	75%	50%	50%	
Hyperlipidemic agents								Avoid all oral hypoglycemic agents on CRRT
Atorvastatin	10 mg/d	80 mg/d	<2	100%	100%	100%	100%	Liver dysfunction, myalgia, and rhabdomyolysis with CsA/FK
Bezafibrate	200 mg bid–qid 400 mg SR q24h		50	50%–100%	25%–50%	Avoid		Avoid
Cholestyramine	4 g bid	24 g/d	None	100%	100%	100%	100%	
Clofibrate	500 mg bid	1,000 mg bid	40–70	q6–12h	q12–18h	Avoid	Avoid	

(continued)

Continued

	Normal Dosage		% of Renal Excretion	Dosage Adjustment in Kidney Disease			Dosage in CRRT	Comments
				GFR >50	GFR 10–50	GFR <10		
Colestipol	5 g bid	30 g/d	None	100%	100%	100%	100%	
Fluvastatin	20 mg/d	80 mg/d	<1	100%	100%	100%	100%	
Gemfibrozil	600 bid	600 bid	None	100%	100%	100%	100%	
Lovastatin	5 mg/d	20 mg/d	None	100%	100%	100%	100%	
Nicotinic acid	1 g tid	2 g tid	None	100%	50%	25%	25%	
Pravastatin	10–40 mg/d	80 mg/d	<10	100%	100%	100%	100%	
Probucol	500 mg bid		<2	100%	100%	100%	Avoid	
Rosuvastatin	5–20 mg/d	40 mg/d		100%	100%	100%	50%	
Simvastatin	5–20 mg/d	20 mg/d	13	100%	100%	50%	50%	
Antithyroid Dosing in Kidney Disease								
Antithyroid drugs								
Methimazole	5–20 mg tid		7	100%	100%	100%	100%	
Propylthiouracil	100 mg tid		<10	100%	100%	100%	100%	

GFR, glomerular filtration rate; CRRT, continuous renal replacement therapy; N/V, nausea, vomiting; CsA, Cyclosporine; FK, tacrolimus; SR, sustained release.

Gastrointestinal Dosing in Kidney Disease

Gastrointestinal Agents	Normal Doses		% of Renal Excretion	Dosage Adjustment in Kidney Disease			Dosage in CRRT	Comments
	Starting Dose	Maximum Dose		GFR >50	GFR 10–50	GFR <10		
Cimetidine	300 mg po tid	800 mg po bid	60	100%	75%	25%	25%	Multiple drug–drug interactions; β-blockers, sulfonylurea, theophylline, warfarin, and so forth
Famotidine	20 mg po bid	40 mg po bid	70	100%	75%	25%	25%	Headache, fatigue, thrombocytopenia, alopecia
Lansoprazole	15 mg po qd	30 mg bid	None	100%	100%	100%	100%	Headache, diarrhea
Nizatidine	150 mg po bid	300 mg po bid	20	100%	75%	25%	25%	Headache, fatigue, thrombocytopenia, alopecia
Omeprazole	20 mg po qd	40 mg po bid	None	100%	100%	100%	100%	Headache, diarrhea
Rabeprazole	20 mg po qd	40 mg po bid	None	100%	100%	100%	100%	Headache, diarrhea
Pantoprazole	40 mg po qd	80 mg po bid	None	100%	100%	100%	100%	Headache, diarrhea
Ranitidine	150 mg po bid	300 mg po bid	80	100%	75%	25%	25%	Headache, fatigue, thrombocytopenia, alopecia
Cisapride	10 mg po tid	20 mg qid	5	100%	100%	50%–75%	50%–75%	Avoid with azole antifungal, macrolide antibiotics, and other P450 IIIA-4 inhibitors.
Metoclopramide	10 mg po tid	30 mg po qid	15	100%	100%	50%–75%	50%–75%	Increase cyclosporine/tacrolimus level; neurotoxic
Misoprostol	100 μg po bid	200 μg po qid		100%	100%	100%	100%	Diarrhea, N/V, abortifacient agent
Sucralfate	1 g po qid	1 g po qid	None	100%	100%	100%	100%	Constipation, decrease absorption of MMF

GFR, glomerular filtration rate; CRRT, continuous renal replacement therapy; N/V, nausea, vomiting; MMF, mycophenolate mofetil.

Neurologic/Anticonvulsant Dosing in Kidney Disease

Anticonvulsants	Normal Dosage		% of Renal Excretion	Dosage Adjustment in Kidney Disease			Dosage in CRRT	Comments
				GFR >50	GFR 10–50	GFR <10		
Carbamazepine	2–8 mg/kg/d; adjust for side effect and TDM		2	100%	100%	100%	100%	Plasma concentration: 4–12, double vision, fluid retention, myelosuppression
Clonazepam	0.5 mg tid	2 mg tid	1	100%	100%	100%	100%	Although no dose reduction is recommended, the drug has not been studied in patients with renal impairment. Recommendations are based on known drug characteristics, not clinical trials data.
Ethosuximide	5 mg/kg/d; adjust for side effect and TDM		20	100%	100%	100%	100%	Plasma concentration: 40–100, headache
Felbamate	400 mg/tid	1,200 mg/tid	90	100%	50%	25%	25%	Anorexia, vomiting, insomnia, nausea
Gabapentin	150 mg tid	900 mg tid	77	100%	50%	25%	25%	Less CNS side effects compared to other agents
Lamotrigine	25–50 mg/d	150 mg/d	1	100%	100%	100%	100%	Auto-induction, major drug–drug interaction with valproate
Levetiracetam	500 mg bid	1,500 mg bid	66	100%	50%	50%	25%	
Oxcarbazepine	300 mg bid	600 mg bid	1	100%	100%	100%	100%	Less effect on P450 compared to carbamazepine
Phenobarbital	20 mg/kg/d; adjust for side effect and TDM		1	100%	100%	100%	100%	Plasma concentration: 15–40, insomnia
Phenytoin	20 mg/kg/d; adjust for side effect and TDM		1	Adjust for kidney disease and low albumin				Plasma concentration: 10–20, nystagmus, check free phenytoin level
Primidone	50 mg	100 mg	1	100%	100%	100%	100%	Plasma concentration: 5–20
Sodium valproate	7.5 to 15 mg/kg/d; adjust for side effect and TDM		1	100%	100%	100%	100%	Plasma concentration: 50–150, weight gain, hepatitis, check free valproate level
Tiagabine	4 mg qd, increase 4mg/d, titrate weekly		2	100%	100%	100%	100%	Total daily dose may be increased by 4–8 mg at weekly intervals until clinical response is achieved or up to 32 mg/d. The total daily dose should be given in divided doses two to four times daily.
Topiramate	50 mg/d	200 mg bid	70	100%	50%	Avoid	Avoid	Kidney stone
Trimethadione	300 mg tid–qid	600 mg tid–qid	None	q8h	q8–12h	q12–24h	Avoid	Active metabolites with long half-life in ESKD; nephrotic syndrome
Vigabatrin	1 g bid	2 g bid	70	100%	50%	25%	25%	Encephalopathy with drug accumulation
Zonisamide	100 mg qd	100–300 mg qd–bid	30	100%	75%	50%	50%	Manufacturer recommends that zonisamide should not be used in patients with kidney disease (estimated GFR <50 mL/min) as there has been insufficient experience concerning drug dosing and toxicity. Zonisamide doses of 100–600 mg/d are effective for normal renal function. Dose recommendations for renal impairment based on clearance ratios.

GFR, glomerular filtration rate; CRRT, continuous renal replacement therapy; TDM, therapeutic drug monitoring; CNS, central nervous system; ESKD, end-stage kidney disease.

Rheumatologic Dosing in Kidney Disease

Arthritis and Gout Agents	Normal Dosage	% of Renal Excretion	Dosage Adjustment in Kidney Disease			Dosage in CRRT	Comments
			GFR >50	GFR 10–50	GFR <10		
Allopurinol	300 mg q24h	30	75%	50%	25%	25%	Interstitial nephritis; rare xanthine stones; renal excretion of active metabolite with $T_{1/2}$ of 25 h in normal renal function; $T_{1/2}$ 1 wk in patients with ESKD; exfoliative dermatitis
Auranofin	6 mg q24h	50	50%	Avoid	Avoid	Avoid	Proteinuria and nephritic syndrome
Colchicine	Acute: 2 mg then 0.5 mg q6h Chronic: 0.5–1.0 mg q24h	5–17	100%	50%–100%	25%	25%	Avoid prolonged use if GFR <50 mL/min.
Gold sodium	25–50 mg	60–90	50%	Avoid	Avoid	Avoid	Thiomalate proteinuria; nephritic syndrome; membranous nephritis
Penicillamine	250–1,000 mg q24h	40	100%	Avoid	Avoid	Avoid	Nephrotic syndrome
Probenecid	500 mg bid	<2	100%	Avoid	Avoid	Avoid	Ineffective at decreased GFR
Nonsteroidal anti-inflammatory drugs							May decrease renal function; decrease platelet aggregation; nephrotic syndrome; interstitial nephritis; hyperkalemia; sodium retention
Diclofenac	25–75 mg bid	<1	50%–100%	Avoid	Avoid	Avoid	
Diflunisal	250–500 mg bid	<3	100%	50%	Avoid	Avoid	
Etodolac	200 mg bid	Negligible	50%–100%	Avoid	Avoid	Avoid	
Fenoprofen	300–600 mg qid	30	50%–100%	Avoid	Avoid	Avoid	
Flurbiprofen	100 mg bid–tid	20	50%–100%	Avoid	Avoid	Avoid	
Ibuprofen	800 mg tid	1	50%–100%	Avoid	Avoid	Avoid	
Indomethacin	25–50 mg tid	30	50%–100%	Avoid	Avoid	Avoid	
Ketoprofen	25–75 mg tid	<1	50%–100%	Avoid	Avoid	Avoid	
Ketorolac	15 mg q6h	30–60	50%–100%	Avoid	Avoid	Avoid	Acute hearing loss in ESKD
Meclofenamic acid	50–100 tid–qid	2–4	50%–100%	Avoid	Avoid	Avoid	
Mefenamic acid	250 mg qid	<6	50%–100%	Avoid	Avoid	Avoid	
Nabumetone	1.0–2.0 g q24h	<1	50%–100%	Avoid	Avoid	Avoid	
Naproxen	500 mg bid	<1	50%–100%	Avoid	Avoid	Avoid	
Oxaprozin	1,200 mg q24h	<1	50%–100%	Avoid	Avoid	Avoid	
Phenylbutazone	100 mg tid–qid	1	50%–100%	Avoid	Avoid	Avoid	
Piroxicam	20 mg q24h	10	50%–100%	Avoid	Avoid	Avoid	
Sulindac	200 mg bid	7	50%–100%	Avoid	Avoid	Avoid	Active sulfide metabolite in ESKD
Tolmetin	400 mg tid	15	100%	100%	100%		

GFR, glomerular filtration rate; CRRT, continuous renal replacement therapy; ESKD, end-stage kidney disease.

Sedative Dosing in Kidney Disease

Sedatives	Normal Dosage	% of Renal Excretion	Dosage Adjustment in Kidney Disease			Dosage in CRRT	Comments
			GFR >50	GFR 10–50	GFR <10		
Barbiturates							May cause excessive sedation, increase osteomalacia in ESKD; charcoal hemoperfusion and hemodialysis more effective than peritoneal dialysis for poisoning
Pentobarbital	30 mg q6–8h	Hepatic	100%	100%	100%	100%	
Phenobarbital	50–100 mg q8–12h	Hepatic (renal)	q8–12h	q8–12h	q12–16h	q12–16h	Up to 50% unchanged drug excreted with urine with alkaline diuresis
Secobarbital	30–50 mg q6–8h	Hepatic	100%	100%	100%	100%	
Thiopental	Anesthesia induction (individualized)	Hepatic	100%	100%	100%	100%	
Benzodiazepines							May cause excessive sedation and encephalopathy in ESKD
Alprazolam	0.25–5.0 mg q8h	Hepatic	100%	100%	100%	100%	
Clorazepate	15–60 mg q24h	Hepatic (renal)	100%	100%	100%	100%	
Chlordiazepoxide	15–100 mg q24h	Hepatic	100%	100%	50%	50%	
Clonazepam	1.5 mg q24h	Hepatic	100%	100%	100%	100%	Although no dose reduction is recommended, the drug has not been studied in patients with renal impairment; recommendations are based on known drug characteristics not clinical trials data.
Diazepam	5–40 mg q24h	Hepatic	100%	100%	100%	100%	Active metabolites, desmethyldiazepam, and oxazepam may accumulate in kidney disease; dose should be reduced if given longer than a few days; protein binding decreases in uremia.
Estazolam	1 mg qhs	Hepatic	100%	100%	100%	100%	
Flurazepam	15–30 mg qhs	Hepatic	100%	100%	100%	100%	
Lorazepam	1–2 mg q8–12h	Hepatic	100%	100%	100%	100%	
Midazolam	Individualized	Hepatic	100%	100%	50%	50%	
Oxazepam	30–120 mg q24h	Hepatic	100%	100%	100%	100%	
Quazepam	15 mg qhs	Hepatic	No data	No data	No data	No data	

Temazepam	30 mg qhs	Hepatic	100%	100%	100%	100%	
Triazolam	0.25–0.50 mg qhs	Hepatic	100%	100%	100%	100%	Protein binding correlates with α-1 acid glycoprotein concentration.
Benzodiazepines: Benzodiazepine antagonist						100%	May cause excessive sedation and encephalopathy in ESKD
Flumazenil	0.2 mg IV over 15 s	Hepatic	100%	100%	100%	100%	
Miscellaneous sedative agents						100%	
Buspirone	5 mg q8h	Hepatic	100%	100%	100%	100%	
Ethchlorvynol	500 mg qhs	Hepatic	100%	Avoid	Avoid	100%	Removed by hemoperfusion; excessive sedation
Haloperidol	1–2 mg q8–12h	Hepatic	100%	100%	100%	100%	Hypertension, excessive sedation
Lithium carbonate	0.9–1.2 g q24h	Renal	100%	50%–75%	25%–50%	100%	Nephrotoxic; nephrogenic diabetes insipidus; nephrotic syndrome; renal tubular acidosis; interstitial fibrosis; acute toxicity when serum levels >1.2 mEq/L; serum levels should be measured periodically 12 h after dose; $T_{1/2}$ does not reflect extensive tissue accumulation; plasma levels rebound after dialysis; toxicity enhanced by volume depletion, NSAIDs, and diuretics
Meprobamate	1.2–1.6 g q24h	Hepatic (renal)	q6h	q9–12h	q12–18h	25%	Excessive sedation; excretion enhanced by forced diuresis

GFR, glomerular filtration rate; CRRT, continuous renal replacement therapy; ESKD, end-stage kidney disease; NSAIDs, nonsteroidal anti-inflammatory drugs.

Anti-Parkinson Dosing in Kidney Disease

Anti-Parkinson Agents	Normal Dosage	% of Renal Excretion	Dosage Adjustment in Renal Failure			Dosage in CRRT	Comments
			GFR >50	GFR 10–50	GFR <10		
Carbidopa	1 tablet tid to 6 tablets daily	30	100%	100%	100%	100%	Require careful titration of dose according to clinical response
Levodopa	25–500 mg bid to 8 g q24h	None	100%	50%–100%	50%–100%	100%	Active and inactive metabolites excreted in urine; active metabolites with long $T_{1/2}$ in ESKD

GFR, glomerular filtration rate; CRRT, continuous renal replacement therapy; ESKD, end-stage kidney disease.

Antipsychotic Dosing in Kidney Disease

Antipsychotics	Normal Dosage	% of Renal Excretion	Dosage Adjustment in Kidney Disease			Dosage in CRRT	Comments
			GFR >50	GFR 10–50	GFR <10		
Phenothiazines							Orthostatic hypotension, extrapyramidal symptoms, and confusion can occur.
Chlorpromazine	300–800 mg q24h	Hepatic	100%	100%	100%	100%	No comments
Promethazine	20–100 mg q24h	Hepatic	100%	100%	100%	100%	Excessive sedation may occur in ESKD.
Thioridazine	50–100 mg po tid; increase gradually; maximum of 800 mg/d	Hepatic	100%	100%	100%	100%	
Trifluoperazine	1–2 mg bid; increase to no more than 6 mg	Hepatic	100%	100%	100%	100%	
Perphenazine	8–16 mg po bid, tid, or qid; increase to 64 mg daily	Hepatic	100%	100%	100%	100%	
Thiothixene	2 mg po tid; increase gradually to 15 mg daily	Hepatic	100%	100%	100%	100%	
Haloperidol	1–2 mg q8–12h	Hepatic	100%	100%	100%	100%	Hypotension, excessive sedation
Loxapine	12.5–50 mg IM q4–6h		100%	100%	100%	100%	Do not administer drug IV.
Clozapine	12.5 mg po; 25–50 daily to 300–450 by end of 2 wk; maximum: 900 mg daily	Metabolism nearly complete	100%	100%	100%	100%	
Risperidone	1 mg po bid; increase to 3 mg bid		100%	100%	100%	100%	
Olanzapine	5–10 mg	Hepatic	100%	100%	100%	100%	Potential hypotensive effects
Quetiapine	25 mg po bid; increase in increments of 25–50 bid or tid; 300–400 mg daily by day 4	Hepatic	100%	100%	100%	100%	
Ziprasidone	20–100 mg q12h	Hepatic	100%	100%	100%	100%	

GFR, glomerular filtration rate; CRRT, continuous renal replacement therapy; ESKD, end-stage kidney disease.

Miscellaneous Dosing in Kidney Disease

Corticosteroids	Normal Dosage	% of Renal Excretion	Dosage Adjustment in Renal Failure			Dosage in CRRT	Comments
			GFR >50	GFR 10–50	GFR <10		
							May aggravate azotemia, Na^+ retention, glucose intolerance, and hypertension
Betamethasone	0.5–9.0 mg q24h	5	100%	100%	100%	100%	
Budesonide	No data	None	100%	100%	100%	100%	
Cortisone	25–500 mg q24h	None	100%	100%	100%	100%	
Dexamethasone	0.75–9.0 mg q24h	8	100%	100%	100%	100%	
Hydrocortisone	20–500 mg q24h	None	100%	100%	100%	100%	
Methylprednisolone	4–48 mg q24h	<10	100%	100%	100%	100%	
Prednisolone	5–60 mg q24h	34	100%	100%	100%	100%	
Prednisone	5–60 mg q24h	34	100%	100%	100%	100%	
Triamcinolone	4–48 mg q24h	No data	100%	100%	100%	100%	

GFR, glomerular filtration rate; CRRT, continuous renal replacement therapy.

Anticoagulant Dosing in Kidney Disease

Anticoagulants	Normal Dosage		% of Renal Excretion	Dosage Adjustment in Renal Failure			Dosage in CRRT	Comments
				GFR >50	GFR 10–50	GFR <10		
Alteplase	60 mg over 1 h then 20 mg/h for 2 h		No data	100%	100%	100%	100%	Tissue-type plasminogen activator
Aspirin	81 mg/d	325 mg/d	10	100%	100%	100%	100%	GI irritation and bleeding tendency
Clopidogrel	75 mg/d	75 mg/d	50	100%	100%	100%	100%	GI irritation and bleeding tendency
Dalteparin	2,500 U sc/d	5,000 U sc/d	Unknown	100%	100%	50%	Avoid	
Dipyridamole	50 mg tid		No data	100%	100%	100%	100%	
Enoxaparin	20 mg/d	30 mg bid	8	100%	50%–75%	50%	25%–50%	1 mg/kg q12h for treatment of DVT; check anti-factor Xa activity 4 h after second dose in patients with renal dysfunction; some evidence of drug accumulation in kidney disease
Heparin	75 U/kg load then 15 U/kg/h		None	100%	100%	100%	100%	Half-life increases with dose
Iloprost	0.5–2.0 ng/kg/min for 5–12 h		No data	100%	100%	50%	50%	
Indobufen	100 mg bid	200 mg bid	<15	100%	50%	25%	25%	
Streptokinase	250,000 U load then 100,000 U/h		None	100%	100%	100%	100%	
Sulfinpyrazone	200 mg bid		25–50	100%	100%	Avoid	Avoid	Acute kidney injury; uricosuric effect at low GFR
Ticlopidine	250 mg bid	250 mg bid	2	100%	100%	100%	100%	Decrease CsA level; may cause severe neutropenia and thrombocytopenia
Tranexamic acid	25 mg/kg tid–qid		90	50%	25%	10%	Avoid	
Urokinase	4,400 U/kg load then 4400 U/kg qh		No data	100%	100%	100%	100%	
Warfarin	2.5–5 mg/d	Adjust per INR	<1	100%	100%	100%	100%	Monitor INR very closely; start at 5 mg/d; 1 mg vitamin K IV over 30 min or 2.5–5 mg po can be used to normalize INR.

GFR, glomerular filtration rate; CRRT, continuous renal replacement therapy; GI, gastrointestinal; DVT, deep venous thrombosis; CsA, Cyclosporine; INR, international normalized ratio.

CHAPTER 36

Extracorporeal Treatment of Poisoning and Drug Overdose

Wajeh Y. Qunibi

EPIDEMIOLOGY OF POISONING

Although poisoning has been reported to health care institutions for a long time, its incidence is clearly underestimated. The incidence of poisoning continues to increase largely due to abuse of over-the-counter medications as well as illicit drugs. Poisoning became the leading cause of accidental death in the United States in 2008, exceeding motor vehicle accident deaths for the first time since 1980 (1). In 2014, the Toxic Exposure Surveillance System (TESS) data compiled by the American Association of Poison Control Centers (AAPCC) revealed that there were almost 2.3 million reported human poison exposure cases. Over 600,000 exposures led to a visit in a health care facility (HCF), 27% of them required hospital admission resulting in 1,261 deaths in the United States (2). The majority (80%) of these cases were unintentional, but suicidal intent was suspected in 10.5% of cases. Poisoning may also result from malicious intent, drug–drug interaction (12.5%), or from occupational or environmental exposure. The top five substance classes most frequently involved in all human exposures are analgesics (11.6%), cosmetics/personal care products (7.9%), household cleaning substances (7.2%), sedatives/hypnotics/antipsychotics (6.0%), and antidepressants (4.1%) (2). Analgesics and sedative/hypnotics/antipsychotics exposures as a class increased most rapidly over the last 13 years for cases showing more serious outcomes. The National Poison Data System (NPDS) documented 2,477 human exposures resulting in death of which 2,113 human fatalities judged related. Again, analgesics were the most common cause of death, and acetaminophen is the analgesic most often implicated in fatal poisoning. Children younger than 3 years were involved in 35.5% of exposures and children younger than 6 years accounted for approximately half of all human exposures (48.0%). Male predominance was found among cases involving children younger than 13 years, but this gender distribution was reversed in teenagers and adults, with females comprising the majority of reported exposures. Most human exposures

(87.9%) were acute cases (single, repeated, or continuous exposure occurring over 8 hours or less). The route of exposure to the poison was ingestion in 83.4% of cases followed in frequency by dermal (7.0%), inhalation/nasal (6.1%), and ocular routes (4.3%). Of the 2,188,013 human exposures reported, 71.8% of calls originated from a residence (own or other), but 93.5% actually occurred at a residence. Another 20.3% of calls were made from an HCF. Beyond residences, exposures occurred in the workplace in 1.6% of cases, schools (1.3%), health care facilities (0.3%), and restaurants or food services (0.2%) (2).

Most cases reported to poison centers were managed in a non-HCF (68.7%), usually at the site of exposure, primarily the patient's own residence. Treatment in an HCF was rendered in 27.5% of cases. Of these, 16.5% were admitted for critical care, and 11.2% were admitted to a noncritical unit. Older age-groups exhibit a greater number of severe medical outcomes. Overall, the mortality rate was 0.11% of all exposures but much higher in hospitalized patients with suicidal overdose, who account for 32% of all deaths. In most of the fatal cases in adolescents and adults, poisoning was intentional. Because most poisoning fatalities occur before the patients reach an HCF, it is probable that the total number of fatalities resulting from poisoning is higher than that gathered by the AAPCC report. Extracorporeal treatments were used in 2,385 cases of poisoning; 97.5% of these were hemodialysis and 2.6 % were hemoperfusion (2).

The approach to diagnosis and treatment of poisoned individuals is usually divided into six stages. These include stabilization, laboratory assessment, decontamination of the gastrointestinal tract, administration of specific antidote if available, enhancing the elimination of the offending agent, and disposition. In this chapter, I will focus on the appropriate use of extracorporeal methods of elimination of common types of poisons.

PRINCIPLES OF MANAGEMENT OF POISONING

Diagnosis of Poisoning

In order to establish the correct diagnosis of poisoning, a systematic approach to the management of poisoned individuals must be followed. This should include careful history, physical examination, routine, and toxicologic laboratory evaluations (**FIGURE 36.1**). Moreover, particular attention should be paid to the clinical course of the patient's condition. The history is clearly of critical importance and should include the time, route of administration, duration, and intent of exposure. The exact name and amount of the drug, chemical, or ingredient involved; the time of onset, nature, and severity of symptoms; and the medical and psychiatric history should also be obtained. Unfortunately, it may not be possible to obtain this information from the victim who may be confused, comatose, unable, or unwilling to admit to self-poisoning. Under these circumstances, relevant history may be obtained from family or friends, paramedics, police, or other physicians. Sometimes, a search of the patients' belongings and residence may reveal a suicidal note or a container of drugs or chemical. Of critical importance is to establish, if possible, the timing of the exposure since this may have implications on the onset of symptoms and the patient's clinical course. It is also important to establish the reason behind the exposure and whether the exposure was a suicide attempt (3). Physical *examination* should focus initially on the vital signs, cardiopulmonary system, rate and depth of breathing, and neurologic status. Moreover, examination of the eyes for nystagmus, pupil size, and reaction; abdomen for bowel activity; and skin for color, dryness,

temperature, and presence of medication patches may reveal findings of diagnostic value. It is also crucial to perform frequent reexamination since the physical findings may change rapidly and patients may abruptly deteriorate. Routine laboratory tests should include complete blood count, chemistries, and arterial blood gases. Other blood tests should be obtained for suspected drugs or toxins in which blood concentration will not only help to confirm exposure but also help to predict toxicity and guide the approach for definitive therapy (**FIGURE 36.1**).

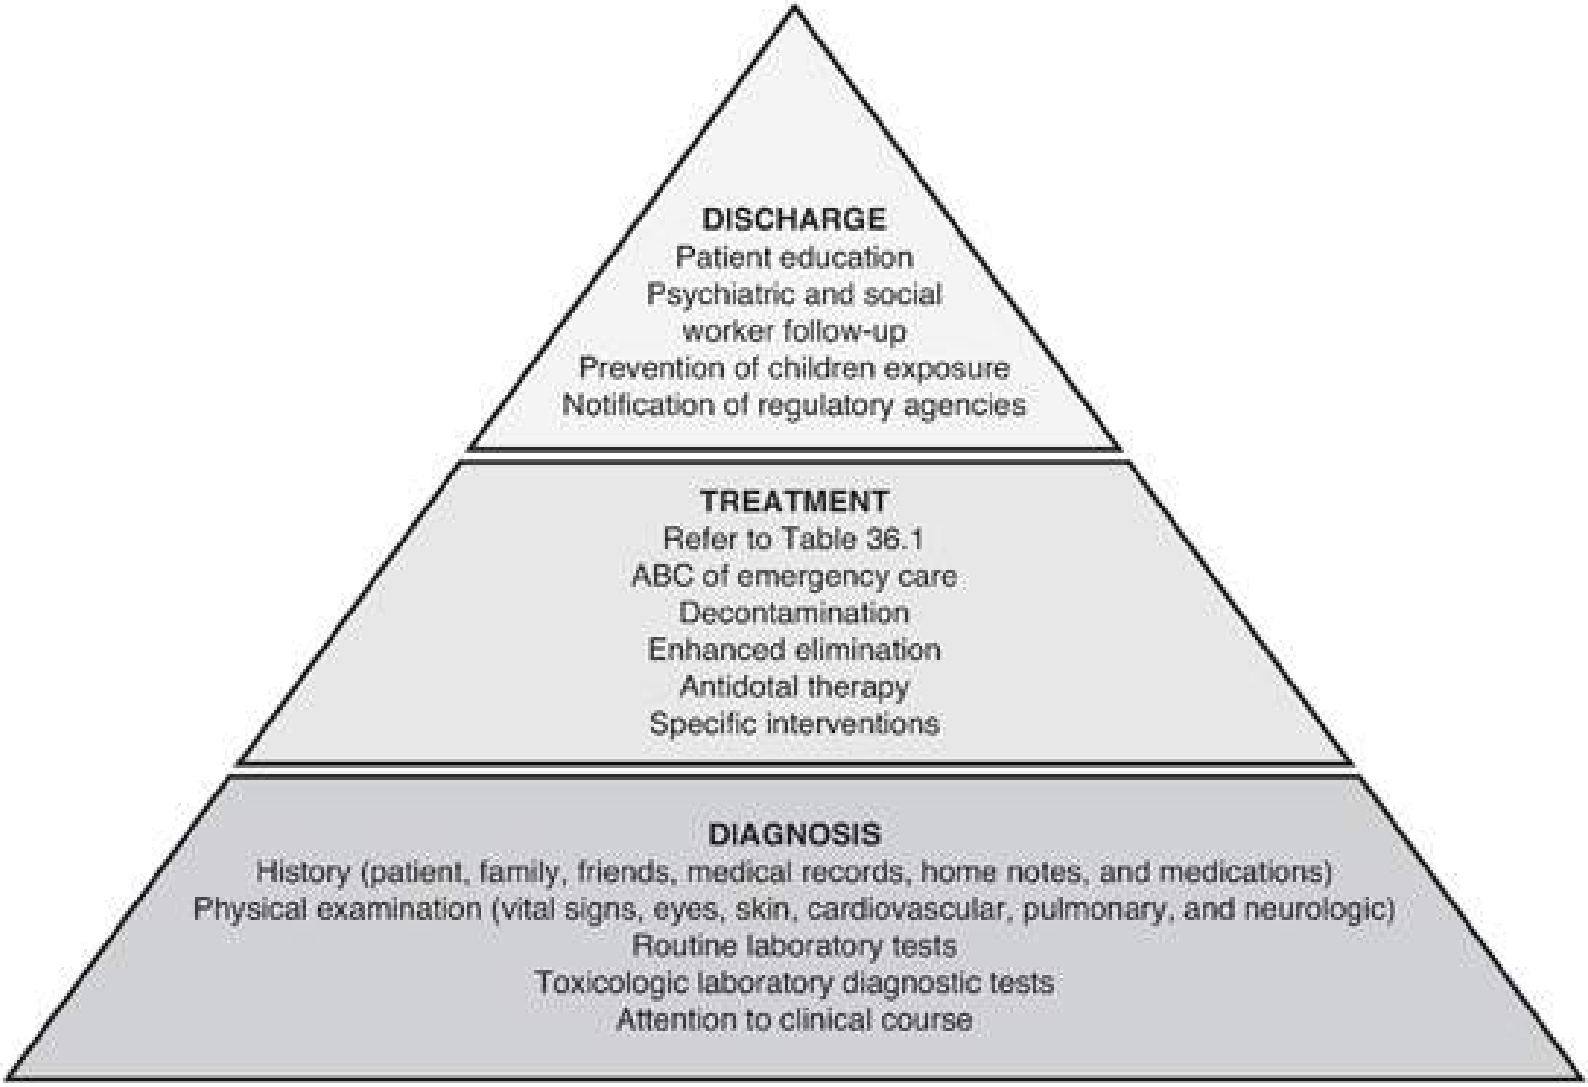

FIGURE 36.1 Approach to management of patients with poisoning.

General Treatment Measures

Administration of appropriate treatment for the patient with poisoning should be done without delay (**TABLE 36.1**). In fact, diagnosis and treatment may have to be done sequentially or simultaneously, depending on the patient's clinical course. Aggressive supportive care is of utmost importance and should follow the ABCs of emergency care; airway, breathing, and circulation for all poisoned victims in order to ensure adequate respiration; stable hemodynamics; and maintenance of fluid, electrolyte, and acid–base balance. These supportive measures have been shown to reduce mortality and morbidity to very low levels (3–6). The recognition of the critical role of supportive care in the treatment of poisoning has led to important changes in our approach to managing poisoning. *First*, abandonment of the use of stimulants (when the offending agent is a sedative). *Second*, reduced emphasis on the use of antidotes, except in a

few special types of intoxications for which specific antidotes are available (**TABLE 36.2**). *Third*, decontamination which refers to preventing or reducing absorption of the suspected substance has also evolved over time. Gastric lavage, ipecac or cathartics, once mainstay of therapy of poisoning, have been questioned and deemed inappropriate since they may increase rather than reduce absorption and may even be harmful (7–12). However, administration of activated charcoal in an awake patient with intact airways may be used to enhance the elimination of ingested toxins (13). This adsorbent can be administered by mouth or by nasogastric intubation, preferably within 1 hour of ingestion and even before the identity of the toxic agent is known because of its capacity to bind a wide variety of toxins. However, activated charcoal does not bind lithium, heavy metals, or toxic alcohols. Multiple-dose activated charcoal (MDAC) can be administered over several hours in an attempt to enhance the elimination of a substance, such as carbamazepine and theophylline (3,14). By virtue of interrupting these toxin's enterohepatic circulation, activated charcoal is effective even when the toxin is no longer present in the stomach or, as in the case of theophylline, when the toxin has already been systemically absorbed. *Fourth*, use of "forced diuresis" which entails administration of large fluid volume coupled with a diuretic agent to ensure a urine flow rate of 3 to 6 mL/kg/h has been largely abandoned. This approach was previously popular because of the belief that it would accelerate the elimination of most intoxicants through the kidney. However, given the lack of evidence for the efficacy of forced diuresis in treatment of poisoning on the one hand, and its association with significant risk of volume overload, pulmonary edema, and electrolyte abnormalities on the other, forced diuresis is no longer recommended in the management of patients with suspected poisoning. *Finally*, alkalinization of the urine is employed to promote the elimination of toxins that are weak acids in patients who have adequate urine output and normal renal function. The basis for this approach is that renal tubular cell membranes are more readily permeated by the lipid-soluble nonionized form of the drug in question. Thus, increasing the urine pH will lead to increasing the ionized fraction of the substance which is lipid insoluble and thus cannot be reabsorbed and will be trapped in the renal tubular lumen and be excreted in the urine. Urine alkalinization is achieved by the administration of one ampule of sodium bicarbonate as a bolus followed by dextrose 5% in water (D5W) to which 100 to 150 mEq of sodium bicarbonate is added to each liter and infused at 150 to 250 mL/h. The goal is to have a urine pH >7.5 (15,16). This degree of urinary alkalinization was thought to be helpful in patients with exposure to drugs that are known to be excreted unchanged by the kidney, have low degree of protein binding, exist in a weakly acidic form, and are primarily distributed in the extracellular fluid compartment such as salicylate, phenobarbital, chlorpropamide, 2,4-dichlorophenoxyacetic acid, diflunisal, fluoride, mecoprop, and methotrexate (15,16). Urinary acidification for weak bases, such as phencyclidine or amphetamines, should not be done due to risk of rhabdomyolysis and acute kidney injury (AKI) (17). Hemodialysis and other extracorporeal methods are commonly used for removal of toxins, particularly in patients with severe acid–base or electrolyte disorders, even when the nature of the toxic agent is not known.

TABLE 36.1 **Management Strategies for Patients with Poisoning**

1. Stabilization (supportive care)

- Admission to intensive care unit
- Secure airways:
  - Oxygenation and/or ventilation
  - Prevention of aspiration
- Treatment of cardiac arrhythmias
- Hemodynamic support
- Control of seizures
- Correction of temperature abnormalities

2. Laboratory assessment

- Complete blood count
- Serum electrolytes, calcium, and phosphorus
- Renal function including urinalysis
- Liver function tests
- Coagulation tests
- Arterial blood gases
- Calculation of anion and osmolar gaps
- Measurement of serum drug level
- Chest x-ray
- ECG

3. Decontamination

- Gastrointestinal decontamination
  - Gastric evacuation by lavage
  - Absorbents such as activated charcoal
  - Catharsis or whole bowel irrigation
- Decontamination of the eyes and skin

4. Administration of antidotes

- Neutralizing antibodies
- Chemical binding of toxins
- Antagonism of the physiologic or metabolic effects

5. Enhancement of elimination of the toxin

- Multiple-dose activated charcoal
- Forced diuresis
- Alkalinization of the urine
- Chelation
- Extracorporeal techniques
  - Peritoneal dialysis
  - Hemodialysis
  - Hemoperfusion
  - Hemofiltration
  - Plasmapheresis
  - Exchange transfusion
- Hyperbaric oxygen for carbon monoxide poisoning

6. Disposition

- Patient education
- Prevention of children exposure
- Notification of regulatory agencies
- Psychiatric evaluation
- Social worker counseling

ECG, electrocardiogram.

TABLE 36.2 Common Emergency Antidotes

Poison	Antidote	Adult Dosage	Mechanism/Comment
Acetaminophen	*N*-acetylcysteine	140 mg/kg initial oral dose, followed by 70 mg/kg q4h for 17 doses or IV as 150 mg/kg × 1 h then 50 mg/kg over 4 h then 100mg/kg over 16 h	Most effective within 16 h; may be useful after 24 h
Atropine, anticholinergics	Physostigmine	Initial dose: 0.5–2 mg (IV); children: 0.02 mg/kg	Cholinesterase inhibitor that antagonizes central and peripheral nervous system effects May cause convulsions, bradycardia, and a systole
Benzodiazepines	Flumazenil	0.2 mg (2 mL) (IV) over 15 s; repeat 0.2 mg (IV) as necessary; initial dose not to exceed 1 mg	Recommended only for reversal of pure benzodiazepine sedation
β-Blockers	Glucagon	1 mg/mL ampoule; 5–10 (IV) initially	Stimulates cyclic adenosine monophosphate synthesis; increases myocardial contractility
Calcium channel blockers	Calcium chloride 10%	1 g (10 mL) (IV) over 5 min as initial dose; repeat as necessary to restore blood pressure	Each syringe contains 1 g or 10 mL of 10% calcium chloride; each milliliter contains 100 mg of calcium chloride or 1.4 mEq of calcium; used for hypotension, bradyarrhythmias
Carbon monoxide	Oxygen	1–3 atm	Hyperbaric oxygen in critical patients
Cyanide	Amyl nitrate Sodium nitrite Sodium thiosulphate	Administer pearls every 2 min Adult: 10 mL of 3% solution over 3 min (IV) Child: 0.33 mL (10 mL 3% solution)/kg over 10 min Adult: 25% solution 50 mL (IV) over 10 min Child: 1.65 mL/kg	Methemoglobin-cyanide complex cause hypotension; dosage assume normal hemoglobin. Forms harmless sodium thiocyanates
Digitalis	Digibind-FAB antibodies (antigen-binding fragments)	IV dose of Digibind in critical patient with unknown ingestion; 800 mg (20 vials); dosage if serum digoxin and patient's weight (in kg) are known: the number of vials to administer = [concentration (in ng/mL) × 5.6 × kg]/600	IV dose of Digibind should be equimolar to total body load of digoxin; one vial of Digibind contains 40 mg of FAB fragments, which neutralize 0.6 mg of digoxin; the number of milligram of digoxin ingested divided by 0.6 is the number of vials required; indicated for life–threatening cardiac arrhythmias, hyperkalemia, serum digoxin level >10 ng/mL in adults or 4 ng/mL in children
Hydrofluoric acid	Calcium	Topical exposure: Apply calcium gluconate gel or calcium carbonate paste; 10% calcium gluconate 10 mL in 40 mL D5W via intraarterial infusion over 4 h may be indicated for significant digital hydrofluoric acid burns Ingestion: 10% calcium gluconate (IV)	An intraarterial infusion of 10 mL 10% calcium gluconate (1 syringe) provides 4.65 mEq (84 mg) of elemental calcium to bind fluoride ion, preventing cellular injury and tissue necrosis Monitor for hypokalemia and treat electrolytes.
Iron	Deferoxamine mesylate	Initial dose: 40–90 mg/kg (IV or IM), not to exceed 1 g Infusion: 15 mg/kg/h (IV)	Deferoxamine mesylate forms renally excretable ferrioxamine complex; IV route to be used in patients with shock
Lead	Dimercapto-succinic acid (succimer)	10 mg/kg/dose, bid × 28 days 35–50 mg/kg/dose (maximum 1.0–1.5 g), bid or as a continuous infusion	Monitor liver function tests; add BAL if lead level >70 μg/dL in children, and >100 μg/dL in adults.
Mercury, arsenic, gold	BAL (Dimercaprol)	4–6 mg/kg (IM), every 4–8 h	Each milliliter of BAL has dimercaprol, 100 mg, in 210 mg (21%) benzyl benzoate and 680 mg peanut oil; forms stable, nontoxic, excretable cyclic compound; contraindicated if patient has peanut allergy
Methyl alcohol, ethylene glycol	Ethyl alcohol Fomepizole	500 mg/kg of 10% ethanol, then continuous infusion of 100 mg/kg/h 15 mg/kg loading dose, 10 mg/kg every 12 h IV	Watch for hypomagnesemia, hypothermia, and lethargy in children. Maintain serum ethanol concentration at 100 mg/dL.

(continued)

TABLE 36.2 (Continued)

Poison	Antidote	Adult Dosage	Mechanism/Comment
Nitrites	Methylene blue	1–2 mg/kg of 1% solution (IV) over 5 min	Accelerates methemoglobin reductase system; often, exchange transfusion is needed for severe methemoglobinemia; can produce hemolysis in high dose Maximum dose: 7 mg/kg/d in adults; 4 mg/kg/d in children
Opiates, propoxyphene, diphenoxylate	Naloxone Nalmefene	Adults: 0.4–2.0 mg (IV or IM) Children: 0.01–0.1 mg/kg (IV or IM) Adults: 1 mg IV Child: 0.25 μg/kg IV	Larger doses may be necessary after sever overdose or overdose of propoxyphene. Antagonizes opiates via its higher for some receptors; naloxone has no respiratory depression.
Organophosphates, nerve carbamates exposure	Atropine Pralidoxime [2-PAM]	Adult: 0.50–2.0 mg IV Child: 0.05 mg/kg Adult: 1g IV then 500–1000 mg/h as needed Child: 15–40mg/kg then 15–40 mg/kg/h	Very large doses of atropine may be needed in sever agents, cases. Must be added to atropine if nicotinic or central symptoms are present
Tricyclic antidepressants	Sodium bicarbonate	1–2 ampules (IV) bolus or infusion	Administer if QRS interval is ≥100 msec; maintain serum pH at 7.45–7.55; avoid severe alkalosis. One ampule of 50 mL sodium bicarbonate contains 50 mEq $NaHCO_3$; IV bolus for life threatening cardiac arrhythmia

D5W, 5% dextrose in water; BAL, British anti-Lewisite; PAM, pyridine aldoxime methyl chloride.
Modified and adapted from Shannon MW. A general approach to poisoning. In: Shannon MW, Borron SW, Burns JM, eds. *Haddad and Winchester's Clinical Management of Poisoning and Drug Overdose*. 4th ed. Philadelphia, PA: WB Saunders, 2007:13–30.

EXTRACORPOREAL TREATMENT OF POISONING

Available Extracorporeal Methods

Extracorporeal treatments (ECTRs) were required in 0.1% of all intoxications in the United States (1). Although the number may represent a small fraction of all toxic exposures, nephrologists are routinely consulted to help in the management of poisoned victims. The basis for their role in this clinical setting is fourfold. First, drugs and toxins may affect the renal function directly or through their effects on renal hemodynamics leading to AKI. Second, poisons may lead to serious clinical consequences such as acid–base and electrolyte abnormalities for which nephrologists are asked to manage. Third, the realization that poisons can be cleared from the body either by the kidney or by the use of extracorporeal techniques. Finally, their expertise in the dialysis procedure and presumed knowledge in the use of extracorporeal methods for enhancing toxins elimination.

The rationale for the application of extracorporeal techniques in the treatment of acute intoxication lies in their ability to increase the clearance of the offending toxin. Thus, active removal of toxins from blood would markedly reduce the duration of exposure to toxins and reduce the morbidity and mortality associated with poisoning and overdose. An array of methods has been proposed and studied, both singly and in combination. These include intermittent hemodialysis (IHD), sustained low-efficiency dialysis (SLED), intermittent hemofiltration (IHF) and intermittent hemodiafiltration (IHDF), continuous renal replacement therapy (CRRT), hemoperfusion (HP), therapeutic plasma exchange (TPE), exchange transfusion, peritoneal dialysis (PD), albumin dialysis, cerebrospinal fluid (CSF) exchange, extracorporeal membrane oxygenation (ECMO), and emergency cardiopulmonary bypass (**TABLE 36.3**) (18). The use of an optimal method of extracorporeal removal of toxins is often based on clinical

judgment and anecdotal reports rather than on evidence-based controlled trials (18,19). A large body of work has emerged in this area and consists of theoretical considerations, *in vitro* and *in vivo* laboratory studies, and clinical observations ranging from large case series to anecdotal reports. However, in the selection of one method over the others, one must consider a number of factors that influence the removal of the toxin by these techniques (**TABLES 36.4** and **36.5**). The following is a brief description of the methods used for removal of toxins.

TABLE 36.3 Extracorporeal Treatments for Toxin Removal

- Intermittent hemodialysis (IHD)
- Sustained low-efficiency dialysis (SLED)
- Intermittent hemofiltration (IHF) and intermittent hemodiafiltration (IHDF)
- Continuous renal replacement therapy (CRRT)
- Hemoperfusion (HP)
- Therapeutic plasma exchange (TPE)
- Exchange transfusion
- Peritoneal dialysis (PD)
- Albumin dialysis
- Cerebrospinal fluid exchange
- Extracorporeal membrane oxygenation (ECMO)
- Emergency cardiopulmonary bypass

TABLE 36.4 Factors Affecting the Removal of Toxins by Extracorporeal Techniques

Toxin-Related Factors	Extracorporeal Therapy–Related Factors
• Water soluble • Distributed in extracellular fluids • Low volume of distribution • Molecular weight (toxins <500 Da are better removed) • Low protein binding • Lipid solubility • Rebound (diffusibility from the intracellular compartment to extracellular compartment)	• High-efficiency dialyzer membrane • High-flux membrane • Large surface area of the dialyzer • High blood and dialysate flow rates • Time on extracorporeal treatment

From Shannon MW. A general approach to poisoning. In: Shannon MW, Borron SW, Burns JM, eds. *Haddad and Winchester's Clinical Management of Poisoning and Drug Overdose*. 4th ed. Philadelphia, PA: WB Saunders, 2007:13–30.

TABLE 36.5 Factors to Be Considered When Choosing between Urinary Alkalinization, Hemodialysis, Hemoperfusion, and Continuous Renal Replacement Therapy (CRRT)

Urine Alkalinization	Hemodialysis	Hemoperfusion	CRRT
Toxin characteristics • Excreted unchanged by the kidney • Low degree of protein binding • Exist in a weakly acidic form • Have extracellular distribution	Toxin characteristics • Low molecular weight • Water solubility • Low protein binding	Toxin characteristics • High molecular weight • Lipid solubility • High protein binding • Low volume of distribution	Toxin characteristics • Slow release from tissues • Large volume of distribution
Patient characteristics • Normal renal function • Adequate urine output	Patient characteristics • Presence of kidney disease • Acid–base, electrolyte • Volume problems • Low platelet count	Patient characteristics • Hemodynamic instability	Patient characteristics • Critically ill • Hemodynamic instability
Examples • Tricyclic antidepressants • Phenobarbital • Salicylates	Examples • Lithium • Salicylate • Valproate • Theophylline • Methanol • Ethylene glycol	Examples • Theophylline • Phenobarbital • Glutethimide	Examples • Lithium • Salicylate • Valproate • Metformin • Acetaminophen • Ethylene glycol

Hemodialysis

HD is the most commonly used technique for extracorporeal removal of toxins. The principles governing toxin removal by HD are essentially similar to those for treatment of uremia (19–23). HD is based mainly on the principle of diffusion. Because small solutes exhibit random molecular motion to a greater extent than larger solutes, the former solutes can diffuse through the semipermeable membrane more readily than the latter. Hence, the efficiency of dialysis in drug removal is inversely related, other things being equal, to the molecular size of the drug involved. The availability of the more permeable high-flux dialysis membranes will facilitate removal of toxins with larger molecular weights (MWs).

Drugs present in the circulation can be removed to a variable degree by HD depending on a number of factors (**TABLE 36.4**). These include the blood and dialysate flow rates; the physical and biologic characteristics of the offending agent such as a molecular size below the cutoff of the dialysis membrane, the volume of distribution (Vd) in the body, degree and affinity of protein binding, water or lipid solubility, state of ionization, and the physical characteristics of the dialyzer membrane [such as surface area, mass transfer area coefficient (KoA), porosity, electric charge, ability to adsorb the offending substance]; rate of ultrafiltration; and concentration gradient between blood and dialysate. For a solute that has a low MW, is not ionized, is water-soluble, and is not protein-bound, plasma dialyzer clearance can even exceed plasma flow rate and approximate blood-flow rate if that particular solute is readily equilibrated across the red cell membrane. Methanol is a drug that best exemplifies this model. Therefore, HD should be considered for poisoning resulting from toxins that have these favorable physical characteristics (**TABLES 36.5** and **36.6**). By contrast, HD may not be effective for removal of toxins that are lipid-soluble, protein-bound, or possess high MWs. However, the newer dialysis membranes have the capacity for removal of larger molecules and highly protein-bound poisons such as carbamazepine and phenytoin (24–27). **TABLE 36.6** lists the various drugs that can be removed by HD.

TABLE 36.6 Representative Drugs Removed by Hemodialysis

Alcohols
- Ethanol
- Ethylene glycol
- Isopropanol
- Methanol

Analgesics
- Acetaminophen
- Colchicine
- Salicylates

Antibiotics and chemotherapeutic agents
- Amoxicillin
- Clavulanic acid
- Penicillin
- Ticarcillin
- Cefixime
- Cefuroxime
- Cephalexin
- Amikacin
- Gentamicin
- Kanamycin
- Neomycin
- Streptomycin
- Tobramycin
- Metronidazole
- Nitrofurantoin
- Sulfisoxazole
- Sulfonamides
- Tetracycline
- Imipenem
- Ciprofloxacin
- Acyclovir
- Isoniazid
- Ethambutol
- Didanosine
- Zidovudine
- Foscarnet
- Ganciclovir
- Cyclophosphamide
- 5-Flurouracil

Sedatives-anticonvulsants
- Butabarbital
- Pentobarbital
- Phenobarbital
- Carbamazepine
- Chloral hydrate
- Ethchlorvynol
- Glutethimide
- Meprobamate
- Primidone
- (Valproic acid)

Cardiovascular drugs
- Atenolol
- Captopril
- Enalapril
- Metoprolol
- Methyldopa
- Nadolol
- Procainamide
- Propranolol
- Sotalol
- Tocainide

Solvents
- Acetone
- Camphor
- Thiols
- Toluene
- Trichloroethylene

Miscellaneous
- Lithium
- Theophylline
- Paraquat
- Aniline
- Boric acid
- Chromic acid
- Chlorates
- Diquat
- Thiocyanate

( ), not well removed.

Reprinted from Winchester JF. Active methods for detoxification. In: Shannon MW, Borron SW, Burns MJ, eds. *Haddad and Winchester's Clinical Management of Poisoning and Drug Overdose*. 3rd ed. Philadelphia, PA: WB Saunders, 1998:175–188, with permission.

There are a number of advantages for intermittent HD use in treatment of poisoning. HD services are now widely available, even in poorer countries, are relatively easy to use and of low cost, and are associated with lower complication rate when compared to other methods of extracorporeal techniques. HD also corrects concomitant electrolyte and acid–base abnormalities and removes excess fluid with ultrafiltration. Clearly, HD should be employed whenever the intoxicated patient suffers concurrently from kidney disease or has developed acid–base, electrolyte, or volume abnormalities that can be readily rectified by HD. Finally, given that it can be quickly prepared and that outcome may be dependent on

prompt removal of the poison from the body, intermittent HD remains the treatment of choice for most poisonings worldwide. However, HD treatment should be adjusted to each patient's individual needs. Therefore, in hemodynamically unstable intoxicated patients, administration of physiologic saline, the use of bicarbonate-based dialysate, cool (e.g., 35°C) dialysate, and the use of vasoconstrictors such as midodrine are helpful. The composition of the dialysate should also be individualized. Therefore, a dialysate potassium concentration of 3 to 4 mEq/L is appropriate in the absence of hyperkalemia or hypokalemia. Similarly, the bicarbonate concentration in the dialysate should be adjusted according to the patient's acid–base balance. Therefore, dialysate bicarbonate level should be lowered in patients' with metabolic alkalosis but maintained at a high value in the presence of severe metabolic acidosis.

Hemoperfusion

This method is based on the adsorption of a poison to a sorbent-containing cartridge that is perfused by blood from a poisoned patient (28–30). The column is most commonly made from activated charcoal, but resins have also been used (28). As mentioned earlier, activated charcoal is an effective and commonly used oral agent for preventing gastrointestinal absorption of poisons. On the other hand, charcoal columns were used since the 1960s in HP to enhance elimination of poisons. Most commonly used HP cartridges are packed with 100 to 300 g of activated charcoal or an exchange resin and coated with a thin (0.05 mm), relatively porous semipermeable membrane. Adsorption occurs because of the hydrophobic properties of charcoal. HP can also be performed using commercially available resins which are made from heat-stable polymeric material in the form of cross-linked insoluble beads which can either be charged (e.g., Amberlite IRA-900) or uncharged, (e.g., Amberlite XAD-4) (24,30–32). The total amount of drug removed by HP is usually small and is not of great clinical consequence. However, although the extraction of highly protein-bound poisons is less than that for unbound poisons (33), studies using an adsorbent cartridge showed extraction ratios >80% when the proportion of protein-bound poison is <90% (30,34).

Removal of many toxins is influenced by the affinity of the charcoal for the toxin and by how avid the toxin binds to plasma proteins (28,30,32,35). In HP cartridges, the semipermeable membrane is not designed to withstand pressure but rather to impede the release of the particulate matter from the sorbent into the circulation and to prevent or reduce the adherence of platelets and other formed elements of blood onto the sorbents. Consequently, this membrane is extremely thin and does not significantly restrict solute diffusion. The process of activation of the charcoal sorbent has lead to enormous increase in the total available surface area of the sorbent. However, despite the large adsorbent area, HP cartridges may become saturated after 4 to 8 hours and lose their efficiency over time, so that they may need to be replaced. Moreover, HP can be associated with several other potential complications including a 20% to 30% decrease in the blood platelet count, leukopenia, hypocalcemia, hypoglycemia, charcoal embolism, and hypothermia. However, the frequency of these complications was reduced with the use of albumin cellulose nitrate to coat charcoal. **TABLE 36.7** lists the various drugs that can be removed by HP.

TABLE 36.7 Representative Drugs and Chemicals Removed by Hemoperfusion

Barbiturates
- Amobarbital
- Butabarbital
- Hexobarbital
- Pentobarbital
- Quinalbital
- Secobarbital
- Thiopental
- Vinalbital

Nonbarbiturate hypnotics, sedatives and tranquilizers
- Carbromal
- Chloral hydrate
- Chlorpromazine
- (Diazepam)
- Diphenhydramine
- Ethchlorvynol
- Glutethimide
- Meprobamate
- Methaqualone
- Methsuximide
- Methyprylon
- Promazine
- Promethazine
- (Valproic acid)

Analgesics, antirheumatic
- Acetaminophen
- Acetylsalicylic acid
- Colchicine
- d-Propoxyphene
- Methylsalicylate
- Phenylbutazone
- Salicylic acid

Antimicrobials/anticancer
- (Adriamycin)
- Ampicillin
- Carmustine
- Chloramphenicol
- Chloroquine
- Clindamycin
- Dapsone
- Doxorubicin
- Gentamicin
- Isoniazid
- (Methotrexate)
- Thiabendazole
- (5-Fluorouracil)

Antidepressants
- (Amitriptyline)
- (Imipramine)
- (Tricyclics)

Plant and animal toxins, herbicides, insecticides
- Amanitin
- Chlordane
- Demeton sulfoxide
- Dimethoate
- Diquat
- Methylparathion
- Nitrostigmine
- (Organophosphate)
- Phalloidin
- Polychlorinated biphenyls
- Paraquat
- Parathion

Cardiovascular
- Digoxin
- Diltiazem
- (Disopyramide)
- Flecainide
- Metoprolol
- *N*-acetylprocainamide
- Procainamide
- Quinidine

Miscellaneous
- Aminophylline
- Cimetidine
- (Fluoroacetamide)
- (Phencyclidine)
- Phenols
- (Podophyllin)
- Theophylline
- Solvents, gases
- Carbon tetrachloride
- Ethylene oxide
- Trichloroethane
- Xylene
- Metals
- (Aluminium)*
- (Iron)*

( ), not well removed; ( )*, removed with chelation.

Reprinted from Winchester JF. Active methods for detoxification. In: Shannon MW, Borron SW, Burns MJ, eds. *Haddad and Winchester's Clinical Management of Poisoning and Drug Overdose*. 3rd ed. Philadelphia, PA: WB Saunders, 1998:175–188, with permission.

A frequently asked question is whether HD or HP is superior for treatment of poisoning. Early

clinical experience with HP suggested that it was more effective than HD or PD for poison removal. However, recent studies have shown comparable results with the newer high-flux, high-efficiency dialyzers (36,37). **TABLES 36.4** and **36.5** list the factors that should be considered when choosing between HD and HP as a treatment modality for poisoning. HP is preferred when the toxin is lipid-soluble or significantly protein-bound (36). Activated charcoal is capable of adsorbing and, thereby, extracting lipid-soluble substances much more efficiently than HD. On the other hand, HP does not contribute to the overall treatment of the patients with kidney disease and/or with acid–base, electrolyte, and fluid problems. Also, poisons with a large Vd are not likely to be efficiently removed by HP. Moreover, HP is associated with more frequent complications and higher cost, particularly since the cartridges need to be replaced regularly because of saturation. As a result, the number of HP reports has steadily declined during the last two decades (**FIGURE 36.2**). It should be noted that both HD and HP require the establishment of a vascular access and the administration of anticoagulants. However, anticoagulant-free HD can be performed by infusing 100 mL of physiologic saline into the dialyzer blood inlet every 30 minutes for short-duration HD.

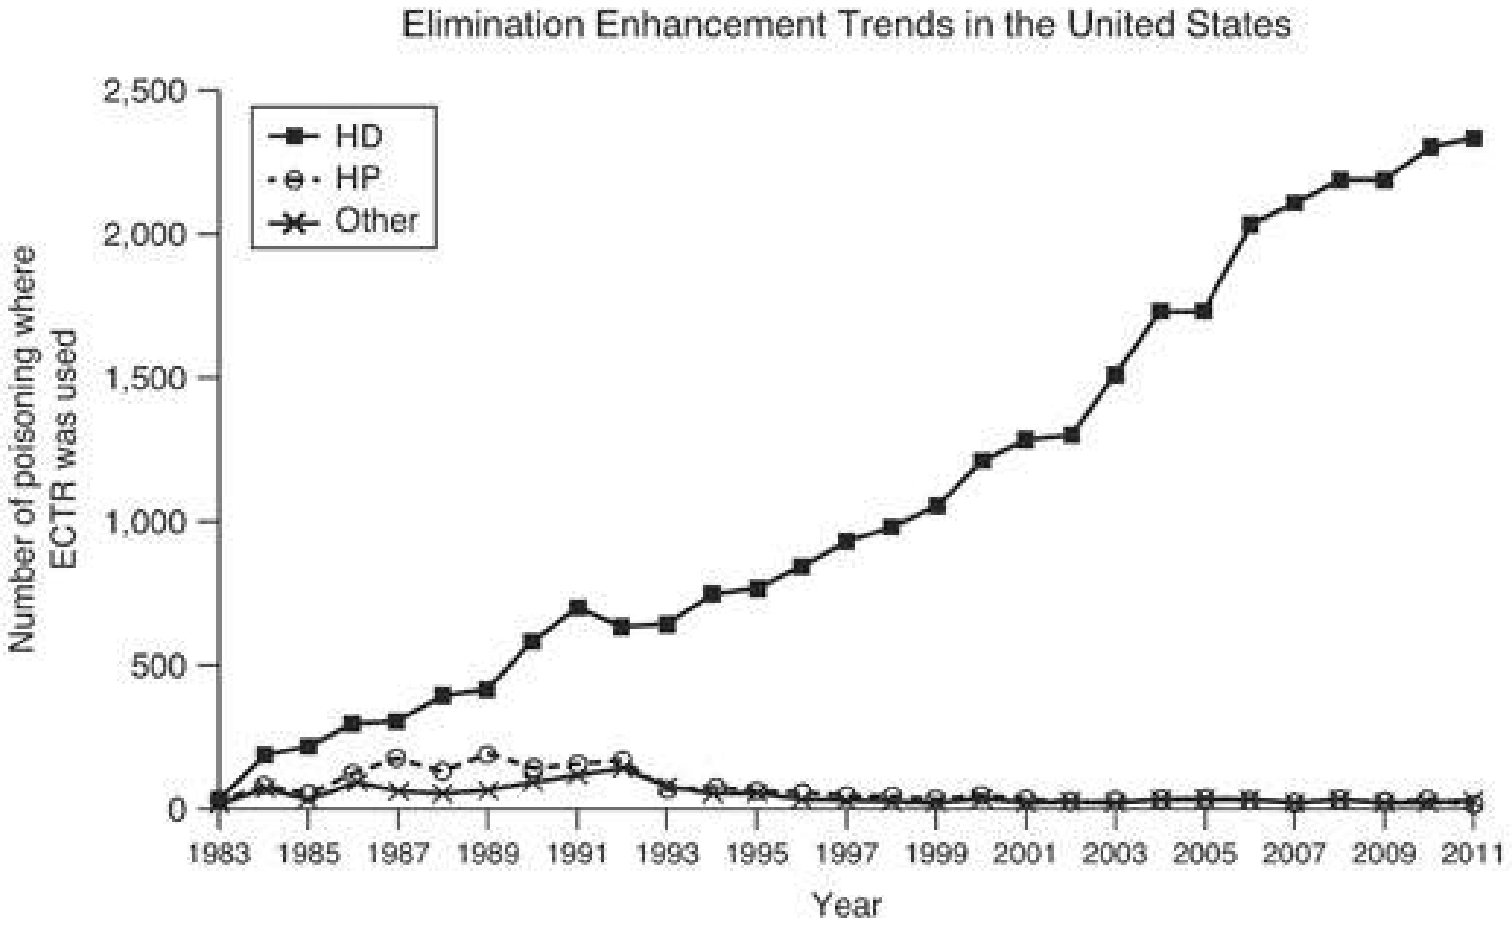

FIGURE 36.2 Temporal changes in the number of cases where hemoperfusion (HP) and hemodialysis (HD) were utilized in the treatment of poisoned patients in the United States. Data obtained from the annual reports of the American Association of Poison Control Centers' National Poison Data System (NPDS). (Reproduced with permission from Ghannoum M, Bouchard J, Nolin TD, et al. Hemoperfusion for the treatment of poisoning: technology, determinants of poison clearance, and application in clinical practice. *Semin Dial* 2014;27:350–361.)

The earlier discussion may not be applicable to those systems that employ sorbent cartridges that regenerate dialysate. These systems employ small volumes of dialysate, and the cartridges used do not effectively bind alcohols. Consequently, such systems are not indicated in the treatment of ethylene glycol,

methanol, or isopropyl alcohol poisoning. Although the cartridge may adsorb salicylate or lithium, there are, to our knowledge, no published studies documenting the effectiveness of sorbent systems in these intoxications. Finally, sorbent-based systems are said to be efficacious in the treatment of theophylline intoxication, but, again, there are no published reports available on this subject.

Sustained Low-Efficiency Dialysis

This technique allows the use of conventional HD machines to perform slow, low-efficiency HD using both reduced dialysate and blood-flow rate (32,35,38,39). Conventional hemodialyzers are used with a reduced dialyzer blood-flow rate of 200 to 300 mL/min and a slower dialysate flow rate of 300 mL/min. Each treatment can last up to 6 to 12 hours daily (35,40). The relatively long treatment duration compensates for the low efficiency of the procedure. Because of the slow blood and dialysate flow rates, the procedure is better tolerated by critically ill patients with hemodynamic instability (35,39). It is conceivable that this method may serve as an adjunctive approach to conventional extracorporeal measures in the treatment of poisoning. Although SLED uses a higher dialysate flow rate than CRRT, small solute clearance is reportedly similar (39,41). However, one study showed that the daily clearance of lithium was higher with SLED than with CRRT (42). Unfortunately, there are only a limited number of reports in the literature that describe the use of SLED in poisoning.

Continuous Renal Replacement Therapy

CRRT includes several techniques that utilize convective transport alone or in combination with diffusive transport. These techniques include (a) continuous venovenous hemodialysis (CVVHD), (b) continuous venovenous hemofiltration (CVVH), and (c) continuous venovenous hemodiafiltration (CVVHDF). The continuous venovenous techniques have largely replaced continuous arteriovenous therapies. Hemofiltration involves the removal of an ultrafiltrate from the blood through the semipermeable membrane of a filter. This is usually accompanied by the simultaneous, appropriate replacement with a physiologic solution that resembles plasma. The efficiency of the procedure is related to the total volume exchanged. Ultrafiltration is based on the principle of convection, and ultrafiltration is obtained by the application of a transmembrane pressure gradient. For all solutes that can pass through the pores of a semipermeable membrane, the relatively larger solutes and their smaller counterparts all pass through the membrane at the same rate (43,44). On the other hand, hemodiafiltration involves simultaneous HD and hemofiltration using the same dialyzer/filter. The procedure is more efficient than either HD or hemofiltration alone in the removal of poisons that are small enough to pass through a semipermeable membrane (36,37,44).

These CRRT techniques were initially promoted as superior to HD in the treatment of poisoning, particularly those associated with lithium, valproic acid, and theophylline (22). However, there is no clear evidence for this assertion (20). CRRT has been proposed as effective in the removal of tissue-bound substances, such as paraquat, in which the offending agent is released slowly from its reservoir and associated with the occurrence of a “rebound phenomenon” (45). However, in most circumstances, the amount of drug removed is hampered by the slow rate of CRRT therapies. Moreover, since most toxins have a relatively small MW, they can be removed easily by HD. In most cases, the need for poison removal is urgent, and therefore, SLED and CRRT should not be used as first-line treatment. In CRRT, the blood and effluent flow rates are lower than during intermittent HD, and thus, clearance will be lower

over a similar period of time (46). This has been shown to be true in methanol poisoning where the clearance is limited to <50 mL/min with CRRT compared with >200 mL/min with HD (47). Also, carbamazepine clearance is 3 times lower with CRRT compared with HD (48). However, CRRT can be used following conventional HD for treatment of poisoning with known tendency for rebound as in lithium intoxication, or they can be started as primary therapeutic modalities when hemodynamic instability militates against the use of conventional HD, hemofiltration, or hemodiafiltration (44). However, there is no clear evidence for a beneficial effect of CRRT or SLED in such circumstances (46).

Peritoneal Dialysis

PD allows the diffusion of toxins from mesenteric capillaries across the peritoneal membrane into the dialysate within the peritoneal cavity. In PD, clearance of solutes including poisons depends on the volume and number of exchanges, the peritoneal surface area, as well as the MW of the solute to be removed. In general, the clearance of solutes is quiet low in the range of 10 to 15 mL/min, and therefore, PD is not considered an effective technique for treatment of poisoning (19,49). In order to enhance clearance by PD, continuous flow peritoneal dialysis (CFPD) was developed. This technique requires the insertion of a dual-lumen PD catheter or two single-lumen catheters at opposite positions. A large volume of dialysate, up to 300 mL/min, is continuously exchanged in and out of the peritoneal cavity (50). Again, there is very limited data using this technique for removal of poisons. Therefore, PD is seldom used as a primary modality in the treatment of poisoning except in circumstances where the more efficient ECTRs are not available or cannot be performed.

Plasmapheresis or Exchange Blood Transfusion

TPE (plasmapheresis) is a process in which separation of plasma from the blood cellular components is archived by centrifugation or filtration. The volume of plasma removed during a single procedure is between 30 and 60 mL/min (51,52), and each treatment lasts 2 to 4 hours (53). The patient's plasma is replaced by other solutions such as fresh-frozen plasma, albumin, or crystalloid solution. On the other hand, exchange blood transfusion involves removal of the patient's own blood and replacing it with fresh blood. These procedures are not usually effective in the treatment of poisoning because of the limitations on the amount of plasma or of blood that can be exchanged, especially in the case of toxins with large volumes of distribution (51,54,55). However, plasma exchange may be useful for removal of toxins that are highly protein-bound or have very low Vd. The American Society for Apheresis (ASFA) guidelines recommend an exchange volume of one to two total plasma volumes per day until clinical symptoms of poisoning have decreased and release of toxin from tissues is no longer significant (55). As of now, there are no clinical indications for the use of plasmapheresis in the treatment of poisoning and thus should be reserved for circumstances where alternative therapies are unavailable.

Albumin Dialysis

Albumin dialysis or extracorporeal liver assist devices (ELAD) includes the Molecular Adsorbent Recirculating System (MARS), the Prometheus system, and single pass albumin dialysis (SPAD) (56). With MARS, selective removal of albumin-bound substances can be achieved in a high-flux dialysis setting by the enrichment of dialysate with human albumin that functions as a molecular adsorbent. The albumin-enriched dialysate is then recirculated over sorbents. This novel dialytic approach has the

theoretical advantage of enhancing elimination of protein-bound poisons in addition to excess water and water-soluble substances (57–59). With that in mind, this technique has been used successfully in anecdotal reports for the treatment of poisoning resulting from acetaminophen and cytotoxic mushrooms in the presence or absence of concomitant renal insufficiency (59,60). However, the role of albumin dialysis in poisonings remains unclear (61).

Clearance versus Drug Removal and Clinical Efficacy

A number of mathematical methods for describing the kinetics of drug removal during various extracorporeal techniques have been proposed in order to assess the efficacy of these techniques in achieving drug removal. During HD, the dialyzer clearance of a substance is defined as the volume of blood from which the substance is completely removed per unit time. If the drug concentrations in the blood entering and exiting the dialyzer and the rate of dialyzer blood flow rate are known, the dialyzer clearance of the drug can be calculated as follows (**EQUATION 36.1**):

$$C = QB\,(A - V) / A \qquad (36.1)$$

where

C = dialyzer clearance
QB = blood-flow rate through the dialyzer
A = the blood concentration of the drug at the blood inlet of the dialyzer
V = the blood concentration of the drug at the blood outlet of the dialyzer.

Alternatively, dialyzer clearance can be calculated by timed collection of spent dialysate from the dialysate outlet of a dialyzer and simultaneously obtaining arterial blood (or plasma) at the blood inlet at 30 seconds (62). Then the dialyzer clearance of a substance (in mL of blood or plasma/minute) will equal the amount of substance in mg collected in dialysate/arterial blood (or plasma) concentration of the substance in milligrams per milliliter.

Using either of these two methods, it can be shown that, given the proper drug characteristics and the use of appropriate dialyzers/ultrafilters or HP apparatus, drugs can be extracted from circulating blood with startling efficiency. In this example, the clearance of many toxins may approximate the blood-flow rate, and the extraction ratio may approach 100%; that is, drug concentration at the dialyzer/ultrafilter outlet may be close to zero.

Although these mathematical calculations imply that drugs are eliminated efficiently, thereby supporting the use of extracorporeal techniques for treatment of various intoxications, such an interpretation is not always accurate. An efficient extracorporeal procedure does not necessarily indicate that a clinically significant amount of intoxicant is being removed from the patient. This is because the total amount of drug removed depends, among several factors, on the apparent Vd of the toxin. A drug with a large Vd indicates that the substance is sequestered somewhere other than the vascular compartment such as the interstitial or intracellular fluid or bound to cellular proteins, cellular lipids, or cellular membranes. Under these circumstances, the extravascular distribution volume of the toxin results in slow release of the toxin into the vascular compartment. Such a scenario means that only a small fraction of the total amount of the toxin present in the body is accessible for removal by extracorporeal techniques during a given period of time. This is often the case with digoxin or tricyclic antidepressants poisoning. With these drugs, the largest amount of the ingested drug is not circulating but rather is bound

to intracellular components; therefore, the total quantity of drug available for extraction from the blood is minimal. Even if one is successful in completely extracting the drug from the circulation in one treatment session by extracorporeal device, only a small fraction of the total body toxin load is removed. Therefore, efforts to remove the drug by extracorporeal techniques may be futile and may even be harmful putting in mind potential complications of the procedure and its cost. Moreover, the use of these techniques for removal of drugs with these characteristics may distract from implementing the full range of supportive measures the value of which vastly outweigh the possible minimal gain derived from the procedure (63–68).

CRITERIA FOR EXTRACORPOREAL TREATMENT OF POISONING

From the preceding discussion, it is clear that not every patient with poisoning is a candidate for ECTR. Therefore, in order to consider extracorporeal means of detoxification, one should determine that this modality will significantly augment toxin removal above that achieved by spontaneous elimination either by metabolism or by the native kidneys. Unfortunately, the indications for ECTR of poisoning are not well delineated since no randomized controlled trials have been conducted in patients with poisoning. However, the EXtracorporeal TReatments In Poisoning (EXTRIP) workgroup is developing recommendations on the use of ECTR for at least 16 poisons (69,70). In clinical practice, the following clinical and toxicologic characteristics must be present before one can justify the use of extracorporeal techniques for toxin removal (**TABLE 36.8** and **FIGURE 36.3**) (69,71):

TABLE 36.8 Clinical and Toxicologic Characteristics That Must Be Present Before Considering the Use of Extracorporeal Techniques for Toxin Removal

1. Progressive deterioration of the patient's condition that is thought to be related to the offending drug such as hypoventilation, hypothermia, and hypotension
2. Development of coma, sepsis, or pneumonia
3. Blood levels that indicate that the quantity of the drug ingested can lead to severe morbidity or mortality
4. Impairment of drug excretion by the concomitant presence of
   - Kidney disease or liver failure for drugs eliminated by the kidney or the liver, respectively
   - Ingestion or administration of "slow-release" drugs
   - Nausea or vomiting that prevents the administration of charcoal to effect drug removal from the gastrointestinal tract
5. The drug has been shown to be removed efficiently by the currently available extracorporeal techniques.
6. The volume of distribution of the drug (Vd) is relatively small.
7. No effective and specific antidotes are available to reverse the effects of the toxin.

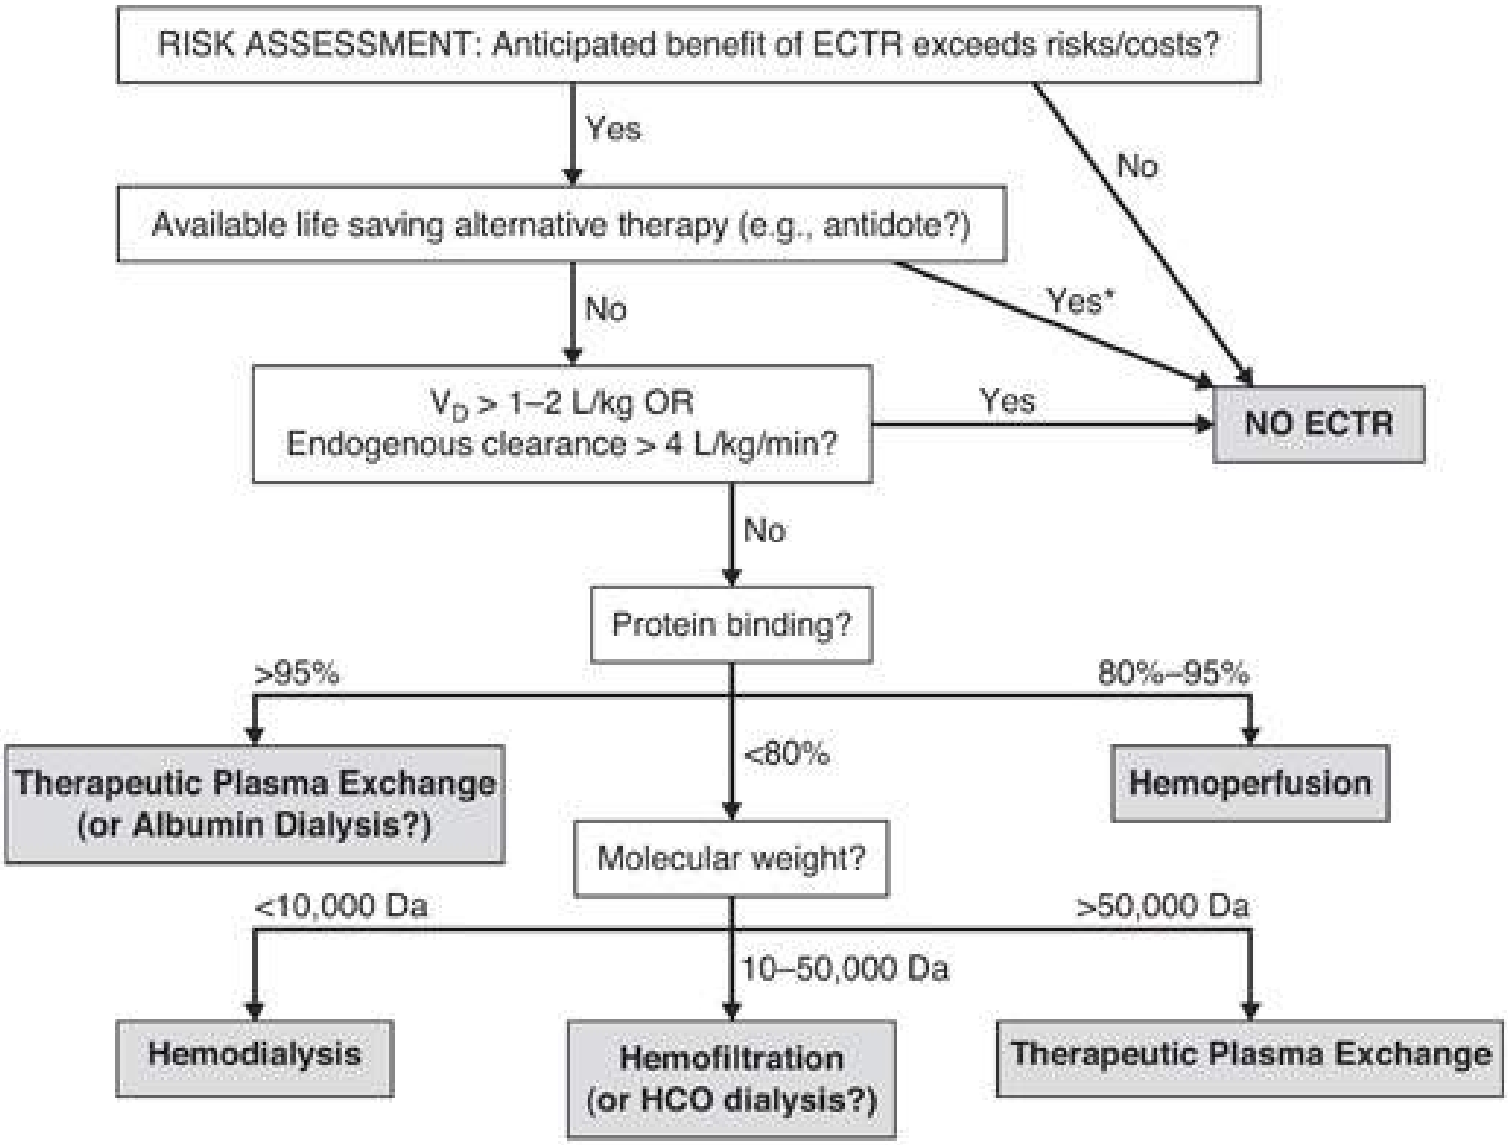

FIGURE 36.3 Stepwise approach for the initiation of extracorporeal techniques for enhanced elimination in a poisoned patients. ECTR, extracorporeal treatment. [Reproduced with permission from Ghannoum M, Roberts DM, Hoffman RS, et al. A stepwise approach for the management of poisoning with extracorporeal treatments. *Semin Dial* 2014;27(4):362–370.]

1. Progressive deterioration of the patient's condition thought to be related to the offending drug
   - Depression of the midbrain functions leading to hypoventilation, hypothermia, and hypotension
   - Development of coma, sepsis, or pneumonia
2. Blood levels indicating that the quantity (dose) of the drug ingested can lead to severe morbidity or mortality
3. Impairment of drug excretion by the concomitant presence of
   - Kidney disease or liver failure for drugs eliminated by the kidney or the liver, respectively
   - Ingestion or administration of "slow-release" drugs
   - Nausea or vomiting that prevents the administration of charcoal to effect drug removal from the gastrointestinal tract, especially in theophylline intoxication
4. The drug has been shown to be removed efficiently by the currently available extracorporeal techniques. This implies that the drug is not significantly bound to plasma proteins or lipids and that its molecular size, shape, and charge permit removal through dialyzer/ultrafilter membranes or by adsorption to sorbents.
5. The Vd of the drug is relatively small, implying that a large fraction of the drug is present in body

water, from which it can be readily removed.

6. No effective and specific antidotes are available to reverse the effects of the toxin [e.g., in digoxin poisoning, the digoxin-specific antibody Fab fragment (Digibind) can be used].

With these criteria in mind, it becomes apparent that only few toxins can be effectively removed by extracorporeal techniques. Unfortunately, many of the toxins that account for a high percentage of total morbidity and mortality are not amenable to removal by extracorporeal techniques despite the high clearance rate achieved by extracorporeal techniques. Examples of such drugs and/or toxins include the following:

Tricyclic antidepressants. The tricyclic antidepressant (TCA) class of drugs is typified by a high Vd because of high lipid solubility. The fraction of drug available for extraction from the circulation is minuscule. The EXTRIP workgroup concluded that TCAs are not dialyzable and stated that ECTR is not recommended in severe TCA poisoning because poisoned patients with TCAs are not likely to have a clinical benefit from extracorporeal removal (72).

Barbiturates. The short-acting barbiturates are highly lipid-bound and poorly dialyzable. On the other hand, longer acting barbiturates, especially phenobarbital, are more water-soluble and therefore are efficiently removed by renal excretion and by HD. Alkalinization of the urine has been used to increase their rate of excretion. HP, although effective in removing circulating long-acting barbiturates, has not been proven to provide clinical benefits. HD is indicated in the patient intoxicated with long-acting barbiturates and who have poor renal function. The EXTRIP workgroup made four key recommendations. (a) The use of ECTR should be restricted to cases of severe long-acting barbiturate poisoning. (b) The indications for ECTR in this setting are the presence of prolonged coma, respiratory depression necessitating mechanical ventilation, shock, persistent toxicity, or increasing or persistently elevated serum barbiturate concentrations despite treatment with MDAC. (c) Intermittent HD is the preferred mode of ECTR, and MDAC treatment should be continued during ECTR. (d) Cessation of ECTR is indicated when clinical improvement is apparent (73).

Acetaminophen. Acetaminophen overdose is one of the most common agents leading to patients' death. Unfortunately, it is not efficiently extracted by extracorporeal procedures. Early and prolonged use of *N*-acetylcysteine (NAC) remains the therapy of choice (74). The EXTRIP workgroup agreed that acetaminophen is dialyzable but recommended ECTR only in patients with excessively large overdoses who display features of mitochondrial dysfunction manifested by early development of altered mental status and severe metabolic acidosis prior to the onset of hepatic failure. They suggested that IHD is the preferred ECTR modality in acetaminophen poisoning (75).

Narcotics and "street" drugs. A common cause of overdose and death, narcotics and other street drugs are not amenable to extraction by extracorporeal techniques. Opium antagonists and supportive therapy are the mainstays of treatment.

Nonbarbiturate hypnotics, sedatives, and tranquilizers. Many of these drugs cause little morbidity and mortality, even in apparently severely intoxicated patients. Furthermore, they all display a high apparent Vd and lipid solubility and therefore are not removed well by extracorporeal means.

Other miscellaneous toxins. This group includes paraquat, amanita mushroom toxin, and methotrexate. Contrary to some opinions and anecdotal reports, there is little evidence that extracorporeal techniques are clinically effective for the treatment of poisonings resulting from these toxins. However,

because paraquat and *N*-acetyl procainamide (NAPA) are tightly tissue bound and released slowly, it has been proposed that CRRT may be efficacious (16,67). Although clinical case reports have suggested that patients suffering from life-threatening NAPA intoxication could be helped with the various extracorporeal measures, their effectiveness remains debatable (67). **TABLE 36.9** lists some agents for which various extracorporeal methods should be used for treatment of acute intoxications.

TABLE 36.9 Toxic Agents for which Extracorporeal Methods Have Been Shown to Have Clinical Effectiveness and Their Main Pharmacologic Characteristics[a]

Toxic Agent	Molecular Weight	Protein Binding (%)	Vd	Toxic Levels[b]
Ethylene glycol	62	–	0.6	unknown
Methanol	32	–	0.6	50 mg/dL
Isopropanol	60	–	0.6	400 mg/dL
Ethanol	46	–	0.6	450 mg/dL
Salicylate	138	60–90[c]	0.2	800–1,500 mg/dL
Lithium	7	–	0.8	2.5 mEq/L
Theophylline	180	40–60[c]	0.5	60 mg/mL

Vd, volume of distribution.

Modified from Garella S. Extracorporeal techniques in the treatment of exogenous intoxications. *Kidney Int* 1988;33:735–740, with permission.

[a]Please note that comments on the effectiveness of hemodialysis are not necessarily applicable to sorbent-based dialysate regeneration systems; these systems are not effective and not recommended for the treatment of ethylene glycol, methanol, or isopropyl alcohol poisonings. Furthermore, whereas the characteristics of the cartridges and/or some anecdotal reports suggest that they may be effective in the treatment of salicylate, lithium, and theophylline intoxication, no specific definitive studies documenting their effectiveness are available.

[b]Commonly accepted potentially lethal concentrations. These should be considered only as approximate guidelines, because toxicity is determined by a variety of clinical characteristics in combination with the serum concentration.

[c]Salicylate protein binding is highest at low (therapeutic) values and progressively lower with increasing (toxic) levels.

POISONING FROM TOXIC ALCOHOLS

The term *alcohol* usually implies ethyl alcohol, the predominant alcohol in alcoholic beverages. However, alcohol also includes any hydroxyl derivative of a hydrocarbon. Methanol is the simplest primary alcohol that can be produced by distillation of wood. It is used in paints, windshield washer fluid, solvents and thinners, plastics, synthetic textiles, as antifreeze, and as a fuel. Ethylene glycol is an organic compound primarily used as a raw material in polyester fibers and fabric industry, and polyethylene terephthalate resins in bottling, and is also used in other applications such as antifreeze. Both methanol and ethylene glycol are low MW, clear, and colorless alcohols. Methanol has an alcoholic taste, but ethylene glycol is sweet. Methanol and ethylene glycol are toxic alcohols that can result in serious morbidity and mortality. Accidental or intentional ingestion of these alcohols may result in blindness, renal dysfunction, chronic brain injury, or death (76). Factors associated with increased mortality include large osmolal gap, anion gap, and low pH <7.22. However, pH <7.22 has the highest predictive value for mortality (77). Methanol and ethylene glycol constitute medical emergencies for which early diagnosis and treatment may be lifesaving. Most of the toxicity related to methanol and ethylene glycol are related to their metabolites such as formate for methanol and oxalate and glycolate for ethylene glycol. The introduction of fomepizole as a competitive inhibitor of alcohol dehydrogenase has revolutionized treatment of toxic alcohol poisonings.

Ethylene glycol and methanol poisoning are common, but ethylene glycol poisoning is very rare in mid- and low-income countries compared to high-income countries. In 2009, there were 8,139 poisoning due to toxic alcohols in the United States. In general, poisoning with these alcohols in industrialized

countries tends to be intentional in adults and accidental in children, while in developing world, it is often accidental. The minimum lethal dose for ethylene glycol is commonly cited as 100 mL or 1 to 1.5 mL/kg but also with considerable variability (76).

METHANOL POISONING

Methanol, also known as wood alcohol, is a clear, colorless, low MW alcohol commonly found in a variety of products including industrial solvents, windshield wiper fluid, windshield deicer, antifreeze, stains, dyes, varnish, shellac, canned fuel (Sterno), as well as an alternate fuel (76). Methanol poisonings most often occur from the ingestion of "moonshine" liquor (78) as well as from ingestion of windshield washer fluid but can also arise from its dermal application or inhalation. Because methanol (MW = 32 Da) possesses inebriating qualities similar to those of ethanol, is inexpensive, and widely available, it has been responsible for large outbreaks of poisoning (79–81). In the United States, during the years 2000 to 2013, there were 30,395 methanol exposures, 85,891 ethylene glycol exposures, and 3,235 combined exposures (82). Most of the exposures that have been recorded were acute and were primarily due to unintentional exposures to windshield wiper fluid and other automotive products with 25% of these occurring among children younger than 12 years old (2).

Methanol is rapidly and completely absorbed from the gastrointestinal tract with peak plasma levels attained in 30 minutes to 1 hour. It can penetrate skin, and thus, there have been reported cases of poisoning by extensive dermal contact or inhalation (83,84). Methanol does not bind to protein and has an apparent Vd of approximately 0.6 to 0.7 L/kg. Only about 5% of ingested methanol is excreted unchanged in the urine; the rest is oxidized in the liver. Some methanol is also eliminated by the lungs. If untreated, the elimination half-life of methanol is 1 to 3 hours at low concentrations and approximately 24 hours at high concentration.

Methanol is initially metabolized by alcohol dehydrogenase to formaldehyde (**FIGURES 36.4** and **36.5**). This process occurs slowly and constitutes the rate-limiting step of this reaction. Formaldehyde is cytotoxic as it may be involved in causing blindness (85,86). However, it does not accumulate because it has a very short half-life of only 1 to 2 minutes and undergoes rapid conversion to formic acid (formate). Formic acid molecule dissociates into a hydrogen ion and a formate anion, which in turn is broken down via a folic acid–dependent pathway to carbon dioxide and water. The body has limited capacity to transform formic acid; thus, accumulation of this toxin may occur increasing the susceptibility to its toxicity. The released hydrogen ion from formic acid lowers the pH of body fluids causing acidosis. In addition to formic acid, lactic acid also contributes to the severe metabolic acidosis (76,85,87). Because the first step of methanol metabolism depends on the action of alcohol dehydrogenase, which has a 10-fold greater affinity for ethanol or fomepizole than for methanol, these compounds are currently used as antidotes in the therapy of methanol poisoning (see section "Treatment"). The same mechanism explains the prolongation of the half-life of methanol to more than 30 hours (compared with the normal of 12 to 20 hours) in patients who had ingested both methanol and ethanol at the same time (88). Oxidation of methanol, like that of ethanol, proceeds independently of the serum concentration but at a rate of only 15% of that of ethanol. Thus, complete oxidation and excretion of methanol usually requires several days which also explains the delay in the onset of toxic manifestations (84).

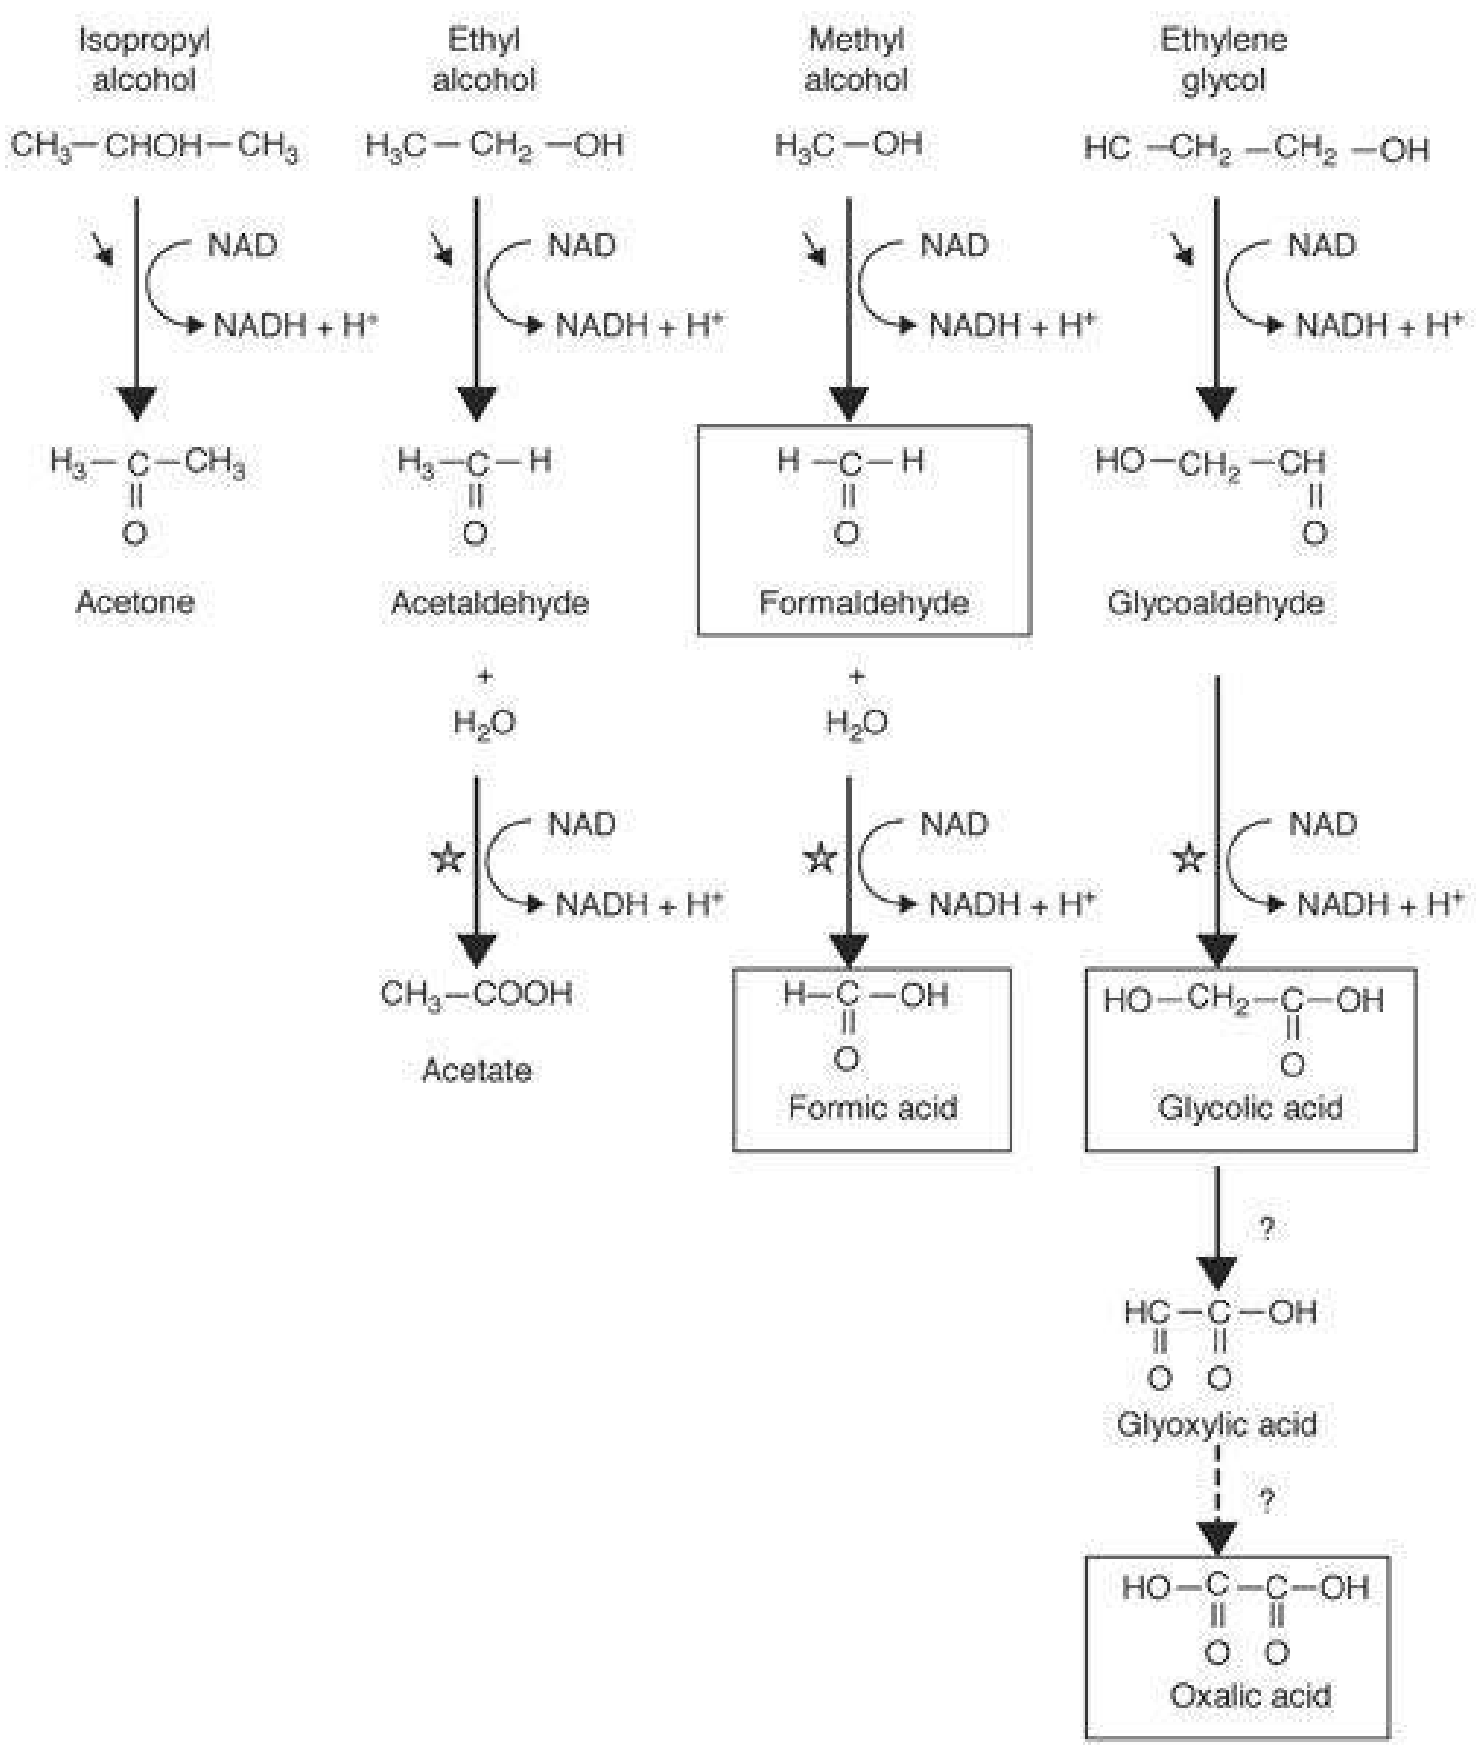

FIGURE 36.4 Pathways of metabolism of the four alcohols that most commonly cause intoxication. Alcohol dehydrogenase (*bold arrow*) is the cytosolic enzyme responsible for the first oxidative step in all four alcohols. Aldehyde dehydrogenase (*star*) is the mitochondrial enzyme responsible for catalyzing the second oxidative step in ethanol, methanol, and ethylene glycol. The main products of metabolism responsible for toxicity are enclosed in boxes. Question marks denote metabolic steps where there is uncertainty on the specific enzymes involved and on the generation of $NADH + H^+$. Note that oxalic acid represents only a small fraction of the metabolites of ethylene glycol and that other metabolites are not shown in the figure. (From Garella S. Extracorporeal techniques in the treatment of exogenous intoxications. *Kidney Int* 1988;33:735–740, with permission.)

Recommendations for the role of extracorporeal treatments in the management of acute methanol poisoning: a systematic review and consensus statement. *Crit Care Med* 2015;43:461–472.)

Clinical Picture and Laboratory Data

The clinical manifestations of methanol poisoning depend on the amount ingested, the elapsed time since ingestion, and whether there was coingestion of ethanol or other toxic substances (76). The clinical course of methanol toxicity is characterized by three distinctive stages and involves the central nervous system (CNS), the eyes, and the gastrointestinal system (**TABLE 36.10**) (88–90). An initial and fairly brief stage is characterized by CNS depression in which the patient appears intoxicated; manifestations largely due to the effects of the parent compound. This is followed by a latent stage of 6 to 30 hours during which the patient may be asymptomatic except for blurred vision. This asymptomatic stage is followed by a third stage in which formic acid accumulates and more serious toxicity develops. Formic acid is directly toxic to the retina, and therefore, visual manifestations of methanol poisoning tend to develop rapidly (91). These manifestations include central scotoma, blurred vision, decreased visual acuity, photophobia, and progression to complete blindness. Examination reveals decreased papillary response to light and visual field defects. Later on, the patient develops fixed dilated pupils, hyperemia of the optic disc, papilledema, and optic atrophy (91,92). The CNS manifestations include headache, vertigo, delirium, restlessness, and confusion. These may progress to seizures, coma, and death in severe methanol intoxication. The minimal lethal doses of methanol are not well established, but it is commonly estimated at 15 mL (76,93). In 10% to 20% of cases, hemorrhagic and nonhemorrhagic necrosis of the putamen can occur (94,95). Permanent blindness and parkinsonism are common sequelae among survivors (96). Indeed, acute Parkinson's syndrome was reported in several patients with severe methanol poisoning and was thought to result from acute hemorrhagic necrosis of the basal ganglia (96–98). Lastly, methanol poisoning commonly result in significant gastrointestinal manifestations such as nausea, vomiting, diarrhea, and abdominal pain (probably as a result of gastritis and/or pancreatitis).

TABLE 36.10 Clinical and Laboratory Manifestations of Methanol Intoxication

Symptoms	Physical Findings	Laboratory Findings
First stage, <6 h • Mild and transient • Inebriation and drowsiness	Nonspecific	• May have high methanol level • Osmolal gap (31 mOsm/100 mg/dL)
Second stage • Asymptomatic • Blurred vision	Nonspecific	• May have high methanol level • Osmolal gap (31 mOsm/100 mg/dL)
Third stage, 6–30 h • Vertigo • Abdominal pain • Vomiting • Restlessness • Dyspnea • Blurred vision, blindness • Seizures, opisthotonus • Coma, death	• ± Kussmaul respiration • Papilledema, hyperemia of discs	• Metabolic acidosis • High anion gap • High formate levels • High lactate levels • Increased serum amylase • Increased mean corpuscular volume

Laboratory findings include increased serum amylase value, high anion gap metabolic acidosis, and elevated serum formate and lactate levels. The increased lactate values are, as in the case of ethylene glycol intoxication, most likely the result of both an increased nicotinamide adenine dinucleotide (NADH/NAD) ratio and a reduction in tissue perfusion. A high osmolal gap may be also apparent. Methanol contributes 31 mOsm/kg for each 100 mg/dL; therefore, a sizable osmolal gap is more likely to be present in the initial stages of the intoxication before the alcohol is metabolized. Other abnormal laboratory tests include an increased erythrocyte mean corpuscular volume attributed to a toxic effect of formaldehyde on cellular ion transport.

The quantity of ingested methanol that is required to cause serious morbidity and mortality is highly variable. While some patients may develop severe complications following the ingestion of a few milliliters of methanol, others survive the ingestion of several hundred milliliters. In addition, the serum concentration of methanol does not correlate well with the severity of the clinical picture or with prognosis (88,89). However, there are a number of findings that indicate poor prognosis (76,99). These include dyspnea and Kussmaul's respiration, which result from severe metabolic acidosis. Moreover, blindness, seizures, coma, elevated formic acid level, bradycardia, and hypotension also indicate poor prognosis (97,98). Respiratory failure is the most common cause of death in methanol poisoning. Untreated methanol poisoning is associated with death in 28% and visual deficits or blindness in 30% in survivors (78).

Laboratory Diagnosis of Methanol Intoxication

Measurements of plasma or serum methanol concentration using colorimetric or enzymatic assays can provide confirmation of toxic exposure to methanol. Unfortunately, these quantitative assays for methanol are not available in most hospitals. Even when these are available, results must be interpreted with caution. Plasma osmolality increases in proportion to the concentration of methanol or ethylene glycol, and its measurement provides a clue to ingestion of these agents if the result is abnormally high. The serum osmole gap provides a simple screening method of checking for increased osmolality that is not

explained by other factors. An increased serum osmole gap in conjunction with a normal serum anion gap and absence of metabolic acidosis is frequently seen early after ingestion of methanol or ethylene glycol, before significant metabolism of methanol to formate or ethylene glycol to glycolate. However, as methanol and ethylene glycol are metabolized, their plasma concentrations decrease, and thus, their contribution to plasma osmolality and the osmolar gap also decrease (100,101). Consequently, if the patient presents after most of these alcohols have been metabolized, the serum osmolar gap may well have returned to normal despite the presence of lethal concentrations of their toxic metabolites (**FIGURE 36.6**). Nonetheless, metabolic acidosis develops, and the anion gap progressively increases, signifying accumulation of the toxic metabolites. The metabolic acidosis of methanol and ethylene glycol poisoning is often very severe with dangerously low blood pH as well as extremely high serum anion gap. Blood lactate levels are occasionally increased in both methanol and ethylene glycol poisoning. This may be due to use of NAD+ and excess accumulation of NADH from the metabolism of methanol or ethylene glycol which raises the NADH to NAD+ ratio, leading to increased transformation of pyruvate to lactate in order to replenish NAD+ (102). Other factors may also contribute to lactic acidosis including shock, hypoxia, and seizures. In methanol intoxication, plasma formate levels correlate with blood pH and serum anion gap (89,100,102). Other laboratory abnormalities that can be seen include hypocalcemia, increased serum amylase, and thrombocytopenia.

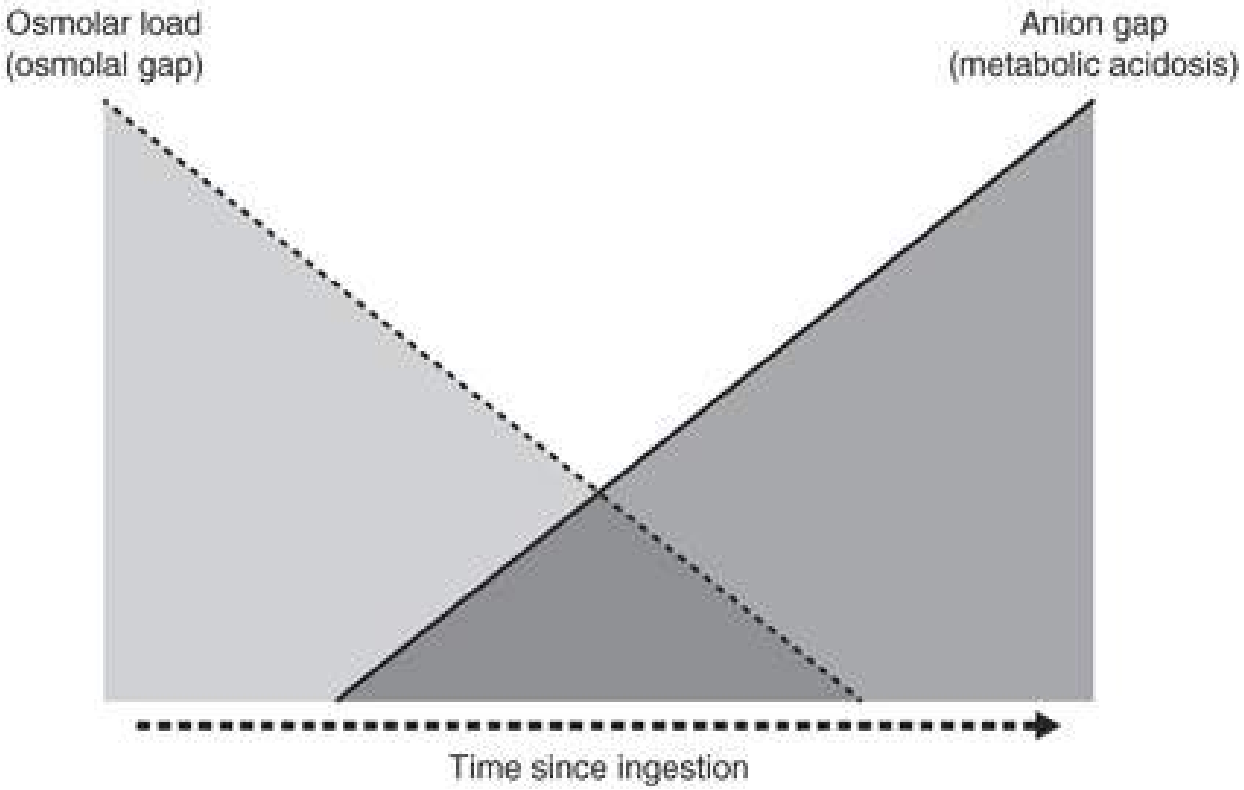

FIGURE 36.6 Schematic demonstrating the relationship between osmolal gap and anion gap in toxic alcohol poisoning. [Reproduced with permission from Mycyk MB, Aks SE. A visual schematic for clarifying the temporal relationship between the anion and osmol gaps in toxic alcohol poisoning. *Am J Emerg Med* 2003;21(4):333–335.]

Treatment

Supportive care should be directed at stabilizing the airways and correcting ventilatory and circulatory disorders. Concomitantly, other interventions should be instituted with the aim to, first, correct metabolic acidosis; second, prevent other serious complications by limiting the accumulation of the toxic

metabolites of methanol; and third, removal of methanol and its byproducts such as formic acid. Metabolic acidosis should be treated with intravenous (IV) infusion of sodium bicarbonate. Seizures are managed primarily with parenteral benzodiazepines. Gastrointestinal drainage can be attempted but is usually ineffective because of the rapid absorption of methanol (88,90,103,104). Folic acid administered as 50 mg IV every 4 hours for five doses then once daily may be helpful as it has been shown to increase the metabolism of formic acid to carbon dioxide and water (87,105). As with chronic ethanol use, routine administration of thiamine to patients with known or suspected toxic alcohol ingestion may be justified (76).

In addition to the aforementioned supportive therapy, aggressive treatment must be started promptly when there is a reasonable suspicion of significant methanol intoxication. The prompt administration of inhibitors of alcohol dehydrogenase enzyme such as ethanol or fomepizole is very effective in preventing the development of metabolic acidosis by markedly decreasing the oxidative metabolism of methanol (87,90,106). Fomepizole was approved in the United States for the treatment of ethylene glycol poisoning in 1997 and in 2000 for methanol toxicity. Indications for starting IV ethanol or fomepizole administration include (a) documented recent history of ingestion of more than 0.4 mL/kg body weight of methanol; (b) a serum methanol level greater than 6 mmol/L (20 mg/dL); (c) osmolar gap greater than 10 mOsm/kg H_2O; and (d) history or strong clinical suspicion of methanol poisoning and at least two of the following findings: arterial pH <7.3, a serum bicarbonate level <20 mEq/L, or an osmolar gap >10 mOsm/kg H_2O (88,90,97) (**TABLE 36.11**). Ethanol administration, both oral and IV, has been used for years as an antidote for both methanol and ethylene glycol poisoning. The basis for ethanol therapy is that both alcohol dehydrogenase and aldehyde dehydrogenase, along with nicotinamide cofactors are involved in the metabolism of both ethanol and methanol. In this reaction, ethanol is converted to acetaldehyde then to acetic acid, while methanol is converted to formaldehyde then to formic acid. Acetaldehyde is less toxic than formaldehyde, and acetic acid is essentially nontoxic, while formic acid has substantial toxicity (76). The two alcohols compete for the active sites on these two enzymes. However, the affinity of alcohol dehydrogenase for ethanol is far greater than for methanol or ethylene glycol. Thus, in presence of ethanol plus either methanol or ethylene glycol, there preferentially metabolizes ethanol and impedes that of methanol of ethylene glycol allowing time for these alcohols to be slowly excreted by the lungs and kidneys or to be slowly metabolized (107). For ethanol, a serum or blood alcohol concentration in the range of 100 to 150 mg/dL (22 to 33 mmol/L) is recommended in order to fully inhibit alcohol dehydrogenase (76). However, fomepizole, which is also a competitive inhibitor of alcohol dehydrogenase, has several advantages over ethanol and is now the preferred antidote for methanol poisoning (76,106). The doses of ethanol or of fomepizole used are similar to those recommended for ethylene glycol poisoning (90). **TABLE 36.12** outlines the various dosing regimens for fomepizole before, during, and after the initiation of HD in patients with both methanol and ethylene glycol poisoning (90,104,108).

TABLE 36.11 Indications for Use of Fomepizole or Ethanol in Methanol Poisoning

1. Documented recent history of ingestion of toxic amounts of methanol and an osmolar gap of >10 mOsm/L
2. Strong clinical suspicion of methanol poisoning and at least two of the following criteria:
   A. Arterial pH <7.3
   B. Serum bicarbonate <20 mEq/L
   C. Osmolal gap >10 mOsm/kg
3. Plasma methanol concentration ≥6.2 mmol/L (20 mg/dL)

TABLE 36.12 Fomepizole Administration for Treatment of Methanol or Ethylene Glycol Poisoning[a]

- Initiating dosing if patient is not on hemodialysis:
  - Give a loading dose of 15 mg/kg IV over 30 min
  - Give 10 mg/kg IV over 30 min every 12 h for four doses and then
  - Give 15 mg/kg IV over 30 min every 12 h until (a) the plasma toxin level is undetectable or (b) the plasma toxin level is <20 mg/dL, the arterial blood pH is within normal limits, and the patient is asymptomatic.
- On initiation of hemodialysis:
  - If <6 h have elapsed since the last dose, skip the next scheduled dose.
  - If >6 h have elapsed since the last dose, give the next scheduled dose (15 mg/kg) immediately.
- During ongoing hemodialysis:
  - Give 15 mg/kg IV over 30 min every 4 h.
- At time of stopping hemodialysis:
  - If <1 h has elapsed since the last dose, do not give a dose at the end of hemodialysis.
  - If 1–3 h have elapsed since the last dose, give a half-dose (7.5 mg/kg) at the end of hemodialysis.
  - If >3 h have elapsed since the last dose, give the next scheduled dose (15 mg/kg).
- Postdialysis dosing:
  - Beginning 12 h after the last dose, give 15 mg/kg IV over 30 min every 12 h until plasma toxin level is <20 mg/dL.

[a]Toxin level refers to methanol or ethylene glycol plasma concentration.

Palo Alto, CA: Jazz Pharmaceuticals, 2006.

Unfortunately, ethanol or fomepizole does not completely prevent the formation of the methanol or ethylene glycol toxic metabolites. However, since these alcohols and their toxic metabolites are small molecules, they are readily dialyzable. Intermittent HD is the most effective means of removal of both methanol and formate with clearance rates of 125 to 215 and 203 mL/min, respectively (90,97,98). However, continuous modalities can be used as alternative therapeutic measures when conventional HD cannot be performed (87). HP using activated charcoal is ineffective.

HD can be critically important in patients with a significant delay between the time of ingestion and the time of administration of either ethanol or fomepizole, since significant amounts of formate or glycolate have already accumulated. The EXTRIP workgroup developed evidence-based consensus recommendations for ECTR indications in the management of methanol poisoning (**TABLE 36.13**) (87).

HD should be performed with a bicarbonate bath because the alkali requirement may be massive due to the presence of severe metabolic acidosis associated with the intoxication (67). Methanol redistributes after discontinuation of the HD procedure and thus may result in rebound increase in methanol levels which usually occurs within the 12- to 36-hour period after stopping HD. The same is true for formate necessitating prolonged HD as a therapeutic measure (109). Also, after HD, close monitoring of acid–base balance, osmolar gap, and electrolytes should be done every 2 to 4 hours for 12 to 36 hours during which fomepizole or ethanol therapy should be continued because rebound is unpredictable. Hypophosphatemia may occur in those patients who require prolonged and intensive dialysis sessions, especially in individuals who are normophosphatemic to begin with. As previously discussed, the addition of sodium phosphate salts to the dialysate (1.3 mmol/L of phosphorus in the dialysate) has been used successfully to prevent hypophosphatemia in such patients. HD must be continued until the serum methanol level is either undetectable or less than 25 mg/dL, there is no significant metabolic acidosis, and the osmolal gap becomes normal (76,88,90,97). The addition of ethanol to the dialysate has been advocated in patients with methanol poisoning in an attempt to maintain stable levels of ethanol during dialysis (110–112). Because of the possibility of intracerebral hemorrhage in methanol poisoning, dialysis should be performed with little or no anticoagulation (113).

TABLE 36.13 Role of Extracorporeal Treatment in the Treatment of a Patient with Methanol Poisoning

We recommend ECTR is initiated in the following circumstances:

1. Severe methanol poisoning (grade 1D), including any of:
   a. Coma (grade 1D)
   b. Seizures (grade 1D)
   c. New vision deficits (grade 1D)
   d. Metabolic acidosis from methanol poisoning
      i. Blood pH ≤7.15 (grade 1D)
      ii. Persistent metabolic acidosis despite adequate supportive measures and antidotes (grade 1D)
   e. Serum anion gap >24 mmol/L (grade 1D); calculated by serum $[Na^+] - [Cl^-] - [HCO_3^-]$
2. Serum methanol concentration
   a. >700 mg/L or 21.8 mmol/L in the context of fomepizole therapy (grade 1D)
   b. >600 mg/L or 18.7 mmol/L in the context of ethanol treatment (grade 1D)
   c. >500 mg/L or 15.6 mmol/L in the absence of an ADH blocker (grade 1D)
   d. In the absence of a methanol concentration, the osmolal/osmolar gap may be informative (grade 1D)
3. In context of impaired kidney function (grade 1D)

To optimize the outcomes from ECTR, we recommend:

4. Intermittent hemodialysis is the modality of choice in methanol poisoning (grade 1D). Continuous modalities are acceptable alternatives if intermittent hemodialysis is not available (grade 1D).
5. ADH inhibitors are to be continued during ECTR for methanol poisoning (grade 1D) as well as folic acid.
6. ECTR can be terminated when the methanol concentration is <200 mg/L or 6.2 mmol/L and a clinical improvement is observed (grade 1D).

ECTR, extracorporeal treatment; ADH, alcohol dehydrogenase.

ETHYLENE GLYCOL POISONING

Ethylene glycol (EG) poisoning may occur either as isolated single cases or as epidemics (114). The majority of clusters of EG poisoning resulted from preparing illicit beverages using EG to fortify or in place of ethanol. Cases of EG intoxication have also occurred because of contaminated water systems (115). The TESS data for the year 2005 indicate a total of 5,469 reported toxic exposures to EG resulting in 16 deaths and 176 life-threatening poisonings (116). In 2007, poison centers in the United States received reports of 5,731 possible EG exposures (117). However, because of underreporting, these data likely underestimate the total number of cases. Most (84%) of the poisonings were unintentional. More recently, a study reported that during the years 2000 to 2013, there were more than 85,000 EG exposures (82). Most of the exposures were acute and again were primarily due to unintentional exposures to windshield wiper fluid and other automotive products with 25% of these occurring among children younger than 12 years old (2). Adults are typically exposed when they ingest EG as a cheap substitute for ethanol or in suicidal attempts. EG, also referred to as *sweet killer*, is an organic solvent commonly found in antifreeze preparations, deicers, coolants, brake and hydraulic fluids, and household cleaners. It is a sweet-tasting, viscous, colorless liquid with a molecular formula of $C_2H_6O_2$ and an MW of 62 Da (88,118). EG ingestion, like methanol, can also result in life-threatening poisoning. While ingestion is by far the most common route of poisoning, a recent case of transcutaneous diethylene glycol poisoning with severe AKI was reported (119).

Pharmacokinetics

EG is an alcohol that is rapidly absorbed from the gastrointestinal tract with peak serum concentrations 1 to 4 hours after ingestion. Being highly water-soluble and nonprotein-bound, it diffuses promptly through the total body water; its Vd is approximately 0.5 to 0.8 L/kg (120). The metabolism of EG is more complex than methanol. The liver metabolizes 80% of the absorbed EG in a stepwise NAD-dependent fashion (108,121,122). Alcohol dehydrogenase, the first enzyme in the pathway, oxidizes EG to glycoaldehyde and is competitively inhibited by both ethanol and fomepizole (**FIGURES 36.4** and **36.7**). Glycoaldehyde is then rapidly converted to glycolic acid. The next step involves the conversion of glycolic acid to glyoxylic acid. The rate-limiting step in the metabolism of EG is the conversion of glycolic acid to glyoxylic acid, which results in the accumulation of glycolic acid in massive poisonings. Glycolic acid, with contribution from lactic acid, causes severe metabolic acidosis (121,122). Finally, glyoxylic acid is converted further to oxalic acid which combines with ionized calcium in plasma to form calcium oxalate and precipitate as calcium oxalate crystals in various tissues including the kidney, brain, meninges, blood vessel walls, liver, spleen, pericardium, and cardiac conduction system. These crystals may also appear in the urine (123). Glycolic, glyoxylic, and oxalic acid all dissociate under physiologic conditions, releasing hydrogen ions from their carboxylic acid moieties (76). Minor pathways involving thiamine and pyridoxine as cofactors can also bring about the conversion of glyoxylic acid to glycine and benzoic acid. However, these pathways are clinically insignificant, and there are no data to support the use of these cofactors in the treatment of EG intoxication (108). The average elimination half-life of EG is approximately 3 hours. Ethanol, at serum concentrations of 22 to 44 mmol/L (100 to 200 mg/dL), can effectively inhibit alcohol dehydrogenase and prolong the half-life of EG to almost 18 hours (124). Fomepizole, at serum concentrations greater than 9.8 mmol/L (0.08 mg/dL), can also prolong the half-life

of EG to 20 hours (125,126).

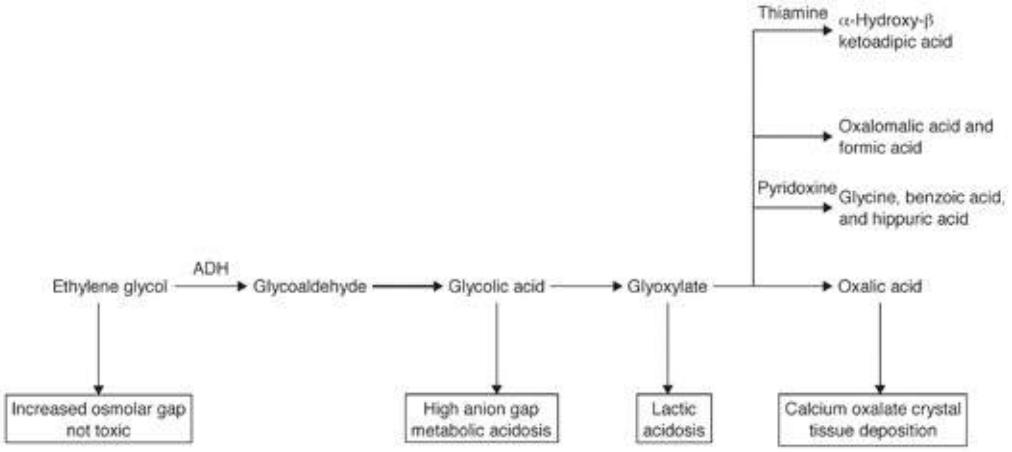

FIGURE 36.7 The oxidative pathway of ethylene glycol metabolism and its clinical effects.

Clinical and Pathologic Effects of Ethylene Glycol

Ingestion of EG leads to a metabolic acidosis and severe damage to the CNS, heart, lungs, and kidneys. EG itself is relatively harmless and eliminated by the kidney. The mechanism of toxicity of EG poisoning is primarily due to its conversion to four toxic metabolites (**FIGURE 36.7**). These metabolites are cell toxins that cause CNS depression and cardiopulmonary and kidney disease. The clinical course of EG develops in three different stages, but overlap is frequently seen (**TABLE 36.14**) (67,127). The stage and its severity depend on the amount of EG ingested, the possible coingestion of ethanol or other chemicals, and the timing of medical interventions (88,97,126). The presence of severe acidosis, hyperkalemia, seizures, and coma on admission indicates severe intoxication (128).

TABLE 36.14 Stages of Ethylene Glycol Poisoning

Stage	Main Manifestations	Signs, Symptoms, and Outcome	Treatment
Stage 1: (1–12 h after ingestion)	CNS	• CNS depression, inebriation, ataxia, slurred speech, convulsions, coma, cerebral edema • Anion gap metabolic acidosis • Tachypnea • Hypocalcemia, calcium oxaluria, hematuria, proteinuria, leukocytosis	• Supportive • Fomepizole • Ethanol
Stage 2: (12–24 h after ingestion)	Cardiopulmonary	• Tachycardia, hypotension • Cardiomegaly • Tachypnea, cyanosis, pulmonary edema • Death most common in this phase • High anion metabolic acidosis • High osmolar gap • Hypocalcemia, hematuria, proteinuria, leukocytosis • Calcium oxalate crystals in urinary sediment	• Supportive • Fomepizole • Ethanol • Hemodialysis
Stage 3: (>24 h after ingestion)	Renal	• Flank pain • Acute kidney injury, anuria • Death	• Hemodialysis

CNS, central nervous system.

Stage 1 is predominantly neurologic and develops as a result of CNS involvement. The symptoms occur shortly after ingestion and may last for 12 hours. Initially, the patient appears intoxicated, sometimes with sustained nausea and vomiting, but without the odor of ethanol (if no ethanol has been ingested concomitantly). These symptoms are probably related to the direct effects of EG on the CNS.

This is followed by hyporeflexia, coma, and focal or generalized seizures, often accompanied by ophthalmoplegia, nystagmus, and papilledema. These manifestations are most likely to reach their peak between 6 and 12 hours after ingestion and have been attributed to the toxic effects of the glycoaldehyde metabolites. Cerebral edema and diffuse petechiae are found in patients who die during this stage; focal deposition of calcium oxalate crystals is also seen. A lesser recognized devastating complication of EG is acute Parkinson's syndrome. In one such case, it was thought to result from acute hemorrhagic necrosis of the basal ganglia (98). Moreover, EG intoxication during pregnancy may mimic eclampsia (129).

During stage 2, cardiopulmonary manifestations develop usually 12 to 24 hours after ingestion. These consist of tachycardia and mild hypertension but usually progress to pulmonary edema and cardiovascular collapse in massive poisoning. These manifestations result from deposition of calcium oxalate crystals in the vessels, myocardium, and lung parenchyma. In severe cases, multiorgan failure develops, and the patient succumbs to the poisoning. It is important to note that most lethal cases occur during this stage.

Stage 3 is predominantly renal and develops in patients who survive for more than 24 hours after ingestion of EG. These patients develop AKI, with oliguria, flank pain, and the presence of calcium oxalate crystals in the urine. Calcium oxalate precipitates in the renal tubules is thought to be the cause of EG-induced AKI, but other studies suggested involvement of other metabolites in causing acute tubular necrosis (130). The mechanisms responsible for the cardiopulmonary and renal manifestations are not entirely clear but are likely due to the toxic effects of the metabolites of EG. Prompt intervention designed at removal of EG and its more toxic metabolites may lead to complete recovery of CNS, cardiopulmonary, and renal manifestations.

Diagnosis

The diagnosis of EG poisoning should be considered in every intoxicated patient without the odor of ethanol. Moreover, the presence of severe metabolic acidosis, large anion gap and a large osmolal gap (greater than 10 mOsm/kg), hypocalcemia, neurologic manifestations, and calcium oxalate crystals in the urine are virtually diagnostic of EG poisoning. Metabolic acidosis develops as a result of the production of glycolic acid and other acidic metabolites secondary to EG breakdown. The plasma anion gap, representing unmeasured anions, is elevated as a result of the accumulation of the anions of the acid metabolites. In addition, because EG, like other alcohols, is an osmotically active compound, it contributes to the high osmolar gap. Therefore, the presence of an osmolal gap is supportive of the diagnosis of EG poisoning. Osmolal gap is the difference between the measured serum osmolality as determined by freezing point depression and the osmolality calculated from the serum levels of sodium, glucose, and urea nitrogen (**EQUATION 36.2**).

$$\text{Calculated serum osmolality (mOsm/kg)} = 2 \times \text{Na (mEq/L)} + \text{Glucose (mg/dL)}/18 + \text{BUN (mg/dL)}/2.8 \quad (36.2)$$

The normal osmolal gap should be between 10 and 12 mOsm/kg. Each 100 mg/dL of EG will produce an osmolal gap of 16 mOsm/kg. An elevated osmolar gap is helpful in several ways. First, it suggests the presence of EG and/or other alcohols in the serum. Second, it helps in estimating the serum concentration of any of these alcohols. Finally, serial measurement is useful in monitoring changes in EG level during removal by HD. However, a normal osmolal gap does not exclude EG intoxication as mentioned earlier. This is because only the parent compound is osmotically active, but its half-life is

about 3 hours; therefore, delayed assessment after ingestion may fail to detect an osmolal gap despite the presence of toxic levels of metabolites. However, under these circumstances, the presence of the acid metabolites will still engender metabolic acidosis and an elevated anion gap (**FIGURE 36.6**).

Three types of crystals can be seen in the urine of patients with EG poisoning. Calcium oxalate crystals are commonly detected in the urine of these patients and are highly suggestive of EG poisoning, particularly in the presence of hypocalcemia. This is seen in nearly 50% of the patients with EG intoxication. Urinary calcium oxalate crystals usually appear after a latent period of 4 to 8 hours; consequently, repeat urinalysis should be carried out after this period (131). These crystals can have the classic appearance of "envelopes" if they consist of calcium oxalate dihydrate or more commonly the appearance of needles or prisms if they consist of calcium oxalate monohydrate (**FIGURE 36.8**) (132). Hippuric acid crystals have also been reported in patients with EG poisoning (133,134). The absence of calcium oxalate crystals in the urine does not exclude EG poisoning. In the rare situation where a kidney biopsy is done, calcium oxalate crystal deposition within the renal tubules and interstitial tissue can be seen even in the absence of crystalluria. Occasionally, urine of patients with EG poisoning fluoresces under Wood's lamp and was thought to be helpful in the diagnosis. This is because antifreeze, one of the most common sources for EG poisoning, contains sodium fluorescein, a marker geared for the detection of radiator leaks in motor vehicles (135). However, more careful studies have shown that determination of urine fluorescence is not a reliable screening tool for suspected antifreeze ingestion (136,137). Finally, the most conclusive method of diagnosis is direct measurement of serum or urine EG concentrations by gas chromatography. Unfortunately, this method is not available in most hospital laboratories, and measurement by referral laboratories may delay the diagnosis.

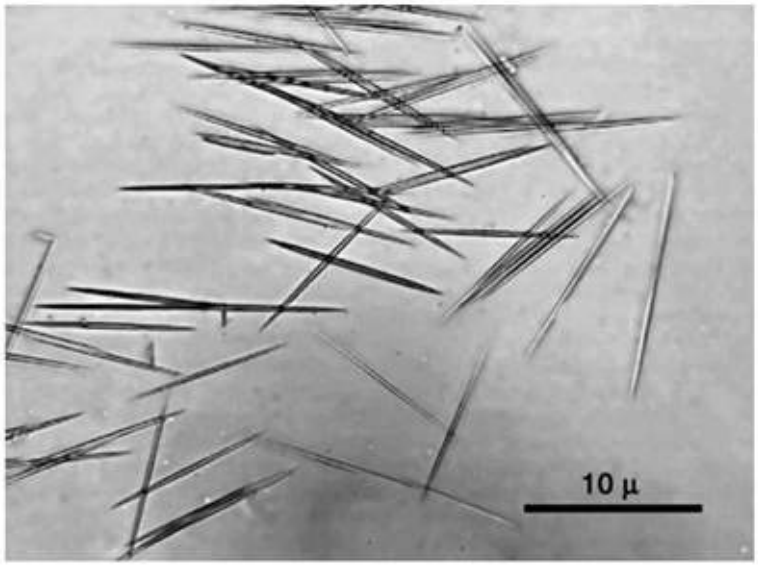

FIGURE 36.8 Urine sediment from a patient with ethylene glycol poisoning showing needle-shaped calcium oxalate monohydrate crystals. (From Marino PL. *Marino's the ICU Book*. 4th ed. Philadelphia, PA: Wolters Kluwer Health, 2014.)

Treatment

Much of what has been discussed previously under treatment of methanol poisoning is applicable to EG poisoning. Again, treatment depends on the severity of the poisoning, depending on the dose ingested, time from ingestion to presentation, as well as on whether there was concomitant ethanol ingestion. Supportive measures such as securing the airway, breathing, and circulation are critically important. Due to the rapid

absorption of EG from the gastrointestinal tract, gastric lavage may be beneficial but only within the first hour after ingestion, before toxic symptoms develop. Moreover, correction of severe metabolic acidosis with IV sodium bicarbonate therapy should be attempted. Aggressive treatment of acidosis and induction of an alkaline diuresis increase the renal elimination of glycolate and decrease the likelihood of AKI (138). Seizures, if present, can be treated with benzodiazepines and by correction of the severe hypocalcemia with 10 to 20 mL of 10% calcium gluconate given by slow IV infusion.

In addition to supportive care in all cases, administration of one of the two specific antidotes to delay further production of EG toxic metabolites is of paramount importance. Either ethanol or fomepizole can be used for inhibition of hepatic conversion of the parent compound by alcohol and aldehyde dehydrogenases, but they should not be used together. The indications for their use are listed in **TABLE 36.15**. Fomepizole, a competitive inhibitor of alcohol dehydrogenase, was approved for the treatment of EG poisoning by the U.S. Food and Drug Administration (FDA) in 1997. The Methylpyrazole For Toxic Alcohols (META) study group documented that fomepizole, if administered early in the course of intoxication, can prevent kidney injury (126). Brent et al. (126) conducted the only prospective clinical trial of fomepizole use in the treatment of EG poisoning. The drug was given intravenously at a loading dose of 15 mg/kg, followed by 10 mg/kg every 12 hours for four doses. Subsequently, it was given at as 15 mg/kg every 12 hours until the plasma EG concentration was less than 3.2 mmol/L (20 mg/dL). The mean time from ingestion to treatment was 11.4 hours. Seventeen of the 19 patients underwent HD, and 18 patients survived; 1 died of cardiogenic shock. Nine patients had normal renal function on presentation. The criteria for administration of fomepizole therapy are identical to those of methanol therapy (**TABLE 36.12**). As can be seen, because fomepizole is dialyzable, it is recommended to increase the frequency of its administration to every 4 hours during HD. Moreover, fomepizole should be given every 12 hours after the completion of dialysis until the EG level is less than 3.2 mmol/L (20 mg/dL) (108). Adverse effects are minimal and include bradycardia, seizure, dizziness, headache, and nausea (139).

TABLE 36.15 Indications for Use of Fomepizole or Ethanol in Ethylene

Glycol Poisoning

1. Documented recent history of ethylene glycol ingestion
2. Strong clinical suspicion of ethylene glycol poisoning and at least two of the following criteria:
   A. Arterial pH <7.3
   B. Serum bicarbonate <20 mEq/L
   C. Anion gap >16 mmol/L
   D. Osmolal gap >10 mOsm/kg
3. Plasma ethylene glycol concentration >3.2 mmol/L (20 mg/dL)
4. Presence of urinary calcium oxalate crystals
5. Unexplained metabolic acidosis with anion gap >16 mmol/L and osmolal gap >10 mOsm/kg

Data from Barceloux DG, Krenzelok EP, Olson K, et al. The American Academy of Clinical Toxicology practice guidelines in the treatment of ethylene glycol poisoning. *Clin Toxicol* 1999;37:537–560.

Ethanol is also an effective antidote because it is a substrate for alcohol dehydrogenase and blocks the conversion of EG to its toxic metabolites. Serum ethanol concentration of 100 to 200 mg/dL (22 to 44 mmol/L) can saturate receptor sites of alcohol dehydrogenase enzyme and thus inhibit the metabolism of EG (124). Ethanol can be administered by any of three different routes: (a) orally or through a nasogastric tube at a loading dose of 0.8 to 1.0 mL/kg of 95% ethanol solution, followed by a maintenance of 0.15 mL/kg hourly, diluted to a 20% solution; (b) intravenously as a 10% solution with a loading dose of 7.6 to

10 mg/kg, followed by maintenance infusion of 1 to 2 mg/kg/h, titrated to achieve the desired serum concentrations; and (c) ethanol may be added to the dialysate at a concentration of 100 mg/dL using 95% ethanol (140). Because the pharmacokinetics of ethanol depend on a multitude of factors such as age, sex, chronic use of alcohol, and conditions that prolong gastric emptying, serum levels of ethanol need to be monitored frequently and the dose should be modified to achieve and maintain serum levels of 100 to 150 mg/dL (22 to 44 mmol/L). Ethanol is commonly administered until EG can no longer be detected in the serum or until the patient is asymptomatic with a normal arterial pH and a serum EG concentration of less than 20 mg/dL (3.2 mmol/L).

Ethanol is readily available and inexpensive compared with the availability and cost of fomepizole. However, ethanol therapy can be associated with intoxication with CNS depression especially in patients who have ingested other CNS depressants. Moreover, it may cause acute pancreatitis and also hypoglycemia has been noted when used in pediatric and malnourished patients (106). Consequently, patients should be monitored closely and, if necessary, treated appropriately. The lack of serious adverse effects appears to favor fomepizole over ethanol in the treatment of EG poisoning (106). Moreover, fomepizole has a longer half-life which negates the need for continuous infusion as with ethanol. Finally, it should be noted that fomepizole and ethanol can only inhibit the breakdown of EG. The elimination of EG from the body, however, still requires either adequate renal function or effective extracorporeal measures. Dialysis is also effective in rapid treatment of metabolic acidosis.

EG and its metabolites are effectively removed by HD but not by HP (85,122,141). Thus, HD has been routinely used to remove both the ingested parent compound as well as any toxic metabolites. Moreover, it should be used whenever patients with EG poisoning have deteriorating vital signs despite intensive supportive care, significant metabolic acidosis (arterial pH <7.3), and kidney disease or electrolyte abnormalities refractory to conventional therapy (67,108). It should also be used without delay in patients whom there has been significant delay between the time of ingestion and the initiation of either ethanol or fomepizole treatment, since during such time significant concentrations of glycolate have accumulated (76). A serum EG concentration greater than 50 mg/dL (11 mmol/L) was previously used as an indication for HD. However, this approach is no longer necessary as patients with such blood levels, and normal renal function, who are asymptomatic and with no metabolic acidosis have been adequately managed with fomepizole or ethanol alone (90,108,142–147). Fomepizole and ethanol, given before or during dialysis, are removed by HD and should be replaced appropriately. In patients who have received an IV loading dose of ethanol, the maintenance dose can be discontinued during dialysis if ethanol is added to the dialysate as previously described (140).

HD should be continued until serum EG is undetectable or until it is less than 20 mg/dL (3.2 mmol/L), the disappearance of acid–base and electrolyte abnormalities, and until signs of systemic toxicity disappear. In patients with severe intoxication, it cannot be overemphasized that prolonged and intensive dialysis is often needed. In normophosphatemic patients, such aggressive dialysis may engender hypophosphatemia. Phosphate-enriched dialysates containing 1.3 mmol/L phosphorus, prepared by the addition of sodium phosphate salts to sodium bicarbonate–containing “dialysate base concentrate,” have been used successfully to prevent such dialysis-induced hypophosphatemia (148,149). Hirsch et al. (150) have proposed a simple formula to estimate the required dialysis time, in hours, to reach a serum EG concentration of 5 mmol/L. Required dialysis time (hours) = [−V ln (5/A)]/0.06K, where V (liter) is the

Watson's estimate of total body water, A is the initial EG concentration in mmol/L, and K is 80% of the manufacturer's specified dialyzer urea clearance (mL/min) at the properly observed blood-flow rate (150).

Being slower, PD remains a less effective treatment option when HD is unavailable (97). CRRT such as hemofiltration has been used for treatment of EG poisoning and should be considered as an alternative modality in patients with circulatory instability (151).

ISOPROPANOL (ISOPROPYL ALCOHOL)

Isopropanol (MW = 60 Da), a clear, colorless liquid with a bitter taste and characteristic fruity odor, is used in the manufacture of several compounds including rubbing alcohol, acetone, and glycerin. It is present in high concentration in deicing products, solvents, cements, antifreezes, cosmetics, inks, and cleaning products. Isopropanol is readily absorbed from the gastrointestinal tract with a peak plasma concentration occurring within 30 minutes. It may also be absorbed by inhalation causing intoxication especially in small children (97,152). Isopropanol is metabolized by alcohol dehydrogenase to acetone, acetol and methylglyoxal, propylene glycol, acetate, and formate with conversion of these metabolites to glucose and other products of intermediary metabolism. The elimination of isopropanol is predominantly by the kidney and in part by the lung (152). It is, however, metabolized more slowly than ethanol, displaying an elimination half-life of 2.5 to 8 hours and a much more protracted half-life when coingested with ethanol (152). Approximately 80% of isopropanol is oxidized by alcohol dehydrogenase to acetone (**FIGURE 36.4**) (153).

Clinical Picture and Laboratory Data

In contrast to methanol and EG, the toxic effects of isopropanol appear to be mostly caused by the parent compound rather than by its metabolites, although acetone may contribute to toxicity. Therefore, no therapeutic attempts to slow its metabolism are needed (88,154). Because isopropanol is quickly absorbed, clinical signs of toxicity usually appear within 1 to 2 hours of exposure (154,155). Initially, the symptoms and signs of isopropanol intoxication may resemble those of ethanol intoxication: dizziness, incoordination, and confusion. However, these manifestations are more protracted, severe, and often progress to ataxia, coma, and death due to respiratory arrest. CNS depression is generally considered to be 2 to 2.5 times more severe compared to that produced by an equal amount of ethanol (97). Some patients may have a "fruity" odor due to the presence of acetone in the breath. The gastrointestinal manifestations, which include nausea, vomiting, abdominal pain, and hematemesis resulting from hemorrhagic gastritis, are frequent. Tachyarrhythmias and, in severe cases, shock and circulatory collapse may occur. Evidence of hepatocellular damage as well as of AKI, myoglobinuria, hypothermia, and hemolytic anemia has been reported (97,153).

Metabolic acidosis is rare because neither the parent compound nor its metabolites are organic acids (156). However, some degree of high anion gap metabolic acidosis may be seen in severe cases due to hypotension, tissue hypoperfusion, and lactic acidosis. Other laboratory tests reveal the presence of an elevated osmolal gap and a normal anion gap. The high osmolal gap results from the combination of two components: (a) isopropanol itself which contributes 17 mOsm/kg per 100 mg/dL and (b) acetone which contributes 18 mOsm/kg per 100 mg/dL. A high serum and urine acetone level in the absence of metabolic

acidosis, hyperglycemia, and glycosuria is strongly suggestive of the diagnosis (97,153). Diagnosis can be made by history, the characteristic smell, clinical presentation, high osmolar gap, ketonemia, and/or ketonuria. Direct measurement of isopropanol serum concentrations can be obtained, although this may not be readily available.

Treatment

Lethal doses of isopropanol have ranged from 150 to 240 mL (157). Hypotension is the strongest predictor of mortality (153). Death has been reported to take place in 45% of patients who suffered from both coma and hypotension. Coma by itself in the absence of hypotension was not associated with a high mortality (153). Severe intoxication along with a higher mortality is seen in patients with a serum isopropanol level in excess of 400 mg/dL (67 mmol/L).

Supportive therapy is essential as previously discussed with other alcohols with emphasis on respiratory and cardiovascular systems. Inhibition of alcohol dehydrogenase with ethanol is not indicated since acetone, the major isopropanol metabolite, is less toxic than the parent compound. Moreover, it may slow the metabolism of isopropanol and lead to continued toxicity. HD is indicated in patients with an isopropanol concentration of 400 mg/dL (67 mmol/L) or higher. It is also indicated in the presence of coma, hypotension, or kidney disease (97,153). However, it is prudent to perform HD in poorly arousable or comatose patients when isopropanol ingestion is highly suspected. Studies on the kinetics of isopropanol elimination by HD have shown that the procedure is highly efficient, given its low MW, the absence of protein binding, and the low Vd (97,154,155,158,159).

SALICYLATE POISONING

In 2014, the TESS data compiled by the AAPCC showed that analgesics were the most common cause of reported human poison exposures (2). Of the 2,142 fatalities due to pharmacologic agents, 946 were due to analgesics. Salicylate-containing compounds were responsible for 49 fatalities. Of these, aspirin (acetylsalicylic acid, MW = 180 Da) is the most commonly prescribed and available preparation. Salicylates can be found in several over-the-counter and prescribed products, which are available in several formulations including liquids, powder, capsules, enteric coated tablets, and suppositories. Poisoning may occur after ingestion of salicylate-containing single agent such as aspirin or when salicylates are present in combination with other toxic compounds (97,160).

The term *salicylates* refers to all forms of salicylate including acetylsalicylic acid (aspirin) and methyl salicylate. However, the most commonly encountered form in clinical practice is acetylsalicylic acid. All salicylates are almost completely absorbed from the gastrointestinal tract. Measurable levels can be obtained within 30 minutes of ingestion of therapeutic doses. However, absorption may be considerably delayed by the dose ingested, enteric coated formulation, variability in the rate of dissolution of different pharmaceutical preparations, and the presence of food in the stomach. Therefore, the onset of symptoms or the attainment of peak serum levels may be delayed for 12 hours or more after ingestion. Methyl salicylate (oil of wintergreen) can also cause intoxication through skin absorption, but this intoxicant is seldom used at the present time. Salicylate poisoning has been reported after accidental ingestion of traditional massage oil (161) and from teething gel (162).

After intestinal absorption, aspirin is initially hydrolyzed rapidly by plasma esterase to its active

metabolite salicylic acid that has a half-life of 15 to 20 minutes. Salicylic acid is then glycinated in the liver to salicyluric acid, a less toxic compound that is excreted by the kidneys. At therapeutic doses, salicylates are 90% protein-bound and only 10% of the parent compound is excreted unchanged (as salicylate) in the urine. However, in salicylate poisoning, several events occur which tend to aggravate the likelihood of toxicity. *First*, the protein-binding sites become saturated, and thereby, the ratio between the "free" to total serum salicylate levels increases. At concentrations of 80 mg/dL (5.8 mmol/L), up to 50% of salicylate is free (163,164). *Second*, the biotransformation of salicylic acid to salicyluric acid is retarded, that is, a fixed amount of salicylic acid is metabolized per unit of time regardless of the dose. This is largely due to glycine depletion as well as to the saturation of the hepatic metabolic pathways (165). This phenomenon results in a relatively higher proportion of the drug being present as salicylate, which is less efficiently excreted by the kidney than salicyluric acid. The combination of these two events engenders a greater and more prolonged toxicity. *Finally*, entry of unbound salicylate into the intracellular compartment and the CSF expands the apparent Vd from 20% at therapeutic serum levels to approximately 50% of the body weight leading to greater toxicity (163,164).

The ability of the kidneys to excrete salicylate and its metabolites is augmented by several factors including preserved glomerular filtration rate (GFR), high urine flow rates, and by an alkaline urine pH. Because this compound has an acidic pK_a, a urine pH higher than 7.0 can greatly enhance its renal excretion. In alkaline urine, salicylate and its metabolites cannot be reabsorbed by the renal tubules in their ionized forms. Entry of these compounds into cells is facilitated by acidosis and hindered by alkalosis, an observation highlighting the deleterious effect of salicylate-induced acidosis and emphasizing the need for prompt alkalinization (166).

Clinical Picture

Acute salicylate poisoning usually presents with tachypnea, hyperpnea, nausea, vomiting, abdominal pain, hyperpyrexia, diaphoresis, and tachycardia. Moreover, it may cause severe CNS symptoms including dizziness, ataxia, tinnitus, deafness, confusion, psychosis, stupor, seizures, and coma (160,167,168). These manifestations are more common in children since they predominantly have metabolic acidosis (169,170). On the other hand, chronic intoxication usually manifests as salicylism in the form of headaches, tinnitus, impaired auditory acuity, dizziness, and weakness progressing to nausea, vomiting, confusion, and hyperventilation. Severe seizures, deepening coma, and cardiovascular collapse are terminal events. Pulmonary edema, while uncommon, may also develop, particularly in patients older than 30 years of age and is considered to be the most common cause of morbidity in salicylate poisoning (171). Studies have confirmed that pulmonary edema in salicylate poisoning is noncardiogenic since the pulmonary wedge pressure in these patients is usually normal (172,173). This form of pulmonary edema is thought to result from increased pulmonary capillary permeability which results from the action of salicylate on inhibiting prostacyclin, platelet–vessel interaction as well as from cerebral edema (172–175).

Salicylates display a variety of toxic effects as a result of their interference with a number of metabolic processes (163). Prominent among these processes is uncoupling of oxidative phosphorylation, which accelerates oxygen utilization, heat generation, and CO_2 production (176). Salicylates in the CSF as well as acidemia directly stimulate the central respiratory center increasing the minute ventilation

(177). The uncoupling, along with direct stimulation of the respiratory center, accounts for the characteristic hyperventilation and, at least in part, for the metabolic acidosis observed, particularly among children (178). Other mechanisms include the inhibition of the tricarboxylic acid (TCA) cycle, inhibition of amino acid metabolism leading to aminoaciduria, and a negative nitrogen balance and catabolism of proteins and fats. Also, salicylates stimulate glucocorticoids and the release of epinephrine leading to glycolysis and gluconeogenesis. Finally, in therapeutic doses, salicylates reduce urate excretion but may increase uric acid excretion at toxic doses (163).

Diagnosis

Despite the frequency of salicylate intoxication, a relatively high percentage of affected patients remain undiagnosed. Even in acute poisoning, the history may be difficult to ascertain, and therefore, physicians often depend on high degree of suspicion and laboratory investigations. In this regard, salicylate poisoning should be suspected in individuals who present with hyperventilation, diaphoresis, tinnitus, and acid–base abnormalities. In addition, routine chemistries and arterial blood gases are usually helpful and should be obtained along with blood salicylate level.

Acid–base disturbances are very common manifestation of salicylate poisoning. The generation of these acid–base abnormalities usually occurs in two phases: an initial phase of acute respiratory alkalosis followed by a high anion gap metabolic acidosis phase. The metabolic acidosis is seen primarily in children less than 4 years old, while the acute respiratory alkalosis tends to predominate in adults, at least initially. However, mixed respiratory alkalosis and metabolic acidosis are frequently encountered in adults. The pathophysiologic basis for the acid–base disturbances is not fully understood. Salicylate directly stimulates the respiratory center leading to hyperventilation. Salicylate-induced metabolic acidosis is clearly multifactorial. The low P_{CO_2} increases intracellular pH which in turn activates phosphofructokinase-1 and accelerates glycolysis. The end result is production of lactic acid. Moreover, the inhibition of TCA cycle enzymes leads to further increase in lactic acid production. Finally, it is also possible that the ability of the liver to metabolize lactate is decreased in salicylate poisoning (179). Thus, metabolic acidosis in salicylate poisoning is primarily due to lactic acid production. Other organic acids that contribute to metabolic acidosis include ketoacids, which result from increased lipid and protein metabolism. It must be emphasized that salicylic acid contributes only a small portion to the increased anion gap metabolic acidosis (167,168,170,180). Therefore, the high anion gap in salicylate poisoning is due to many factors including lactic acid, ketoacids, salicylates, and other organic acids (180). The degree of acidosis is a major determinant of the severity of neurotoxicity and patient survival. Given that salicylic acid is a weak acid, >99% will be ionized under physiologic pH and only a minute amount will exist in the unionized form. This unionized molecule can easily move across cellular barriers, including the blood–brain barrier and the epithelium of the renal tubule while the ionized form penetrates poorly. The concentration of the unionized form increases as the blood pH falls; thus, severe academia increases the penetration of unionized fraction into the brain cells. This causes an increase in the salicylate concentration in the CNS and an increase in the amount of salicylate reabsorbed from the renal collecting system. Thus, it is the unionized fraction that is responsible for the increased mortality in patients with salicylate poisoning. In rare cases, high serum salicylate levels have been reportedly associated with false increase in serum chloride level which in turn falsely lowers the anion gap. In one such report, two

cases of moderate to severe salicylate poisoning had a normal anion gap and apparent hyperchloremia (181). Other reports also reported an even negative anion gap in salicylate poisoning (182,183). This may occur with some ion-selective electrodes but not others and may be due to loss of selectivity over the operational life of the chloride electrode as well as competition between salicylate and chloride ions to bind to albumin (184).

Apart from metabolic acidosis, a number of other abnormalities can be observed in patients with salicylate poisoning. Severe hypouricemia may develop as a result of inhibition of renal tubular urate reabsorption by the high salicylate levels. Also, hypokalemia may be seen and is usually due to vomiting and potassium losses in the urine, which can be aggravated by distal tubular alkalization from respiratory alkalosis. Hypoglycemia is rare, but hyperglycemia may develop in almost 20% of cases (185). Finally, prolongation of prothrombin time, a positive ferric chloride test, and a positive Phenistix test may also be seen (186,187). The Phenistix reagent strips are impregnated with ferric and magnesium salts which produce a purple color in the presence of salicylate concentration greater than 70 mg/dL (5 mmol/L). A positive test essentially confirms the presence of salicylate in patients suspected of having salicylate intoxication (186,188).

Management of Salicylate Poisoning

The severity of salicylate poisoning can be determined by one or more of the following parameters. *First*, acute ingestion of less than 150 mg/kg is not usually associated with serious consequences. On the other hand, with ingestion of more than 150 mg/kg, toxicity is likely to occur. Clinical toxicity is usually mild with ingestion of 150 to 300 mg/kg, moderate with 300 to 500 mg/kg, and severe if the amount ingested exceeds 500 mg/kg (189). Doses of 10 to 30 g of aspirin or of sodium salicylate may result in death, although patients who ingested much larger doses have also recovered. *Second*, severe clinical symptoms and signs such as severe CNS manifestations, pulmonary edema, or AKI also indicate severe toxicity. *Lastly*, it has been suggested that serum salicylate level exceeding 750 mg/L indicates severe poisoning, while levels between 500 and 700 mg/L are seen in moderate toxicity. However, symptoms of salicylism are usually present at much lower serum levels of 30 mg/dL (2.2 mmol/L). It is now believed that the serum salicylate levels may not correlate well with the severity of intoxication (190). This is particularly true in patients with chronic salicylate ingestion, those with AKI, those with acidosis, the presence of confounding factors, and the lack of knowledge of the precise time of ingestion. Moreover, one should not rely on a single blood salicylate level because of a possible delayed absorption. Therefore, the widely available nomogram that estimates the severity of intoxication from plots of salicylate levels at different times has not been predictably useful when sustained-release or enteric coated preparations have been consumed (191–193).

Supportive Care

Salicylate poisoning is a medical emergency. There is no specific antidote to treat salicylate intoxication. However, as discussed for all poisoned patients, the mainstay of therapy is supportive measures with particular attention to establishing an adequate airway. Intubation may be necessary in patients with severe tachypnea, but manual ventilation may be needed to maintain the blood pH at 7.5 to 7.55 to minimize the entry of salicylate into the CSF. Other important measures include gastric emptying should only be done for patients presenting within 1 hour of ingesting a large dose of salicylate. Moreover,

administration of IV fluids that contain glucose and electrolytes is critically important in order to correct volume, electrolyte, and acid–base abnormalities as well as hypoglycemia if present.

Elimination

The above maneuvers may be adequate for patients with moderate salicylate poisoning and serum levels less than 50 mg/dL (3.6 mmol/L). However, for patients with higher serum levels of salicylate, and those with more severe clinical presentation, especially when metabolic acidosis is present, measures designed to eliminate salicylates are indicated. These maneuvers include repeated administration of activated charcoal (97,194) and alkalinization of urine. Activated charcoal is effective in decreasing the gastrointestinal absorption of salicylates, although other studies cast doubt on its effectiveness (195–197). Administration of activated charcoal is recommended especially in patients who present within 1 hour following ingestion. Dargan et al. (198) suggested an initial oral bolus of 50 g in adults or 1 g/kg for children preferably within 1 hour of ingestion followed by additional doses at 2 to 6 hours if necessary.

Alkalinization of the urine is also effective in enhancing the excretion of salicylates. This is based on the notion that the unbound fraction of salicylate undergoes glomerular filtration, tubular secretion, and absorption. In an acid medium, salicylate is maximally nonionized and can be reabsorbed across the renal tubular cell membranes. Excretion, however, is greatly accelerated in presence of high urine flow rate and alkaline urine (pH greater than 7.5) (166). Forced alkaline diuresis has been shown to be more effective than forced diuresis in augmenting salicylate excretion in the urine. Indeed, a recent position paper from the American Academy of Clinical Toxicology and the European Association of Poison Control Centers and Clinical Toxicologists recommended that urine alkalinization should be considered as first-line treatment for patients with moderately severe salicylate poisoning who do not meet the criteria for HD (15). Forced diuresis may not only correct the commonly found dehydration of these patients but may also be deleterious as it may exacerbate the tendency of salicylates to induce pulmonary edema in overhydrated patients. Consequently, the administration of isotonic sodium bicarbonate at a rate sufficient to correct the metabolic acidosis and induce alkaline urine is now preferred (193,196). The volume of isotonic sodium bicarbonate necessary to achieve these goals may be substantial. A suggested protocol would involve administration of 225 mL of an 8.4% sodium bicarbonate intravenously in the first hour followed by additional boluses to maintain urine pH of 7.5 to 8.5. An alternative approach includes a continuous infusion of D5W mixed with 150 mmol of sodium bicarbonate. Loop diuretics should be avoided because they may decrease salicylate excretion (196).

Salicylates are readily removed by various extracorporeal techniques due to their relatively low MW, low apparent Vd, and the small degree of protein binding (97,165,199). HD is currently the preferred technique for ECTR of salicylate poisoning. PD is less efficient and should be reserved for children in whom HD may be more difficult to perform (97). Various forms of CRRT can also be used for treatment of salicylate poisoning particularly in patients who are hemodynamically unstable (200). Although HP provides a higher clearance of salicylate, HD remains the preferred technique (21,97,201,202). The indications for ECTR in patients with salicylate poisoning have been poorly defined but generally include the presence of severe clinical presentation such as seizures or coma, cerebral edema, kidney disease, severe metabolic acidosis, and clinical deterioration despite adequate therapy. Moreover, patients at risk of developing noncardiogenic pulmonary edema such as older patients, those with history of smoking, and those with inability to establish diuresis should be considered for HD

(97,165,172–175,199). HD was also recommended to patients with acute salicylate poisoning and blood salicylate levels greater than 100 mg/dL or at least 60 mg/dL in those with chronic salicylate toxicity regardless of their clinical state (165). However, data from the AAPCC in 2004 showed that approximately half of the fatal acute cases reported had salicylate levels less than 100 mg/100 mL (203). Similar data were also reported from Ontario, Canada (160). Unfortunately, HD continues to be underutilized in cases of salicylate poisoning because physicians, including nephrologists, prefer to try alkalinization of urine before HD, a perceived aggressive therapy. Although urine alkalinization should be attempted as soon as the patient presents to the emergency department, it should be done in addition to, and not instead, of HD particularly in clinically severe cases of salicylate poisoning (204). The EXTRIP workgroup has recently conducted a systematic literature review and derived consensus-based recommendations for ECTR in salicylate poisoning. The workgroup concluded that ECTR is the only intervention that convincingly and rapidly reduces the burden of circulating salicylate (201). It does so efficiently (ECTR clearance can surpass 100 mL/min) and also allows correction of acidemia, which will lessen the delivery of salicylate to the brain (201).The workgroup thus recommended ECTR in patients with severe salicylate poisoning, including any patient with altered mental status, with acute respiratory distress syndrome requiring supplemental oxygen, and for those in whom standard therapy is deemed to be failing regardless of the salicylate concentration (201) (**TABLE 36.16**). High salicylate concentrations warrant ECTR regardless of signs and symptoms, with lower thresholds applied for patients with impaired kidney function. ECTR is also suggested for patients with severe academia (pH <7.20 in the absence of other indications). Intermittent HD is the preferred modality, although HP and CRRT are acceptable alternatives if HD is unavailable, as is exchange transfusion in neonates.

TABLE 36.16 Indications for Extracorporeal Treatment of Salicylate Poisoning

General Recommendation

ECTR is recommended in severe salicylate poisoning (1D).

Indications for ECTR

ECTR is recommended if any of the following are met:

- If [salicylate] >7.2 mmol/L (100 mg/dL) (1D)
- If [salicylate] >6.5 mmol/L (90 mg/dL) in the presence of impaired kidney function (1D)
- In the presence of altered mental status (1D)
- In the presence of new hypoxemia requiring supplemental oxygen (1D)

If standard therapy (supportive measures, bicarbonate, etc.) fails (1D), ECTR is suggested if any of the following are met:

- If [salicylate] >6.5 mmol/L (90 mg/dL) (2D)
- If [salicylate] >5.8 mmol/L (80 gm/dL) in the presence of impaired kidney function (2D)
- If the systemic pH is ≤7.20 (2D)

ECTR Cessation

ECTR cessation is indicated if

- Clinical improvement is apparent (1D) *and*
- [salicylate] <1.4 mmol/L (19 mg/dL) (1D) *or* ECTR has been performed for a period of at least 4–6 h when salicylate concentrations are not readily available (2D)

Choice of ECTR Modality

- Intermittent HD is the preferred modality in patients with salicylate poisoning (1D)
- The following are acceptable alternatives if HD is not available:
  - Intermittent HP (1D)
  - CRRT (3D)
  - Exchange transfusion in neonates (1D)
- **Miscellaneous: It is recommended to continue intravenous bicarbonate therapy between ECTR sessions (1D)**

ECTR, extracorporeal treatment; HP, hemoperfusion; CRRT, continuous renal replacement therapy.

LITHIUM

Lithium, from the Greek word *stone*, was discovered in 1818 and used for treatment of various ailments including gout and renal stone disease. Almost a century later, lithium was used as a salt substitute in

patients with hypertension or congestive heart failure and was even added to the soft drink 7 Up (205–208). However, because of its toxicity, its use was abandoned until 1950s when it was used for treatment of bipolar syndrome and remains in use for that indication until the present time (209). In addition, lithium has been successfully used in modern medicine as a mood stabilizer and for the treatment of severe depression and acute mania (210,211).

Unfortunately, lithium has a narrow therapeutic index and most patients experience some toxicity from long-term use. In the 2013 Annual Report of the AAPCC NPDS, there were 6,815 cases of toxic lithium exposures in 2012 including 11 deaths in the United States (2). Most commonly, lithium intoxication occurs in patients who have been receiving chronic lithium therapy. Acute toxicity may be superimposed on those of chronic toxicity but may also occur as a result of accidental or suicidal ingestions (97,212–214).

Lithium is dispensed in various formulations including carbonate salt in tablets, capsules, and slow-release formulations or as citrate salt in liquid preparations. It is rapidly absorbed by the gastrointestinal tract within 8 hours of ingestion. Peak serum levels are seen 1 to 3 hours after ingestion of regular formulation and 4 to 12 hours in sustained-release preparations. Lithium is a small molecule (74 Da) that is neither bound to proteins nor is it metabolized, distributes promptly in the extracellular fluid, and has a distribution volume of 0.4 L/kg. However, it slowly enters the intracellular compartment, and as a result, its Vd increases to 0.6 to 0.9 L/kg (215). Lithium is actively transported out of cells by a Na^+/Li^+ exchanger. However, because of the negative intracellular potential in certain cells, intracellular lithium concentrations may become twice as high as those of the plasma (216). Given that the rate of equilibration of lithium across cellular membranes is slow, and that its effects occur intracellularly, it is no surprise that, at comparable serum lithium levels, chronic intoxication is more likely to be accompanied by toxic effects than acute poisoning (217,218). Lithium has a predilection to certain tissues such as the white matter of the brain, the thyroid, liver, muscle, skeleton, and the distal tubular cells of the kidney (97,212–214); its highest concentrations, however, are found in the brain and the kidney (215). Within cells, lithium is capable of inhibiting adenyl cyclase and inositol-1-phosphate, both being important intracellular messengers (97,212–214). Whether this mechanism is the one through which lithium exerts its therapeutic or toxic effects is unclear.

Lithium is almost entirely (95%) eliminated through the kidney where it is handled in a way similar to that of sodium. Therefore, it is freely filtered by the glomerulus and approximately 80% of the filtered amount is reabsorbed by the proximal tubule and a small amount is reabsorbed in the distal tubule (217). Moreover, dietary salt restriction and volume depletion profoundly increase its renal tubular reabsorption. This phenomenon accounts for the frequent occurrence of toxicity in patients receiving stable doses of lithium when they develop volume depletion from any cause such as vomiting, diarrhea, or diuretic therapy (219,220). Moreover, concomitant administration of drugs that reduce GFR such as the angiotensin-converting enzyme inhibitors and nonsteroidal anti-inflammatory drugs decrease lithium clearance and raise its serum levels (220–222). By contrast, factors that augment sodium excretion enhance lithium excretion only to a minor extent (97,212–214).

Clinical Picture

Lithium toxicity may be seen under three different patterns. Acute toxicity occurs in patients who have not previously taken the drug but overdose on lithium. Acute on chronic toxicity occurs in patients on chronic

therapy but overdose on the drug. Chronic toxicity occurs in patients on maintenance lithium therapy in the clinical context of a recently increased lithium dose, a decline in kidney function, or a drug–drug interaction that impairs elimination (223,224). The last category is usually associated with the more severe toxicity. Gastrointestinal symptoms may help to distinguish between acute lithium poisoning, where they are usually present, from chronic toxicity, where they are almost invariably absent. The clinical relationship between lithium levels and toxicity is complex as clinical features are both highly variable and largely dependent on the pattern of poisoning (218,225,226). The therapeutic steady-state lithium level is 0.6 to 1.2 mEq/L (223,227), but mild lithium toxicity may be observed at lithium levels of 1.5 to 2.5 mEq/L. Moderate toxicity may develop at levels between 2.5 and 3.5 mEq/L. On the other hand, severe toxicity is usually seen when the levels exceed 3.5 mEq/L (227,228). In the elderly, toxic manifestations may appear at serum levels of 1.5 mEq/L or at even lower. Therefore, serum lithium levels should only be used as a guide to the risk of toxicity but always taken in the context of other patients' characteristics including history, clinical presentation, as well as the level of renal function.

Although lithium toxicity may lead to multiorgan dysfunction, its clinical manifestations are primarily due to CNS and renal impairment. The CNS findings may start with nervousness and agitation then followed by coarse tremors, dysarthria, confusion, delirium, ataxia, hyperpyrexia, slurred speech, stupor, seizures, and coma (212). Several case reports document the syndrome of irreversible lithium-effectuated neurotoxicity (SILENT) as a neurologic complication of lithium toxicity (229,230,231). Patients with this syndrome usually have chronic cerebellar sequelae, even after lithium has been discontinued and concentrations have fallen to therapeutic or undetectable levels. The clinical features of SILENT may include tremor, extrapyramidal symptoms, gait difficulties, nystagmus, dysarthria, and cognitive deficits (219–231). Unfortunately, there are no definitive treatments for SILENT at the present time (223).

Renal toxicity includes polyuria, nephrogenic diabetes insipidus, sodium-losing nephropathy, and proteinuria, which can be in the nephrotic range (232). Polyuria, which is more common with chronic therapy, occurs in up to 37% of patients with therapeutic doses of lithium before full-blown nephrogenic diabetes insipidus develop (233). Lithium is the most common cause of drug-induced nephrogenic diabetes mellitus (234). Moreover, renal acidification defects, evidence of chronic interstitial nephritis, and nephrotic syndrome are also seen (97,212–214,216). Renal biopsies in patients with lithium nephrotoxicity have documented high prevalence of focal and segmental glomerulosclerosis (232). Long-term lithium intake has also been reportedly associated with increased risk of renal tumors and renal cysts. Over a 16-year period, a recent retrospective study reported that 14 of 170 lithium-treated patients had renal tumors, including 7 malignant and 7 benign tumors. The percentage of renal tumors, particularly cancers and oncocytomas, was significantly higher in lithium-treated patients compared with 340 gender-, age-, and estimated glomerular filtration rate (eGFR)-matched lithium-free patients (235). Prolonged lithium treatment may cause hyperchloremic metabolic acidosis, which is believed to be caused by diminished net proton secretion in the collecting duct or excessive back diffusion of acid equivalents, or both (236). Interestingly, the anion gap may be low or absent in presence of exceedingly high serum level of lithium (237,238).

Other toxic effects of lithium include leukocytosis, enlargement of the thyroid gland, and evidence of hypothyroidism (97,211–214,216,224,239). Gastrointestinal symptoms are commonly encountered in acute intoxication and include nausea, vomiting, diarrhea, anorexia, and bloating (218,224,225,239,240).

Lastly, cardiovascular manifestations are usually mild and include hypertension, bradycardia or tachycardia, and ST-segment depression and T-wave flattening on electrocardiogram (ECG). More serious findings include QT prolongation, QRS widening, intraventricular conduction defects due to sinus node dysfunction, ventricular arrhythmia, and myocardial infarction (241,242). Lithium toxicity is thought to correlate primarily with intracellular lithium concentrations. Therefore, at comparable serum levels, the clinical picture of the chronically intoxicated patient (with higher intracellular levels) may be more severe than that of the acutely intoxicated counterpart (224,225).

Treatment

Lithium intoxication is always a serious problem even when manifestations of toxicity appear relatively minor as seizures and other CNS complications may occur unexpectedly. There is no known antidote for lithium. Thus, supportive care including discontinuation of lithium, securing the airways and other hemodynamic parameters, as well as volume repletion with isotonic saline, must be instituted without delay. In patients with mild clinical manifestations and serum lithium level less than 2.5 mEq/L, aggressive supportive treatment may suffice. However, in patients with accidental or suicidal ingestion, gastric lavage should be employed. Administration of activated charcoal is not useful because this agent does not bind lithium ions (243). Whole bowel irrigation with polyethylene glycol electrolyte lavage solution (GoLYTELY) at 2 L/h for 5 hours after ingestion can reduce lithium absorption by 67% and reduce peak lithium levels by >50% (244). This approach may enhance the elimination of sustained-release preparations of lithium (244). Sodium polystyrene sulfonate has previously been suggested to enhance elimination of lithium but is not currently recommended.

A serum level of 2.5 mEq/L or greater typically is associated with significant morbidity and mortality and must be treated aggressively (97,212–214,218). An important goal of therapy is to maintain the GFR and urine output. This entails administration of appropriate volume of 0.9% saline IV to maintain urine output but forced diuresis is not recommended. Volume depletion can occur because of a defect in renal concentrating ability, diuretic therapy, vomiting or diarrhea. Consequently, vigorously replacing preexisting volume losses is of paramount importance in reestablishing a desirable level of renal lithium excretion (97,212–214,216–218).

HD is highly effective and currently considered the most efficient method of removing lithium from a patient with lithium poisoning (227,245). This is because its low atomic weight and minimal protein binding makes it readily diffusible across dialyzer membranes. The extraction ratio for lithium is in the range of 0.7 for plasma and 0.5 for whole blood, the discrepancy resulting from the low extraction of lithium from red blood cells (246). In view of these characteristics and of the relatively low Vd, dialysis can produce a rapid fall in total body lithium burden. In this regard, HD can reduce the half-life of lithium from 12 to 27 hours to 3.6 to 5.7 hours and can raise its clearance rate from 10 to 40 mL/min (via the patient’s own kidneys) to 70 to 170 mL/min and minimize the length of time that the brain is exposed to toxic lithium levels. (97,219,228). Despite its efficacy, there is no consensus on precise indications for HD (247). This is because removal of lithium from the extracellular fluid has little effect on intracellular lithium concentration. Moreover, serum levels correlate poorly with clinical picture of toxicity. Differences in opinion in the management of lithium poisoning was highlighted at a workshop at the 2013 Annual Scientific Meeting of European Association of Poison Control Centers and Clinical Toxicologists in Copenhagen, Denmark (248). Nonetheless, recent recommendations from the EXTRIP workgroup on

treatment of lithium poisoning were published and include the following (**TABLE 36.17**): (a) The workgroup concluded that lithium is dialyzable. (b) ECTR is recommended in severe lithium poisoning. (c) ECTR is recommended if kidney function is impaired and the lithium level is >4.0 mEq/L, or in the presence of a decreased level of consciousness, seizures, or life-threatening dysrhythmias irrespective of the lithium level. (d) ECTR is suggested if the lithium level is >5.0 mEq/L, significant confusion is present, or the expected time to reduce the lithium level to <1.0 mEq/L is >36 hours. (e) ECTR should be continued until clinical improvement is apparent or lithium level is <1.0 mEq/L. (f) ECTRs should be continued for a minimum of 6 hours if the lithium level is not readily measurable. (g) HD is the preferred ECTR, but CRRT is an acceptable alternative. Finally, the workgroup suggested that clinical decisions on when to use ECTR should take into account the lithium level, kidney function, pattern of lithium toxicity, patient's clinical status, and availability of ECTRs (223).

TABLE 36.17 Indications for Extracorporeal Treatment of Lithium Poisoning

- ECTR is recommended if any of the following conditions are present:
  1. If kidney function is impaired and the lithium level is >4.0 mEq/L
  2. In presence of a decreased level of consciousness, seizures, or life-threatening dysrhythmias, irrespective of the lithium level
- ECTR is suggested if any of the following conditions are present:
  3. If lithium level is >5.0 mEq/L
  4. If significant confusion is present
  5. If the expected time to reduce lithium level to <1.0 mEq/L with optimal management is >36 h
- Cessation of ECTR is recommended:
  1. If either the lithium level is <1.0 mEq/L or clinical improvement is apparent
  2. After a minimum of 6 h of ECTR if the lithium level is not readily measurable
- Choice of ECTR
  1. Intermittent hemodialysis (HD) is the preferred ECTR modality in lithium poisoning (1D).
  2. CRRT is an acceptable alternative if intermittent HD is not available (1D).
  3. After an initial treatment with intermittent HD, both CRRT and intermittent HD are equally acceptable modalities for additional lithium removal (1D).

ECTR, extracorporeal treatment.
Modified from Decker BS, Goldfarb DS, Dargan PI, et al. Extracorporeal treatment for lithium poisoning: systematic review and recommendations from the EXTRIP Workgroup. *Clin J Am Soc Nephrol* 2015;10(5):875–887.

The relatively slow equilibration of lithium across cellular membranes may complicate response to HD treatment. This is because following dialysis and a rapid fall in extracellular lithium concentration, the patient may not improve. Indeed, the slow exit of lithium from cells often results in rebound increase in serum lithium values after dialysis cessation. Rebound may also occur in cases of poisoning resulting from the ingestion of sustained-release preparations as a result of continued gastrointestinal absorption. Thus, rebound may result either from a redistribution of lithium from deeper compartments/red blood cells to the plasma or from ongoing absorption from the gastrointestinal tract. While the former is not usually associated with worsening symptoms, the latter, which develops from ongoing absorption from extended-release formulations or patients with decreased gastrointestinal motility, is usually associated with clinical deterioration. Consequently, HD must be repeated or continued until the serum level 6 to 8

hours after dialysis is less than 1 mEq/L (223). Prompt determination of serum lithium levels may not be readily available in many health care institutions. Under such circumstances, it would seem prudent to offer patients conventional dialysis treatment for 4 to 6 hours followed by SLED for several hours. The use of a bicarbonate bath is preferred to that of an acetate bath since acetate may reduce lithium clearance. Acetate bath, in contrast to bicarbonate bath, is thought to activate the sodium-hydrogen antiporter on the cell membrane, driving lithium (substituting for sodium) into the cells (248).

Besides HD, various CRRTs modalities [continuous arteriovenous hemodiafiltration (CAVHDF) and CVVHDF] have also been used successfully in lithium intoxication, achieving lithium clearance rates of 60 to 85 L/d (Leblanc). Because of their continuous nature, these therapies create a persistent concentration gradient between the intracellular and extracellular compartments over longer periods, allowing a gradual and more complete elimination of lithium from intracellular compartments, thereby avoiding significant rebound (249). In addition, these procedures may be especially helpful in patients with hemodynamic instability who are unable to tolerate IHD (250). Unfortunately, there are no controlled trials comparing the safety, efficacy, and cost of these CRRT techniques with those of conventional HD.

THEOPHYLLINE

Theophylline is 1,3-dimethylxanthine (MW = 180 Da) that is closely related to caffeine and is a member of the methylxanthine family of pharmacologic agents. Theophylline was popular for treatment of asthma for several decades, but its use has dramatically declined in the United States in recent years due to the introduction of newer and safer pharmacologic agents and because of concern about its toxicity. Nonetheless, it is still used as a bronchodilator in other countries in the treatment of asthma, chronic obstructive pulmonary disease, and acute mountain sickness but also used for treatment of apnea and bradycardia of premature infants (251). Theophylline intoxication is most commonly unintentional as an inadvertent consequence of chronic theophylline therapy for asthma and other chronic obstructive pulmonary diseases (252). Intoxication can also occur in toddlers or because of suicidal overdose in adults (97,251,253,254).

When taken orally, theophylline is promptly and efficiently absorbed, with peak serum levels occurring at approximately 2 hours. However, the sustained-release capsule is not completely absorbed until 6 to 8 hours after ingestion, and the peak serum levels may be delayed to 12 to 17 hours after ingestion of these agents (255). Once absorbed, theophylline is distributed predominantly in the extracellular water, with an apparent Vd of about 0.45 L/kg body weight. Infants and elderly patients tend to have larger Vds. In the circulation, theophylline is loosely bound to albumin: The fraction bound is highest (approximately 60%) at relatively low therapeutic serum concentrations but is lower at toxic serum levels as well as in adults with liver disease and in infants (256,257). The therapeutic serum concentration of theophylline is 10 to 20 µg/mL (56 to 111 µmol/L) when used for treatment of asthma. Theophylline has a narrow therapeutic index (ratio of 50% toxic dose to 50% effective dose) of 1 to 1.5.

In adults, only 10% to 15% of theophylline is excreted unchanged in the urine, the remainder is metabolized in the liver by the cytochrome P450 pathway. The rate of endogenous hepatic clearance of theophylline is relatively slow in the order of 0.7 mL/min/kg in adult nonsmokers in whom the half-life is approximately 8 hours. The metabolic clearance of theophylline is relatively slow and is influenced by many factors including age. Neonates and the elderly eliminate the drug more slowly. In infants, hepatic

metabolism is also slower leading to longer half-life and higher renal excretion (50% excreted via this route). Theophylline clearance becomes maximal between the ages of 1 and 9 years but subsequently decreases by almost 50% in adults (254). Moreover, metabolism can be profoundly modified by genetic factors, environmental agents, and other drugs that alter the activity of the liver isoenzymes. Fever, severe chronic liver disease, and congestive heart failure prolong theophylline half-life, whereas smoking and hyperthyroidism reduce the half-life of the drug. The metabolism of theophylline is highly influenced by concomitant drug use. Antibiotic therapy with macrolides and quinolones prolong theophylline half-life, whereas administration of barbiturates, phenytoin, rifampin, carbamazepine, and oral contraceptives reduce the half-life of the drug (254). Theophylline exhibits Michaelis-Menten (saturable) kinetics. Consequently, increments in dose are associated with parallel increases in serum theophylline levels. With severe theophylline intoxication, drug elimination rates are very low and follow zero-order (dose-dependent) kinetics. In the latter situation, metabolic pathways may become saturated, with reduction in endogenous clearance and a consequent increment in half-life (251,253,254,257). It is usually this kinetics in addition to the drug–drug and drug–disease interactions that are often responsible for inadvertent theophylline intoxications (253,254).

Four major potential mechanisms have been proposed to explain theophylline's mode of action. First, theophylline has been thought to act as an inhibitor of cyclic nucleotide phosphodiesterase, the enzyme that breaks down intracellular cyclic adenosine monophosphate (AMP) (251,254,258). Second, recent evidence indicates that both the therapeutic and toxic effects of theophylline may be mediated by its action as a competitive antagonist at adenosine receptor sites (259,260). Third, theophylline results in a release of catecholamines and has positive inotropic and chronotropic effects on the heart (261). Lastly, its effects may result directly from changes in intracellular calcium transport.

Clinical Picture

Because theophylline has a narrow therapeutic index, it is often associated with a high rate of adverse events. Some therapeutic effects of theophylline are observed at serum levels as low as 5 mg/L (27.5 mmol/L), but response to therapy is achieved at serum concentrations in the range of 10 mg/L (55 mmol/L). On the other hand, toxic manifestations may develop in some patients at concentrations as low as 15 mg/L (82.5 mmol/L), but most patients manifest toxicity at levels greater than 25 mg/L (138 mmol/L) (262). Clinically, symptoms and signs of toxicity usually reflect the effects of theophylline on five organ systems. First, gastrointestinal symptoms are common and may include nausea, vomiting, diarrhea, heart burn, hematemesis, and abdominal pain. Second, neurologic symptoms appear at relatively low serum levels of theophylline. These include tachypnea, anxiety, restlessness, agitation, and tremors progressing to confusion and eventually to seizures. However, the most serious of these manifestations is repeated seizures, which can be associated with hyperthermia. Third, cardiovascular effects, which can be life-threatening, include sinus tachycardia, supraventricular tachycardia (atrial flutter and fibrillation), multifocal atrial tachycardia, ventricular premature beats, ventricular tachycardia, and vasodilatation with hypotension (263). The cardiac toxicity of theophylline may be due to inhibition of the cardiac adenosine receptors or increased catecholamine release. Fourth, generalized muscle aches with occasional myoclonus and elevation of creatine phosphokinase. Fifth, metabolic consequences of theophylline intoxication such as hypokalemia and hyperglycemia are commonly observed and develop as a result of

catecholamine-induced β_2-adrenergic stimulation (264). Hypokalemia is the most important metabolic abnormality and is likely due to increased shift of potassium ions to the intracellular compartment as a result of increased activity of Na-K-ATPase. Moreover, hypercalcemia, hypomagnesemia, and hypophosphatemia have also been reported. In severe and advanced cases, lactic acidosis (most likely secondary to hypotension) and rhabdomyolysis (the consequence of muscular hyperactivity, hyperthermia, and hypokalemia) are observed (252,262–265).

The development of seizures is considered the most serious of all neurologic manifestations of theophylline poisoning. The presence of seizures portends a high mortality or may result in permanent neurologic damage (266,267). Once seizures develop, they may be very difficult to control. Seizures may occur at serum theophylline concentrations less than 20 μg/mL (268). They also tend to occur at lower serum concentrations in patients receiving chronic theophylline therapy than in those with acute intoxication. The probability of seizures in patients on chronic theophylline therapy with theophylline concentration of 220 mmol/L (40 mg/L) is 50%, whereas the same probability was not reached in patients with acute intoxication until a theophylline concentration of 660 mmol/L (120 mg/L) (258,263). This observation may well be related to the fact that patients receiving chronic theophylline therapy often suffer from other concomitant diseases or receive concurrent medications that lower the seizure threshold (254,262–265). A prior history of neurologic abnormalities does appear to increase the likelihood of seizures (269,270). The exact mechanism of seizures in theophylline toxicity is unclear. However, it has been suggested that it may be related to dysfunction of the γ-aminobutyric acid-ergic (GABAergic) inhibitory neurons and depressed serum pyridoxal levels (271). Also, theophylline may reduce cerebral hyperemia and enhances brain damage induced by seizures; actions related to inhibition of brain adenosine activity (272).

Management of Theophylline Poisoning

Supportive Care

Supportive care is clearly important in theophylline poisoning. Patients should be closely monitored, preferably in the intensive care unit, where special attention can be paid for cardiac arrhythmia, hypotension, respiratory distress, and seizures. If respiratory failure or seizure develops, the patient should have immediate endotracheal intubation. Moreover, serious cardiac arrhythmias should be treated without delay. In this regard, the use of adenosine as a first-line therapy for tachyarrhythmia is recommended given the notion that these arrhythmias are due to theophylline-induced cardiac adenosine receptor antagonism. However, the use of β-blocking agents for control of cardiac arrhythmias should also be considered. Although noncardioselective agents such as propranolol may offer some advantage because of their capacity to counteract theophylline-induced vasodilatation and hypokalemia (273), cardioselective β-blockers are usually required in patients with bronchial asthma (274). Moreover, seizures should be anticipated and managed appropriately. Some advocate the use of prophylactic anticonvulsant therapy in patients with theophylline poisoning (275). Once they appear, seizure should be treated aggressively (253,254). The drug of choice is either benzodiazepine or a phenobarbital. If these patients do not respond to anticonvulsant therapy, general anesthesia and neuromuscular paralysis may become necessary (276). Phenytoin is relatively contraindicated as animal studies have suggested that it may increase the risk of theophylline-induced seizures (277). It should be noted that seizures may occur

hours after peak theophylline levels have been reached. Moreover, seizures may occur with slow-release preparations of the drug, and in patients with chronic overdose who may have different severities of intoxication at the same serum levels as acute overdose (258,262–267). In addition to the usual supportive measures, treatment of theophylline intoxication should include close monitoring of serum potassium and phosphorus concentrations with aggressive replacement of any deficits.

Elimination

Theophylline toxicity can be clearly life-threatening, and thus, it should be removed from the gastrointestinal tract and blood immediately if possible. The oral administration of repeated doses of activated charcoal has been proven to markedly shorten theophylline half-life, even in patients who have received theophylline by the IV route. Charcoal binds the fraction of ingested theophylline that has not yet been absorbed as well as that which diffuses into the intestine from the circulation. The latter phenomenon is referred to as *enterocapillary exsorption* (278,279). Activated charcoal is administered in the form of slurry in a dose of 1 g/kg every 4 hours or 15 to 20 g every 2 hours in adults and 2.5 to 10 g hourly in children. Alternatively, it can be given by a continuous nasogastric infusion. Activated charcoal administration should continue until serum concentrations of theophylline decrease to less than 20 mg/L (110 mmol/L), and clinical improvement can be documented (278–280). Such maneuvers should be employed routinely in all theophylline-intoxicated patients except for those with minimal signs and symptoms of toxicity. Unfortunately, the concomitant nausea and vomiting may make the use of MDAC difficult in many afflicted patients. Under such circumstances, antiemetic therapy with metoclopramide or ondansetron may be necessary. Because prochlorperazine may lower seizure threshold, its use is contraindicated (281). Use of cathartics with activated charcoal may hasten the evacuation of charcoal-theophylline complex (282). However, forced diuresis is not recommended.

Theophylline can be removed more rapidly by HP or HD. HP with either resin cartridges (such as Amberlite XAD-4) or activated charcoal cartridges is the most effective extracorporeal technique for elimination of theophylline with an extraction ratios of close to 0.75 (283–286). Indeed, because of the ease of transmembrane movement of theophylline, the drug is efficiently removed not only from the plasma but also from the erythrocytes. More than 65% of theophylline dose can be removed in 3 hours of HP; the amount can be calculated by using blood rather than plasma flow rates through the HP cartridge (287). Unfortunately, the capacity of HP cartridges to extract theophylline is not without limits, and the efficiency of theophylline elimination falls with time as the cartridge becomes saturated. Consequently, the cartridge must be replaced every 2 hours (283,285,286,288).

HD is also effective in removing theophylline but was thought to be less effective than HP (289,290). However, recent studies indicate that HD is just as effective in treating theophylline poisoning as HP (18,291–296). Substantial amounts of the drug may be removed in a relatively short period of time. This is particularly true with the use of high-efficiency hemodialyzers with a high KoA as well as high blood and dialysate flow rates. These hemodialyzers can increase the extraction ratio of theophylline to 0.5 to 0.6 (254). Prolonged HD sessions may be required to obtain results equivalent to those achieved by HP. Finally, HD may be comparable to HP in reducing the morbidity and mortality from theophylline poisoning and may be associated with fewer procedural complications (293). The simultaneous use of HD and charcoal HP (HD/HP) “in series” can increase the amount of theophylline removed. This

combined procedure, if available, may also retard the saturation of the charcoal cartridge and thus represents a favorable treatment option for patients with heavy theophylline intoxication (288,289).

The indications for use of HP and/or HD are controversial. However, the EXTRIP workgroup (ECTR) recently published their recommendations for treatment of theophylline poisoning. The workgroup made the following recommendations: ECTR is recommended in severe theophylline poisoning with a theophylline concentration >100 mg/L (555 µmol/L) in acute exposure, the presence of seizures, life-threatening dysrhythmias or shock, a rising theophylline concentration despite optimal therapy, and clinical deterioration despite optimal care. In chronic poisoning, ECTR is suggested if theophylline concentration >60 mg/L (333 µmol/L) or if the theophylline concentration is >50 mg/L (278 µmol/L) and the patient is either less than 6 months of age or older than 60 years of age. ECTR is also suggested if gastrointestinal decontamination cannot be administered. ECTR should be continued until clinical improvement is apparent or the theophylline concentration is <15 mg/L (83 µmol/L). Following the cessation of ECTR, patients should be closely monitored. Intermittent HD is the preferred method of ECTR. If intermittent HD is unavailable, HP or CRRTs may be considered (292). These include sorbent-based dialysate regeneration systems such as the REDY machine (297,298), CVVH (299,300), and plasmapheresis (301). Some studies have shown no significant difference in the elimination rate of theophylline between charcoal HP and plasmapheresis (299,300). By contrast, PD is clearly not effective in the treatment of theophylline poisoning (302). Exchange transfusion is an adequate alternative to HD in neonates. MDAC should be continued during ECTR (292). In those who appear clinically stable, the administration of charcoal may suffice until serum theophylline levels become available. However, serial measurement of theophylline levels should then be obtained every 2 to 4 hours until peak levels are reached. If the level is greater than 100 µg/mL, even in the absence of major toxic manifestations, HP or HD should be started as soon as possible particularly in the presence of concomitant kidney disease, hepatic failure, cardiac failure, or advanced age (254,289).

ETHANOL

Ethanol (MW = 46 Da) is one of the most frequently encountered toxins in the emergency departments in the United States (303). Chronic alcohol-related health problems are common. Detailed description of these problems as well as ethanol pharmacokinetics and management of withdrawal syndromes are beyond the scope of this chapter. Ethanol has low MW, is highly soluble in water and lipid, and has Vd similar to water. It is rapidly absorbed from the stomach and small intestine, with a peak level at approximately 20 to 60 minutes after ingestion. Once absorbed, ethanol is initially metabolized to acetaldehyde then to acetone. Women attain higher blood ethanol levels after ingestion of equal amounts than men due to their smaller size, higher body fat content, and lower alcohol dehydrogenase enzyme in their stomach.

When ethanol is consumed in low doses, it is perceived as a stimulant owing to the suppression of central inhibitory systems. However, as the plasma levels of ethanol increase, sedation, motor incoordination, ataxia, and impaired psychomotor performance appear (304). At very high blood levels, ethanol may lead to coma and death. Acute alcoholic intoxication is responsible for a high number of deaths in the United States annually, most notably among young college students with binge drinking habits (305). Most of the deaths are caused by respiratory depression, aspiration-induced asphyxia, or traumatic

injuries in severely inebriated subjects. Acute intoxication can also lead to severe hypotension and cardiac arrhythmias. Lethal level is at the realm of 450 mg/dL (98 mM) for half of the non–ethanol-dependent population, although individuals with serum concentrations as high as 1,500 mg/dL (326 mM) have survived (306,307). Most patients can be treated adequately with proper supportive care consisting of administration of fluids, electrolytes, thiamine, folate, and other vitamins in addition to the prevention of hypoglycemia and hypoxia. Gastric emptying is ineffective in decreasing the blood ethanol level due to the rapid absorption of ethanol. Charcoal may be administered if circumstances suggest the coingestion of other toxins (303). The vast majority of inebriated individuals recover on their own with supportive care (303,308). However, in severely intoxicated patients with lethal serum ethanol levels, and in those at risk of respiratory depression and circulatory failure, extracorporeal techniques such as HD, hemofiltration, and hemodiafiltration can be employed (308–310). Because of its small MW and the absence of protein-binding, ethanol is readily removed by these techniques. HD increases the plasma elimination rate of alcohol from 15 mg/dL/h to nearly 100 mg/dL/h (308).

ACETAMINOPHEN POISONING

Acetaminophen (*N*-acetyl-p-aminophenol; APAP; paracetamol) has been the most frequently used analgesic and antipyretic medication used worldwide since the advent of Tylenol in the United States in 1955 and Panadol in the United Kingdom in 1956. In therapeutic doses, APAP is usually safe. However, it has long been recognized that if APAP is taken in excessive amounts or as an overdose, it can cause fatal and nonfatal liver failure (311). Even in smaller doses, particularly in combination products, APAP can cause serious liver damage. Severe liver injury has been reported in patients who took higher than the prescribed dose of an acetaminophen-containing product in a 24-hour period, took two or more acetaminophen-containing products simultaneously, or combined alcohol with acetaminophen products (312,313). In fact, the FDA issued a statement in January 2014 stating that “combination prescription pain relievers that contain more than 325 mg of acetaminophen per tablet, capsule, or other dosage unit should no longer be prescribed because of a risk of liver damage” (313). Data from the U.S. Acute Liver Failure Study Group registry of >700 patients with acute liver failure implicates APAP poisoning in nearly 50% of all acute liver failure in the United States (314). Currently, APAP is the leading cause of acute liver failure in both United States and United Kingdom.

Acetaminophen is one of the most frequent poisoning reported to the poison centers in the United States (311). In the 2013 Annual Report of the APPCC NPDS, there were 311,347 exposures to analgesics in 2012 in the United States. There were 946 deaths involving an analgesic agent. Of these, APAP is responsible for almost one-third of poisoning-related deaths as it was recorded in 103 of acetaminophen poisoning as a single agent, 133 from acetaminophen/hydrocodone, and 24 from acetaminophen/oxycodone combinations (2). APAP toxicity is the most frequent cause of hepatic failure. Ingestion of a single dose of more than 10 to 15 g can cause severe or fatal liver injury secondary to massive hepatic necrosis (315). Moreover, ingestion of daily doses of less than 10 g on consecutive days carries a risk for liver injury in some individuals (316). It has also been suggested that APAP hepatotoxicity may even occur in those ingesting therapeutic doses under certain conditions, such as fasting or alcohol use (317,318).

APAP is rapidly and almost completely absorbed primarily in the small bowel with a peak serum

level within 2 hours of ingestion, but absorption can be delayed if taken with other medications. Its Vd is 0.95 L/kg, and its half-life is 1.5 to 2 hours. Only 2% of APAP is excreted in the urine unchanged. The drug is metabolized in the liver into two major metabolites: two-thirds as glucuronide and one-third as sulfate conjugate (**FIGURE 36.9**) (319). These nontoxic inactive conjugates are largely excreted in the urine and bile. However, 5% of the APAP dose ingested undergoes oxidative conversion by the cytochrome P450 (CYP2E1) enzyme system to the toxic metabolite *N*-acetyl-p-benzoquinoneimine (NAPQI). This metabolite is usually detoxified in the liver via irreversible glutathione, conjugation which helps to reduce NAPQI to cysteine, and mercapturic acid conjugates, which are safe renally excretable metabolites. Unfortunately, in overdose, large amounts of NAPQI are produced leading to overuse of this metabolic pathway and depletion of intracellular glutathione stores; thereby limiting the nontoxic metabolism of APAP, leaving NAPQI free in the liver, resulting in direct liver injury from NAPQI (**FIGURE 36.9**) (320). Since the glucuronide and sulfate metabolites are actively secreted by the renal tubules, it is no surprise that patients with kidney disease accumulate these metabolites which are implicated in the toxic manifestations of APAP.

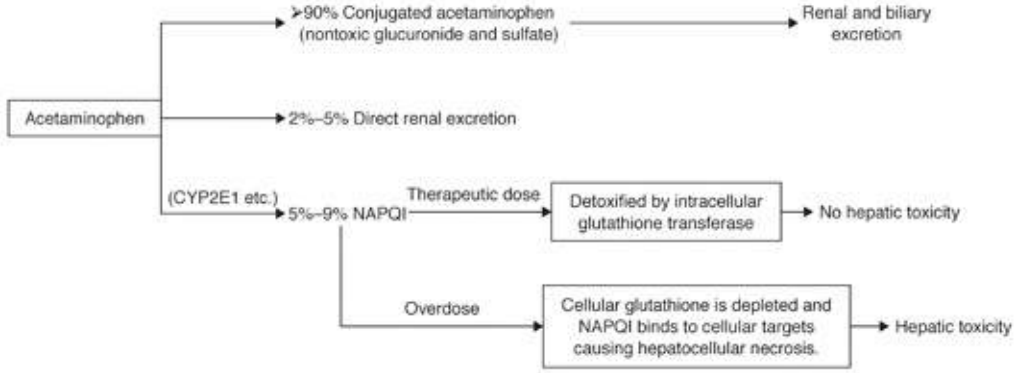

FIGURE 36.9 Acetaminophen metabolism with therapeutic doses and with overdose.

Clinical Picture

Early recognition of APAP toxicity is critically important in preventing morbidity and mortality. The clinical presentation of acute APAP toxicity has been categorized into four phases (321): (a) In the first 24 hours, the patient may be totally asymptomatic or may have nonspecific symptoms such as nausea, vomiting, anorexia, diaphoresis, and lethargy. The liver function tests may initially be normal but start to increase after 16 hours of overdose. (b) The next 24 to 72 hours represent the second phase of APAP poisoning during which the patient begins to develop clinical and laboratory evidence of hepatotoxicity. The patient may develop right upper quadrant pain along with increases in transaminases, bilirubin, and prothrombin time. The kidney function may start to deteriorate. (c) In the third phase, 72 to 96 hours after overdose, the patient usually progresses to fulminant liver failure as well as kidney disease. With progression to fulminant hepatic failure, patients may develop hepatic encephalopathy, jaundice, coagulopathy, and multiorgan failure. AKI occurs in more than 50% of patients and is generally attributable to acetaminophen-induced acute tubular necrosis, which results from NAPQI production in the kidney. Patients may rarely develop severe metabolic acidosis and coma. Death usually occurs in this phase from multiorgan failure unless urgent liver transplant is done. Poor prognostic indicators include a pH less than 7.3, evidence of AKI with serum creatinine greater than 3.3 mg/dL, liver failure with international normalized ratio (INR) greater than 2 at 24 hours, 4 at 48 hours, or 6 at 72 hours, and blood lactate level greater than 3.5 mmol/L. The later criterion is often used as an indication for liver

transplantation (322). Patients who present with hepatic failure have a mortality rate of 20% to 40% (323,324). (d) Patients who survive the initial insult enter into phase 4, usually 4 to 14 days after ingestion, during which resolution of liver and renal functional abnormalities and complete recovery occurs. In massive ingestions (doses >500 mg/kg), patients may present with altered level of consciousness and lactic acidosis, usually within 12 hours postingestion and often prior to biochemical or clinical evidence of hepatotoxicity. In these cases, APAP concentrations are extremely high (>750 mg/L or 5,000 μmol/L). This clinical scenario represents mitochondrial failure and early cell death from overwhelming reactive oxygen species and exhausted glutathione reserves (325,326).

Diagnosis

History, when available, often leads to the correct diagnosis. However, other causes of fulminant liver failure such as hepatotoxic mushrooms, carbon tetrachloride, halothane, viral hepatitis, Reye syndrome, acute fatty liver of pregnancy, and ischemic hepatitis must also be considered. A characteristic finding in APAP hepatotoxicity is the marked elevations in the aminotransferases, usually greater than 3,000 IU/L, and levels as high as 48,000 have been reported (327,328). Unfortunately, history of APAP ingestion may not be readily available particularly in patients with intentional overdose. Because of the potentially disastrous consequences of unrecognized APAP ingestion, it is recommended that all intentional overdoses should be screened for APAP toxicity (329,330). The rate of potentially hepatotoxic APAP levels in patients without history of ingestion is approximately 0.3%. It should be noted, however, that false positive APAP levels have been reported in presence of high bilirubin level (331). In addition to serum APAP level and bilirubin, other laboratory data should include baseline serum transaminases, prothrombin time, arterial blood gases, and renal function tests as well as blood lactate level. Hepatotoxicity in patients with APAP overdose is defined as any increase in aspartate aminotransferase (AST) concentrations, while severe hepatotoxicity as an AST greater than 1,000 IU/L. Hepatic failure is defined as hepatotoxicity with hepatic encephalopathy.

Treatment

After attempting to establish an accurate time of ingestion, the first step in the management of APAP toxicity is aggressive supportive care. Also, activated charcoal should be given to all patients who present within 6 hours of ingestion. Subsequently, NAC should be administered since it is considered an effective antidote for APAP toxicity. NAC has been shown to limit hepatotoxicity in APAP-poisoned patients by several mechanisms (332). First, after administration, NAC is hydrolyzed in the body to cysteine, which replenishes glutathione, where glutathione covalently binds NAPQI in a 1:1 ratio preventing hepatocellular damage (333,334). Second, NAC can serve as a sulphate precursor to help maintain APAP metabolism through the sulfonation pathway. Third, NAC has been shown to blunt the hepatocellular toxicity of NAPQI (335). Finally, NAC improves hemodynamics and oxygen use and may decrease brain edema (336). NAC dramatically reduces the incidence of APAP-induced hepatotoxicity and progression to fulminant liver failure when administered within the first 8 to 10 hours following an acute overdose. Studies have shown that in patients who receive NAC within the first 8 hours after an acute overdose, the risk of hepatotoxicity is <5%, but those who receive NAC after 10 hours are at increased risk of hepatic injury (337,338).

Current treatment of APAP poisoning involves initiating a three-phase NAC infusion after comparing

a plasma concentration, taken >4 hours postoverdose, to a nomogram. In this second step, the risk of hepatotoxicity after a single acute APAP ingestion should be determined by plotting the serum APAP concentration in the patient, taken between 4 hours and 24 hours postingestion on the Rumack-Matthews nomogram (339,340). The result will help to indicate whether or not a patient is at *no* risk, *possible* risk, or *probable* risk of developing APAP hepatotoxicity. Thus, patients have a 60% risk of developing fulminant liver failure if the plasma level of APAP was above the line drawn from the 200 µg/mL level at 4 hours or the 50 µg/mL level at 12 hours (339) (**FIGURE 36.10**). However, given that NAC is an effective antidote in patients with APAP poisoning and is relatively benign, it is my belief that it should be given to anyone with suspected or confirmed APAP overdose, regardless of the serum APAP concentration, particularly if the time of ingestion is unknown and in those with repeated supratherapeutic ingestion. However, many poison control centers in the United States and other countries still recommend NAC administration only for patients who have a serum concentration that is above the "probable toxicity" line, which starts at 200 µg/mL 4 hours after ingestion (333). It should be stated here that NAC administration does affect subsequent APAP levels (333).

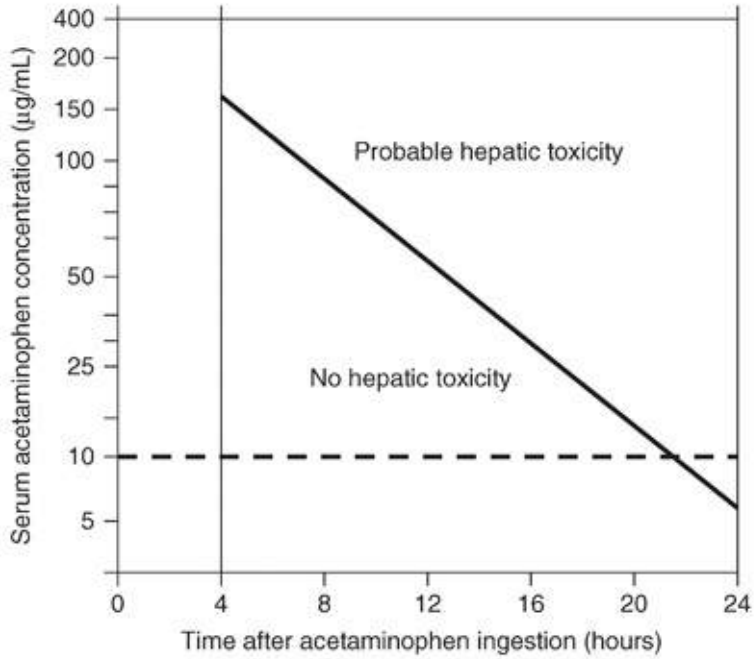

FIGURE 36.10 Acetaminophen metabolism. Relationship between plasma acetaminophen concentration, the time after ingestion, and the risk of hepatic toxicity. The *solid diagonal line* represents a 25% likelihood of hepatic injury. The *horizontal dotted line* compares the low risk at plasma concentration of 10 µg/mL soon after the ingestion versus the high risk at 24 hours since it reflects a high initial load, which has now distributed into tissues. (Reproduced with permission from Rumack BH. Acetaminophen hepatotoxicity: the first 35 years. *J Toxicol Clin Toxicol* 2002;40:3–20.)

NAC can be administered to patients with known or suspected APAP toxicity by oral or IV routes (333,338,341). There are no clinical trials comparing the oral versus IV routes of administration. Thus, the choice of oral or IV administration will have to be determined based on the prevailing clinical circumstances. In the United States, NAC therapy is usually given orally, but since it is sterile, it can be given in identical doses by IV route in patients who cannot tolerate oral administration (342,343). An IV preparation was approved by the FDA for use in the United States. The dose of oral NAC does not have to change when activated charcoal is given concomitantly (335). Orally administered NAC has minimal

adverse effect profile, consisting mostly of nausea and emesis, and increased tolerance can be achieved by coadministration of an antiemetic. On the other hand, adverse effects of IV administration include pruritus, flushing, skin rash, and anaphylactoid reactions. These adverse effects can be treated by administration of antihistamines and temporarily discontinuing the IV infusion and restarting the infusion at a lower rate (335). The FDA-approved NAC treatment protocol for the treatment of acute APAP poisoning involves a loading dose of 140 mg/kg followed by 17 maintenance doses of 70 mg/kg every 4 hours. The IV loading dose is 150 mg/kg over 1 hour, followed by an infusion of 50 mg/kg over 4 hours, and then 100 mg/kg over 16 hour period. The dose does not require adjustment for renal or hepatic impairment or for dialysis (327,333,337,344). Shorter courses as given in Canada, Europe, and Australia proved to be just as effective (345,346). Fortunately, NAC therapy is effective at any point after poisoning. Thus, it should be administered to all patients with history of APAP overdose even if they present after 24 hours of ingestion if their APAP level is elevated (336,347). Likewise, it should be administered if there is hepatic toxicity even in the absence of measurable APAP levels. Moreover, its administration should not be restricted to the 18 doses if there is evidence of liver toxicity. In these circumstances, therapy should continue until evidence of liver injury has resolved and transaminases values have declined to near-normal levels (327).

Dialysis is not as effective as NAC therapy in APAP poisoning. The EXTRIP workgroup suggested that NAC is the mainstay of treatment of APAP poisoning and that ECTR is not warranted in most cases. However, given that APAP is dialyzable, the workgroup agreed that ECTR is suggested in patients with excessively large overdoses who display features of mitochondrial dysfunction. This is reflected by early development of altered mental status and severe metabolic acidosis prior to the onset of hepatic failure. Specific recommendations for ECTR include (a) an APAP concentration over 1,000 mg/L if NAC is not administered, (b) signs of mitochondrial dysfunction and an APAP concentration over 700 mg/L (4,630 mmol/L) if NAC is not administered, (c) signs of mitochondrial dysfunction and an APAP concentration over 900 mg/L (5,960 mmol/L) if NAC is administered, and (d) IHD is the preferred ECTR modality in APAP poisoning (**TABLE 36.18**) (348). Other forms of extracorporeal techniques have not been studied in APAP poisoning except liver dialysis, which was tried in only 4 patients (349).

TABLE 36.18 Extracorporeal Treatment of Acetaminophen (APAP) Poisoning

- ECTR is recommended:
  - If the [APAP] more than 1,000 mg/L (6,620 μmol/L) and NAC is NOT administered
  - If the patient presents with altered mental status, metabolic acidosis, with an elevated lactate, and an [APAP] is more than 700 mg/L (4,630 μmol/L) and NAC is NOT administered
  - If the patient presents with an altered mental status, metabolic acidosis, an elevated lactate, and an [APAP] is more than 900 mg/L (5,960 μmol/L) even if NAC is administered
- ECTR is not recommended on the basis of the reported ingested dose if NAC is administered.
- ECTR is not suggested:
  - On the basis of reported ingested dose alone even if NAC is NOT administered
  - Solely on the basis of the [APAP] if NAC is administered
- ECTR is continued until sustained clinical improvement is apparent.
- Choice of ECTR
  - Intermittent hemodialysis is the preferred ECTR in patients with APAP poisoning.
  - The following are acceptable alternatives if HD is not available:
    - Intermittent HP
    - CRRT
    - Exchange transfusion in neonates
- Miscellaneous
  - NAC therapy should be continued during ECTR at an increased rate

NAC, *N*-acetylcysteine; HD, hemodialysis.
Modified from Gosselin S, Juurlink DN, Kielstein JT, et al. Extracorporeal treatment for acetaminophen poisoning: recommendations from the EXTRIP workgroup. *Clin Toxicol (Phila)* 2014;52(8):856–867.

Finally, patients with repeated supratherapeutic ingestions have a worse prognosis than patients admitted after acute overdose (343,350). Approximately 30% of patients admitted for APAP overdose had repeated supratherapeutic ingestions (323). A recent systematic review with consensus recommendations stated that repeated supratherapeutic ingestions need to be referred to an emergency department only if at least 10 g or 200 mg/kg (whichever is less) during a single 24-hour period, or at least 6 g or 150 mg/kg (whichever is less) per 24-hour period for the preceding 48 hours or longer, is ingested (351). Other patients may be considered for outpatient therapy, particularly those with a supratherapeutic serum APAP concentration <70 μg/mL and less than 3 times the upper limit of alanine aminotransferase concentration (333).

CHAPTER 37

Chronic Dialysis in Children

Bradley A. Warady, Kathy L. Jabs, and Amy L. Skversky

This chapter reviews current approaches to the clinical application of hemodialysis (HD) and peritoneal dialysis (PD) in children. Much of the information contained in this chapter reflect current practice in the authors' pediatric dialysis centers and incorporates advancements in the provision of renal replacement therapy (RRT) to children introduced subsequent to the publication of the prior edition of this text. We have tried to focus on those areas of care in which the pediatric patient differs most from the adult patient, and we have also tried to keep the nephrologist who does not routinely care for pediatric patients in mind. Although we do not encourage those who rarely treat children to embrace this difficult patient group when referral to a pediatric dialysis center is an option, we recognize that referral is not always possible.

This chapter addresses maintenance HD and PD in children; acute dialysis in children is covered in Chapter 38.

EPIDEMIOLOGIC ISSUES

Incidence and Prevalence of End-Stage Kidney Disease in Children

End-stage kidney disease (ESKD) is not a common pediatric disorder. In the United States, there are about 13 new pediatric ESKD cases per million children of similar age reported each year. A higher incidence of ESKD with older age is found within both the pediatric and adult cohorts when adjusting for differences in gender and race. In 2012, the incidence rate for children 15 to 19 years of age (23 per million) was twice the rate of children 0 to 4 years (11 per million) (1). Of note, the incidence of children treated with RRT (dialysis or transplantation) varies across the world from <4 per million (Russia) to 18 per million (New Zealand) (2). The majority of children treated with RRT live in Europe, Japan, or North America, where there is access to this level of care for all children (2). The incidence of ESKD in children contrasts sharply with the incidence of other chronic childhood disorders such as congenital heart disease (8,000 per million) and leukemia (57 per million) (3,4). The incidence of ESKD in children is also substantially lower than the incidence among adults, as is shown by data from the United States

Renal Data System (USRDS) (**TABLE 37.1**) (1). The incidence of ESKD in young children (<5 years of age) has increased over the last three decades, while there has been little change in the incidence of ESKD in older children (1). The apparent increase in the incidence in the youngest pediatric patients in the 1970s and 1980s was likely due to improvements in RRT for smaller patients, notably the availability of automated peritoneal dialysis (APD). These improvements allowed for successful treatment of the youngest pediatric patients who previously had been considered too small to survive (5).

TABLE 37.1 End-Stage Kidney Disease Incidence in the United States in 1982, 1992, 2002, and 2012 at the Start of End-Stage Kidney Disease Therapy (per Million Population, Adjusted for Age, Gender, and Race)

Age Group (y)	1982	1992	2002	2012
0–4	5	7	8	11
5–9	7	6	9	7
10–14	12	13	15	12
15–19	22	29	26	23
0–19	12	14	14	13
20–44	75	119	119	122
45–64	226	500	612	570
65–74	328	1,030	1,451	1,270
75+	194	896	1,731	1,618

From United States Renal Data System. *USRDS 2014 Annual Data Report: Epidemiology of Kidney Disease in the United States*. Bethesda, MD: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, 2014.

Children account for only a small fraction of the total dialysis patient population. On December 31, 2012, the USRDS counted a total of 449,342 dialysis patients in the United States (1). Of these, only 2,060 (0.5%) were younger than 20 years (1,134 treated with HD and 898 PD) (1). Absolute pediatric dialysis patient counts increased from 1,857 to 2,060 between 1992 and 2012, compared with an adult dialysis patient count increase from 159,060 to 448,542 during the same period (1). The small number of children treated with dialysis reflects both the relatively low incidence of ESKD in children and the extensive use of renal transplantation among pediatric ESKD patients. It remains widely accepted that renal transplantation is the optimal treatment for children with irreversible, severe chronic kidney disease (CKD). Recent USRDS data show that 73% of children with ESKD in the United States are maintained by a functioning renal transplant, compared with 29% of adults (1).

Causes of End-Stage Kidney Disease in Children

Approximately one-half of pediatric patients with ESKD have a congenital or hereditary disorder, and one-half have an acquired renal lesion (6). This is in contrast to the adult ESKD population in whom more than 80% of patients have acquired renal disease (1). **TABLE 37.2** lists the primary renal disorders of 7,039 pediatric dialysis patients reported between 1992 and 2011 to the dialysis patient database of the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) (6). The most frequent disorders were congenital anomalies of the kidneys and urinary tract (CAKUT: aplastic/hypoplastic/dysplastic kidneys, urinary obstruction or reflux; 34.3%), focal and segmental glomerulosclerosis (14.4%), and chronic glomerulonephritis (14.5%). This is contrasted with adult patients with ESKD in whom more than 79% of prevalent cases are accounted for by only three primary renal diseases: diabetic nephropathy, hypertensive nephropathy, and chronic glomerulonephritis (1).

TABLE 37.2 Primary Renal Disease Diagnosis in Pediatric Dialysis Patients

Diagnosis	% of Patients
Congenital anomalies of kidney and urinary tract	34.3
Hereditary nephropathies	6.3
Focal segmental glomerulosclerosis	14.4
Chronic glomerulonephritis	14.5
Cystic kidney disease	4.8
Hemolytic uremic syndrome	3.1
Renal infarct	1.3
Diabetic nephropathy	0.1
Miscellaneous or unknown	21.2

PRINCIPLES OF DIALYSIS IN CHILDREN: PERITONEAL DIALYSIS

Peritoneal Membrane Function in Children: Physiologic Concepts

It has long been held that the peritoneal membrane of the child is functionally different from that of the adult and that peritoneal transport kinetics change as a consequence of normal growth and development (7). This concept can be traced to comparative measurements of the peritoneal surface area performed more than 100 years ago. In 1884, in a paper read before the Siberian Branch of the Russian Geographic Society, Putiloff (8) presented comparative data on the peritoneal membrane surface areas of infants and adults. Using direct oiled paper tracings of peritoneal contents, Putiloff (8) found that the peritoneal surface area of an infant weighing 2.9 kg was 0.15 m^2, compared with 2.08 m^2 for an adult of unspecified weight. If a weight of 70 kg is assumed for Putiloff's adult subjects, the infant's peritoneal surface area was found to be almost twice that of the adult when scaled for body weight (522 cm^2/kg vs. 285 cm^2/kg). Earlier studies by Wegner (9) had suggested that the peritoneal surface area closely approximated the body surface area (BSA) of an adult.

The clinical implications of these anatomic relationships were explored in 1966 by Esperanca and Collins (10). Direct measurements of peritoneal surface areas were made during autopsies performed on six neonates and six adults. The mean peritoneal surface area to body weight ratio in the infants was found to be roughly twice that of the adults, confirming Putiloff's (8) measurements made 80 years earlier. Esperanca and Collins (10) assumed that the peritoneal surface area and peritoneal membrane function were directly correlated, postulating that "peritoneal dialysis should be twice as efficient in the infant." Peritoneal urea clearance studies in puppies and adult dogs performed by these same investigators seemed to support their hypothesis (10). When scaled for body weight, peritoneal urea clearance measured in puppies was 2 to 3 times greater than clearances measured in adult animals. However, these clearance studies were seriously flawed. Widely different dialysate delivery rates were used in the puppies and adult animals (128 vs. 42 mL/kg/h, respectively). In this range, urea clearance is directly proportional to the dialysate flow rate, providing ample explanation for the observed differences in urea clearances between the two study groups.

The report by Esperanca and Collins (10) provides an early example of the pitfalls associated with

the use of variable dialysis mechanics when studying peritoneal membrane function. These pitfalls can be avoided if peritoneal transport studies are performed in accordance with the following principles, as defined by Gruskin et al. (11) in 1987:

1. Constant inflow, dwell, and outflow times must be used for all study exchanges.
2. Identical dialysate composition must be used in all study subjects.
3. Exchange volumes must be identically scaled per unit body size. Gruskin et al. (11) allow the use of body weight, height, or surface area as the scaling factor, but other work has shown BSA to be the most reliable scaling factor in pediatric patients (12).
4. Results must be reported according to the body size scaling factor used to determine the exchange volume.

Subsequent peritoneal kinetic studies performed in accordance with these principles have more clearly defined the relative performance characteristics of the peritoneal membrane in children of different ages and in adults (see subsequent text). It is also now evident that the total membrane size is likely less relevant than the total membrane pore area involved in the exchanges (see subsequent text) (13,14).

Principles of Peritoneal Membrane Solute and Fluid Transfer

The peritoneal transfer of solutes reflects two simultaneous and interrelated transport mechanisms: diffusion and convection (15). Diffusion refers to the movement of solute across a semipermeable membrane in response to differing concentrations of that solute on either side of the membrane. The solute moves from the side with higher concentration to the side with lower concentration, down an electrochemical gradient, and in accordance with basic thermodynamic principles. Convection refers to the movement of solutes swept across the membrane within the flux of fluid that arises as a consequence of ultrafiltration. Convective transport is determined by the ultrafiltration rate. Studies of peritoneal membrane function have classically characterized membrane transport properties in terms of effective membrane surface area and solute permeability, fluid transfer (ultrafiltration), and peritoneal lymphatic absorption (16,17). Characterization of the three-pore model has helped to better explain the movement of solute and water across the peritoneal membrane. This model postulates three types of pores: (a) ultrasmall transcellular water pores (aquaporin-1 channels), which account for 1% to 2% of total pore area and 40% of water flow; (b) small pores, accounting for 90% of total pore area and subject to both concentration gradients (diffusive forces) and osmotic gradients (convective forces); and (c) large pores, accounting for 5% to 7% of total pore area and allowing for movement of large molecules such as albumin. The three-pore model has been applied to studies of PD in infants and children (13,14,18).

Effective Membrane Surface Area and Solute Permeability: Diffusive Transport

In the absence of an osmotic gradient between blood and dialysate, the rate of diffusive transfer of a solute is directly related to the product of the mass transfer area coefficient (MTAC) and the concentration gradient of the solute across the peritoneal membrane. The MTAC is a single parameter that is essentially independent of dialysis mechanics (e.g., exchange volume or dialysate dextrose concentration) and represents the functional peritoneal surface area and the diffusive permeability of the membrane. The MTAC also reflects the rate of solute removal that would be achieved in the absence of ultrafiltration or solute accumulation in the dialysate. The MTAC, as applied to the current three-pore model of

transperitoneal solute and water flux, is in turn equal to the product of the free diffusion coefficient for the solute, the fractional area available for diffusion, and the term A_0/D_x, the diffusion distance (19).

In an early study, Morgenstern et al. (20) found that the MTACs for urea, creatinine, uric acid, and glucose in eight children aged 1.5 to 18 years were similar to adult reference values. In contrast, Geary et al. (21) determined MTACs in 28 children and suggested that solute transport capacity varies with age and does not approach adult values until late childhood. Warady et al. (22) determined MTACs for various solutes in 83 children younger than 1 to 18 years. This study had the advantage of standardized dialysis mechanics, including a consistent test exchange volume scaled to BSA at 1,100 mL/m^2. Mean MTACs (normalized to BSA) for creatinine, glucose, and potassium significantly decreased with age, in support of the notion that peritoneal permeability and/or effective membrane surface area relative to BSA is greater in children than in adults. Later, MTAC studies by Bouts et al. (23) based on the three-pore model, found that the values for children, when scaled to BSA, are similar to those of adults.

Diffusive transfer, as noted earlier, is dependent on the MTAC and the transmembrane concentration gradient, which dissipates during exchanges. The amount of "wetted peritoneal membrane," or that portion of the membrane in contact with dialysate, is also of importance since this factor influences the recruitment of small pores for diffusion (24). Recognition that dissipation of the transmembrane concentration gradient is in part related to the dialysate exchange volume (e.g., geometry of diffusion) and of the importance of using a consistent test exchange volume scaled to BSA represents important advances in methodology that are essential to the proper performance of another measure of peritoneal membrane function in children, the peritoneal equilibration test (PET) (see subsequent text) (25).

Scaling the test exchange volume by BSA allows for an equivalent relationship between dialysate volume and peritoneal membrane surface area for children of all ages and sizes so that any detectable differences in solute equilibration rates in this setting are the result of true differences in diffusive transport (24). The use of BSA as the most appropriate "scaling factor" has been validated in studies conducted by Kohaut et al. (26), Warady et al. (22), de Boer et al. (27), and Schaefer et al. (13). Studying their patients in accordance with the three-pore model of peritoneal transport developed by Rippe et al. (28,29), Schaefer et al. (13) demonstrated that the functional peritoneal exchange surface is a linear function of BSA and independent of patient age.

It is also noteworthy that posture may influence the diffusion process. The proportion of the peritoneal surface area that is recruited for an exchange can be 30% higher in the supine position compared to the upright position (14).

Ultrafiltration

Ultrafiltration, the movement of fluid from blood to dialysate, is a complex process that is incompletely understood and reflects the interaction of a number of factors including the hydraulic permeability of the peritoneal membrane, the permeability of the peritoneum to the osmotically active solutes on either side of the membrane, the absorption of fluid into peritoneal tissue, and lymphatic absorption. Most important is the fact that osmotic conductance drives the transport of free water across the aquaporin-1 channels and is counteracted by the absorption of glucose via the small pores with a subsequent time-dependent loss of the crystalloid osmotic gradient (30). Convective mass transfer occurs as a consequence of ultrafiltration. When considered in the context of total solute removal during PD, convective mass transfer contributes

little to the movement of small solutes but is responsible for most large solute removal (15). For example, during a 4-hour continuous ambulatory peritoneal dialysis (CAPD) exchange with 4.25% dextrose solution, the contributions of convection to total transport have been estimated by Pyle (31) to be 12% for urea, 45% for inulin, and 86% for total protein.

Early studies and much clinical experience suggested that adequate ultrafiltration could be difficult to achieve in infants and younger children. Initial studies found a more rapid decline in dialysate dextrose concentration and osmolality in younger children (32,33). Subsequent work by Kohaut et al. (26) suggested that apparent age-related differences in ultrafiltration capacity disappear when the test exchange volume is scaled to BSA rather than body weight. As mentioned earlier, proper scaling of the exchange volume is an important determinant of the rate of dissipation of the osmotic gradient that determines ultrafiltration. Finally, some data actually suggest that even the body size-normalized fluid reabsorption rate may be slightly increased in young infants compared with older children and adults and have an impact on net ultrafiltration (13). Whereas this finding may be a manifestation of a greater lymphatic absorption rate in the youngest children, it is more likely the result of a reversed movement of fluid with hydrostatic and oncotic pressure gradients as a result of greater intraperitoneal (IP) pressures being generated in the smallest patients (34,35).

Peritoneal Lymphatic Absorption

To some extent, studies of ultrafiltration in children have been hindered by the absence of information on the contribution of lymphatic absorption to net ultrafiltration. Mactier et al. (36) studied lymphatic absorption in six children aged 2 to 13 years. Peritoneal lymphatic drainage was reported to reduce mean ultrafiltration by 27%. When lymphatic absorption rates were scaled to body weight, higher values were obtained for pediatric patients when compared with adult reference values. When scaled to BSA, these differences were no longer seen. More recently, fluid absorption has been felt to primarily be related to movement directly into the tissues surrounding the peritoneal cavity. Lymphatic absorption is only thought to account for 20% of fluid absorption. The limited data on lymphatic absorption in children makes this a potential area for future investigations (34,36,37).

PRINCIPLES OF DIALYSIS IN CHILDREN: HEMODIALYSIS

The principles of HD, extracorporeal perfusion, solute clearance, ultrafiltration, and mass balance, are very similar when applied in children and adult patients. Certain pediatric-specific issues with respect to patient size, however, do require comment.

Characteristics of Dialyzers

The ideal pediatric hemodialyzer would have a very small blood volume, a safe ultrafiltration coefficient, a low resistance blood circuit, a high degree of biocompatibility, and a predictable relationship between clearance and blood-flow rates (BFRs). Hollow-fiber dialyzers have now supplanted previously used flat-plate dialyzers in virtually all pediatric centers. Improvements in the manufacturing process of hollow-fiber dialyzers have led to decreased dialyzer volumes, rendering them more useful for the treatment of infants and small children in whom a small extracorporeal volume is desirable. Hollow-fiber dialyzers also have more predictable clearance characteristics and can be easily cleaned and

reprocessed. There are several characteristics of dialyzers that should be considered before their clinical use: clearance, ultrafiltration, and biocompatibility.

Clearance

In the clinical setting, the clearance achieved by a dialyzer is a function of its mass transfer area coefficient (K_oA) and the blood- and dialysate flow rates (Q_B, Q_D). K_oA, expressed in mL/min, is a property of the dialyzer that describes the maximum ability of a dialyzer to clear a given solute at infinitely high blood- and dialysis flow rates (38). The relationship between BFRs and clearance for two different dialyzers is shown in **FIGURE 37.1**. In that representation, dialyzer 2 has a larger K_oA (urea) than does dialyzer 1. Several important conclusions can be drawn from the shape of the curves. First, at low BFRs, the small solute clearance is equivalent to the BFR and is the same for both dialyzers 1 and 2, and for virtually all dialyzers. Second, for each dialyzer, a maximum clearance will be achieved at a certain BFR, above which increasing the blood flow will not increase clearance. Therefore, the difference between larger and smaller dialyzers is principally the BFR at which the maximum urea clearance is achieved. Thus, when choosing a dialyzer for a pediatric patient, one must consider not only the target clearance but also the maximum achievable BFR. For example, for a large child in whom BFRs of 350 to 400 mL/min are possible, a large dialyzer would be preferable because a higher clearance could be achieved. In contrast, for a small child who achieves BFRs of 70 to 85 mL/min, the difference in clearance rates at low BFRs would be negligible, and other considerations would be more appropriate when selecting a dialyzer, such as dialyzer volume. This will be addressed in more detail later in the chapter.

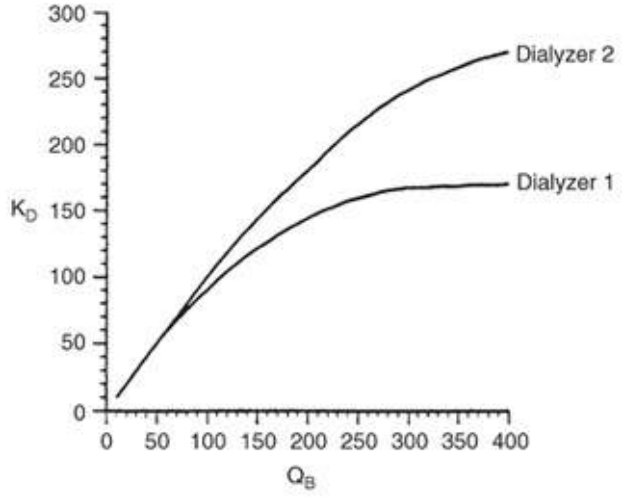

FIGURE 37.1 Relationship between blood flow (Q_B) and dialyzer clearance (K_D) for two different dialyzers. Dialyzer 2 has a K_oA for this solute that is twice that of dialyzer 1.

A dialyzer has different clearances for different solutes, which are generally inversely related to molecular weight. Although typically not considered in the dialysis prescription for young infants, the relatively low BFRs at which clearance of high molecular weight solutes reach their maximum levels means infants and young children usually receive high-efficiency dialysis (39). Although infants and young children receive an equivalent overall clearance of these solutes compared with adults because their volumes of distribution are significantly less, the overall mass transfer is much greater. A practical example in which this may have clinical relevance is the clearance of vancomycin as dosing intervals for vancomycin in infants receiving HD are much shorter than in adults (40).

Ultrafiltration

The ultrafiltration coefficient of the dialyzer should be sufficient to allow the desired ultrafiltration during the planned duration of a dialysis session. Concern has been raised in the past about the ultrafiltration coefficient of dialyzers used for pediatric patients because excessive ultrafiltration could lead to hypotension and shock. Theoretically, this could be a particular problem with the now standard high-efficiency dialysis. However, the routine use of dialysis machines with volumetric ultrafiltration control and noninvasive blood volume monitoring has greatly reduced these concerns.

Biocompatibility

Although there is debate concerning the preferred use of specific membranes for the chronic treatment of adults with respect to biocompatibility, there is indeed evidence that certain membranes can affect long-term leukocyte function, inflammatory markers, protein catabolism, and perhaps overall mass transfer of β_2-microglobulin, which may have long-term adverse clinical consequences (41–44). Newer generation dialysis membranes constructed from materials such as polysulfone and polymethyl methacrylate (PMMA) cause less proinflammatory cytokine activation compared with older generation membranes from cellulose or cuprophane (45). Whereas there are no data available on changes in patient outcomes with polysulfone or PMMA membranes, the incidence of anaphylactoid, complement-mediated, immediate membrane reactions are far less common with the newer biocompatible membranes that are commonly used. Although there have not been any long-term studies on this issue in pediatrics, a study from Egypt has examined the expression of adhesions molecules, particularly intercellular adhesion molecule one (ICAM-1), as a marker of biocompatibility of dialysis membranes in 80 pediatric HD patients. In this study, which compared the use of polysulfone low-flux filters and polysulfone high-flux filters, the high-flux group showed a significant decline in predialysis serum levels of ICAM-1 with decreased neutrophil activation as compared to those patients using the low-flux filters (46). At present, however, there are no clear-cut advantages associated with the use of any specific type of membrane for pediatric patients.

DIALYSIS FOR END-STAGE KIDNEY DISEASE IN CHILDREN

Choice of Hemodialysis or Peritoneal Dialysis as a Chronic Renal Replacement Therapy in Children

HD, PD, and renal transplantation are all successful long-term treatments for ESKD in children. Renal transplantation has been widely recognized as the treatment of choice for children with ESKD because it can relieve the burden of continuous and repetitive treatments while restoring the child to a virtually normal metabolic homeostasis and permitting near-normal growth and development (47,48). Unfortunately, because tolerance has not yet been achieved in humans after organ transplantation, and nonadherence with medications remains a substantial issue, virtually all grafts are eventually lost and pediatric patients are on a continuous cycle of alternating between dialysis and transplantation over the course of their lifetime. Renal transplantation should, therefore, be considered a treatment rather than a cure for kidney disease. Despite the preference for renal transplantation and the fact that up to 24% of

children may receive a preemptive transplant without prior dialysis, large-scale registry data indicate that a large portion of children with ESKD require a prolonged period of treatment with chronic dialysis either before or between renal transplants, making chronic dialysis a significant component of the treatment for all children with ESKD (26,49,50).

Few studies have directly compared the efficacy of chronic HD and PD in pediatric patients. The proposed advantages of HD include minimal technical assistance required for the patient and family and decreased treatment times. The proposed advantages of PD, especially APD, include decreased dependence on the treatment center, increased flexibility of the treatment schedule with improved school attendance, somewhat decreased dietary restrictions, and a decreased need for repeated venipunctures. A very early comparison of the two chronic dialysis modalities in children from a single center showed that PD appeared to be associated with lower transfusion rates, improved rehabilitation, and better metabolic control (51). However, advancements over the last two decades with respect to erythropoiesis-stimulating agent (ESA) therapy, and the availability of smaller extracorporeal circuits and volumetrically controlled HD machines, have minimized many of the previous negative aspects of HD. A 2011 review of 6,573 adult dialysis patients in Ontario, Canada, who received ≥4 months of predialysis care and who started dialysis electively demonstrated no difference in survival between PD and HD (52). The advent of nightly home HD and frequent daytime HD has made available additional effective alternative RRT options for adults that are now being used in some pediatric centers as well (see below).

There are many patient factors that play a role in the selection of a dialysis modality including patient age, lifestyle choice, parental preference, assessment of whether individual patients and families can be adherent with the dialysis regimen, and the ability of a center to provide HD or support a home-based dialysis program (53,54). Factors related to the overall success of the dialysis patients may also be involved in the selection of a dialysis modality for an individual child (e.g., children with greater social support are more likely to be treated with PD and more likely to attend school full-time). Comparison of the children in NAPRTCS has demonstrated higher full-time school attendance rates in those treated with chronic peritoneal dialysis (CPD) versus those receiving HD (e.g., 78% vs. 53% for children aged 6 to 18 years) (6). Recent reports of successful home-based HD therapies now extend the advantages of home-based programs to pediatric patients who cannot perform CPD for medical reasons (55–57).

At present, it is virtually impossible to find convincing evidence that either form of dialysis is clearly preferable for most children with ESKD, although clear preferences exist in individual cases. As noted above, the choice of dialysis treatment may be influenced by the preference of the center or by its technical capabilities. In these circumstances, it is important that patient and family choice be preserved whenever possible and not be subverted by the overt or subtle influence of the unit's personnel.

Characteristics of a Pediatric Dialysis Center

The provision of optimal chronic pediatric dialysis requires a program philosophy that is geared to the particular needs of infants, children, adolescents, and young adults. Although the equipment used for delivering pediatric dialysis is similar to that found in adult dialysis units, specialized personnel in addition to physicians and nurses with expertise in pediatric care, are necessary to ensure that children receiving dialysis can receive developmentally appropriate care in the setting of a never ending cycle of dialysis and renal transplantation (58). Child life specialists and pediatric-trained ESKD social workers are essential team members of any pediatric dialysis program (53). Child life specialists lend critical

expertise to provide developmentally appropriate evaluations and assistance to children and their families during procedures and can serve as liaisons to help educate school personnel with respect to the particular medical and psychosocial needs of children with ESKD; this is especially important if a dialysis-based teacher is not available. Pediatric-trained ESKD social work personnel are essential to evaluate the psychosocial development of children with ESKD. Regular assessment of the pediatric patient's health-related quality of life (HRQOL) is mandatory, and there are a number of validated assessment tools, including the Pediatric Quality of Life Inventory generic (PedsQL4.0) and ESKD-specific (PedsQL3.0) modules. This assessment helps identify important psychosocial issues that ideally should prompt the implementation of interventions designed to address and potentially minimize the psychological stresses that negatively impact quality of life (QOL) in patients with ESKD (59,60). Assistance provided to families to help navigate complex socioeconomic challenges and barriers associated with ESKD is also crucial. Dietitians who are expert in the nutritional requirements and restrictions imposed by ESKD are vital to the development of palatable menus for children with ESKD; they also work with school lunch programs and closely monitor a multitude of nutrition status markers (see below) (61).

CHRONIC PERITONEAL DIALYSIS FOR CHILDREN

Although successful as treatment for acute kidney injury (AKI), PD historically appeared to have much less to offer to the child with ESKD. Initial CPD techniques required reinsertion of the dialysis catheter for each treatment, making prolonged use in small patients difficult. The development of a permanent peritoneal catheter, first proposed by Palmer et al. (62,63) and later refined by Tenckhoff and Schechter (64), made long-term PD an accessible form of RRT for pediatric patients. When Boen et al. (65) and then Tenckhoff et al. (66) devised an automated dialysate delivery system that could be used in the home, chronic intermittent peritoneal dialysis (IPD) became a practical alternative to chronic HD for children. Largely, as a result of the pioneering efforts of the pediatric ESKD treatment team in Seattle (67,68), pediatric chronic IPD programs were established in a few prominent pediatric dialysis centers (69–72). However, enthusiasm for chronic IPD among pediatric nephrologists during this period was limited, perhaps because chronic IPD for children included many of the least desirable features of chronic HD (e.g., substantial dietary restrictions, fluid intake limits, immobility during treatments, and complex machinery), without providing the one great advantage of HD: efficiency.

A new era in the history of PD as an RRT modality for children with ESKD was heralded by the description of CAPD in 1976 by Popovich et al. (73). CAPD appeared particularly well suited for use in children. Potential advantages of CAPD over HD of special importance to children included near steady-state biochemical control, reduced dietary restrictions and fluid limits, and freedom from repeated dialysis needle punctures. CAPD also allowed children of all ages to receive dialysis in the home, offering them the opportunity to experience a more normal childhood. Finally, CAPD made possible the routine treatment of very young infants, thereby extending the option of RRT to an entire population of patients previously considered too young for chronic dialysis.

CAPD was first used in a child in 1978 in Toronto (74,75). Subsequent experience was soon reported from growing pediatric CAPD programs in North America and Western Europe (76–78). Continuous cycling peritoneal dialysis (CCPD) was first used in a child by Price and Suki (79) in 1981.

APD or cycler dialysis has since grown in popularity among many pediatric PD programs throughout North America and the world (80). In those centers where APD is freely available, this PD modality is usually preferred over CAPD. Pediatric PD registries in North America and Italy have reported that an average of 70% of children who are prescribed PD perform APD, with a substantial increase in APD usage over time (81,82). Although personal preference and lifestyle are the factors that most frequently influence the choice of CPD modality in children, individual variation in peritoneal transport characteristics may determine a patient's suitability for a particular therapy (22,83,84).

Permanent Peritoneal Dialysis Catheters for Children

A reliable peritoneal catheter is the cornerstone of successful CPD, well worth the attention and effort required to "perfect" the procedure in each center that proposes to treat children with long-term PD. There are multiple types of PD catheters presently available with a variety of configurations. In general, most long-term PD catheters are constructed of a soft material such as silicone rubber or polyurethane. The catheters can be thought of as having two separate regions, the IP portion and the extraperitoneal portion. The IP portion contains holes or slots to allow passage of peritoneal fluid. The shape of the IP portion typically is straight or curled; the latter configuration is often associated with less patient pain with dialysate inflow and a decreased predisposition to omental wrapping of the catheter. The most common catheters with these characteristics used by pediatric patients have been the straight and curled Tenckhoff catheters. The extraperitoneal portion of each of these catheters has one or two Dacron cuffs to prevent fluid leaks and bacterial migration and most importantly, to fix the catheter's position. The shape of this portion of the catheter is variable and may be straight or have a preformed angle (e.g., swan neck) to help create a downward directed catheter exit site (85).

The variability in the choice of catheter characteristics is reflected in the data from NAPRTCS, collected between 1992 and 2010 (6). Of the 4,391 catheters, 62.1% were of the Tenckhoff curled variety, and 15 different combinations of characteristics each represented at least 2.0% of the catheters placed (**TABLE 37.3**).

TABLE 37.3 Peritoneal Dialysis Access Characteristics

Catheter	Cuffs	Tunnel	Exit Site	*N* (4,391)	% (100.0)
Curled	One	Straight	Lateral	619	14.1
Curled	Two	Swan-necked/curved	Down	458	10.4
Curled	Two	Straight	Lateral	315	7.2
Straight	One	Straight	Lateral	313	7.1
Curled	Two	Straight	Down	277	6.3
Curled	One	Straight	Down	267	6.1
Curled	One	Straight	Up	209	4.8
Curled	Two	Swan-necked/curved	Unknown	145	3.3
Straight	One	Straight	Up	136	3.1
Curled	Two	Swan-necked/curved	Lateral	132	3.0
Presternal	Two	Swan-necked/curved	Down	129	2.9
Straight	One	Straight	Unknown	123	2.8
Straight	One	Swan-necked/curved	Lateral	105	2.4
Straight	One	Straight	Down	102	2.3
Straight	Two	Straight	Lateral	100	2.3
Curled	One	Swan-necked/curved	Lateral	78	1.8
Curled	One	Swan necked/curved	Down	78	1.8
Curled	One	Straight	Unknown	76	1.7
Curled	Two	Straight	Unknown	57	1.3
Straight	Two	Straight	Up	54	1.2

From North American Pediatric Renal Trials and Collaborative Studies. *Annual Dialysis Report*. Rockville, MD: EMMES Corp, 2011.

The two most common approaches to PD catheter placement are the open and laparoscopic techniques, as was recently reviewed in guidelines published by the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) (86). Currently, there is no data that shows the superiority of one technique over the other, and two recent meta-analyses have yielded differing results (87,88). Whichever insertion approach is used, lateral placement through the body of the rectus muscle should be encouraged as a means of decreasing the likelihood of catheter leakage (89–91). Daschner et al. (92) have reported on the laparoscopic placement of 25 two-cuff Tenckhoff catheters in 22 pediatric patients. Postoperative leakage occurred in only two patients, and the procedure facilitated the removal of adhesions and inguinal hernia repair at the time of catheter placement. Catheter placement should always be accompanied by prophylactic antibiotic therapy, a practice that has resulted in a significantly reduced risk of early peritonitis (89,93–95). Additional commentary regarding recommendations pertaining to the laparoscopic placement of PD catheters has recently been published (96).

In general, it is believed that infants and young children with vesicostomies, ureterostomies, or colostomies require placement of the PD catheter exit site as far from the stoma as possible to prevent contamination and infection. Placement of the exit site on the chest wall has successfully limited the number of infections in such high-risk situations in a small number of children and adults (97–102). The primary reason for catheter revision is catheter malfunction, often caused by omental wrapping of the catheter (103,104). In a single study of 101 pediatric PD patients who underwent reoperation for infection or malfunction of their PD catheter, lack of an omentectomy was the only independent risk factor to be associated with the need for catheter revision (105). With this in mind, an omentectomy was performed with the insertion of 82.4% of catheters in the Italian pediatric PD registry and is performed by at least 59% of North American surgeons placing chronic PD catheters (91). However, the decision to perform an omentectomy in conjunction with catheter placement is not universal (106–108).

Finally, in the most recent report of the NAPRTCS and as has been shown in previous reports, the annualized peritonitis rate decreased with increasing age and was best in association with Tenckhoff

catheters with double cuffs, swan-neck tunnels, and downward-pointed exit sites (6,109). In addition, time to first peritonitis episode was longer for catheters with two cuffs compared with one, with swan-neck tunnels compared with straight tunnels, and with downward exit sites compared with lateral exit sites or exit sites directed upward. These results confirm findings from the adult PD population and prompted recommendations for use of a two-cuff Tenckhoff catheter in the *Consensus Guidelines for the Prevention and Treatment of Catheter-Related Infections and Peritonitis in Pediatric Patients Receiving Peritoneal Dialysis: 2012 Update* (95).

Role of Peritoneal Equilibration Test in Prescribing Peritoneal Dialysis for Children

The PET was developed by Twardowski et al. (83) as a simple means of characterizing solute transport rates across the peritoneum that could have direct clinical applications. The construction of reference curves based on the kinetics of solute equilibration between dialysate and plasma (D to P ratio) after a 2-L exchange volume made possible the categorization of adult patients into those with high, high-average, low-average, and low peritoneal membrane solute transport rates and served as the basis for the dialysis prescription process (see subsequent text).

However, Twardowski et al.'s (83) adult PET reference curves should not be applied to the pediatric PD population primarily because a uniform 2-L test exchange volume was provided to all study patients, regardless of their size, in the Twardowski scheme. Obviously, this approach does not allow for modification of the exchange volume to reflect differences in body size (e.g., pediatric patient, small adult, large adult) and has contributed to the limited usefulness of this approach in children.

Application of a standardized PET procedure for children has, on the other hand, resulted from an appreciation of the previously mentioned age-independent relationship between BSA and peritoneal membrane surface area and the recommended use of an exchange volume scaled to BSA whenever one conducts studies of peritoneal transport kinetics (22,26,27,110). In the largest pediatric study to date, the Pediatric Peritoneal Dialysis Study Consortium (PPDSC) evaluated 95 children for their membrane solute transport capacity (22). Similar reference data has been generated from pediatric studies in Europe with a test exchange volume of 1,000 mL/m^2 BSA (111). Although the standard PET is conducted over 4 hours, use of a 2-hour PET has proven reliable and less labor intensive in pediatric patients new to PD (112,113).

Because the transport capacity of a patient's peritoneal membrane is such an important factor to consider when determining the dialysis prescription, a PET evaluation should be conducted soon after the initiation of dialysis (114–116). There is, however, evidence that a PET performed within the first week after the initiation of PD may yield higher transport results than a PET performed several weeks later (117–119). Accordingly, whereas it may be most convenient to perform the initial PET at the conclusion of PD training, the Kidney Disease Outcomes Quality Initiative (KDOQI) has recommended that the PET be conducted 4 to 8 weeks following the initiation of CPD (116–118). The PET evaluation should be repeated when knowledge of the patient's current membrane transport capacity is necessary for determination of the patient's PD prescription, especially when adverse clinical events have occurred (e.g., repeated peritonitis) and are followed by clinical evidence of altered transport characteristics (e.g., worsening hypertension as a result of unexplained fluid overload, increasing need for hypertonic dialysate, ESA-resistant anemia secondary to hypervolemia) (120). In addition, knowledge of a patient's transport capacity may have a profound impact on the overall care because of the important relationships

that exist between transport status and patient outcome in children and adults (121–123).

Chronic Peritoneal Dialysis Prescription

In general, the CPD prescription for children has evolved empirically from guidelines that adapted adult CAPD to the pediatric patient. A CAPD regimen of four to five exchanges per day with a fill volume of 900 to 1,100 mL/m^2 BSA (35 to 45 mL/kg) of 2.5% dextrose dialysis solution has routinely yielded net ultrafiltration volumes of up to 1,100 mL/m^2/d. The KDOQI Clinical Practice Recommendations for Peritoneal Dialysis Adequacy that pertain to children, most of whom receive APD, target an individual fill volume of 1,000 to 1,200 mL/m^2 for patients older than 2 years and a lower initial volume (600 to 800 mL/m^2) for younger infants (116,124,125). The greatest percentage of children receiving APD utilize a regimen consisting of 5 to 10 exchanges over 9 to 12 hours per night with a daytime dwell consisting of approximately 50% of the nocturnal fill volume, the latter to enhance solute and fluid removal particularly in anuric patients (18,126). More recently, the concept of adapted PD, with initial cycles using a relatively small fill volume and short duration to maximize ultrafiltration, followed by a larger fill volume with a longer dwell time to promote solute clearance, has been suggested as a means to improve dialysis efficiency (24).

The current goal of achieving dialysis adequacy in the most cost-effective manner has highlighted the need to be cognizant of a patient's BSA, peritoneal membrane solute transport capacity, and residual kidney function (RKF) when designing the dialysis prescription (22,84,115,116,127). The prescribed PD schedule should also be compatible with the psychosocial needs of the patient and family. In most patients (except for the rapid transporter), the most effective way to increase solute clearance is to initially increase the fill volume followed by an increase in dialysis duration by prolonging the dwell time. Measurement of the IP pressure generated by escalating fill volumes can be useful in determining the maximal tolerated IP volume because, as noted previously, an exceedingly high IP pressure (>14 cm H_2O) may result in back-filtration and compromise ultrafiltration capacity and be poorly tolerated by the patient (24,128–133). In the case of the rapid transporter, an increase in the number of exchanges and a reduction of the dwell time per cycle can result in improved solute clearance.

As mentioned earlier, the categorization of a patient's peritoneal membrane transport capacity can best be determined by the performance of a PET and comparison of the individual patient data to reference values (22,111). In turn, this information makes it possible to optimize the dialysis prescription in terms of the exchange dwell time. Recognizing that it is often impractical to consider the provision of a dialysis prescription based solely on kinetic data without reference to social constraints (e.g., school attendance, working parent), the use of the results of a PET can be particularly helpful in PD modality selection (e.g., high transporter: cycling PD; high- to low-average transporter: CAPD or APD with the option of an additional daytime exchange). Often, this selection process can be most easily achieved with the use of one of several computer modeling programs that have been validated in pediatric patients and that can provide accurate estimates of solute clearance (13,134,135). It must be emphasized that in pediatric patients, as well as in adults, predicted values are only estimates and do not substitute for actual measurements of solute clearance (see subsequent text).

The RKF, a characteristic that appears to be better preserved by PD versus HD, is calculated as the average of urea and creatinine clearance and assumes greatest importance in the patient who does not

attain target clearances with dialysis alone (116,136–139). Whereas the contribution of RKF toward a target goal may be significant early in the course of dialysis, a progressive loss of RKF usually occurs and mandates an associated enhancement of the dialysis prescription if target clearances are to be maintained. Efforts to preserve RKF include the prevention of nephrotoxic insults such as exposure to radiocontrast dye and possibly the use of an angiotensin-converting enzyme inhibitor (ACEI) or angiotensin receptor blocker (116,140–142). Diuretic therapy has also recently been shown to help preserve RKF in pediatric patients receiving CPD (143).

Peritoneal Dialysis Adequacy

The goal of achieving dialysis adequacy in children emphasizes the clinical status of the patient as an important qualitative target (116). Clinical manifestations of inadequate dialysis may include congestive heart failure, hyperphosphatemia/excessive calcium–phosphorus product, overt uremia manifested as pericarditis/pleuritis or clinical, and/or biochemical signs of malnutrition or wasting. All of these outcomes may be the result of one or more of the following factors:

- Loss of RKF
- Prescription inadequate for peritoneal membrane transport characteristics
- Reduced peritoneal membrane surface area caused by extensive intra-abdominal adhesions
- Loss of peritoneal membrane solute transport/ultrafiltration capacity
- Noncompliance with PD prescription
- Poorly functioning PD catheter

Despite the emphasis on clinical parameters, PD adequacy and solute clearance have been used almost interchangeably since the performance of the National Cooperative Dialysis Study in the adult HD population. The Adequacy of Peritoneal Dialysis in Mexico (ADEMEX) study and a randomized trial of different solute clearance targets in adult CAPD patients conducted by Lo et al. have provided data that supports the current recommendation for a target total (peritoneal and kidney) Kt/V_{urea} of at least 1.7 per week in adults (116,144,145). It has also been suggested that the determination of peritoneal creatinine clearance has little added value to the prediction of outcome in adults on CAPD such that adequacy targets should be based on urea kinetics only. In contrast, due to a more variable relationship between urea and creatinine with APD, an additional target of 45 L/wk/1.73 m^2 for creatinine clearance has been recommended (146). Because there are no data that correlate solute removal with outcome in pediatrics, making it impossible to define PD adequacy in children with confidence, it has been recommended that the pediatric population should use clearance goals that meet or exceed current KDOQI adult standards. Specifically, the minimal delivered dose of total (peritoneal and kidney) small solute clearance should be a Kt/V_{urea} of at least 1.8 per week (116). Reports by Holtta et al. (147), McCauley et al. (148), Champoux (149), and Chadha et al. (150) have all presented data suggestive of a correlation between patient outcome and solute clearance. The experience of Chadha et al. (150) was also significant for demonstrating the influence that RKF has on patient outcome and the apparent contradiction of the presumed equivalence of PD and native solute clearance.

Can the solute clearance targets be achieved by children on CPD without introducing a prescription that has a significant negative impact on their QOL? Whereas data by van der Voort et al. (151) suggests otherwise, the clinical experiences of Holtta et al. (147) and Chadha et al. (150) provide good evidence

that if the dialysis fill volume is maximized and if the frequency of the exchanges is individualized and adjusted according to the peritoneal membrane transport characteristics, it should be possible to achieve the current KDOQI clearance targets in most children receiving PD. In fact, data from the Clinical Performance Measures project has revealed median Kt/V_{urea} values of 2.43 and 2.45 for pediatric patients receiving CCPD and nightly intermittent peritoneal dialysis (NIPD), respectively (152).

As mentioned earlier, Kt/V_{urea} has found widespread acceptance as a marker of small-solute clearance and is calculated as the urea clearance normalized for the volume of urea distribution or total body water (TBW). Therefore, the ability to accurately estimate a patient's TBW (or V) is integral to the determination of this adequacy measure. Whereas some investigators have recommended the use of bioelectrical impedance as a means of determining V, this procedure is not regularly conducted in most pediatric dialysis centers (153). Previously published anthropometric equations and formulas derived from the study of healthy individuals also do not provide reliable information for the pediatric dialysis population (154–157). Fortunately, the publication by Morgenstern et al. (158) of data derived from studies of children on CPD conducted with heavy water (H2 O18 or D2 O) also permitted the development of equations, which permits one to predict TBW with acceptable accuracy and precision. The gender-specific equations are as follows (**EQUATIONS 37.1** and **37.2**):

$$\text{Boys: TBW} = 0.010 \times (\text{height} \times \text{weight})^{0.68} - 0.37 \times \text{weight} \quad (37.1)$$

$$\text{Girls: TBW} = 0.14 \times (\text{height} \times \text{weight})^{0.64} - 0.35 \times \text{weight} \quad (37.2)$$

Because the height × weight parameter predicts BSA, the prediction equations can be simplified (with somewhat less precision) in the following manner (**EQUATIONS 37.3** and **37.4**):

$$\text{Boys: TBW} = 20.88 \times \text{BSA} - 4.29 \quad (37.3)$$

$$\text{Girls: TBW} = 16.92 \times \text{BSA} - 1.81 \quad (37.4)$$

In all cases, the Gehan and George (159) equation should be used to determine BSA.

Implicit in the approach to achieve and maintain dialysis adequacy is the need to repeatedly measure total solute clearance. Ideally, 24-hour collections of urine and dialysate fluid should be obtained a minimum of two times per year or when there have been significant changes in the patient's clinical status that may influence dialysis performance (e.g., severe or repeated episodes of peritonitis). For infants incontinent day and night, we currently attempt to achieve total clearance targets using dialysis clearances alone, rather than using indwelling urinary catheters for these patients to facilitate determination of RKF.

Finally, ultrafiltration capacity and overall fluid status should also be considered a component of adequate PD, and a patient's membrane transport capacity may be particularly important in this context. Adult studies have demonstrated that the relative risks of technique failure and patient mortality are significantly increased in patients categorized as high transporters by the PET (123). It is postulated that the rapid glucose absorption that characterizes the high transport state may predispose patients to chronic fluid overload and cardiovascular morbidity (160). Noteworthy is data from the NAPRTCS, which demonstrated that 57% of 4,000 pediatric PD patients had hypertension, in addition to the results of another study, which revealed that 68% of pediatric patients on CPD were found to have left ventricular hypertrophy (161,162). Additional pediatric experience with dialysis solutions characterized by improved peritoneal membrane biocompatibility, as well as with solutions using alternatives to glucose

as the osmotic agent, should be a priority in view of the high incidence of hypertension and cardiovascular morbidity in children on dialysis (18,163–165). In patients experiencing decreased ultrafiltration capacity and resultant hypervolemia, therapeutic interventions may include use of a long daytime exchange with icodextrin, an increase in the number of exchanges or an increased overall treatment time, and/or an increase in the dialysate glucose concentration (18). Diuretic therapy may also be beneficial in those patients with maintained RKF (143). In some patients, however, a change in dialysis modality to HD is necessary to best control fluid status.

Nutritional Management of Children on Peritoneal Dialysis

A normal nutritional status is uncommon among children treated with CPD, despite access to a diet primarily restricted only in terms of phosphorus, and possibly sodium intake (166,167). Compared with healthy children, those on CPD have a significantly lower energy intake and diminished height, weight, triceps skinfold thickness, and mid arm muscle circumference (166). Hypoalbuminemia and hyperlipidemia are commonly seen (167,168). Anorexia and dysgeusia are often accompanied by gastroesophageal reflux and other feeding disorders (169). As part of the KDOQI process, pediatric nutritional guidelines were updated in 2009 and provide recommendations for the assessment of a patient's nutritional status and for the provision of optimal nutrition (61). In the opinion of the working group, parameters of nutritional status and growth to be followed include dietary intake, length or height, height velocity, estimated dry weight, body mass index (BMI), and head circumference (for children <3 years) (61). BMI (weight^2 / height) should be normalized to height age to account for the age dependency of the value and the growth-retarded nature of the dialysis population. Growth and nutritional parameters should be measured at the initiation of dialysis and at regular intervals as recommended in the guidelines.

Children should receive 100% of the recommended dietary reference intake (DRI) for energy, referenced to height, age, and gender (170). Whereas it is estimated that total energy intake will be augmented by an additional 8 to 20 kcal/kg/d derived from dialysate dextrose absorption, little information on this topic is available from the pediatric APD population (171).

The members of the KDOQI working group were unable to recommend with evidence the optimal protein intake for each child receiving CPD, and therefore, an initial dietary protein intake equal to 100% of the DRI for ideal body weight plus anticipated protein losses across the peritoneum is recommended (61). The efficacy of the prescribed intake must be assessed regularly to ensure that it is adequate (172). Dialysate protein losses are proportionately greater in children than in adults (173–175), and children often begin CPD with evidence of protein wasting (167,176). At the same time, excessive dietary protein intake can result in hyperphosphatemia and an increased risk for cardiovascular disease (CVD) (177–180). Therefore, current recommendations are for daily protein intakes of 1.8 g/kg for patients 0 to 6 months, 1.5 g/kg for children aged 7 to 12 months, 1.3 g/kg for children aged 1 to 3 years, 1.1 g/kg for patients 4 to 13 years, and 1.0 g/kg for the adolescent population. Supplementation of dietary protein intake with amino acids administered by the IP route has been performed on occasion, but the use of these solutions has failed to result in a significant improvement of nutritional parameters (181,182).

As suggested earlier, dietary phosphate intake must be monitored closely because of the potential adverse impact hyperphosphatemia has on bone and cardiovascular health. The guidelines recommend limiting dietary phosphorus intake to 100% of the DRI in normophosphatemic patients if the serum parathyroid hormone (PTH) concentration exceeds the target range and to 80% of the DRI when the serum

phosphorus exceeds the target range and hyperparathyroidism is established (**TABLE 37.4**) (61). Age-appropriate serum phosphorus levels should be targeted (183).

TABLE 37.4 Recommended Maximum Oral and/or Enteral Phosphorus Intake for Children with Chronic Kidney Disease

		Recommended Phosphorus Intake (mg/d)	
Age	DRI (mg/d)	High PTH and Normal Phosphorus[a]	High PTH and High Phosphorus[b]
0–6 mo	100	<100	<80
7–12 mo	275	<275	<220
1–3 y	460	<460	<370
4–8 y	500	<500	<400
9–18 y	1,250	<1,250	<1,000

DRI, dietary reference intake; PTH, parathyroid hormone.
[a] <100% of the DRI.
[b] <80% of the DRI.

Although there are no data on the levels of water-soluble vitamins that occur in children undergoing dialysis without vitamin supplementation, supplements of water-soluble vitamins are generally recommended for all children receiving CPD since these patients are at risk for alterations in vitamin levels as a result of decreased intake secondary to anorexia or dietary restrictions, loss per dialysis, or interference with absorption, excretion or metabolism (61,184–186). Supplements of the fat-soluble vitamin A should be avoided, and total vitamin A intake should be limited to the DRI. In the absence of the renal clearance of vitamin A metabolites, children with ESKD are at risk for hypervitaminosis A (187). Carnitine, zinc, and copper supplementation have been reported on occasion, as treatment for clinical evidence of deficiency (188–192). Because acidemia has a negative effect on growth and nutritional status, serum bicarbonate levels below 22 mmol/L should be corrected with alkali supplementation (61).

Infants receiving CPD require aggressive nutritional support. *Ad lib* food intake frequently falls below recommended levels, requiring forced feeding through nasogastric or gastrostomy tubes/buttons (61,176,193–198). Regular oral stimulation should continue irrespective of the quantity of voluntary intake to preclude problems with feeding following transplantation (199). Infants also frequently require aggressive supplementation with sodium, potassium, and phosphorus. Sodium losses into the dialysate are compounded in polyuric infants by urinary sodium losses and can result in poor growth as well as systemic hypotension and vascular events such as anterior ischemic optic neuropathy (200–203). Standard infant formulas do not contain sufficient sodium to replace these losses. Both hypophosphatemia and hypokalemia can also occur and require supplementation in the vigorously growing infant who is maintained on a low-phosphorus, low-potassium formula (204).

The complexity of the nutritional management of pediatric CPD patients is magnified by the critical

importance of proper nutrition to the growing and developing child. The crucial role of the pediatric renal dietitian in the care of these fragile patients has previously been emphasized (58,205).

COMPLICATIONS OF CHRONIC PERITONEAL DIALYSIS IN CHILDREN

Peritonitis

The single most common complication that occurs in children maintained on CPD is peritonitis (109,206–211). Data from the USRDS reveal that infection is the most common cause for hospitalization among children receiving CPD, and infection is the most common reason for modality change (212). Unfortunately, present data make it clear that children experience a significantly greater rate of peritonitis than adults, with a substantial percentage of children experiencing an episode of peritonitis during their first year of PD treatment. Reductions in observed peritonitis rates have been reported in children in association with treatment of *Staphylococcus aureus* nasal carriage or application of topical antibiotics (e.g., mupirocin or gentamicin) at the dialysis catheter exit site, use of a two-cuff catheter with a downward-oriented exit site, as well as with technical developments such as disconnect systems and the flush-before-fill technique (89,206,213–216). The important contribution of prolonged dialysis training with an emphasis on hand hygiene has also been demonstrated in children (217,218).

Evaluation of the most recent data from the NAPRTCS database has revealed a total of 4,248 reported episodes of peritonitis in 6,658 years of follow-up, resulting in an annualized peritonitis rate of 0.64 or 1 infection every 18.8 patient-months (6). The rate of peritonitis was highest in the youngest patients (0 to 1 year) who had an annualized peritonitis rate of 0.79 or 1 infection every 15.3 patient-months versus an annualized rate of 0.57 or 1 episode every 21.2 patient-months in children older than 12 years. Noteworthy is a significant improvement in the overall annualized infection rate from 0.79 in 1992 to 1996 to 0.44 in recent years, likely related to the prophylactic measures noted above, in addition to recommendations pertaining to prophylactic antibiotic usage at the time of PD catheter placement and prior to invasive procedures (e.g., gastrostomy placement) (95,219,220).

When peritonitis is suspected, empiric antibiotic therapy should be administered by the IP route and should provide coverage for gram-positive and gram-negative organisms, commonly by a combination of a first-generation cephalosporin or a glycopeptide (e.g., vancomycin), with a third-generation cephalosporin or an aminoglycoside (215). The recently published pediatric peritonitis treatment guidelines also allow for empiric monotherapy with the fourth-generation cephalosporin cefepime where available and in the absence of a history of methicillin-resistant *S. aureus* (95,215). Most important is recognition of the marked regional variation of antibiotic resistance patterns and the accompanying need to prescribe the empiric therapy based on the local antibiotic resistance profile (53,215,221,222). To minimize the risk for glycopeptide- or aminoglycoside-related toxicity, maintenance antibiotic therapy should be instituted as soon as the antibiotic susceptibilities are made known.

Finally, encapsulating peritoneal sclerosis (EPS) is a rare but extremely serious clinical entity characterized by the presence of continuous, intermittent, or recurrent bowel obstruction associated with gross thickening of the peritoneum (223–226). Although primarily diagnosed in adults, it may also occur in children, typically those who have received CPD for more than 5 years. The presence of peritoneal

calcifications on abdominal computed tomographic (CT) scan in association with a long duration of dialysis and ultrafiltration failure is highly suggestive of the diagnosis and may be an indication for prompt conversion to HD (223,227). Additional management options include immunosuppressive and antifibrotic medications and surgical intervention accompanied by aggressive nutritional support.

CHRONIC HEMODIALYSIS FOR CHILDREN

The clinical use of an "artificial kidney" was pioneered in 1944 in adult patients suffering from AKI by Willem J. Kolff, a Dutch physician during World War II (228). The purification of heparin from an extract of liver tissue in 1916 by a second year medical student at Johns Hopkins was another key development in the evolution of HD. Finally, when cellophane tubes became widely used as sausage casings in the 1920s, subsequent studies in animals revealed that the casings made excellent diffusion membranes, critical to the development of Kolff's invention of the rotating drum kidney in 1944 (229).

The initial application of the drum kidney in pediatrics took place in 1950. Soon thereafter, the Children's Hospital of Pittsburgh used a coil kidney design, turning Kolff's rotating drum on its end and submerging the coils of cellophane tubing in the dialysate bath, to treat five severely uremic children on an acute basis with clinical improvement in all (230).

The development of a reusable vascular access was yet another critical requirement and was first addressed by Dr. Belding Scribner and his team in Seattle (231). Use of the Scribner shunt and a pumpless system developed by Robert Hickman and Scribner for pediatrics in the early 1960s prompted the establishment of several pediatric chronic HD programs in the United States and Europe (232).

Challenges for these initial programs included the selection of patients by the so-called "Life and Death Committees," the use of flat-plate dialyzers, the need for regular transfusions, and repeated shunt clotting and infection. However, developments that led to successful pediatric HD programs as we know them today, included (a) improved vascular access with the introduction of arteriovenous fistulas and permanent double-lumen catheters, (b) the introduction of smaller more efficient dialyzers and lower volume dialysis circuits, and (c) the development of dialysis equipment with more precise ultrafiltration monitoring and control capability (233).

Vascular Access

Adequate HD delivery depends on a functional vascular access without compromising future potential access sites. Current HD access options are divided into two categories: permanent access in the form of an arteriovenous fistula (AVF) or arteriovenous graft (AVG) and a semipermanent access in the form of catheters with a subcutaneous (SC) cuff.

The risk of death in dialysis patients 18 years of age and older is lowest in patients with AVFs, followed by AVGs and then HD catheters (234). In turn, the KDOQI Pediatric Vascular Access guidelines recommend using an AVF or AVG for HD access in children and adolescents more than 20 kg who are expected to receive HD for more than 1 year (116). The weight cutoff takes into account the fact that relatively small vessels in the youngest patients may not be able to support AVF placement and maturation. Although certain centers have reported successful AVF placement in small children, maturation can take up to 6 months, which may not be practical in many situations (235,236).

AVFs are composed of a connection between a patient's native artery and vein. The most common

sites for AVFs are the wrist (radiocephalic or Brescia-Cimino) and the antecubital fossa (brachial artery to cephalic vein). AVFs require at least 4 to 12 weeks for enough venous segment dilatation or maturation to allow for successful needle placement (116,235). The most common complications of AVFs include aneurysm formation from repeated puncture at the same site, arterial inflow stenosis with resultant poststenotic vessel dilatation, and collateral vessel development.

If native blood vessels are inadequate for an AVF, artificial materials can be used to create an AVG. Currently, the most commonly used material is polytetrafluoroethylene (PTFE)/Teflon, although some vascular surgeons are now using bovine carotid artery grafts in adults with equally as good if not superior outcomes in patency rates (237). The advantages of AVGs over AVFs include an expanded variety of anatomic placement sites (distal arm, upper arm, and thigh) and configurations (loop or straight). The major disadvantage associated with an AVG is the development of intimal hyperplasia and venous outflow stenosis, which can lead to decreased intra-access flow and thrombosis. Proactive noninvasive monitoring (NIVM) of AVG blood flow coupled with rapid referral for balloon angioplasty for a low AVG blood-flow reading has led to a significant decrease in thrombosis rates (238,239).

In 2002, Sheth et al. (240) demonstrated 1-, 3-, and 5-year patency rates for AVFs (74%, 59%, 59%) and AVGs (96%, 69%, 40%), excluding primary failure, that were not statistically different. Somewhat lower but again not statistically different 1-, 2-, and 3-year survival rates were reported from Argentina, where it was also noted that access stenosis, thrombosis, and infections were more frequent in AVGs than AVFs ($p = 0.02$) (241). Finally, a recent retrospective study was conducted at the Children's Hospital of Los Angeles on 101 AVFs that were created in 93 patients at that institution between 1999 and 2012. The patients were a mean age of 14 years (range, 3 to 19 years) and had a mean weight of 51 kg (range, 12 to 131 kg). The average 2-year and 4-year primary and secondary patency rates were 83% and 92%, and 65% and 83%, respectively. During the 2.5 years of follow-up, 68 patients (75%) received a transplant, with a mean time to transplant of 556 days, arguing for concerted efforts to improve the use of AVFs in pediatric patients not likely to receive a transplant within 1 year of dialysis initiation (242).

Cuffed indwelling catheters serve as the most common form of vascular access for children receiving chronic HD in the United States (243), which is unfortunate given the higher complication rate and shorter survival time of catheters compared with AVFs and AVGs (244). Prior to 1998, dual-lumen configurations were the only options for pediatric HD catheters (245,246). Alternative catheter configurations now include dual-lumen catheters with split distal venous and arterial lumens to allow for free tip movement within the vein (Ash Split catheter) and twin separate single-lumen catheter systems inserted into the same vein with different exit sites or in different veins altogether (Tesio catheter system). Although single-center pediatric data demonstrate that Tesio catheters enjoy a longer survival and provide superior clearance more consistently than dual-lumen catheters of similar size, the use of this catheter in adults was noted to be associated with a longer insertion time (41.5 min) compared to the Ash Split (29.4 min), with increased complications and with no significant difference in BFRs at 30 and 90 days postinsertion (247,248). There are currently sufficient catheters of various designs, diameters, and lengths to permit chronic HD in infants and children of all sizes (**TABLE 37.5**). The optimal site is the right internal jugular vein or femoral vein. The subclavian vein should be avoided for risk of the subsequent development of subclavian stenosis and loss of further potential access sites in that arm (249).

TABLE 37.5 Cuffed Hemodialysis Catheter and Patient Size Guideline

Patient Size (kg)	Catheter Options
<20	8-Fr dual lumen
20–25	7-Fr twin Tesio 10-Fr dual lumen
25–40	10-Fr Ash Split 10-Fr twin Tesio
>40	12- or 14-Fr Ash Split 10-Fr twin Tesio 11.5- or 12.5-Fr dual lumen

Equipment for Pediatric Hemodialysis

Hemodialysis Circuit

The HD circuit is composed of the patient's vascular access, blood tubing connecting the access to the hemodialyzer, and the hemodialyzer itself. Blood tubing is produced in a variety of sizes and should be matched to the patient's size to allow for optimal blood flow while minimizing the volume of the extracorporeal circuit, which is the sum of the blood tubing volume and the hollow-fiber dialyzer volume (**TABLE 37.6**). To prevent excessive repeated blood loss in the circuit and hemodynamic instability, the extracorporeal circuit should not exceed 10% of the patient's calculated blood volume. Neonatal lines with a volume of 40 mL are available for use in children less than 15 kg. A wide variety of dialyzers with different blood volumes are available from various manufacturers that can be matched to pediatric patient sizes. In some infants, for whom even the smallest blood tubing and dialyzer volumes exceed 10% of patient blood volume, the circuit should be primed with colloid [5% albumin or packed red blood cells (PRBCs) diluted with albumin to a measured hematocrit of 35%] instead of crystalloid.

TABLE 37.6 Hemodialysis Circuit

	Blood Volume in Tubing (mL)[a]	Inner Diameter of Pump Segment (mm)[b]
Infant	29	2.6
Pediatric	52	4.8
Intermediate pediatrics	110	6.4
Adult	149	8

Hemodialysis Machine

Provision of safe pediatric HD requires machines that have accurate blood pump flow rates and volumetric control of ultrafiltration. Volumetric ultrafiltration controllers are critical to prevent rapid and excessive ultrafiltration rates in infants and young children receiving HD and are now required by Centers for Medicare & Medicaid Services (CMS) in children less than 35 kg (250).

Frequent home HD (see below) is a newer modality offered to pediatric patients. Pediatric results are similar to adult data with respect to improved biochemical control and HRQOL (251,252). These studies all used conventional HD machines that rely on a treated municipal water supply, potentially repeatedly exposing patients to proinflammatory components. Goldstein et al. (253) have reported on the use of the NxStage system for frequent home HD, which uses sterile dialysis fluid to provide dialysis in

the home. They found similar biochemical improvements with variable changes in proinflammatory cytokine levels.

Noninvasive Monitoring of Hematocrit

Since red blood cell volume remains constant during dialysis, changes in hematocrit will be inversely proportional to changes in intravascular volume. Continuous optical methods of NIVM of the hematocrit take advantage of this relationship to demonstrate a real-time association between fluctuating hematocrit and intravascular volume during the HD treatment, which serves as an adjunct to patient monitoring designed to decrease the frequency of adverse events (254,255). In pediatric patients, the use of NIVM has been associated with lower rates of ultrafiltration-associated event rates (defined as hypotension, headache, or cramping that required a nursing intervention such as saline bolus, Trendelenburg position, slow/stop ultrafiltration), especially for patients less than 35 kg (256,257). Analysis of the timing of events associated with different blood volume changes using NIVM has led to NIVM-guided ultrafiltration modeling algorithms that optimize fluid removal during dialysis, lessen the need for antihypertensive medications, minimize intradialytic and interdialytic patient symptoms, and decrease the need for additional HD treatments or hospitalization for treatment of fluid overload and hypertension (239,258).

Chronic Hemodialysis Prescription

Patients initiating HD may suffer from any combination of fluid overload, hypertension, malnutrition, and a variety of electrolyte abnormalities. The transition from CKD to maintenance HD must be safe and calculated with the first month goals of establishing an estimated dry weight, normalization of blood pressure (BP) and electrolyte abnormalities, as well as achieving adequate urea reduction. Rapid osmolar changes of large magnitude can be associated with cerebral edema, disequilibrium syndrome, and seizures, especially during the first few HD treatments (259). The intravenous (IV) infusion of mannitol at a dose of 0.25 to 0.50 g/kg has been proposed as a method by which these symptoms can be avoided or ameliorated in children by maintaining a relatively high extracellular fluid osmolality as urea is removed from the patient, although the clinical utility of this procedure has never been clearly established (260,261). Furthermore, accumulation of mannitol after repeated infusions may be harmful (261). An alternative method to prevent large osmolar shifts during the initial HD treatments is to limit the amount of urea clearance delivered at each treatment. Practically, this can be achieved by limiting the decrease in the blood urea nitrogen (BUN) to only 30 to 40 mg/dL at each of the first few dialysis treatments. The proportional fall in urea can be estimated by calculations using the following mass transfer equation (**EQUATION 37.5**):

$$C_t/C_0 = e^{-Kt/V} \qquad 37.5$$

where C_t is the concentration of BUN after t minutes of dialysis, C_0 is the initial concentration, K is the urea clearance (mL/min), t is the duration of dialysis (minutes), and V is the urea volume of distribution (mL).

As noted earlier, the urea volume of distribution is equivalent to the TBW, which is approximately 60% of the patient's weight. For example, if a 10-kg child is to begin HD and has a BUN of 100 mg/dL, the following calculations could be used: At a BFR of 25 mL/min, a dialyzer will achieve a urea

clearance of 25 mL/min. If the desired fall in BUN is 30 mg/dL, then C_t = 70 mg/dL at the conclusion of the dialysis treatment. Assuming an average body composition, the TBW is approximately 6,000 mL. Therefore,

$$C_t / C_o = 70/100 = 0.7 \text{ and } 0.7 = e^{-25 \text{ mL/min} \times t \text{ minutes}/6{,}000 \text{ mL}}$$

$$\text{Ln } (0.7) = -25 \text{ mL/min} \times t \text{ minutes}/6{,}000 \text{ mL}$$

$$t = 0.36 \times 6{,}000/25$$

$$t = 86 \text{ minutes}$$

The time of dialysis could be further shortened if a higher BFR and therefore a higher clearance can be tolerated. Conversely, when lower BFRs are required, proportionately longer dialysis times are necessary to achieve the same outcome. The standard BFR is 5 to 7 mL/kg/min up to 300 to 400 mL/min with a dialysis flow rate of at least 1.5 times the BFR to prevent dialysate saturation from limiting solute clearance.

While there is no standard dialysis bath, the serum targets are a normal serum sodium and potassium, bicarbonate of 22 mEq/L, and a serum calcium level which varies by age from 8.7 to 11.3 mg/dL (61). In general, the calcium target is the lower side of normal per age group in order to decrease the risk for vascular calcifications. Some centers continue to implement sodium modeling programs to create a hyperosmolar dialysate sodium concentration at the beginning of the dialysis treatment in an attempt to limit the development of hypotension during dialysis. The increased sodium concentration early in the dialysis treatment leads to an increase in serum osmolality and thereby offsets a decline of serum osmolality caused by urea clearance. A decrease of the dialysate sodium concentration subsequently occurs throughout the treatment and can be configured in an exponential, linear, or stepwise pattern. Sodium modeling has been shown to reduce dialysis morbidity in both adolescent and adult HD patients (262).

Anticoagulation

As mentioned previously, the vascular access is of utmost importance when administering HD. With that said, maintenance of access patency and prevention of clots within the extracorporeal circuit is imperative. When using a catheter for access, the vast majority of centers lock the catheter with unfractionated heparin in concentrations that vary from 1,000 to 5,000 U/mL in each lumen (263). This inactivates thrombin and inhibits fibrin formation and thrombin-induced platelet activation (264). There is some systemic infiltration of the anticoagulant, and accidental flushing of a heparin-locked catheter can result in serious bleeding and needs to be prevented by appropriate labeling of the catheter. A less common practice is to lock the HD catheter with recombinant tissue plasminogen activator (rTPA) or sodium citrate, which if accidently flushed can result in severe hypocalcemia and cardiac events. Bolus and maintenance heparin infusion are typically prescribed during the dialysis treatment to prevent clotting and blood loss in the extracorporeal circuit, with standard dosing of 10 to 20 U/kg bolus and 10 to 20 U/kg/h maintenance. Lower molecular weight heparin has also been used for maintenance anticoagulation; however, there is limited data on its efficacy and safety in pediatric HD.

Hemodialysis Adequacy

Adequate HD is usually defined as a minimum level of toxic substance clearance (usually using urea

clearance as a surrogate), below which a clinically unacceptable rate of poor outcome occurs. A more complete definition of HD adequacy recognizes both HD treatment urea clearance and the patient's metabolic state as manifested by urea generation in between HD treatments. Significant research over the last 20 years has also focused on the refinement of complex mathematical models to more accurately quantify the total urea mass removed during a dialysis treatment (265–268).

The ideal parameter to use when prescribing an individual dialysis treatment should recognize the individual patient's size and metabolic state. It should be simultaneously informative of the overall production and removal of toxic substances. The conceptual basis of urea kinetic modeling (UKM) is based on the analysis of the rates of accumulation and removal of urea. Urea is generated at a constant rate that is proportional to the patient's protein catabolic rate (PCR). At the beginning of dialysis, urea is distributed in a single body pool that is equivalent to the TBW, so the distribution of urea can be described by a single-pool mathematical model. The rate of removal of urea is depicted by the term Kt/V [dialyzer urea clearance at a particular BFR (K; mL/min), HD treatment duration (t; minutes), and the patient's pretreatment and posttreatment weight (kg)]. The interdialytic accumulation of urea reflects the amount of protein catabolized during the time between dialysis treatments (269). In a steady state, this PCR (g/d) reflects the amount of protein ingested by the patient and, hence, is a marker of nutritional status (270,271).

The validity of the urea kinetic model was demonstrated in the National Cooperative Dialysis Study, which demonstrated a higher probability of "patient failure" (i.e., patient death or hospitalization) in adult patients who received lower doses of HD and/or who were in a poor state of nutrition (267). In adults, the individual dialysis treatment should be such that the single-pool Kt/V (spKt/V) is greater than 1.2 (116). Corresponding target Kt/V values for children have not been defined, although it is presumed and recommended that pediatric patients should receive dialysis that is at least equivalent to that provided for adults (116). Some initial pediatric outcome data have shown the utility of Kt/V in controlling for HD and normalized protein catabolic rate (nPCR) in the assessment of the nutrition status in malnourished patients receiving HD (272–274).

Pediatric data have demonstrated that simplified algebraic equations reliably approximate Kt/V and nPCR (275,276). Some formulas further refine urea clearance measurement to account for the double-pool distribution of urea during dialysis and the resultant BUN rebound seen in the first hour after HD ends as urea re-equilibrates between the intracellular and extracellular compartments (277–280). HD outcome study validity requires a control for HD dose, so the application of simpler and more accessible HD adequacy measurement methods should lead to an increase in pediatric HD outcome study research. Initial single-center and multicenter pediatric studies are starting to assess the impact of dialysis dose on outcome (272,281). However, a pediatric study from the CMS's Clinical Performance Measures Project demonstrated that little difference in HD prescription management would result when comparing spKt/V versus equilibrated Kt/V values from the same treatment (282). As a result, KDOQI states that spKt/V assessment is appropriate for patient management, whereas equilibrated Kt/V values should be used when an outcome study is conducted (116).

Frequent Hemodialysis

Nightly home HD has been reported by some to be associated with better survival in adults than thrice-weekly in-center HD (283). In those centers using nightly home HD, patients have experienced improved

BP control, anemia management and phosphorus control, and a better HRQOL (284). In the Frequent Hemodialysis (FH) Trial Group, in which patients were randomized to either three or six weekly dialysis sessions, the latter regimen exhibited statistically significant benefits with respect to both co-primary composite end points of death or 12-month change in left ventricular mass and death or 12-month change in self-reported physical health; however, patients in the FH group experienced an increased rate of vascular access interventions (285). More recently, the Frequent Nocturnal Hemodialysis (FNH) Trial Group surprisingly reported a statistically significant increased overall mortality HR of 3.88 in the six-times weekly home nocturnal HD group compared to those patients receiving three-times weekly HD. The authors cautioned that there was a surprisingly low mortality rate for individuals randomly assigned to conventional HD (286).

In contrast to the growing experience in adults, there is limited data pertaining to home or frequent HD in children (251). Two small studies, each of four adolescents undergoing slow nocturnal HD with a follow-up of 6 to 20 months, found that the treated patients had a rapid decrease in their predialysis phosphate and PTH levels without the need for phosphate binders or diet restriction, as well as a decreased need for fluid restriction and an improved HRQOL (55,287). Fischbach et al. (288) reported improved growth of patients, with and without the need for growth hormone (GH) therapy, in association with a hemodiafiltration regimen of six times weekly, 3 hours per treatment as compared to growth with conventional dialysis plus GH therapy. In an additional experience, Goldstein et al. (253) described four patients who received home HD six times weekly over 16 weeks. The patients exhibited a decreased BP load by ambulatory BP monitoring, improved phosphorus control, and an improved nPCR. These data suggest that frequent HD is an additional dialytic alternative that should be considered for the pediatric patient, although a great deal more study of this approach to therapy is necessary in children.

Nutritional Management of Children on Hemodialysis

The nutritional goal for children undergoing chronic HD is to optimize their growth and development, while avoiding exacerbation of their underlying fluid and electrolyte disturbances and uremia. An individual child's prescribed intake is based on an analysis of RKF and nutritional needs. Malnutrition, which plays a role in the poor growth of children with CKD, may result from inadequate dietary intake resulting from uremic anorexia and dysgeusia and prescribed nutrient restrictions (289,290). Monitoring the nutritional status of the child on HD is, in turn, a crucial element of patient management. Parameters to monitor have been published in the KDOQI Nutrition Guidelines for CKD, and in addition to traditional measurements of height, weight, and serum albumin, the nPCR has emerged as an accurate marker of nutritional status in the adolescent HD patient (61,291).

The dietary protein and caloric intake of each child should be sufficient to allow a positive nitrogen balance associated with an increase in lean body mass and stature. An increase in dietary energy intake without sufficient protein intake may result in obesity without increasing a child's lean body mass. In contrast, an increase in the dietary protein intake without sufficient energy intake will increase the amount of protein used for energy needs rather than increasing lean body mass and, therefore, will increase the urea generation rate. The concept of protein-energy wasting (PEW), defined as a state of decreased body protein mass and fuel reserves (body protein and fat mass), is common in ESKD and multifactorial in nature with contributions from hormonal imbalances, low nutrient intake, low RKF, inadequate dialysis dose, chronic inflammation, and metabolic acidosis (292). Whereas adult PEW is well defined, there is

no accepted pediatric definition of PEW (293,294). A multidisciplinary approach has been suggested to gauge an individual pediatric patient's overall nutritional status by incorporating dietary intake, anthropometric parameters, and for adolescents on HD, nPCR (293).

The dietary needs of children with CKD are not the same as the National Research Council's Food and Nutrition Board's recommended nutrient intakes (RNIs) because these recommendations are for populations of healthy children. For example, the needs of children on HD are affected by the catabolic effects of HD, including the loss of amino acids in the dialysate. Protein intake must be sufficient to allow an increase in muscle mass and maximize growth while minimizing urea generation. An ongoing assessment of the balance of dietary protein intake and urea removal can be gained through the use of UKM, which can calculate the nPCR in patients undergoing maintenance HD (270). Pediatric data demonstrate algebraic nPCR approximation equations to be accurate, and in adolescents, a low nPCR (less than 1 g/kg/d) is a sensitive and specific means by which to predict impending weight loss over the next 3 months (276,295).

The KDOQI pediatric guidelines recommend a caloric requirement equivalent to that of healthy children and an initial dietary protein intake to meet the recommended dietary allowance (RDA) for chronologic age with an additional increment of 0.1 g/kg/d when receiving HD (61,291). The usual dietary requirements for protein and calories may, however, be most accurately estimated in terms of stature because this measure is independent of fluid balance or the amount of body fat. In one report, a positive nitrogen balance was attained in children receiving a diet that provided 0.3 g of protein per 1 cm of statural height with an energy intake of 10 kcal/cm (270). Intradialytic parenteral nutrition (IDPN) may also have a role in treatment of severe protein-energy malnutrition in children receiving HD (273,274,296,297). IDPN is composed of a 70% dextrose solution and a 15% amino acid solution and is prescribed to provide 1.2 to 1.4 g protein per kilogram of patient weight each treatment. In addition, patients may receive IV lipids. In two pediatric studies, patient's nutrition status as measured by nPCR increased monthly with IDPN, with no change in their dialysis dose (273,274).

Children receiving HD have a pattern of lipid abnormalities similar to that seen in familial endogenous hypertriglyceridemia or type IV hyperlipidemia (298,299) with a prevalence of 39% to 65% (300). In children with ESKD, the lipid profile consists of elevated triglycerides, triglyceride-rich lipoproteins, and apolipoprotein C3, as well as decreased levels of cholesteryl ester transfer protein and high-density lipoproteins (HDLs). There is also enhanced hepatic synthesis of serum very low-density and reduced conversion of intermediate-density lipoproteins to low-density lipoproteins (LDLs) (300). The significance of these lipid abnormalities in children with ESKD is unclear, but such abnormalities may increase the risk of atherosclerosis in a patient population already at risk for CVD, and it is the recommendation of the American Heart Association Expert Panel on Population and Prevention Science that prevention of CVD in high-risk pediatric patients (including dialysis patients) is warranted (301). Although the basis for the lipid abnormalities has not been completely ascertained, possible contributing factors include a high fat content in the diet and decreased lipoprotein lipase and hepatic triglyceride lipase activities. In addition, carnitine levels are decreased in children treated with HD as compared with healthy controls (296,302–304). Carnitine, a low molecular weight molecule that transports fatty acids from the cytoplasm to the mitochondria for oxidation, may be lost in the dialysate.

Treatment of lipid abnormalities is first directed at therapeutic lifestyle changes. The role of

pharmacologic lipid-lowering agents, such as statins, in children on HD has not been determined. However, supplementation with L-carnitine has been suggested as a potential treatment. Although one short-term trial of IV L-carnitine (5 mg/kg during dialysis) resulted in a marked decrease in triglyceride levels and an increase in HDL cholesterol concentration, two more recent studies failed to confirm these findings (302,304,305).

Water-soluble vitamins are removed during HD making supplementation with these vitamins, especially vitamins B_6, C, and folate, necessary. Restriction of water intake is necessary to prevent interdialytic volume overload. A child's fluid restriction is generally the sum of insensible losses, residual urine output, and an amount that can be safely accumulated and ultrafiltered after a 2- to 3-day interdialytic period. The sodium intake of most children is restricted to help maintain the desired fluid restriction and avoid hypertension. In contrast to older children, infants with minimal urine output or with large urinary sodium losses from dysplastic renal syndromes who are receiving low-sodium formulas are at risk for hyponatremia. The accumulation of water over an interdialytic period coupled with very low sodium content in the formula may result in dilutional hyponatremia.

HEMODIALYSIS FOR NEONATES AND INFANTS

Although all pediatric HD requires specialized nursing and medical expertise, HD for neonates and infants is an especially complicated procedure. Few infants receive HD as maintenance RRT; the 2011 NAPRTCS report reveals that only 70 out of 927 children less than 1 year of age received HD as their initial dialysis modality since 1992 (6). Therefore, little evidence base exists to guide the provision of maintenance HD for infants (306).

As noted earlier, neonatal-sized blood tubing is available to minimize the blood volume of the extracorporeal circuit. Neonatal tubing is one-fourth the diameter of standard tubing, so the blood pump flow rate must be quadrupled to deliver the same blood volume per minute (e.g., a Q_B of 160 mL/min on the dialysis machine yields an actual blood flow of 40 mL/min through the dialyzer when neonatal tubing is used). Even with smaller neonatal tubing, the extracorporeal volume usually comprises greater than 10% of patient blood volume in infants less than 8 kg. Therefore, the circuit should be primed with 5% albumin when performing HD treatments in infants less than 8 kg in size. Circuit priming with PRBCs diluted with albumin or saline to a hematocrit of 35% should be considered in small infants expected to receive a prolonged course of maintenance HD to prevent anemia resulting from repeated red blood cell loss in the circuit.

Adequate urea clearance can be achieved with blood pump flow rates of 30 to 50 mL/min, flows which generally require a 7-Fr or 8-Fr dual-lumen HD catheter, but catheter choice and anatomic insertion site will need to be made on a case-by-case basis in the small infant (116,307).

Current volumetric HD machines produce an ultrafiltration accuracy of 50 to 100 mL, which is acceptable for most pediatric patients but is not tolerable for neonates. Digital scales, which are accurate to within 10 g, can be placed under an infant warmer and help guide ultrafiltration during a neonatal HD treatment. A newer product, the Newcastle infant dialysis and ultrafiltration system (Nidus), has been shown to be effective in both the pediatric intensive care unit and outpatient intermittent HD setting for babies weighing less than 8 kg. (**FIGURE 37.2**) This device generates higher dialysis clearances than PD

and delivers more precise ultrafiltration control than either PD or conventional HD (308).

Haemodialysing babies weighing <8 kg with the Newcastle infant dialysis and ultrafiltration system (Nidus): comparison with peritoneal and conventional haemodialysis. *Pediatr Nephrol* 2014;29(10):1873–1881.]

Complications of Hemodialysis in Children: Access Infection

Of the 8,060 courses of dialysis registered to 6,300 pediatric patients reviewed in the 2011 NAPRTCS dialysis report, 42% were HD courses, and 78.7% of those were via a percutaneous catheter as the HD access. When change of modality was the reason for termination of HD, 7% were due to excessive infection and 12.6% were due to access failure (6). A study of HD patients aged 12 to <18 years old identified in the 2000 ESRD Clinical Performance Measure Project found that of 418 patients, 58% had a central venous catheter. Patients in this study with a catheter had an adjusted relative risk of hospitalization due to infection of 4.74 [95% confidence interval (CI) 2.02 to 11.14] compared to those with an AVF or AVG (309). Despite a clear understanding that central catheters are associated with an increased risk of infection as compared to AVF or AVG, recent literature continues to show that catheters are the predominant vascular access in pediatric dialysis (263).

In 2011, the Centers for Disease Control and Prevention (CDC) published Guidelines for the

Prevention of Intravascular Catheter-Related Infections, recommending the use >0.5% chlorhexidine solution to clean the exit site and application of prophylactic antibiotic ointment or cream at the catheter exit site (310). More recently, investigators examined the efficacy of chlorhexidine solutions and a 5% povidone-iodine solution on the incidence of central venous catheter–related infections in children on HD. Although the numbers were small, 14 catheters in the povidone-iodine group and 13 in the chlorhexidine group, the investigators found that 10 exit-site infections and 5 blood stream infections occurred in the povidone-iodine group as compared to only 1 exit site and 1 blood stream infection in the chlorhexidine group, $p = 0.008$ and $p = 0.06$, respectively (311). While the push remains for AVFs or AVGs over central venous catheters, when caring for those patients with catheters, one must be diligent about hand hygiene and exit-site care in order to prevent infections in this at risk population. The Standardizing Care to Improve Outcomes in Pediatric ESRD (SCOPE) quality collaborative is a multicenter, pediatric initiative that is currently aiming to define best practice in terms of infection prevention in the pediatric HD population (218).

ADDITIONAL CLINICAL ISSUES IN THE PEDIATRIC DIALYSIS PATIENT

Anemia Management

The most recent KDOQI guidelines confirmed that anemia in a child with CKD is defined as a hemoglobin (Hgb) below the normal range for age/gender [i.e., <5th percentile based on National Health and Nutrition Examination Survey (NHANES) II reference data]. In turn, the KDIGO guidelines recommend that the evaluation for anemia in children with CKD should be initiated for an Hgb <11 g/dL in children <5 years, <11.5 g/dL in children 5 to 12 years, and <12.0 g/dL in those 12 to 15 years; adult values apply to those >15 years (<13.0 for males; <12.0 for females) (312). The factors contributing to the anemia associated with CKD in children are similar to those in adults and include erythropoietin deficiency, decreased erythrocyte survival, inhibition of erythropoiesis, and increased blood loss (313–316). The average red blood cell life span is reduced from a normal value of 120 days to a mean of 80 days in uremic individuals. This shortened life span is in part due to intestinal losses and to losses related to the HD procedure (e.g., anticoagulation, blood lost in HD tubing, repeated blood tests). Intestinal blood loss in 12 children undergoing chronic HD was reported as 11.1 ± 2.3 mL/m^2/d. Extraintestinal blood losses were 8.3 ± 5.1 mL/m^2 per dialysis treatment. In this same group of children, the erythrocyte life span was 80% of normal (316).

Erythropoiesis-Stimulating Agents

Before the availability of ESAs, essentially all children on HD were transfusion dependent; now, virtually all children treated with ESAs have little or no transfusion requirement (317). Similarly, a child being treated with CPD typically required a red blood cell transfusion every 1.5 to 5 months to maintain a hematocrit of 22% to 25% before the availability of ESAs (318). With the advent of ESAs, the need for transfusions has been essentially eliminated, and Hgb levels can be maintained at near-normal levels. Currently, an ESA is used by more than 90% of children being treated with dialysis (6). Correction of anemia with ESAs may be associated with the development or exacerbation of hypertension, making

careful monitoring of BP and aggressive treatment of hypertension mandatory. It is noteworthy that the USRDS report revealed that only 29% of children (less than 20 years) who initiated chronic dialysis in 2012 were receiving an ESA at dialysis initiation; however, the reported mean Hgb was 10.5 g/dL, suggesting that greater attention to anemia management is occurring in the patient with CKD before dialysis (1).

ESAs may be administered through the IV, SC, or IP routes. Subcutaneously administered ESAs, particularly epoetin-α, may have a longer half-life than intravenously administered drug, with the sustained lower level being more physiologic and cost-effective, and with a potentially greater erythropoietic effect. However, as a practical matter (including issues of pain and convenience), 85% of children on HD receive an ESA by the IV route during their regular HD sessions and 95% children on CPD receive SC ESAs (6). A small number of CPD patients (less than 3% in the NAPRTCS registry) receive IP ESAs (6). Epoetin-α is well absorbed from the peritoneal cavity when administered in a small volume (e.g., 50 mL) of dialysis fluid during a prolonged dwell (319,320). In one study, children were changed from SC to IP ESA administration and maintained their hematocrit levels with an ESA dose that was not significantly greater than the SC dose (321). In an evaluation of the pharmacokinetics of IP dosing, a history of repeated peritonitis was associated with lower peritoneal absorption (321). The small volume of dialysate also has the potential of compromising dialysis clearance. In the United States, most children on dialysis (87% of children on CPD, 90% on HD) receive erythropoietin-α as a result of reimbursement policies; the remainder are receiving darbepoetin-α (6). Darbepoetin-α administered intravenously once per week has been shown to be as effective as shorter acting ESAs administered three times per week with a pharmacokinetic profile that is similar to that found in adult dialysis patients (322,323).

Although ESA requirements vary among children due to underlying disease, treatment modality, and route of administration, the most marked variation in dosing is based on age. Infants may require significantly higher doses, as high as 350 to 450 U/kg/wk, to achieve their target Hgb (6,312,324). In one multicenter European trial in HD patients aged 2 to 21 years, the median weekly maintenance epoetin dose varied from 136 U/kg in those older than 15 years to 321 U/kg in children younger than 5 years (317). The higher ESA requirement in infants may be related to nonhematopoietic binding and elimination, expanding blood volume with rapid growth, or a greater percentage of blood volume lost with phlebotomies and dialysis losses (324–327). Analysis of data from the International Pediatric Peritoneal Dialysis Network (IPPN) has shown that although weight-related dosing is inversely related to age, the weekly ESA dose normalized to BSA is age independent: 4,208 U/m^2 BSA in this analysis of children on CPD (120).

In addition to the influential issues above, the most important cause of ESA hyporesponsiveness is insufficient iron stores. Additional causes include latent blood loss, hyperparathyroidism, and infection or inflammation (328). In patients with severe hyperparathyroidism who are hyporesponsive to ESAs (329), the poor response may be due to inhibition of erythropoiesis by circulating parathyroid hormone (PTH) or to osteitis fibrosa resulting in decreased marrow space for erythropoiesis. Uremia may be an inflammatory state *per se*, altering both iron transport and erythropoietin receptor expression (328). The most frequent form of infection in children undergoing CPD is peritonitis. The effect of a peritonitis episode on erythropoiesis may persist beyond the period of evident infection. In one center, the hematocrit

remained at least 20% below baseline 4 weeks following the infection in association with 50% of peritonitis episodes. Whereas the hematocrit had returned to baseline by 8 weeks, some patients required an increase in the ESA dose (330). The blunting of erythropoiesis by peritonitis or other inflammatory processes results from decreased erythropoietin levels, the inhibitory effects of circulating cytokines on marrow activity, and a decreased ability to mobilize iron from the reticuloendothelial system (RES) (331,332). Elevated levels of hepcidin that occur in the setting of inflammation likely play a key role in iron homeostasis by impairing iron absorption across the gastrointestinal tract and by restricting release of iron from the RES by binding to ferroportin (333,334). Pure red cell aplasia (PRCA) due to circulating anti-ESA antibodies is an uncommon cause for ESA resistance, but it has been reported in pediatric patients (335–337).

The optimum Hgb level for children being treated with dialysis (HD or CPD) and ESAs has not been determined. The issues to be considered in choosing a target in adult dialysis patients include QOL, with the suggestion that higher Hgb levels may be associated with improvement of some QOL parameters, and concerns about potential adverse cardiovascular outcomes with higher Hgb levels (338–340). There may well be an additional adverse effect associated with the administration of higher doses of ESAs, in addition to an effect related to the Hgb level *per se* (341,342). Data from the IPPN has revealed the risk of patient mortality to be significantly increased in association with a weekly ESA dose of > 6,000 U/m^2/wk versus a lower dose, even when correcting for the Hgb value (120). In children, there is no definitive evidence for benefit or harm associated with a given level of Hgb for an individual child. Most of the demonstrated benefits accrue with the change from severe anemia to an Hgb level greater than 10 g/dL. Certainly, the risk of requiring a transfusion increases with an Hgb <10 g/dL and the prevention of transfusion is a primary goal of ESA treatment. As stated in the most recent KDOQI update on anemia management, there are no studies to support targeting pediatric Hgb levels greater than the targets set for adults with CKD (11 to 12 g/dL); accordingly, the pediatric practitioner will have to consider whether an individual child is likely to have an incremental benefit to QOL, school performance, or exercise tolerance with a higher Hgb level (341,342).

In one of the few studies that has evaluated the impact of anemia management in children with ESKD, the outcome of 1,942 pediatric dialysis patients enrolled in the NAPRTCS registry from 1992 to 2001 was reviewed to determine if there was an association between anemia (defined as a hematocrit less than 33%) 30 days after dialysis initiation and subsequent morbidity and mortality (343). Overall, 67.8% of patients were anemic at the start of dialysis with a decrease from 79.7% of children in 1992 to 50.6% in 2000. Anemic HD or CPD patients were hospitalized for more days in the first year of dialysis than those with a hematocrit of 33% or more. Importantly, after adjusting for age, treatment modality, etiology of ESKD, as well as iron and ESA use, patients with a hematocrit less than 33% had a 52% greater risk of death compared with those with a hematocrit in the range of 33% to less than 36%. In addition, there was an 81% increased risk of death for those with a hematocrit of 27% to 30% or less, and an 80% increased risk for those with a hematocrit less than 27%. There was no difference in the risk of death for those with a hematocrit 30% to 33% or 36% or more (343).

In a second study, Amaral et al. (344) reviewed data from the CMS's ESRD Clinical Performance Measures Project to evaluate the correlation between average Hgb level achieved in adolescent HD patients, hospitalization, and mortality. In this assessment of 677 patients, an Hgb level of 11 to 12 g/dL

(vs. less than 10 g/dL) was associated with a decrease in mortality risk of 69%. No statistically significant difference in risk between Hgb categories with respect to hospitalization was found (344). Most recently, a report from the IPPN found a relationship between Hgb <11 g/dL as compared to a higher Hgb and an increased risk of mortality (120).

Despite the apparent benefits of Hgb >11.0 g/dL, this target has not been consistently achieved historically. An analysis of data in a prior USRDS report compared the anemia management of children (0 to 19 years) and adults on dialysis between 1996 and 2000 (345). The mean annual Hgb was calculated. In each year, 54.1% of children on HD had a mean annual Hgb of less than 11 g/dL, whereas 39.3% of adults were anemic. In children treated with CPD, low mean Hgb levels were found in 69.5% of patients as compared to 55.1% of adults (345). Children also used less IV iron than adults in this time period. More recently, treatment outcomes have improved, and in 2005, more than 75% of all prevalent pediatric dialysis patients had an Hgb of >11 g/dL (346).

Iron Supplementation

The goal of iron supplementation during ESA treatment is to maintain sufficient iron stores for optimal erythropoiesis without the development of hemosiderosis. In the past, children on HD were multiply transfused and eventually became iron overloaded. Now that children are no longer regularly transfused, the blood and iron losses associated with CKD and dialysis are not replaced, and children have a net iron loss, prompting the need for iron supplementation. In a NAPRTCS report from 2001, after 12 months on dialysis, 77% of pediatric HD patients and 84% of CPD patients were receiving oral iron. The most recent report from 2011, however, reported that only 29% of those on HD and 77% on CPD were receiving enteral iron (6,103). Oral iron supplementation is often associated with poor adherence secondary to gastrointestinal intolerance and rarely is it sufficient to maintain the iron stores necessary for erythropoiesis, especially in patients who receive HD. Therefore, it is now recognized that most HD patients and some CPD patients receive IV iron on a regular or maintenance basis: in one report from 2011, 52% of HD and 12% of CPD patients (6). In part, this is related to the fact that there is limited gastrointestinal iron absorption in patients with ESKD who have relative, but not absolute iron deficiency, possibly as a result of elevated hepcidin levels. Intestinal iron absorption is also inversely related to the body's iron stores (347).

Current recommendations (primarily based on data in adult patients) are to treat with iron to maintain a transferrin saturation (TSAT) of at least 20% and a serum ferritin of greater than 100 ng/mL in those on CPD, greater than 200 ng/mL for adult HD patients and greater than 100 ng/mL for pediatric HD patients (348). The age-related differences in the recommendations pertaining to serum ferritin during HD are merely the result of the lack of pediatric data available on the subject; in children with CKD, a TSAT <20% has been shown to be predictive of iron deficiency, whereas the ferritin value has been less predictive (349–352). Caution is advised when the serum ferritin level is greater than 500 ng/mL (341), highlighting the need to evaluate such patients for their Hgb level, ESA responsiveness, and the likely impact of their clinical status on iron availability (e.g., inflammatory block vs. functional iron deficiency) before considering additional iron therapy (341,353). As noted earlier, due to a poor response to oral iron, the IV route is recommended for HD patients, whereas the oral route alone may be sufficient for some CPD patients (341). IV iron treatment includes both repleting iron stores (with a short course of a series of iron doses) and maintaining iron stores with regular IV iron administration. Trials of

maintenance IV iron dosing have demonstrated decreased ESA requirements in both children and adult patients receiving HD (354–357).

Three formulations of IV iron are currently in use: iron dextran, ferric sodium gluconate, and ferric saccharate (iron sucrose). Iron dextran was used extensively in the United States until the other formulations became available. Although iron dextran was relatively safe, there were anaphylactic-like reactions consisting of dyspnea, wheezing, abdominal cramps, and hypotension occasionally associated with its use. Whereas data on the incidence of anaphylactic-like reactions in children is sparse, review of the adult HD patient experience has demonstrated that 4.7% of patients experience adverse events attributable to iron dextran (358). The other forms of IV iron, ferric gluconate and iron sucrose, are associated with fewer serious adverse effects and have been given in multiple doses to pediatric dialysis patients safely (357,359,360). Therefore, they have replaced iron dextran in most adult and pediatric dialysis programs (361). In a prospective multicenter trial, ferric gluconate was shown to be safe and effective in children when administered at doses of 1.5 to 3 mg/kg dosed intermittently to treat iron deficiency or on a maintenance schedule to avoid iron deficiency (357,362). Iron sucrose has been shown to be safe and effective on a maintenance schedule using 0.5 to 2.0 mg/kg/dose every 2 weeks in HD patients and every 4 weeks in CPD patients (359). A newer iron preparation, ferric pyrophosphate, is administered per the dialysate of HD patients and was recently approved for clinical use (363). Pediatric trials with this medication should begin in late 2015.

Growth Retardation

Before the use of recombinant human growth hormone (rhGH), severe growth retardation was almost universally present in children with ESKD. The impact of growth retardation on adult height is greatest for those children with ESKD during infancy and puberty, the periods of most rapid growth. Recent publications have provided evidence for the significant negative impact that growth retardation may have on the QOL experienced by adults with childhood onset ESKD (364,365). Several factors may contribute to the poor growth of children with impaired kidney function, including protein and calorie malnutrition, metabolic acidosis, renal osteodystrophy, endocrine abnormalities, and the accumulation of uremic toxins. Although some of these factors are improved by dialysis, many persist despite aggressive dialytic therapy (366).

A number of endocrine abnormalities are present in CKD that may contribute to poor growth. These endocrine alterations include abnormalities of vitamin D metabolism, alterations of the GH axis, hypothyroidism, and peripheral insulin resistance. Alterations in GH secretion and the activity of insulin-like growth factor 1 (IGF-1) are particularly important (366). IGF-1 stimulates the clonal expansion of chondrocytes and collagen formation in the long-bone growth plates. The bioactivity of IGF-1 is limited in uremic children through an increase in IGF-1–binding proteins. Treatment with rhGH may accelerate growth by increasing IGF-1 levels to supraphysiologic levels with a resultant increase in its bioactivity (366–370).

The treatment of children who have developed ESKD with rhGH has been extensively reviewed elsewhere, and the therapy has proven to be safe and effective (367,371). Although rhGH improves the growth of children undergoing CPD and HD, the response may be blunted after the initial year of treatment (367,372–375). There is also evidence that the impact of therapy may be greatest in those patients who are treated before the development of ESKD, in part related to differences in the severity of

alterations in IGF-binding protein concentrations and GH receptor density (375,376). Most importantly, when all other factors associated with growth retardation in children receiving HD or CPD (i.e., acidosis, hyperphosphatemia, secondary hyperparathyroidism, sodium losses, and poor nutrition) are being aggressively and successfully treated and poor growth persists, rhGH therapy is indicated. The KDOQI nutrition guidelines recommend the initiation of rhGH treatment in children with a height standard deviation score (SDS) more negative than −2.0 or a height velocity more negative than −2.0 SDS (61,377). Similarly, a consensus committee recommended that rhGH therapy be considered in children with CKD whose height SDS was less than −1.88 or whose height velocity SDS was less than −2 (**FIGURE 37.3**) (366). Nevertheless, for reasons that are not clear, a minority of growth-retarded patients with CKD/ESKD receive rhGH therapy. In the 2011 NAPRTCS annual report, the mean height SDS for patients initiating CPD was −1.71; however, only 10% of patients were treated with rhGH at 1 month, increasing to 20% at 1 year, and 25% at 2 years postdialysis initiation (6). Children treated with HD had an initial mean height SDS −1.4, and 10% were receiving rhGH at 1 month, increasing to 12% at 1 year and 16% at 2 years (6). Equally impressive and concerning is data from the USRDS which demonstrates that 37.2% of pediatric HD patients are more than 2 SD below the standardized mean height for their age, gender, or race/ethnicity, but only 14.6% of this group receive rhGH (**FIGURE 37.4**) (378). Clearly, greater attention to this issue should be encouraged.

Chronic Kidney Disease–Associated Mineral and Bone Disorder: Calcium and Phosphorus Homeostasis

The metabolic abnormalities that may arise in children treated with chronic dialysis are common to all children with CKD and include elevated body phosphate stores, insufficient 1-α-hydroxylation of 25-hydroxy-cholecalciferol, and resultant inadequate intestinal absorption of calcium. In fact, children being treated with dialysis may experience progression of the bone disease that starts before dialysis. Data collected from the IPPN registry of 890 children treated with CPD showed that 15% had symptoms or radiologic evidence of mineral and bone disorder (MBD) at the start of dialysis including 44% with intact parathyroid hormone (iPTH) levels above the K/DOQI target. Of note, an iPTH >500 pg/mL was associated with impaired growth (379). In turn, aggressive medical management with vitamin D analogs, calcium supplements, oral dietary phosphorus binders, and diets with reduced phosphate content are all essential components of the effective prevention and/or management of renal bone disease in children with ESKD.

Treatment with Vitamin D, Vitamin D Analogs, and Calcimimetics

Vitamin D deficiency is common in the general population, and the majority of children on dialysis are vitamin D insufficient or deficient necessitating supplementation with vitamin D_2 (ergocalciferol) or D_3 (cholecalciferol) (183,380–382). The KDOQI guidelines recommend screening and supplementation to replete stores for 25-hydroxyvitamin D levels <30 ng/mL. As a consequence of decreased 1,25-dihydroxyvitamin D and depressed serum ionized calcium concentrations, there is an increase in fibroblast growth factor-23 (FGF-23) and iPTH levels in children with ESKD. The resultant renal osteodystrophy may impede growth and lead to long-term bony abnormalities. Therefore, supplementation with vitamin D or an analog is an essential component of the treatment of children being treated with HD or CPD (383). The optimal iPTH level to avoid suppressing growth with adynamic bone disease or

worsening renal osteodystrophy during rhGH treatment has been debated; however, the most recent opinion from the KDOQI working group for Bone Metabolism and Disease in Children has recommended iPTH values of 200 to 300 pg/mL for patients on dialysis (183). Observational data from the IPPN has suggested that an iPTH value of 100 to 300 pg/mL should be targeted in children on CPD (379).

Oral calcitriol, which has been the mainstay of treatment, has been shown to be effective in controlling renal bone disease in children receiving CPD (384). In addition to stimulating intestinal calcium absorption, calcitriol directly suppresses the parathyroid gland growth and iPTH synthesis (385,386). IV forms of the vitamin D analogs, calcitriol and paricalcitol, are also currently available to treat the secondary hyperparathyroidism associated with ESKD (387,388). In a placebo-controlled trial in pediatric HD patients, IV paricalcitol was shown to decrease iPTH levels without significantly increasing serum calcium, phosphorus, or calcium–phosphorus product (389). Paricalcitol has the advantage in many patients of suppressing the parathyroid glands with less effect on intestinal calcium absorption (388). In a single-center crossover trial comparing calcitriol to paricalcitol in pediatric HD patients, there was no difference in the mean calcium–phosphorus product between the agents; however, there was a greater incidence of hypercalcemia and a calcium–phosphorus product greater than 70 mg^2/dL^2 during calcitriol treatment (390). Doxercalciferol (Hectorol) is also available as an oral and a parenteral preparation and has been shown to treat secondary hyperparathyroidism; however, there are currently limited data on its use in children (183). Calcitriol or analogs are utilized by 73% of CPD patients (3% IV) and 71% of HD patients (46% IV) after 1 year of dialysis in the NAPRTCS registry (6). Finally, calcimimetic agents (e.g., cinacalcet hydrochloride), which suppress iPTH without increasing calcium by enhancing the activity of the calcium-sensing receptor (CaSR) of the parathyroid gland, are efficacious and have been approved for treatment in adults (391). Anecdotal reports of the efficacy of this agent in children have been published and a formal multicenter study in pediatric patients in currently being conducted (392,393). Of note, there is the potential for adverse effects of this treatment as the CaSR is also located in the growth plate (183).

Phosphate Binders

Hyperphosphatemia may lead to extraskeletal metastatic calcifications. Prevention requires dietary phosphate restriction, administration of intestinal phosphate binders, and supplementation with vitamin D analogs. The KDOQI pediatric bone guidelines recommend a target phosphorus level of 4 to 6 mg/dL for children aged 1 to 12 years and of 3.5 to 5.5 mg/dL for adolescents, whereas the KDOQI nutrition guidelines target a normal phosphorus level for age in view of the contribution of hyperphosphatemia to CVD (61). To minimize the risk of soft tissue (including vascular) calcification, KDOQI also recommends that phosphate binders and vitamin D analogs be adjusted in children to maintain a calcium–phosphate product less than 65 mg^2/dL^2 for children aged 1 to 12 years and less than 55 mg^2/dL^2 for adolescents (183). Of note, in the 2007 USRDS report, there was an association noted between a low calcium–phosphorus product and abnormal height: 76.9% of those with calcium × phosphorus less than 30.8 had heights more than 2 SDs below the mean for age (378).

Calcium-containing phosphate binders have replaced aluminum-based binders in pediatric patients because of the development of osteomalacia, anemia, and severe neurologic complications associated with aluminum exposure (394). However, when high doses of calcium-containing phosphate binders are

required to maintain the serum phosphate level within normal limits, hypercalcemia may be seen especially in the setting of adynamic bone disease. When calcium carbonate is used as a phosphate binder, there is significant absorption of the ingested calcium. In addition to adversely affecting bone, the role of an elevated serum calcium or an elevated calcium–phosphate product in the progression of vascular calcification has been demonstrated and very likely is a factor in the cardiovascular morbidity and mortality described in children with CKD/ESKD (395). Hypercalcemia may be averted by the use of a different form of calcium (e.g., calcium acetate), by decreasing the dialysate calcium content, and by adding or replacing the calcium-based binder with polymeric forms of phosphate binders such as sevelamer (396–399).

In a randomized crossover trial comparing sevelamer with calcium acetate in children, there was equivalent phosphorus control with the two agents without a change in the overall calcium level (400). However, there was a higher incidence of hypercalcemia during calcium acetate treatment. Metabolic acidosis was more frequent during treatment with sevelamer. Interestingly, the levels of total cholesterol and LDL cholesterol were both significantly lower during sevelamer therapy, as has been seen in adults (395,401). The use of sevelamer carbonate in children on dialysis has been associated with an increase in the serum bicarbonate level (402). Both forms of sevelamer have also been used to pretreat breast milk and reduce its phosphorus content (403).

In addition to the use of non–calcium-containing phosphate binders, decreased doses of vitamin D analogs or low-calcium dialysate help to control the serum calcium level. Traditionally, the dialysate calcium concentration in HD has been 3.0 to 2.5 mEq/L, producing a positive calcium balance during an HD treatment. The use of physiologic, low-calcium (2 to 2.5 mEq/L) dialysate will produce a negative calcium balance during the dialysis treatment (404). Similarly, low-calcium (with or without low magnesium) dialysate is available for CPD (405).

Blood Pressure Management

Hypertension is a significant problem in children with ESKD as it contributes to acute and long-term cardiovascular events. As such, the KDOQI guidelines on hypertension have recommended target BPs of less than the 90% for gender, age, and height for pediatric patients (406,407). Irrespective of the dialysis modality used (e.g., HD or CPD), children with ESKD develop hypertension due to varying degrees of intravascular volume expansion, elevated activity of the renin-angiotensin system, increased sympathetic tone, and elevated serum calcium levels with resultant increased peripheral vascular resistance (408–410). The relative contributions of the sympathetic nervous system, renin and volume overload can be determined in part by the BP response to ultrafiltration. BP should improve with ultrafiltration when hypertension is due to volume overload (409). One caveat is that the BP may increase during HD in those patients in whom BP is controlled with antihypertensive medications that are cleared by the dialysis treatment. In patients with primarily sympathetic overactivity or renin-mediated hypertension, the BP will not decrease and may actually increase with ultrafiltration during the dialysis treatment (408–410). Children with CKD/ESKD as a result of glomerular disease, chronic or recurrent pyelonephritis, or reflux nephropathy are most likely to have renin-mediated hypertension.

Minimization of intravascular volume expansion (overhydration) requires both a decrease in the intake of salt and water—the former is the most important area of focus as effective removal of fluid typically occurs on dialysis. The first approach to hypertension control in a HD patient should always be

a reassessment of the patient's dry weight. Correction of overhydration will ameliorate hypertension for most patients (409). However, ultrafiltration of large volumes of fluid during HD may result in increased dialytic morbidity, including cramps, nausea, vomiting, and fatigue. These symptoms may be decreased with the use of "sodium modeling" techniques and NIVM of the hematocrit. The initial approach to the management of children with suspected renin-mediated hypertension in terms of antihypertensive agents is the use of ACEI and angiotensin II (A-II) receptor blockers, with close monitoring for the development of hyperkalemia. In some cases, nephrectomies are needed to achieve BP control. Apart from ACEIs/A-II blockers in those patients with renin-mediated hypertension, there is no single ideal or recommended type of antihypertensive medication for children receiving chronic dialysis (406,407,409). Use of a vasodilator will increase the incidence of intradialytic symptoms of intravascular depletion such as hypotension and cramps and therefore may limit ultrafiltration capacity.

Despite the availability of antihypertensive agents with multiple physiologic targets of action and an understanding of many of the factors contributing to the elevated BP values, BP remains poorly controlled in children treated with chronic dialysis, although recent reports with patients receiving frequent HD have provided evidence of a reversal of this trend (57,162,411,412). Information on children in the NAPRTCS dialysis database who had been treated with dialysis between 1992 and 2004 was retrospectively analyzed to determine the frequency of BPs greater than or equal to 95th percentile (162). Uncontrolled hypertension (95% or more) was present at baseline in 56.9% of patients, systolic hypertension alone in 7.3%, diastolic in 16.9%, and both systolic and diastolic hypertension in 33.2%. Hypertension at baseline was more common in those on HD (65.1%) when compared to those on CPD (52.9%). Hypertensive children were also younger, more likely to be African American, and to have an acquired kidney disease (162). The prevalence of uncontrolled hypertension decreased from 56.9% at baseline to 51% at 1 year and 48% at 2 years of follow-up (162). Similarly, an analysis of 71 children treated in 10 dialysis centers demonstrated hypertension (BP greater than or equal to the 95th percentile) in 59% of patients and prehypertension (BP between the 90th and 95th percentiles) in 15.5%. Only 25.3% of patients had a normal BP (412). Clearly, greater attention to this issue is mandatory if the incidence of CVD is to decrease. To that end, in the most recent NAPRTCS dialysis registry report, 63% of children on CPD and 68% of those on HD were on antihypertensive medication at the initiation of dialysis (6).

Educational Needs

School attendance is an important factor contributing to the development of children, in terms of providing the occasion to both interact with peers and to develop their academic skills. Therefore, the impact of school on a child's QOL can be significant. Therefore, the goal of any pediatric dialysis program is to ensure that children attend school regularly. There is generally greater school attendance in children treated with CPD (e.g., 78% full-time attendance in children aged 6 to 12 years on CPD vs. 53% in those on HD) (413). A greater proportion of children treated with in-center HD attend school part-time (28%) and may require supplementation of schoolwork with tutoring due to the timing of the HD sessions (413). Of note, some of the data on school attendance are confounded by the increasing trend among well children in some parts of the country to be home schooled. Young children may benefit from placement in an early intervention program as well.

Neurophysiologic and Cognitive Deficits

Early research into the neurocognitive development of children with CKD revealed substantial risk for delays in infants and young children (414). Polinsky et al. (415) evaluated 85 pediatric patients with ESKD; 72% of whom had been diagnosed with ESKD in the first year of life. They found the head circumference to be more than 2 SD below the mean in 62% of patients and that most patients demonstrated some form of developmental delay. Whereas similar findings were noted by Rotundo et al. (416) and McGraw and Haka-Ikse (417), attention to the prevention of malnutrition and elimination of aluminum-containing phosphate binders from the medical regimen led to more positive neurocognitive outcomes as documented by Warady et al. and Lederman et al. (418–420,421). Although an earlier initiation of RRT should lead to a lower prevalence of neurocognitive delay in at-risk children with CKD, only recently has a standardized approach been developed to evaluate neurocognitive functioning in children with CKD (414). In the most recent data pertaining to the long-term neurocognitive follow-up of children who initiated dialysis at <16 months of age as well as the patient's siblings, Johnson and Warady (422) found that younger age at transplant and fewer months on dialysis were associated with better neurocognitive outcomes.

Intradialytic seizures have been described in 7% to 16% of children receiving chronic HD treatment and may be more common in children with a prior history of seizures (423). Because some anticonvulsant medications are removed by HD, additional intradialytic dosing may be necessary to prevent seizures during the dialysis treatment. Anticonvulsant therapy has been prescribed to 14% and 8% of the HD and PD populations, respectively, in the NAPRTCS registry (6).

Finally, it is imperative that health care providers for children with ESKD be aware of the support services available to their patients so that referral to early intervention programs designed to improve specific developmental areas such as motor functions, language abilities, and social-emotional skills can occur when deemed necessary.

Health-Related Quality of Life

As most children are surviving with ESKD into adulthood, provision of optimal dialysis requires attention to the pediatric patient's psychologic status and HRQOL (424). Early research into the HRQOL of pediatric patients with ESKD, occurring over 20 years ago, demonstrated that although pediatric patients with ESKD have some developmental and psychosocial issues that are similar to those of children with other chronic illnesses, they also have challenges that are specifically related to ESKD (425–429). Obstacles common to most chronically ill children include physical changes related to illness, the need to take many medications and undergo medical treatment, and time away from school and peers, which can lead to perceived differences and isolation. Additional challenges include maintaining a restricted dietary and fluid regimen, chronic dependence on medical equipment to sustain life, very obvious physical changes associated with transplantation and the use of steroids and calcineurin inhibitors, and the knowledge that they will live their whole lives with the recurrent cycle of dialysis and transplantation. To better understand this important issue, pediatric studies have begun to use specific instruments to assess the pediatric ESKD patient's HRQOL. Most of these studies demonstrate that pediatric patients with ESKD and their parents report worse HRQOL than healthy peers, and patients receiving dialysis report a worse HRQOL than patients with a renal transplant (59,430). The standardized measures of HRQOL are no longer research tools alone, and their use is essential to identify areas for interventions as part of clinical care. Therefore, the CMS mandates that all dialysis patients in the United

States have an HRQOL assessment at least annually (431–433), and there are pediatric-specific, validated HRQOL tools that can be utilized (59,431,434,435).

School attendance is an important part of childhood development. As noted earlier, ESKD, and especially in-center HD, imparts significant constraints and restrictions on this activity, which may have a significant negative impact on normal psychosocial development. The medical requirements for HD, which include receipt of HD in an HD center multiple times throughout the week during school hours, may isolate the child with ESKD from their healthy peers. Such interruptions in the normal daily life of a child are a likely primary cause for the relatively low self-esteem and low rates of independent living, close interpersonal relationships, and employment reported in adult survivors of pediatric ESKD (436,437). Studies of adolescent and young adult patients with ESKD have previously reported lower employment rates and greater concern about body image than a similarly aged cohort of diabetic patients. Therefore, a goal of any pediatric dialysis program is to ensure that children attend school regularly and have access to normal socialization. A cohort of adult Dutch patients (32 to 52 years) who had started RRT at <15 years was assessed for long-term QOL and social outcomes. As compared the general Dutch population, QOL in the areas of general health, vitality, and physical problems was most affected, particularly in those individuals currently being treated with dialysis. Interestingly, these patients scored better than the general population in the emotional and mental health domains. However, compared to the general population, they were less likely to work full-time (61.8% vs. 81.0% of the general population) and less likely to have completed high school. There was a nonsignificant difference in the frequency of being married or living with a partner (67.4% vs. 74.4% of the general population) (438). A similar survey was conducted in the United Kingdom to evaluate the impact of CKD from infancy in a group of young adults (439). Forty-one young adults who had CKD from infancy and required RRT in childhood were compared to the general population. At the time of survey, 12.5% of the patients were being treated with dialysis, and 85.5% had a functioning transplant. Half of the patients had significant comorbidities, including heart disease, neurologic involvement, or underlying syndromes. The employment rate was comparable to the general population, and educational attainment of the patients was similar to their parents (439). The patients did not differ from the general population in their perceptions of limitations due to physical health, emotional problems, vitality, emotional well-being, or pain. However, they did have reduced scores for physical and social functioning and the general perception of their health. Lower scores were associated with the presence of comorbidities, being on dialysis at the time of the survey, and short stature (439).

LONG-TERM OUTCOMES AND PATIENT MORTALITY

An analysis of children in the NAPRTCS dialysis registry from 1992 to 2006 showed an overall patient survival of 95%, 90%, and 86% at 12, 24, and 36 months, respectively, with the lowest survival estimates for those younger than 12 months at the initiation of dialysis: 83%, 74%, and 66% at 12, 24, and 36 months, respectively (440). The most frequent cause of death was infection, followed by cardiopulmonary events. The most recent report describes an overall improvement in survival by era with the overall 24-month survival improving from 92.9% for those initiating dialysis in 1992 to 1994 to 96.9% for those who started dialysis in 2007 to 2010 (440). Similar improvements in 12-month survival

by era are described in the most recent USRDS report (**FIGURE 37.5**) (1). In 2007 to 2011, the 1-year-adjusted all-cause mortality was 35 per 1,000 patient-years, a decrease of 22.2% from 2002 to 2006. The decrease was shown across age-groups and treatment modalities. However, the mortality of the youngest patients (85 per 1,000 patient-years) and those treated with HD remains highest (57 per 1,000 patient-years) (1). It is most striking to compare the expecting remaining lifetime in years for various populations of children aged less than 15 years: 23.7 years for patients on dialysis, 63.0 years for those with a functioning transplant, and 72.3 years in the general population (1). This remarkable data emphasizes the need to pursue transplantation in virtually every pediatric patient who receives chronic dialysis therapy.

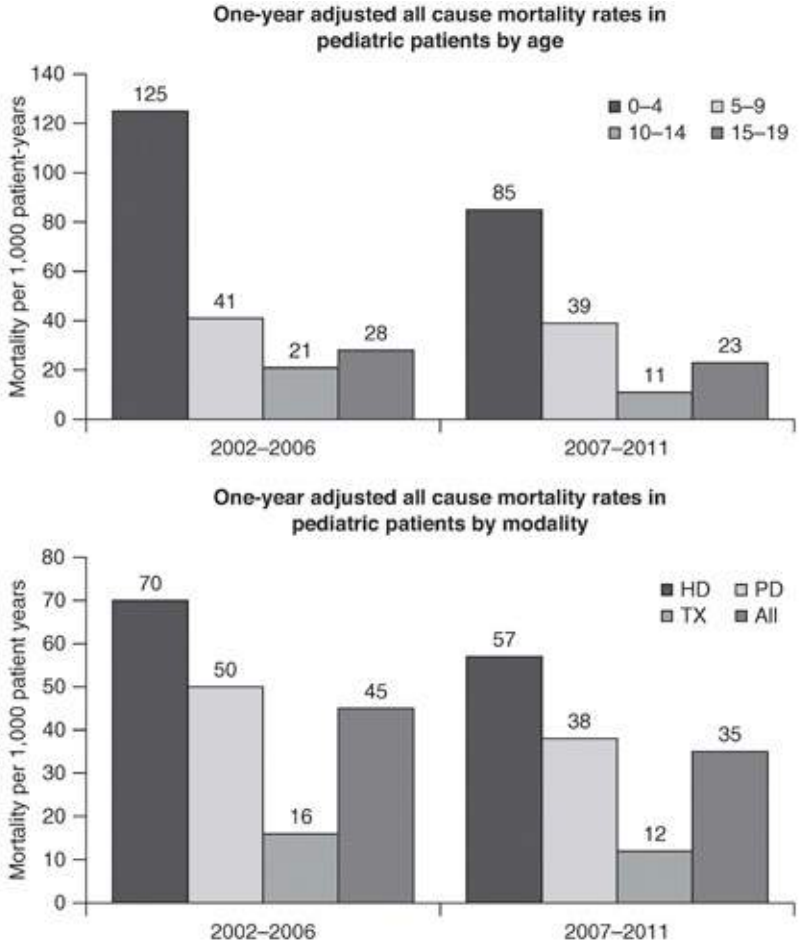

FIGURE 37.5 One-year-adjusted all-cause mortality rates (per 1,000 patient-years) in pediatric dialysis patients by age (*upper panel*) and treatment modality (*lower panel*); comparison of patients who initiated dialysis in 2002 to 2006 versus 2007 to 2011. HD, hemodialysis; PD, peritoneal dialysis; TX, transplant. (Charts from United States Renal Data System. *USRDS 2014 Annual Data Report: End-Stage Renal Disease in the United States*. Bethesda, MD: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, 2014.)

CHAPTER 38

Acute Dialysis in Children

Susan R. Mendley

Renal replacement therapy (RRT) options for the pediatric patient include the full spectrum of modalities available for adults—peritoneal dialysis (PD), intermittent hemodialysis (HD), and continuous renal replacement therapy (CRRT) (1–4). Historically, PD had been preferred because peritoneal access is easier to achieve than vascular access and the technique is simpler to perform, not requiring specialized equipment or a need for highly trained personnel. However, advances in vascular access placement techniques, availability of pediatric-sized catheters, and improvements in CRRT machines and associated equipment (dialyzers and blood lines) have increased the use of CRRT for management of pediatric acute kidney injury (AKI) (2,3). The incidence of AKI requiring RRT is lower in hospitalized children than in adults, so prospective randomized studies comparing treatment modalities for management of pediatric AKI are lacking. The choice of RRT continues to be strongly influenced by the physician's experience and the technical expertise available at each hospital.

ACUTE KIDNEY INJURY IN CHILDREN

A full picture of the incidence and outcome of AKI in children is made more complicated by the use of varying definitions: the Pediatric Risk, Injury, Failure, Loss, End-Stage Renal Disease (pRIFLE) (5), the AKI network (6), and the Kidney Disease: Improving Global Outcomes (KDIGO) (7) assessments. The incidence of AKI in a large pediatric study varied from 37% to 51% depending upon the definition; capture rates and stages of AKI differed between methods (8). However, AKI, by any definition, was associated with higher mortality and longer length of stay. Furthermore, pediatric intensive care unit (PICU) patients showed increasing mortality with greater severity of AKI irrespective of definition.

The causes of AKI in children differ substantially from those in adults and between industrialized and developing countries (9,10). Common causes of AKI in referral centers in industrialized countries include complications of cardiac surgery, treatment of malignancies, and nephrotoxins (11,12). Additional causes common to both settings include hemolytic uremic syndrome, sepsis with multiorgan dysfunction, ischemia, glomerulonephritis, and congenital kidney disease (9,13,14). In a larger referral center, two

decades of observation showed neonates and infants were commonly affected and had higher mortality than older children (15). Several comprehensive reviews on pediatric AKI are available (16–19).

Conservative management of the child with AKI includes careful fluid resuscitation, if intravascular volume depletion is present. Once euvolemia has been restored, if oligoanuria is present, maintenance of fluid balance is attempted through the use of diuretics and fluid restriction. Additional measures include diet modification (restriction of potassium and phosphorus, using specialized formula in infants) to minimize development of metabolic disturbances and the use of medications (sodium polystyrene, sodium bicarbonate, and phosphate binders) to correct electrolyte disturbances. Conservative measures, however, are often not sufficient to allow optimal management particularly with prolonged and severe AKI when fluid restriction often compromises the ability to provide appropriate nutrition, which is essential for recovery (20).

INDICATIONS FOR RENAL REPLACEMENT THERAPY

The indications for initiation of RRT in pediatric AKI are similar to those in adults. The indications include (a) oligoanuria requiring fluid and/or electrolyte removal to optimize nutritional and medical support; (b) hypervolemia complicated by congestive heart failure, pulmonary edema, or severe hypertension despite diuretic therapy and fluid restriction; (c) hyperkalemia refractory to medical management or associated with cardiac involvement as evidenced by electrocardiogram changes; (d) metabolic acidosis refractory to medical management with sodium bicarbonate or limited by sodium overload; (e) symptomatic uremia with pericarditis, neuropathy, or encephalopathy; (f) tumor lysis syndrome or severe hyperuricemia; and (g) toxic ingestions (21). Furthermore, RRT in children is used for specific nonkidney disease indications including inborn errors of metabolism with hyperammonemia or unremitting acidosis and toxic ingestions (22–24). These rare conditions require prompt recognition and emergency resuscitation to allow nephrologists to provide rapid, efficient clearance of accumulated metabolites and toxins (see below).

Fluid overload is recognized to be an independent risk factor for mortality in pediatric patients in PICU settings (25,26). Single-center and multicenter retrospective studies have supported the observation that survivors of AKI are more likely to have a lesser degree of volume overload at the time of initiation of CRRT (27–29). This has led some pediatric centers to develop protocols for initiation of CRRT when patients become 10% fluid volume overloaded or at initiation of mechanical ventilation regardless of glomerular filtration rate (GFR) (30–32).

PERITONEAL DIALYSIS

PD offers several advantages for the care of the pediatric patient with AKI. Technically, it is a simple procedure that does not require specialized personnel. Nurses in PICUs can be trained to perform the procedure with an acceptably low infection rate. Currently available automated cycler devices permit frequent dialysis exchanges without repeatedly opening the circuit, further lowering the infection risk. Fluid and solute removal occur gradually, making the procedure well tolerated in the hemodynamically compromised child and eliminating the risk of hypotension or dialysis disequilibrium (33–35). From a practical standpoint, placement of a PD catheter is technically easier than placement of vascular access,

which can be particularly challenging in the small infant (36) (**TABLE 38.1**).

TABLE 38.1 Causes of Acute Kidney Injury in Children

Etiologies of Acute Kidney Injury	Referral Center in Developing Country	Tertiary Center in Industrialized Country
	n (%)	*n* (%)
Hemolytic uremic syndrome	25 (31)	5 (3)
Glomerulonephritis	18 (23)	–

Adapted from Flynn JT. Causes, management approaches, and outcome of acute renal failure in children. *Curr Opin Pediatr* 1998;10(2):184–189, with permission.

PD provides particularly efficient solute and fluid removal in the youngest patients. Peritoneal membrane surface area correlates with body surface area rather than with body mass; this ratio is most favorable in infants and young children who can thus achieve large peritoneal clearance (37,38). Use of PD also avoids the need for anticoagulation and blood exposure through priming of a blood circuit. Because PD is the preferred mode of dialysis for children with chronic kidney disease, initiating the therapy in the acute setting can facilitate the transition to chronic dialysis. This form of dialysis is less expensive to perform and requires a smaller initial capital investment than other CRRTs (see subsequent text) (1).

PD has been used to manage volume overload and AKI after cardiac surgery in infants with some success (39–41). However, not all studies demonstrate benefit from PD or superiority over CRRT (42,43).

PD, however, is not appropriate for all patients. It is contraindicated in those with abdominal wall defects (e.g., bladder exstrophy, omphalocele, and gastroschisis) and diaphragmatic lesions (e.g., diaphragmatic hernia and surgical defects). It cannot be used immediately after abdominal surgery. The presence of a ventriculoperitoneal shunt is a relative contraindication because of the risk of ascending infection should peritonitis develop; many pediatric nephrologists choose another modality in that setting. PD may not be successful after extensive abdominal surgery because adhesions can cause failure of dialysate drainage, which is manifested as slow outflow rates or poor ultrafiltration.

In clinical situations in which rapid removal of solute (e.g., hyperkalemia), toxin (ingestion), or metabolite (e.g., ammonia) is required, PD does not provide an optimal response. The gradual nature of the treatment, which is advantageous in uremia, will limit the rapid response those emergencies require. Furthermore, in states of acute volume overload with pulmonary edema or congestive heart failure, the ultrafiltration provided by PD may not be rapid or predictable enough to prevent clinical deterioration or mortality (42). Nonetheless, in life-threatening emergencies, PD may be the most accessible and familiar dialysis modality available and can be used until alternate modalities can be arranged (24,44).

Peritoneal Dialysis Catheters

Neonatal and pediatric sizes of most adult catheter configurations are available. These include acute "temporary" catheters and chronic catheters appropriate for operative placement. Acute catheters can be placed percutaneously at the bedside after filling the abdomen with dialysate, as is done in adults (36,45). This permits dialysis therapy to be initiated quickly even in patients too unstable for surgery. Before placement of the dialysis catheter, a Foley catheter should be inserted to empty the bladder and decrease the risk of bladder perforation.

Temporary catheters have several disadvantages: Percutaneous placement can result in injury to an abdominal viscus; bowel and bladder perforations are recognized complications (46). Older catheters were stiff, and even after successful placement, they could cause bowel injury; this often necessitated immobilizing the child while the catheter was in place. Newer more flexible catheters perform better (45). In addition, temporary catheters are uncuffed and, therefore, carry a much greater risk of dialysate leakage at the exit site and subsequent infection. The risk of catheter complications increases significantly after 6 days of use, and it is usually impossible to predict renal recovery at the initiation of PD (47). Therefore, many nephrologists prefer an operatively placed catheter that is used immediately.

The Tenckhoff catheter, although designed as a chronic catheter, is often used in the acute setting (47,48). The catheter can be placed in the intensive care unit or in an operating suite; laparoscopic placement may have advantages (49). There is an increased risk of leakage at the exit site when the catheter is used immediately after placement, and strategies to limit that complication are described in the subsequent text.

Data from the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) do not suggest that one type of chronic catheter design is superior to the others. However, data do suggest a downward (caudally) oriented exit site is preferable because this has been associated with a reduced risk of peritonitis in chronic dialysis (50,51). In infants, it is preferable to position the exit site above the diaper area to reduce the risk of fecal contamination. Similarly, in children with ostomies, it is preferred that the dialysis catheter be positioned on the contralateral side to maximize the distance between the ostomy and the catheter exit site, thereby minimizing the risk of exit-site contamination and infection. Omental obstruction resulting in poor outflow is common especially in small children; therefore, many advocate performing an omentectomy at the time of the original surgery to avoid outflow obstruction (52–55). This issue, however, remains controversial because other authors do not believe that it is necessary (56). Intraoperatively, should any hernial defects be noted, they should be repaired to minimize this potential complication of PD.

Peritoneal Dialysis Solutions

Acute pediatric PD is usually performed using the commercially available lactate-based dialysis solution. Calcium concentrations (1.25 and 1.75 mM) are chosen based on the need for calcium-based phosphorus binders and vitamin D supplements, but that choice may be less relevant in the acute setting. Lactate-based dextrose solutions have the disadvantages of low pH and glucose absorption with prolonged dwells. Low pH can contribute to pain on inflow and impaired phagocytic activity resulting in increased risk for infection (57). More biocompatible PD solutions, such as neutral-pH low-glucose degradation product solution (58) and bicarbonate-based solution (59), have been tested in children. Short-term and

intermediate-term safety has been demonstrated in chronic PD. A comparison of bicarbonate and lactate PD solution in adults with AKI showed improved serum bicarbonate, lactate, and pH with the former solution (60). There are no similar data in children.

Because peritoneal surface area in children is large relative to body surface area, glucose absorption during PD can, unfortunately, prove to be too efficient (38). Such glucose absorption during prolonged dwells dissipates the osmotic gradient between plasma water and dialysate leading to suboptimal ultrafiltration, hyperglycemia, hyperinsulinemia, and hyperlipidemia (61,62). Short dwells are used to limit glucose absorption. Alternative osmotic agents such as amino acids may prove useful, at least permitting nutritional benefit from the enhanced absorption. Combined amino acid–glucose-based dialysate has been used in children for acute PD (63). There are no data on icodextrin use in acute PD in children, although it has been studied in chronic PD patients (64).

Dialysis Prescription Considerations

Acute PD is usually initiated with small volumes to limit leakage around a new catheter. Small fill volumes of approximately 10 to 20 mL/kg are often the starting range, although poor drainage, slow clearance, and inadequate ultrafiltration may limit the effectiveness of low-volume therapy. Fill volumes are gradually increased over many days to a goal of 40 to 50 mL/kg, as tolerated. Short exchange times (45 to 90 minutes) may be used to overcome the limitations of low fill volume and to facilitate ultrafiltration by limiting glucose absorption (65). Even shorter dwell times are possible; however, they are less efficient because a larger proportion of time is spent filling and draining leaving less time for actual dialysis (66).

Although efficient peritoneal glucose absorption may necessitate high dextrose concentrations for infants and small children to achieve ultrafiltration with long dwell times, short exchanges usually provide acceptable or even excessive ultrafiltration using 1.5% dextrose. Therefore, frequent dialysis exchanges for adequate clearance may result in unpredictable fluid removal in small children; careful reassessment of volume status and supplemental fluid, either enteral or parenteral, must be provided to prevent intravascular volume depletion that, in turn, may impair renal recovery.

PD can be performed manually or with an automated cycler. Low-volume manual PD exchanges use a Y-type connector, one limb of which is attached to the inflow line and dialysate bag and the other limb is attached to the drain line and bag to avoid repeatedly opening the catheter connection. A commercially available product (Gesco Dialy-Nate Set) is available as a closed system which permits repeated small exchanges by using an in-line graduated measuring device inserted between the dialysate bag and inflow tubing; this allows more precise measurement of fill volumes and infrequent opening of the dialysis circuit to limit potential contamination. An automated cycling PD machine can be programmed for short dwell treatments appropriate for acute PD; this method also limits opening the catheter circuit to once a day, which decreases the risk of contamination. Currently available cyclers that permit very low volume exchanges (beginning at 60 mL) and low-volume tubing (to decrease the dead space or recirculation volume) facilitate therapy in infants and small children.

Complications of Peritoneal Dialysis

The most common complications of acute PD are catheter malfunction and infection. Catheter malfunction includes dialysate leakage, inflow problems, and outflow problems. Leakage can be external, occurring

around the exit site or the incision used to insert the catheter, or internal, resulting in a hernia. Risk factors for external leaks include use of a stiff temporary catheter, frequent catheter manipulation, malnourishment, and initiation of PD with large fill volumes immediately after catheter placement. Strategies to minimize the risk of leakage include use of small fill volumes, minimal catheter manipulation, and two purse-string sutures to seal the peritoneum around the catheter and to seal the posterior rectus sheath opening (67). Temporary discontinuation of PD and use of smaller fill volumes is the initial approach to catheter leaks, but surgical repair is sometimes required. Three retrospective reviews of pediatric acute PD found an increased rate of complications with temporary catheters compared with Tenckhoff catheters (1,47,68).

Obstruction to dialysate flow or excessively slow flow is a frequent catheter complication. Inflow obstruction is usually due to a mechanical blockage: a kink in the catheter, clamp on the catheter, or the presence of blood clot or fibrin. Addition of heparin to the dialysate at a concentration of 250 to 1,000 U/L may diminish fibrin and blood clots. Outflow obstruction is more common and is usually a greater impediment to successful therapy. Catheter entrapment or occlusion by omentum can limit flow and may require reoperation for omentectomy; many surgeons, therefore, perform this at the time of catheter placement. Intra-abdominal adhesions may prevent free flow of dialysate throughout the abdomen, and poor outflow will be noted. Catheter migration can occur and result in painful inflow of dialysate and poor outflow; this may be correctable using a stylet under fluoroscopy or it may require laparoscopic repositioning. Constipation and intestinal distention often limit outflow and should be managed with stool softeners, enemas, or laxatives (avoiding magnesium and phosphorus) (69).

Infectious complications may involve the exit site, tunnel, and/or peritoneum. In the acute setting, an exit-site infection is essentially a surgical wound infection and should be managed as such with parenteral antibiotics. The risk for dialysate leakage and contamination of the peritoneal space is high. Peritonitis is a serious complication of acute PD. It presents a large inflammatory burden to already debilitated, catabolic patients. Resistant organisms and fungi are a greater risk in the intensive care setting where patients are often already receiving antibiotic therapy. Frequent surveillance cell counts and cultures are advisable in this setting because the typical features of fever, abdominal pain, and cloudy effluent may be difficult to discern. Empiric broad-spectrum antibiotic therapy is often required until culture results are available. Intravenous or intraperitoneal therapies are appropriate, depending on the severity of the infection; combined therapy has been used in debilitated patients. Risk factors for developing peritonitis include use of a temporary catheter for more than 3 days, leakage around the exit site, age younger than 2 years, and poor dialysis technique (46).

Hernias are more often a complication of chronic PD, resulting from dialysis performed in an upright posture and increased intra-abdominal pressure. However, a diaphragmatic defect (pleuroperitoneal fistula) can result in hydrothorax even at initiation of dialysis, compromising ventilation and preventing adequate dialysis drainage. A patent processus vaginalis can cause a hydrocele or genital edema. Although these hernias could be corrected surgically, in the acute setting, one is more likely to turn to an alternate modality of dialysis.

Acute PD can cause metabolic complications, most often resulting from glucose absorption. Hyperglycemia may occur and require insulin therapy. Hypertriglyceridemia can result from glucose absorption and be difficult to distinguish from the effects of hyperalimentation. There is spontaneous loss

of albumin into dialysate, which can cause hypoalbuminemia; this loss is dramatically increased if peritonitis complicates therapy (46). Lactic acidosis secondary to lactate absorption from the dialysate can occur in small children, but most patients see an improvement in acidosis with initiation of PD. Hyponatremia is common, particularly in very young patients. It is exacerbated by the administration of hypotonic fluids; hypernatremia can develop with excessive ultrafiltration and insufficient free water intake.

HEMODIALYSIS

Acute HD can be safely and effectively performed in infants and children of all sizes (70–73). It requires highly trained personnel, specialized equipment, and a well-functioning vascular access. Acute HD is often preferred in situations requiring rapid removal of fluid, solute, or toxins (e.g., hyperammonemic coma or other inborn errors of metabolism, ingestion, or hyperkalemia) (21,22,74–77). In fact, HD treatments in small children can be strikingly efficient because body water space (V) is small relative to the potential clearance that one can provide with standard or high-flux dialyzers and typical blood flows (Q_B) (78). Improvements in HD machinery and availability of size-appropriate equipment (blood lines, dialyzers, and vascular access) have facilitated the use of HD in infants and small children. However, the ability to perform HD is contingent on vascular access, which is a challenge in infants and small children.

Technical Considerations

Although the principles of HD are the same in children as in adults, there are several technical aspects unique to children.

Personnel

Skilled dialysis nurses with pediatric experience are required to perform acute HD in children. A nurse-to-patient ratio of 1:1 is needed to provide focused continuous attention to small patients. Keen observation skills and an awareness of age-dependent norms for vital signs are necessary to assess pediatric HD patients and intervene appropriately. Children who are ill are often unable to communicate their distress verbally. Warning signs of decompensation such as agitation or poor perfusion must be recognized quickly. Normal blood pressure in small children is much lower than in adults, leaving little margin for error and hypotension may develop precipitously (79).

Hemodialysis Machines

Technologic improvements in the design of HD machines that have benefited children include the incorporation of volumetric ultrafiltration controllers and blood pumps capable of being calibrated for neonatal, infant, and pediatric blood lines. The blood pump must be able to accurately deliver blood-flow rates within the range 20 to 300 mL/min, appropriate for neonates through older adolescents. The presence of an accurate volumetric ultrafiltration controller is also essential because even small errors in ultrafiltration volume of a few hundred milliliters can result in symptomatic fluid overload or intravascular volume depletion and hypotension.

Extracorporeal Circuit—Blood Lines

In infants and small children, the extracorporeal circuit volume may represent a significant fraction of total blood volume, and severe hypotension can occur at initiation of the treatment. The typical extracorporeal circuit for adult patients may exceed 150 mL; neonatal, infant, and pediatric blood lines are available to limit the circuit volume for some manufacturers. Low demand has caused many manufacturers to withdraw pediatric-specific dialysis supplies. In some cases, the blood pump must be calibrated for the chosen blood line for accurate blood flow. Neonatal lines may not be compatible with available volumetric dialysis machines. However, even using low-volume bloodlines and dialyzers, the total circuit volume cannot always be reduced to less than 10% of the patient's blood volume, particularly in the case of newborns and small infants. When the circuit volume exceeds 10% of the patient's blood volume or when the patient is severely anemic, the circuit can be primed with blood to maintain hemodynamic stability (71). Packed red blood cells may be diluted 1:1 with normal saline to decrease the hematocrit to approximately 35%, thereby decreasing the viscosity and risk for clotting. Blood priming carries its own particular risks. The greatest concern is that of potential antigen exposure, which will complicate future renal transplantation in patients who do not regain renal function. The risk of sensitization to antigens is multiplied by the number of HD treatments required, because each will require a separate blood prime. In addition, a blood prime is a potential infectious exposure, and young children may acquire cytomegalovirus infection as a result. Furthermore, even if the primed blood circuit is infused at a low blood-flow rate (20 to 50 mL/min), it represents a rapid rate of blood transfusion. This may result in a transfusion reaction or hypocalcemia from citrate infusion. Finally, the potassium load associated with transfusion of packed red blood cells may produce sudden hyperkalemia with cardiac arrhythmias, which may not be corrected quickly enough by HD. This risk is diminished by washing packed red blood cells before the procedure. At the end of an HD treatment which began with a blood prime, the blood circuit is not returned to the patient.

Dialyzers

A wide variety of dialyzers have been used in children; no pediatric data suggest an advantage of one type of membrane. Extrapolating from studies in adults suggesting a benefit of biocompatible membranes on survival and recovery of AKI (80–82), these dialyzers have become standard in children. A more significant challenge is finding dialyzers of sufficiently small volume, surface area, and ultrafiltration coefficient (Kuf). Choices in dialyzers with surface area less than 0.4 m^2 are limited, and availability changes often. Small priming volume is an advantage when dialyzing infants and small children because it may allow one to avoid priming the circuit with blood. Dialyzers with relatively large surface area may be advantageous when rapid clearance is needed, but in most cases, clearance will be determined by the blood flow that one can achieve throughout the treatment, rather than the surface area or KoA of the dialyzer. In practice, all standard and high-flux dialyzers have a higher Kuf than is needed for adequate ultrafiltration in small children. Earlier, this was a great concern because small errors in setting the dialysis machine transmembrane pressure (TMP) could result in large ultrafiltration errors and hypotension. In addition, because pediatric vascular access is generally of small caliber, one finds high venous pressures that, in turn, result in greater TMP. This concern has been alleviated by the widespread use of machines with volumetric ultrafiltration controllers. However, during isovolemic HD (or even during modest ultrafiltration) with a high-flux dialyzer, backfiltration of dialysate is to be anticipated; this can be avoided by increasing the ultrafiltration rate sufficient to reverse negative TMP and infusing saline

through the treatment (TABLE 38.2).

TABLE 38.2 Vascular Access Recommendations for the Pediatric Patient

Patient Size	Catheter Size	Access Site
Neonate	Umbilical artery catheter 3.5–5.0 Fr OR Umbilical vein catheter 5.0–8.5 Fr OR 5.0 Fr single lumen OR 7.0 Fr dual lumen	Umbilical vessels Femoral vein
5–15 kg	7–8 Fr dual lumen	Femoral/subclavian/ internal jugular vein
16–30 kg	9–11 Fr dual lumen	Internal jugular/femoral/ subclavian vein
>30 kg	10–12 Fr dual or triple lumen	Internal jugular/femoral/ subclavian vein

Adapted from Bunchman and Donckerwolcke (83) and Hacbarth et al. (84).

Vascular Access

Obtaining a well-functioning vascular access remains a challenge in small patients. Vascular access for acute HD is usually established by percutaneous placement of a double-lumen catheter. Whether a temporary or permanent (tunneled) dialysis catheter is chosen depends on one's estimate of the duration of dialysis therapy needed. This is often merely an approximation; patients typically begin urgent dialysis therapy with a temporary catheter, and a tunneled catheter is placed electively. Double-lumen catheters are available in sizes from 7 Fr to 14 Fr and come in various lengths; manufacturers and availability of the smallest catheters change frequently. Single-lumen catheters of 5 Fr and smaller are used for neonates. TABLE 38.2 provides guidelines for catheter selection based on patient size. Ideally, the catheter should offer low resistance to blood flow and, therefore, should be a stiff catheter with a short length but large internal diameter (85). Broviac catheters, often already placed in oncology patients, are inappropriate because of their flexibility, length, and small lumen size. Acute dialysis catheters can be placed in the femoral vein, subclavian vein, or internal jugular vein; the choice depends on the size of the patient and the availability of central venous sites. Femoral catheters are technically easier to insert and are not associated with the risks of pneumothorax and pneumomediastinum or hemothorax and hemomediastinum. However, there is an increased risk of infection when left in place for more than a few days and patients are confined to bed. Catheters placed in the subclavian vein or internal jugular vein should have their tips positioned at the junction of the superior vena cava and right atrium to allow adequate blood flow and minimize recirculation. They may be left in place for several weeks, although a tunneled catheter would be a better choice for such a duration of dialysis.

In an infant, vessel size may make placement of even a small-caliber double-lumen catheter impossible, and one may be obliged to place single-lumen catheters in two sites. In the newborn, HD can be performed through small single-lumen catheters placed in the umbilical artery and vein. Small-caliber catheters increase the risk of hemolysis from sheer stress and can cause wide swings in access pressures affecting ultrafiltration and compromising the overall success of the treatment.

Dialysis Prescription

There are no prospective trials to assist clinicians in determining the adequacy of acute HD therapy in children with AKI. Because the spectrum of diseases causing AKI is different from that in adults, extrapolation from that literature may be difficult. Therefore, the duration, frequency, and efficiency of the HD treatments are a matter of judgment aided by an understanding of kinetic modeling and of the modifiable variables (blood flow, dialysate flow). Often, a single metabolic derangement (e.g., intoxication, hyperammonemia) defines the length and efficiency of the treatment. Nonetheless, when children are dialyzed for advanced uremia with standard dialyzers, the urea clearances that are achieved may be sufficient to cause true disequilibrium or seizures (which are a more common complication in children than in adults) (86,87). Blood-flow rate for the first few treatments may be decreased to target urea clearance of 2 to 3 mL/kg/min, and treatment length will usually be shortened to 1.5 to 2 hours to avoid precipitous falls in blood urea nitrogen (BUN) (86). Single-pool Kt/V for a first treatment in a uremic child should probably not exceed 0.6. Short daily treatments are often the most appropriate way to initiate HD therapy without patient discomfort or instability. Subsequent treatments are lengthened to 3 to 4 hours or longer if needed, and higher urea clearance rates can be targeted (blood-flow rates of 4 to 5 mL/kg/min). Smaller blood vessels and catheters cause higher venous resistance than in adults, and this will eventually limit blood flow, perhaps as low as 25 to 100 mL/min.

Acute HD treatments in children should only be performed with bicarbonate-based dialysate. Otherwise, small patients will be presented with a disproportionately large acetate load, and their small muscle mass will be inadequate to metabolize it. Dialysate flow rates range from 300 to 900 mL/min, as in adults. For treatments using low blood flows and dialyzers of low KoA, dialysate flow rates are not rate limiting for clearance and the lower range will be sufficient.

Ultrafiltration is targeted to the patient's clinical situation. If severe volume overload is present, rapid ultrafiltration may be appropriate. Otherwise, one attempts to limit total fluid removal per session to 5% of the patient's body weight (71). Critically ill patients in intensive care units often require large volumes of medications, feedings, and blood products resulting in ongoing fluid overload and hemodynamic instability with HD treatments. Close monitoring of blood pressure, ideally by an arterial line, is required. If isolated ultrafiltration without dialysate is planned in an infant or small child, hypothermia may develop because the dialysis circuit acts as a radiator that is relatively large for the patient's total blood volume.

Some form of anticoagulation is generally needed when performing HD in children particularly because the blood-flow rates are often slow, increasing the risk of clotting. Systemic heparinization is used most commonly with doses scaled to body size and then adjusted according to activated clotting times (ACTs). A loading dose of 10 to 30 U/kg is given at the start followed by a maintenance dose of 10 to 20 U/kg/hr. ACTs are followed at the bedside when machines and trained personnel are available, and the heparin dose is titrated to keep the ACT between 150 and 200 seconds (88).

There are alternative strategies for maintaining circuit patency in children at high risk for bleeding complications including (a) saline flushes without other anticoagulation, (b) regional heparinization with protamine reversal, (c) low-dose heparin, and (d) regional citrate anticoagulation. There is little published experience on the use of these other anticoagulation strategies in pediatric HD patients, and many nephrologists rely on saline flushes and avoid the use of anticoagulation (88). However, the volume

of saline used to flush the circuit increases the treatment ultrafiltration and may be poorly tolerated in small child. Heparin-induced thrombocytopenia has been reported in children receiving dialysis, although the largest pediatric experience comes from patients on extracorporeal life-support systems after cardiac repair; argatroban, danaparoid, and hirudin have been used successfully for anticoagulation in this setting (89–92). See Chapter 4 for further details regarding anticoagulation on HD.

Dialysis Prescription for Nonkidney Disease Indication—Hyperammonemia and Other Inborn Errors of Metabolism

Prescription considerations are somewhat different when children are being dialyzed for nonkidney disease indications such as intoxications, hyperammonemia, or other inborn errors of metabolism. In this situation, rapid clearance from the blood is paramount (74); therefore, it is essential to have a well-functioning vascular access because blood-flow rates as high as 10 to 15 mL/kg/min may be needed (75,77). Dialysis disequilibrium is not a concern in this situation because patients are not uremic. These children are critically ill and are often intravascularly volume depleted because there is often a preceding history of lethargy, poor intake, and vomiting. In addition, because their kidney function is normal, they continue to produce urine. Careful monitoring of intravascular volume status and electrolyte balance is required. Supplemental intravenous fluids should be provided as needed, and pressor support may be required to tolerate the dialysis procedures. Dialysate potassium and bicarbonate must be adjusted to avoid creating hypokalemia and metabolic alkalosis, and one should avoid high-calcium dialysate. Phosphorus levels can be expected to fall, and supplementation may be required (76,77). Metabolite levels are monitored and dictate the duration, efficiency, and frequency of HD sessions, but prolonged and repeated sessions are often required (93). Rebound and ongoing production of metabolites following HD should be anticipated. CRRTs have also been used successfully alone and in conjunction with HD to control the hyperammonemia and other inborn errors of metabolism (94–97).

Hemodialysis for Management of Toxic Ingestions

Initial management of toxic ingestions involves gastric decontamination measures, administration of antidotes if available, and supportive care (98). Certain drugs and toxins have been shown to be effectively removed by extracorporeal therapies (99). HD may be beneficial for removal of small molecular weight compounds (e.g., lithium, salicylates) that are not highly protein bound and that have a small volume of distribution. In addition, HD allows correction of metabolic disturbances that may result from the ingestion. For toxins with a large volume of distribution in which one anticipates a rebound following acute HD, addition of continuous hemofiltration or continuous HD has been reported to be effective (21,100). For toxins that are highly protein bound, hemofiltration may still be of benefit to remove free drug once the protein is saturated (101). Charcoal hemoperfusion has also been shown to be effective in removing certain drugs that are protein bound (e.g., phenytoin, phenobarbital, theophylline, carbamazepine). Published reports on the use of hemoperfusion in pediatrics are limited but suggest that the procedure can be safely performed in children (101–103). As with HD, the volume of the extracorporeal circuit is of concern and should not exceed 10% of the child’s blood volume to ensure hemodynamic stability. See Chapter 36 for further detail regarding hemoperfusion and its indications. Case reports suggest that high-efficiency HD may be an effective alternative therapy to charcoal hemoperfusion for removal of certain drugs (e.g., vancomycin, carbamazepine) (104,105). Potential

complications associated with charcoal hemoperfusion such as thrombocytopenia, coagulopathy, hypocalcemia, and hypothermia can also be avoided using high-efficiency HD.

Selected Complications of Hemodialysis in Infants and Children

Hemodynamic instability is one of the most common complications occurring on dialysis. Risk factors in the pediatric patient include (a) hypotension due to multiple organ dysfunction syndrome (MODS), (b) excessive ultrafiltration, (c) extracorporeal circuit volume exceeding 10% of the patient's blood volume in the absence of a blood prime, and (d) removal of vasopressors by dialysis. Under normal conditions, children have lower blood pressures than adults and a narrower margin to development of hypotension. Intradialytic hypotension may develop abruptly; therefore, volume removal must be closely monitored during treatments.

As mentioned earlier, overly rapid urea clearance is more likely to occur in small children and in those with high BUN or prolonged azotemia. It may precipitate osmolar shifts and symptomatic disequilibrium with nausea, vomiting, headache, and even seizures and coma. Strategies to limit clearance (as mentioned earlier) for the first few treatments in children with long-standing uremia are usually advisable.

Dialyzer reactions are infrequent but potentially fatal when they occur; therefore, prompt recognition and management are essential. Mild forms include itching, urticaria, wheezing, flushing, cough, and emesis, whereas severe reactions include dyspnea and hypotension. Various inciting agents have been implicated including ethylene oxide, bradykinin (with the AN69 membrane), contaminated dialysate, and heparin (106–108). If suspected, dialysis should immediately be terminated and the blood not returned to the patient (see Chapter 1).

Additional potential complications include bleeding, infection, air embolus, and thrombosis. Those with a catheter in the subclavian or internal jugular vein are also at risk for developing the superior vena cava syndrome given the placement of a relatively large diameter catheter into a small vessel.

CONTINUOUS RENAL REPLACEMENT THERAPIES

CRRT offers several advantages over the other forms of RRT including more gradual and predictable, yet more efficient, correction of hypervolemia and uremia. However, as with HD, a well-functioning vascular access is mandatory, and some form of anticoagulation is typically needed (see Chapter 10). With the development of more sophisticated CRRT machines, it is possible to provide precise ultrafiltration control, thermal control, and a variety of blood-flow rates appropriate for infants through adolescents. The machines offer a wide range of therapeutic options: slow continuous ultrafiltration (SCUF), continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), or continuous venovenous hemodiafiltration (CVVHDF), with some machines having the added flexibility for use in conventional HD (109). Additional improvements have included the development of pediatric blood lines and hemofilters and hemodialyzers. CRRT can now be safely and effectively performed in infants and children, and it has become the preferred mode of therapy in many tertiary care pediatric hospitals in the industrialized world (3,10,27,110). Prospective registry data on CRRT in infants and children is now available, providing valuable insights into practice patterns and outcomes (111). The recognition that fluid overload is an independent risk factor for mortality in children with AKI has

spurred earlier use of CRRT to manage diuretic-resistant hypervolemia (28,29).

The use of CRRT in pediatrics extends beyond therapy for AKI. Phosphorus clearance through CRRT is superior to HD and is frequently employed in tumor lysis syndrome in children with Burkitt lymphoma and acute lymphoblastic leukemia (112,113). It may be used alone or as an adjunct to HD in cases of toxic ingestions, and inborn errors of metabolism where rebound of solute is anticipated (74,95,97,114–116). In addition, it is used as an adjunctive therapy with extracorporeal membrane oxygenation (ECMO) (see below) (117–119).

Slow Continuous Ultrafiltration

SCUF is shown to be beneficial in clinical situations such as postoperative congenital heart repair in which isolated fluid removal is required (120). Significant volume overload (usually considered greater than 10% body weight) is a risk factor for mortality in AKI and after bone marrow transplant (BMT), encouraging earlier initiation of CRRT, although SCUF is usually not described separately in those reports (14,16,17,27–29). Ultrafiltration volumes must be carefully monitored to prevent excessive fluid and solute loss. Furthermore, hypothermia may occur in small children if warmed dialysate or replacement fluid is not used. In-line blood warmers are available for some machines, but they may add significantly to the volume of the extracorporeal circuit.

Continuous Arteriovenous Hemofiltration

Continuous arteriovenous hemofiltration (CAVH) has been used successfully in the management of pediatric AKI and in the management of fluid overload and azotemia in oliguric children following surgical repair of congenital heart disease (42,120–124). It is tolerated well in hemodynamically unstable children and offers the advantages of technical simplicity, low priming volume, and gentle fluid removal. However, it requires both arterial and venous vascular access. In the neonate, this may be accomplished by cannulating the umbilical vessels or the femoral vessels, whereas in an older child, arterial access can be obtained through the radial artery. Reasonable blood-flow rates have been reported with mean arterial pressures greater than 40 mm Hg (83). However, because the circuit is driven by the patient’s arterial blood pressure, the blood-flow rate and ultrafiltration rate may vary as the blood pressure fluctuates, which in turn increases the risk for clotting. Some form of anticoagulation is, therefore, necessary to maintain circuit patency. Incorporation of a pump into the circuit to provide more consistent blood flow (pump-assisted CAVH) has been reported to be beneficial in patients with low blood pressures (125,126). If needed, dialysis can be added for better metabolic control (continuous arteriovenous HD or hemodiafiltration).

Continuous Venovenous Hemofiltration/Hemodialysis/Hemodiafiltration

The development of more sophisticated CRRT machines that are suitable for use in small children makes CVVH, CVVHD, and CVVHDF the more common choice for initial management of pediatric AKI; venovenous forms of CRRT are the most common of the continuous modalities used in children (3,27). With the venovenous forms of CRRT, one avoids the need for arterial catheter placement and its associated risks of bleeding, thrombosis, and limb ischemia with potential impaired future limb growth. Incorporation of a blood pump into the circuit increases the extracorporeal circuit volume and complexity of the procedure, but it also allows consistency in blood-flow rate which stabilizes clearance and

ultrafiltration (127). Fluid or blood warmers provide thermal control and the addition of integrated balances and tightly calibrated pumps allows for greater confidence in monitoring ultrafiltration (83,128). Newer machines are also equipped with software programs to assist in troubleshooting problems at the bedside, a particularly beneficial feature for the intensive care unit staff providing therapy. Nonetheless, currently available machines are not designed to provide sufficient precision in ultrafiltration and replacement solutions for children under 10 kg, and clinicians must be vigilant for unintended volume overload or depletion. A truly miniaturized CRRT device for neonates is still in development (129).

Vascular Access and Extracorporeal Circuit

As with HD, a well-functioning venous vascular access is critical. See section "Hemodialysis" of this chapter for a review of issues related to pediatric vascular access. An analysis of catheter size in CRRT showed that circuit survival was significantly worse for the smallest catheters (5 Fr, 7 Fr, and 9 Fr, although not 8 Fr) and better when the catheter was placed in the internal jugular vein (84). There did not seem to be a difference in circuit survival when comparing larger catheters (10 to 12 Fr).

As in HD, whenever possible, the blood lines and hemofilter or hemodialyzer should be selected to keep the extracorporeal circuit volume less than 10% of the patient's blood volume or a blood prime may be necessary. Some systems offer flexibility in choosing blood lines and hemofilters. However, even with this flexibility, the circuit volume may still exceed 10% of the patient's blood volume and a blood prime may be necessary (83). Risks associated with use of a blood prime are reviewed in detail in section "Hemodialysis" and include potential antigen exposure, potential infectious exposure, transfusion reaction, hyperkalemia, and citrate overload with hypocalcemia. Washing red blood cells diminishes excess potassium but does not remove concerns of rapid antigen exposure or electrolyte disturbance. Furthermore, use of a blood prime in conjunction with an AN-69 membrane may result in the bradykinin release syndrome. Brophy et al. (130) described this potentially fatal syndrome in two children beginning CRRT with an AN-69 hemofilter. Symptoms of hypotension, tachycardia, vasodilatation, and anaphylaxis typically begin within minutes of CRRT initiation and resolve with discontinuation of CRRT. It is important to be cognizant of this potential complication as it is may be preventable. On the basis of the theory that exposure of blood to the AN-69 hemofilter in an acidotic milieu results in the generation of bradykinin, prevention strategies have been proposed. One strategy, zero-balance ultrafiltration, entails circulating the blood prime through the CRRT machine with a customized, electrolyte-balanced replacement solution to normalize potassium, calcium, and pH prior to initiating therapy (131). Another strategy involves buffering the packed red blood cells with tromethamine (THAM) and bicarbonate to correct the pH closer to physiologic (7.3 to 7.6) before priming the circuit (132). If the CRRT procedure is interrupted for a short time, the blood prime may be recirculated. However, the circuit pH and electrolyte composition should be rechecked before resuming the CRRT treatment. If clotting or deterioration in the circulated blood occurs, a new blood prime should be performed. Finally, larger infants and toddlers may tolerate a normal saline prime and simultaneous direct transfusion of blood into the patient at therapy initiation (130).

Anticoagulation

Anticoagulation strategies are evenly divided between heparin and citrate, but individual centers have marked preferences (133). There is no difference in circuit life, although there are more bleeding

episodes associated with heparin use. In large series, 7% to 12% of treatments were performed without anticoagulation because of bleeding concerns. This practice is associated with shorter circuit life (133,134).

Heparin anticoagulation is more often used in infants and children less than 10 kg (134). Heparin doses are adjusted for body weight as for HD and then titrated as per the ACT or activated partial thromboplastin time (aPTT). A loading dose of 10 to 50 U/kg is administered at the start, followed by a maintenance dose of 10 to 20 U/kg/h. ACT levels are monitored postfilter and the heparin dose adjusted to keep the ACT between 150 and 220 seconds or the aPTT 1.5 to 2 times control (83). Potential complications associated with heparin use include risk of bleeding, heparin-induced thrombocytopenia, and allergic reactions.

Regional citrate anticoagulation offers the advantage of anticoagulating the extracorporeal circuit but not the patient and, therefore, reduces the risk of hemorrhage. Citrate exhibits its effect by chelating calcium, a necessary cofactor for the coagulation cascade. Citrate is infused into the arterial limb of the circuit at a rate that results in a postfilter ionized calcium level of 0.35 to 0.45 mmol/L and a systemic calcium infusion is administered postfilter or through a separate vascular access at a rate that maintains a systemic ionized calcium level of 1.1 to 1.3 mmol/L (135,136). Placement of a triple-lumen dialysis catheter can be advantageous when citrate anticoagulation is used because the third port can be used for calcium infusion. Calcium-free dialysate is preferable because calcium present in dialysate may chelate with citrate on the surface of the hemofilter membrane resulting in a higher citrate requirement to achieve adequate anticoagulation. Monitoring is much easier than with heparin and consists of following the postfilter ionized calcium and systemic ionized calcium. Citrate use can, however, result in several metabolic complications; therefore, close monitoring of serum electrolytes is also required. Generally, these metabolic derangements can be anticipated, allowing appropriate interventions to be made in a timely fashion. Metabolic alkalosis is the major disturbance that arises as citrate is metabolized into bicarbonate. Children are particularly prone to the development of metabolic alkalosis because the rate of citrate infusion is proportional to the blood-flow rate, which is relatively higher in small children as compared with adults. Management requires adjustment of the bicarbonate concentration in the dialysate. In one pediatric series, metabolic alkalosis was noted in every patient who required more than 7 days of CRRT (136). Additional metabolic complications include hypomagnesemia resulting from citrate chelation of magnesium and hypernatremia resulting from the sodium content of the citrate solution. Two citrate preparations are currently available: trisodium citrate (4% sodium citrate) and anticoagulant citrate dextrose-A (ACD-A; sodium citrate, anhydrous citrate, and dextrose) that differ in their sodium and dextrose content. ACD-A contains 2.45% dextrose and can result in hyperglycemia, particularly in infants. Trisodium citrate solution is more likely to result in hypernatremia. “Citrate lock,” another potential risk, manifests by a rising total serum calcium associated with falling ionized calcium and results from citrate accumulation, when the rate of infusion exceeds the clearance and metabolism. Caution with the use of citrate is, therefore, required in the presence of liver disease and frequent blood transfusions. Overall regional citrate is a successful anticoagulation strategy in children with comparable circuit survival time (133) and decreased nursing time compared with the use of heparin (136).

Alternative strategies for maintaining patency of the CRRT circuit are similar to those used in HD and include (a) use of saline flushes and no anticoagulation, (b) regional heparinization with protamine

reversal postfilter, (c) low molecular weight heparin, (d) prostacyclin, and (e) use of other anticoagulants such as hirudin and argatroban. Regional heparinization with protamine reversal has been problematic because of difficulty achieving good control over the degree of anticoagulation and because of the potential risk of hypotension and anaphylaxis associated with protamine (83). There are no data to guide the use of low molecular weight heparin or hirudin in children on CRRT. However, the successful use of argatroban in two neonates undergoing extracorporeal life-support therapy (ECMO) has been reported (137).

Solutions

Dialysate solutions specifically designed for use with CRRT are commercially available with a bicarbonate buffer. PD fluid is not a desirable choice for dialysate with CRRT. Studies in adults and children have shown improved hemodynamic stability and lower lactate levels when a bicarbonate-based solution is used as compared to lactate solutions (138).

While commercially manufactured solutions are approved by the U.S. Food and Drug Administration (FDA) as dialysate, most centers use them as replacement solution in CVVH or for both fluids when CVVHDF is performed (139). Standard intravenous fluids such as lactated Ringer's and normal saline with or without other supplemental electrolytes are sometimes infused simultaneously or alternated with commercial dialysate when severe metabolic alkalosis occurs. However, if lactated Ringer's or normal saline are used alone as replacement solutions in small patients, one can anticipate metabolic perturbation because of the nonphysiologic pH and electrolyte composition of the solutions. Custom-made solutions prepared by hospital pharmacists have been used with the goal of tailoring the electrolyte replacement to individual patient needs, but they lack regulated quality control standards, are time-consuming to prepare, and carry the well-recognized risk of formulation error (139). Replacement fluid can be administered either prefilter or postfilter. Hemodilution from prefilter replacement could theoretically decrease the risk of filter clotting in children requiring slow blood-flow rates, but comparative data to support this are lacking.

Prescription Considerations

Descriptive data are available on typical blood-flow rate (Q_B), dialysate flow rate (Q_D), and ultrafiltration rate for pediatric patients receiving CRRT (27,134). Data regarding the adequacy of CRRT for pediatric AKI do not exist. Prescription guidelines are, therefore, based on experience and extrapolation from the adult literature. Although the blood-flow rate for adults receiving CRRT is significantly lower than that required for HD, the blood-flow rate required for small children on CRRT is comparable to that required for HD to maintain circuit patency. It typically ranges from 3 to 5 mL/kg/min, although reported ranges are much wider and the lowest Q_B delivered by most machines (20 to 30 mL/min) results in very large flow rates in the smallest patients (83,128,134). Dialysate and replacement fluid flow rates, on the other hand, generally range from 35 to 50 mL/kg/h and is similar to the rate of 2 to 3 L/1.73 m^2/h used for adults. Data regarding a safe rate of fluid removal on CRRT are lacking. There are no prospective pediatric data indicating that one modality (CVVH vs. CVVHD vs. CVVHDF) is superior to another. Small molecular weight solutes are removed equally well with continuous hemofiltration and continuous HD; larger molecular weight solutes are cleared better with hemofiltration than HD. However,

due to small patient size and relatively large Q_B, clearance can be very efficient by all modalities.

CRRT is utilized for nonkidney disease indications as well. Current practice in many PICUs is to consider initiating therapy based upon degree of volume overload rather than waiting for severe electrolyte disturbance. CRRT is the preferred mode of clearance in the tumor lysis syndrome because it permits efficient phosphate removal without rebound and it can be sustained while cell lysis is ongoing (92,112,140). It provides efficient urate clearance as well. CRRT has been combined with acute HD in the management of hyperammonemia from inborn errors of metabolism to prevent rebound at the end of HD treatment (94,95).

Selected Complications

Although CRRT seems to be better tolerated hemodynamically than intermittent HD, hypotension still occurs, particularly at the initiation of therapy if the extracorporeal circuit volume is large relative to the patient's circulating blood volume, or when excessive fluid is removed. Unpredictable and excessive fluid removal is a concern when pediatric CRRT is performed using ad hoc or adaptive machinery: Medication infusion pumps used to measure dialysate flow and ultrafiltration are unreliable at high flow rates (83,128,141). Currently available sophisticated CRRT machines contain integrated, precise scales or pumps that reduce errors in fluid balance, although there remains concern for excessive volume removal or overload in neonates. A blood prime can reduce hemodynamic instability, yet the use of a blood prime in association with an AN-69 hemofilter membrane may result in the potentially fatal yet potentially preventable bradykinin release syndrome discussed in section "Vascular Access and Extracorporeal Circuit" (130). Rapid transfusion of the blood prime at CRRT initiation can cause hypocalcemia, hyperkalemia, or transfusion reaction. Other risks of blood priming are discussed earlier in the chapter.

In addition to solute and electrolyte losses on CRRT, data in children and neonates indicate that amino acid losses on CRRT can also be significant, contributing to negative nitrogen balance (142). Therefore, to maintain a positive nitrogen balance, nutritional supplementation adjusted to provide higher protein intake (up to 3 to 4 g/kg/d) may be required. The potential catabolic complications of pediatric CRRT require further research.

CVVH can provide extremely efficient clearance in a small child, rivalling endogenous renal function. Critical medications which may have had dose adjustments applied for kidney disease may then circulate at ineffectively low levels. Vasopressor clearance can be corrected based upon measured blood pressure, but antibiotics or antineoplastic agents may be erroneously underdosed in this situation. Pediatric pharmacokinetic guidelines have not been developed, and one often extrapolates from adult studies (where clearance and circuit volume are in a very different relationship than in children) (143). Finally, if CRRT is paused for any reason, the pharmacokinetic extrapolations may no longer be valid. Repeated reevaluation of medication dosing in relation to CRRT efficiency and clinical response is required.

Dialysis disequilibrium generally does not occur with continuous therapies because solute removal occurs more slowly, thereby avoiding the development of rapid osmolar shifts and risk for the disequilibrium syndrome (144).

Hypothermia occurs more commonly when adaptive machinery is used for pediatric CRRT. Newer

machines are available with an integrated fluid warmer or a blood warmer. Additional risks associated with CRRT relate to the need for anticoagulation to maintain circuit patency and include (a) hemorrhage if heparin is used, (b) metabolic alkalosis if regional citrate is used (see section "Anticoagulation" for more complete discussion on potential complications associated with citrate use), and (c) blood loss through circuit clotting if anticoagulation therapy is not administered. Finally, there are also risks associated with placing and maintaining vascular access. This is reviewed in the subsection regarding complications of pediatric HD.

Continuous Renal Replacement Therapy and Extracorporeal Life-Support Therapy

The use of ECMO for management of children with cardiac and respiratory failure has become more widespread. Hypervolemia and AKI are well-recognized complications during ECMO (145). CRRT has become an important adjunctive therapy in this setting when diuretic therapy alone is insufficient for fluid removal. CRRT can be performed simultaneously with ECMO in critically ill children (118–120,146–149). A hemofilter can be incorporated into the ECMO circuit without the need for additional vascular access or the need for additional anticoagulation (96,97). While some centers will use only a dialyzer and permit pressure-driven ultrafiltration, use of a CRRT machine allows more precise volume control and chemical clearance by hemofiltration, continuous HD, or hemodiafiltration. The CRRT circuit is placed in line with the ECMO circuit before the oxygenator (150–152). Consideration should be given to positioning of the hemofilter within the ECMO circuit with regard to blood recirculation and shunting away from the oxygenator, although the blood flow through the CRRT circuit is a small fraction of the flow within the overall ECMO circuit (150).

Continuous Renal Replacement Therapy and Cardiopulmonary Bypass

Hemofiltration has also been beneficial for fluid removal in children receiving cardiopulmonary bypass (153). In a novel extension of hemofiltration in this setting, Journois et al. (154) reported initial experience with high-volume zero-balanced hemofiltration (5 L/m^2) in 10 children during the rewarming phase of cardiopulmonary bypass in an attempt to decrease the inflammatory response to cardiopulmonary bypass. The authors attributed the improved outcome (less blood loss, fever, and ventilatory support) to the removal of proinflammatory mediators during the rewarming phase.

SUMMARY

Nephrologists have the tools to provide all forms of RRT to infants and children. However, despite these advances, the mortality rate from AKI in children remains high, likely in part the result of the severity of the underlying disease process (10,155). While no prospective data exist comparing the three treatment modalities for management of pediatric AKI, the Pediatric CRRT Registry has gathered more complete data on pediatric experience with CRRT from which prescription guidelines may emerge. At present, however, the choice of modality for RRT in children continues to be made at the bedside based upon the best institutional experience.

CHAPTER 39

Depurative Modality Options

Tushar Chopra, Iheanyichukwu Ogu, Rafia Chaudhry, Thomas A. Golper, and Gerald Schulman

This chapter discusses the therapeutic options for the management of patients with end-stage kidney disease (ESKD), exclusive of kidney transplantation. The decision begins with an understanding of the implications of patients arriving at the threshold of needing treatment for ESKD. This is discussed in the section of life plans and treatment options. The next step involves the education of the patients, their families, and health care providers. In particular, recent trends suggest that a greater proportion of patients may start their treatment with peritoneal dialysis. An appreciation of the benefits of peritoneal dialysis is required. In addition, particularly for elderly patients or those with serious comorbid conditions, an important consideration is to offer the option of conservative management. The role of conservative management is included. The indications and contraindications for the depurative therapies are also discussed in this chapter. Finally, the reasons for transferring from one method of renal replacement therapy to another is discussed at the end of the chapter.

LIFE PLANNING

A patient facing ESKD must understand that no matter how successful his or her therapy (dialysis and/or transplantation), life span is less than if ESKD were not present. Therefore, it is imperative for the patient, in conjunction with his or her advisors (medical and nonmedical), to establish some form of life plan with ESKD. Early in the course of the disease, education will be important: that education coming from the patient's research on the subject and that provided by the health care team. The strategy in developing a life plan is to live well and extend life with ESKD. To do so, one must recognize a possible distinction between quantity and quality of life. Of course, one prefers both, and an organized plan is the best way to achieve that goal. A life plan is a roadmap to such success and does so by anticipating risks

and considering options. Thus, decisions become structured along the lines of the life plan. For example, a living donor for transplantation may not be available for a year, but ESKD is now. Rather than create an arteriovenous fistula (AVF), a permanent use of the vessels, consider short-term peritoneal dialysis (PD). In 15 years when the transplant is no longer functional, those vessels may be used for fistula creation, and hemodialysis (HD) can be performed with the access that offers the best chance of healthy HD. The life plan leverages all modalities over the lifetime and would emphasize the right therapy at the right time for this individual. During the education process leading to the life plan, all therapies should be presented in a positive light. Patients highly motivated and intensely engaged in their care may disparage in-center dialysis. That is not a healthy approach. All therapies must be respected as they may unexpectedly be necessary. So while discussions take place, the nephrologist should make sure that all therapies are included in a positive light. Crucial to this understanding is the recognition that transition points will inevitably occur. These are not therapy or human failures. They are events that make us change our approach. An example is an incapacitating stroke in a self-care dialysis patient who is now dependent on a helper, usually to in-center dialysis or to the rare skilled nursing facility that performs PD. This is not a "failure" to either the patient or therapy. It represents a transition point and should be described as such in the life plan's attempt at anticipating risk. So the Life Plan is frequently revisited, and adjustments to it become a standard operation.

OPTIONS WHEN FACING LOSS OF KIDNEY FUNCTION

As chronic kidney disease (CKD) progresses, patients may die from other causes or survive to face either death from their kidney disease or seek renal replacement therapy. It takes repeated observations over time and familiarity to at least reasonably predict outcomes in this setting. More and more observations on such outcomes are being published including updated guidelines as to how best approach the decision involved (1). This becomes particularly relevant as the population ages bringing numerous comorbidities into the CKD arena. Herein, we describe a practical and successful approach to the decision making on clinical options for patients, families, and physicians as ESKD approaches.

There are several components to the decision-making processes, but first up are the team members. The patient and family with the nephrologist are the obvious participants, but also variably important are the referring physician(s), especially the primary care physician, friends, coreligionists or spiritual leaders, other patients, and CKD education team. The latter could be a designated group, a staff nurse, a nurse practitioner, a physician assistant, a dietitian, a technician, or a home dialysis trainer. Oftentimes, this may be just the physician using visit discussions, written and/or online materials, or videos provided by kidney organizations or dialysis providers. The key here is to individualize the education to suit the patient and family's unique situation, including economic status, education, discipline, and overall stability. This cannot succeed without the knowledge of these conditions by the attending nephrologist(s), hence the previous comment on familiarity. Repetition helps, even when initially rejected as consuming too much time.

For the education process to succeed for the unique situation for that patient, the nephrologist must offer, or have at immediate access, all services needed for an integrated ESKD care system. For what is available in 2015 that includes conservative care, in-center dialysis, home dialysis, and transplantation

(FIGURE 39.1). Some of those services may be indirectly provided by referral or specifically and directly provided by the attending nephrologist.

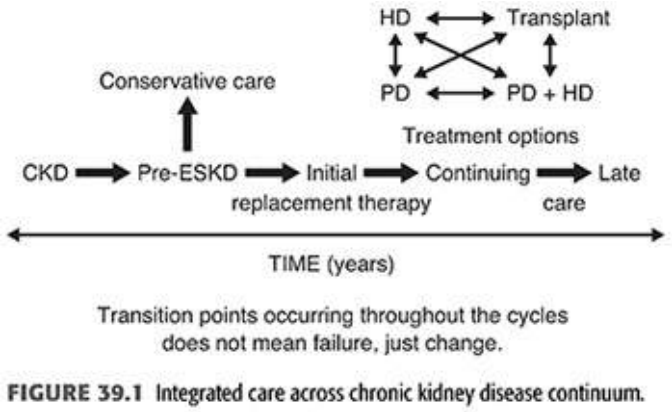

FIGURE 39.1 Integrated care across chronic kidney disease continuum.

PATIENT PERSONAL CHARACTERISTICS

Occasional patients facing ESKD are completely unaware of their disease and have no preparation for the shock facing them. In those situations, salvage approaches are required with an increasingly popular approach to urgent start PD (further discussion in the following text). However, even patients unaware of their situation can be rapidly educated to the point of at least making some informed decisions. Easiest of all is to simply insert a central venous catheter (CVC) and initiate HD. However, this often sets the stage for complacency where in-center HD with the CVC becomes permanent. We strongly urge the rejection of this approach unless a life-threatening need can only be addressed by the CVC. So in this situation, the patient's personal characteristics have an immediate and dramatic influence on decisions.

Far more often however is the case where the patient has been seeing a physician and often a nephrologist for months. It is in this setting that some of the most rewarding aspects of delivering chronic care are experienced. Learning about the patient, the family, life style choices, health status, needs, wants, and desires all contribute to advising patients about their options. Education status may play a role but is often for secondary to psychosocial and economic issues. Fear is not unique to any groups. Explanations and instilling confidence can often overcome fear. Throughout this process of probing, provoking, listening, and addressing, patients, families, and the physician all acquire knowledge such that more informed advice is given and decisions made.

It is through this process that a sequence of decisions is made. Without the knowledge of the physician about the patient and the patient about the options, unsatisfactory decisions are likely to result. The first decision is whether to actively pursue some form of renal replacement therapy versus letting nature take its course with progressive kidney failure and ultimate death from it. Not embarking on replacement therapy is called undergoing conservative care. It is imperative that the physicians involved in the care and decision making emphasize that there is no abandonment of care. Depending on the patient's and family's preferences, the primary care provider under conservative care could well be the nephrologist. This is just one of the many shared decisions. In any case, all of the care providers must be prepared to acknowledge that abandonment is not going to occur at any level.

Too often, this first decision is never formally addressed, and assumptions are made about renal replacement therapy. We consider this a serious mistake both ethically and practically. Without a complex ethical argument, informing/discussing conservative care is mandatory simply because it is an option, and

no options are withheld in this setting. Practically, it is important because it empowers patients about a choice, and if they are making a choice to pursue renal replacement therapy (versus death from kidney failure), then they are committing to the attempt to succeed at the renal replacement therapy.

The second decision is a derivative of the first. Having decided to pursue renal replacement therapy will then lead to deciding on preemptive transplantation versus dialysis. Often, this decision is out of the hands directly of the patient and physician due to availability of a donor kidney. Nonetheless, the decision step is important for the same reason, as in the first decision. It requires an education, understanding, and commitment, all critical attributer for success. Because of health conditions, transplantation may be eliminated, but the understanding of why that is so is helpful and educational going forward with dialysis and the subsequent decisions.

If transplantation is not an immediate option, then the third decision is what type of dialysis will be performed. This third decision is then dialysis at home versus dialysis at a center. While independence often dominates this decision, other important factors contribute. Here again, knowledge about the patient is beneficial. Patients have fears about self-care, may have other dominating obligations at home, or may prefer to be around other patients with similar conditions. That can work the other way as well because the sicker ESKD patients are often dialyzed in-center. Nonetheless, the third decision of dialyzing at home or in-center is an important shared decision requiring thoughtful knowledge and understanding.

Because there are only limited in-center PD programs, for these purposes, we will consider in-center dialysis to mean HD. Thus, if the third decision is in-center dialysis, by virtue of the aforementioned assumption, that implies HD. However, if the third decision is to perform home dialysis, then the fourth decision is HD versus PD. Some of the reasons for selecting either of these options are listed in **TABLE 39.1**. Our dialysis program varies at any time between one-quarter to one-third of all patients dialyze at home, so our experience with this decision process is vast. While it would be ideal if all aspects of the two therapies would be considered in this decision, that is typically not what occurs, despite our best efforts to make it so. The overriding factor tends to be the time necessary for training. By virtue of its simplicity and less severe immediate complications, PD takes 1/2 to 1/8 of the training time than does home HD. Furthermore, HD generally requires another person so that training time commitments involve two people. Thus, at least in our program and we suspect in many others, patients choosing to dialyze at home tend to make PD the fourth decision. We do not prefer PD over home HD except in special circumstances such as very poor options for angio access, and in marginally stable patients who do not have a helper for home HD. The fourth decision can be made in a short time frame when circumstances dictate. PD can still be a viable option in this urgent setting. Small-volume supine exchanges can be performed either in the home training unit or hospital while the catheter implant heals.

TABLE 39.1 Some Reasons for Selecting Home Hemodialysis versus Peritoneal Dialysis

Training time needed (1–8 wk)
Cosmetics of the dialysis access
Actual treatment schedule
Portability
Fear of needles
Perceived complexity
Space
Need or availability of a helper

The fifth and final decision in our options process is what type of home HD or PD is preferred. Our HD options include nocturnal three to six times per week, daytime thrice weekly, traditional flows and times, and short frequent HD which averages 5.2 times weekly, generally for about 2.5 hours. It is with these varieties of HD that the greater difference in training time is noted. In New Zealand, some HD training may last for many months, whereas in our program, 2 to 3 months. Rarely is this training on specific technique but more likely to concern preparation for complications. For nocturnal, especially when performed more than thrice weekly, and for short frequent HD, because of the frequency, complications are less frequent and often never observed during training. Hence, the duration of training tends to be far less than training for traditional thrice-weekly HD. The decision on frequency of HD depends on many factors such as status of access, hemodynamic stability, psychosocial factors, availability of a helper, time to set up and take down the equipment, and many more. We try to determine this at the time of the fourth decision, so factors of the fifth decision impact on the fourth decision. For PD, a helper is less often needed and manual exchange techniques are generally learned within 2 weeks. Cycler techniques can be learned in this same time frame, and in the United States, 80% of PD patients utilizes a cycler in what is termed automated PD. As in the varieties of home HD, the varieties of PD are often determined as part of the fourth decision, home HD versus PD.

The last point to be made regarding dialysis options is the flexibility to accept that in a dialysis patient's lifetime, there will be transitions from one therapy to another. These are almost inevitable and should be truly considered transitions of therapy rather than a failure of a patient or the therapy. We refer to these transitions points as moving in either direction and as guides to selecting and utilizing the right therapy for that patient at that point in time (**TABLE 39.2**).

TABLE 39.2 Transition Points in Dialysis

PD Transfer to HD	HD Transfer to PD
Recurrent infection	Recurrent volume excess
Catheter malfunction	Angio access failure
Ultrafiltration failure	Hypercoagulable
Solute removal failure	Malnutrition
Psychological burnout	Hypertension
Activity of daily living failure	Loss of transportation
Overwhelming comorbidities	
Peritoneal membrane disrupting surgery	
Uncontrolled diabetes	
Excessive obese weight gain	
Hypotension	
Malnutrition	

PD, peritoneal dialysis; HD, hemodialysis.

ROLE OF EDUCATION AND CONSERVATIVE CARE

Section: Role of Education

The commencement of maintenance dialysis is a major life-altering event (2), and a patient-centered approach which involves a partnership among nephrologist and other health care providers, patients, and their families should be established to ensure that decisions respect patients' wants, needs, and preferences and that patients have the education and support they need to make decisions and participate

in their own care. Clinical guidelines recommend that treatment option for CKD include the preference of a fully informed patient (3).

However, data from observational studies and the United States Renal Data System suggest that patients with CKD may not be presented with adequate information on treatment option or given sufficient time in which to discuss management alternatives with their family or caregivers (3). Incomplete presentation of treatment option and poor education are responsible for the inconsistencies noted in most studies about the preferred and actual modality of patients' treatment choice (2).

Patient and Family Education

Most CKD patients at baseline generally do not have sophisticated knowledge about their kidney disease or modalities of management of ESKD. This also causes a significant amount of worry. Finkelstein et al. (4) in their study about perceived knowledge among patients about CKD and ESKD therapies noted that 23% patients reported having extensive knowledge, while 35% reported no knowledge about their disease. Also, 43% reported having no knowledge of HD, 57% had no knowledge of chronic ambulatory PD, 66% had no knowledge of automated PD, and 56% had no knowledge of transplant. A total of 35% of patients had no knowledge of therapeutic modality for ESKD.

From the 2012 United States Renal Data System, 114,813 incident ESKD patients began renal replacement therapy with 98,954 starting HD, 9,175 PD, and 2,803 receiving a preemptive kidney transplant—this data has remained relatively stable over the past years. The United States Renal Data System (Wave 2) Study surveyed patients shortly after they initiated renal replacement therapy, with either of HD or PD, to determine who took the lead in deciding on the mode of dialysis. Among the patients who received HD, 53% had physicians taking the lead, 17% patients, and 30% had a joint decision. Of the patients undergoing PD, physicians led in 17%, patients in 36%, and joint decision in 48%. Thus, of all the patients undergoing PD, 84% had contributed substantially to the decision, whereas of all patients undergoing HD, only 47% contributed to the decision.

Mehrotra et al. (2) examined the effect of pre-ESKD processes on the selection of renal replacement therapy among incident ESKD patients (2). Of the 1,365 eligible patients, 93% was undergoing maintenance HD and 7% were undergoing PD, and of the 427 who completed the study, 94 % were on maintenance HD and 6% on PD. In this study, they found that 70% of incident HD patients reported that chronic PD was not offered as an option for renal placement therapy. However, they noted that there was a strong relationship between the probabilities of presentation of PD as a treatment option to the selection of PD as a treatment modality.

Patient education has multiple benefits. It allows an informed choice of renal replacement therapy, improves patient–doctor relationship, and also enhances compliance (5). Studies have suggested that education of CKD patients can delay the onset of dialysis and improve outcomes after they start dialysis (4). Also, provision of educational programs for patients with CKD can increase the percentage of patients who will start dialysis with less expensive self-care as opposed to traditional facility-based, standard care dialysis, and significantly reduce urgent dialysis which might impact on patient survival given that the mortality rate in emergent situation is high.

With a CKD, patient education is not just nice to have—it is fundamental to long-term survival. The content and depth of patient education should be guided by current best practices. To achieve improved

outcomes, we must emphasize predialysis and dialysis education and ensure that it is designed to empower patients (6).

Nephrologist Education

Providing education about therapy options to patients with CKD/ESKD is uniformly accepted as important; however, there appears to be a problem in its delivery (7). There is a significant relationship between the timing of presentation to the length of time the patient knew of his or her kidney failure and the duration of predialysis nephrologist care (2). Research on nephrologist–patient communication suggests that nephrologist provides information on treatment option over an extended period of time but increases the amount of detail about specific treatment when the patient requires renal replacement therapy (3). This approach reduces the amount of time available to patient to make decision and means that information provision may coincide with the time patients are symptomatic and cognitively impaired to make informed decision about their treatment. The value of education and an appreciation for the timing for its occurrence are clear (7); thus, nephrologists should be educated to be aware of this challenge that limit effective communication with patients and work in a timely manner so that patients' knowledge of ESKD is improved.

In terms of modality selection when patients approach ESKD, nephrologists have reported that patient choice is the most important factor in choosing a dialysis therapy, yet there exists a disparity in knowledge of the different treatment options (4). For example, there has been a renewed interest in home HD, but as Jayanti et al. (8) showed, despite the interest and belief in this therapy among providers, home HD is still not available to a majority of patients. Suboptimal patient preparation pathways, lack of appropriately trained personnel, and physician unwillingness were some of the key barriers to widespread adoption of this therapy resulting in the disconnect between belief and practice of home HD. Adequate exposure of physicians during their fellowship to the various modalities of dialysis will give them the capacity to educate patient on treatment options and also care for them, and as Jayanti et al. (8) noted, a generation of nephrologists may lose out to the training opportunities in this field if knowledge of home-based dialysis is not made an integral part of the training curriculum.

Other Provider Education

Given the complexity of CKD, patients approaching ESKD are often managed by a multidisciplinary team —primary care provider, nurses, dietitians, social workers, and other medical specialist (cardiologist, endocrinologists, etc.). Encounter with these providers has a potential effect on a patient's knowledge, belief, and attitude about CKD, ESKD, and treatment modalities.

The recognition of early CKD and referral to a nephrologist is an obligation providers have to these patients. Timing of referral of patients with CKD to a nephrology service affects their outcomes. The majority of patients with kidney disease are referred close to the time of initiation of renal replacement therapy, which contributes to poor patient outcomes on renal replacement therapy (e.g., the use of central venous catheters vs. AVFs). There are now several measures that have proven efficacy for slowing progression of CKD and a number of treatments that are effective at preventing and reversing the morbidity of CKD that patients will benefit from if they are referred early to nephrologists. Also, timely referral can allow informed decision to be made about renal replacement therapy.

Other providers who are directly involved in provision of ESKD treatment modalities should have a

purposeful education about renal replacement therapies as inexperienced staff might present negative views about treatment modalities. A synchronized education of these providers leads to a consistent message transmitted to patients about the various treatment modalities (7).

Role of Conservative Care

Definition

Conservative care or nondialytic treatment is a viable option in the integrated management of patients with advanced CKD. It includes treatment of anemia, bone mineral metabolism disorders, hyperkalemia, metabolic acid–base abnormalities, hypertension, and protein-energy malnutrition associated with CKD. Conservative care also pays careful attention to psychological, social, and spiritual support to the patient as well as their families. Furthermore, it involves advanced care planning and adopting palliative care principles to improve symptom burden and functional status to maximize quality of life (QOL) prior to death.

It is crucial to learn about the statistics of CKD in the elderly.

Incidence and Prevalence of Chronic Kidney Disease and End-Stage Kidney Disease in the Elderly

Important subsets of CKD population are the elderly. They are the fastest growing CKD subset. The percentage prevalence of all CKD in the National Health and Nutrition Examination Survey (NHANES) population with age 60 years and older is 33.2%, compared to 8.9% in the 40- to 59-year-old subset during 2007 to 2012. Of these, the percentage prevalence of CKD with estimated glomerular filtration rate (eGFR) <60 mL/min/1.73 m^2 is 22.7% in the age group >60 years of age compared to 2.3% in 40- to 59-year-old subset (9).

The elderly is also highly represented in the prevalent and incident cases of ESKD. The prevalence of ESKD increases in all age groups, with a sharp increase in ages 45 years and older (**FIGURE 39.2**) (9).

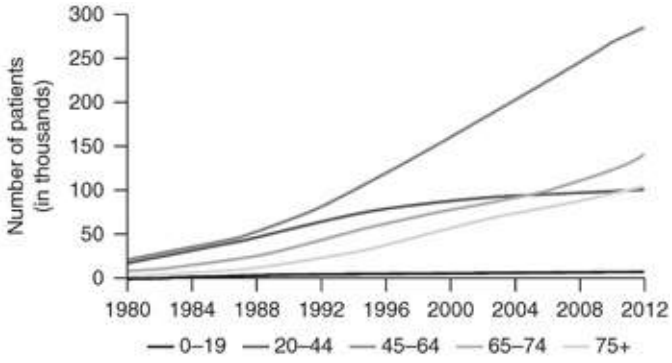

FIGURE 39.2 Prevalent end-stage kidney disease cases in the U.S. population, 1980 to 2012, per United States Renal Data System annual report 2014. United States Renal Data System. Mortality. In: *USRDS 2014 Annual Data Report: Atlas of End-Stage Renal Disease in the United States*. Bethesda, MD: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, 2014:145–152.

The incident cases of ESKD per year was steadily rising for age 45 years and older, with an impressive rise for age 65 years and older initially, followed by a flat trend in recent years (**FIGURE 39.3A**). The ESKD incidence rates have slightly declined among older age groups: For ages 65 to 74 years, the incidence rates are lower than before, and in age group 75 years and older, a downward trend is noted (**FIGURE 39.3B**) (9).

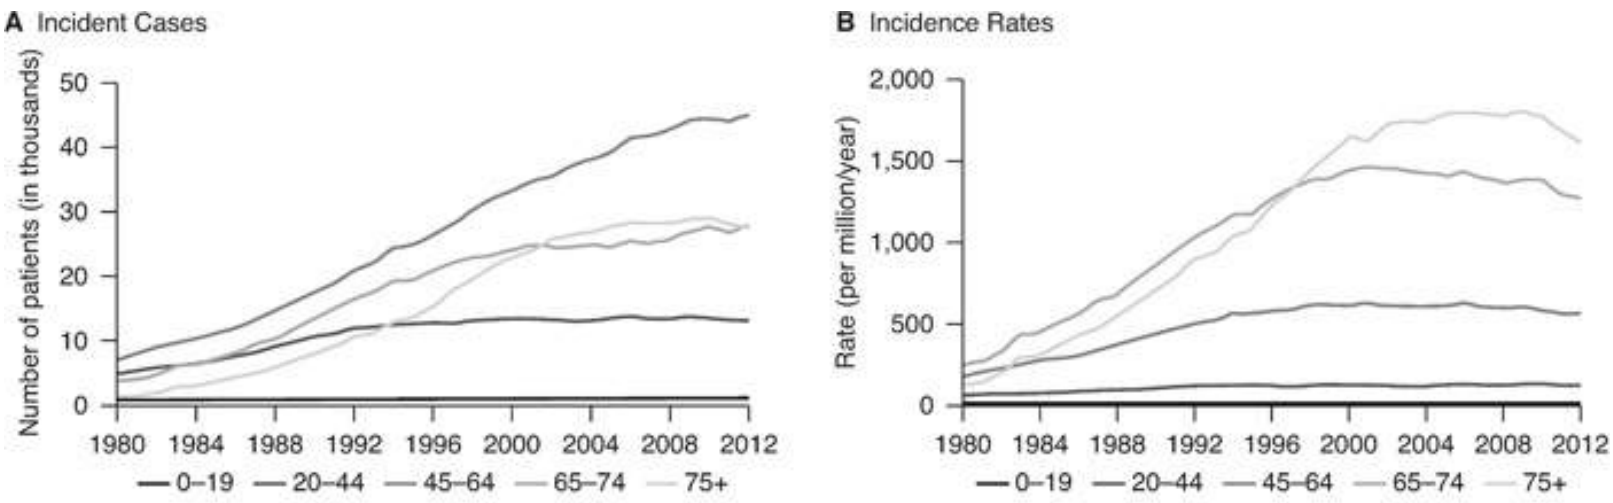

FIGURE 39.3 Trends in (**A**) ESRD incident cases, in thousands, and (**B**) adjusted end-stage kidney disease incidence rate, per million/year, by *age group*, in the U.S. population, 1980 to 2012. United States Renal Data System. Mortality. In: *USRDS 2014 Annual Data Report: Atlas of End-Stage Renal Disease in the United States*. Bethesda, MD: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, 2014:145–152.

Other factors leading to increased diagnoses of CKD in the elderly are their longevity, inherent risk of CKD, normal aging process with expected loss of eGFR, and better access to care.

Survival Statistics in the Elderly Chronic Kidney Disease Population

It is also known that the prognosis of geriatric patients on dialysis is poor. The expected remaining lifetime years of the prevalent ESKD patients age 65 and older is limited to 4.6 years compared to 15.5 years of the general U.S. population (**FIGURE 39.4A**) (10). The adjusted as well as unadjusted mortality rates are 2 to 3 times higher in prevalent dialysis patients 65 years and older compared to that of age-matched patients with cancer, congestive heart failure (CHF), diabetes mellitus (DM), and other comorbid conditions shown in **FIGURE 39.4B** (9).

Who Should Be Offered Conservative Care?

The decision whether the benefits of conservative care would outweigh the burden associated with dialysis needs to be personalized for each patient. Nephrologists need to lead realistic discussions with patients and their families about survival and the burden of dialysis. Difficult situations can arise, but the crux of medical ethics supports what is right for the patient. Providers have to lead a patient-centered shared decision making and communicate a recommendation to the patient and his or her family. It is important to recognize that patient "autonomy" does not overshadow other ethical principles. However, there are certain well-defined situations with CKD, acute kidney injury (AKI), or ESKD where conservative care would be appropriate to offer. These are the elderly frail individuals with significant comorbidities or nursing home residents, patients with nonkidney terminal disease, profound neurologic impairment/persistent vegetative state, if the patient/proxy declines dialysis, and how the nephrologist answers the question, "Would you be surprised if your patient died within 12 months?" (11).

There is evidence supporting that predialysis functional status declines after initiating dialysis in elderly nursing home patients with a mortality rate approaching 58% in the first year (12). Hence, offering supportive care to an elderly nursing home patient with significant comorbidities and poor functional status would be appropriate. This data cannot be extrapolated to a cognitively intact elderly patient seen

in an ambulatory clinic. The evidence for conservative management in this patient population is summarized in the following section.

The Renal Physicians Association (RPA) has published guidelines about shared decision making, informing patients, facilitating advanced care planning, making decisions withhold or discontinue dialysis, conflict resolution, and provisions for palliative care in the comprehensive management of a patient with kidney disease. The revised recommendations are summarized in **FIGURE 39.5** (11).

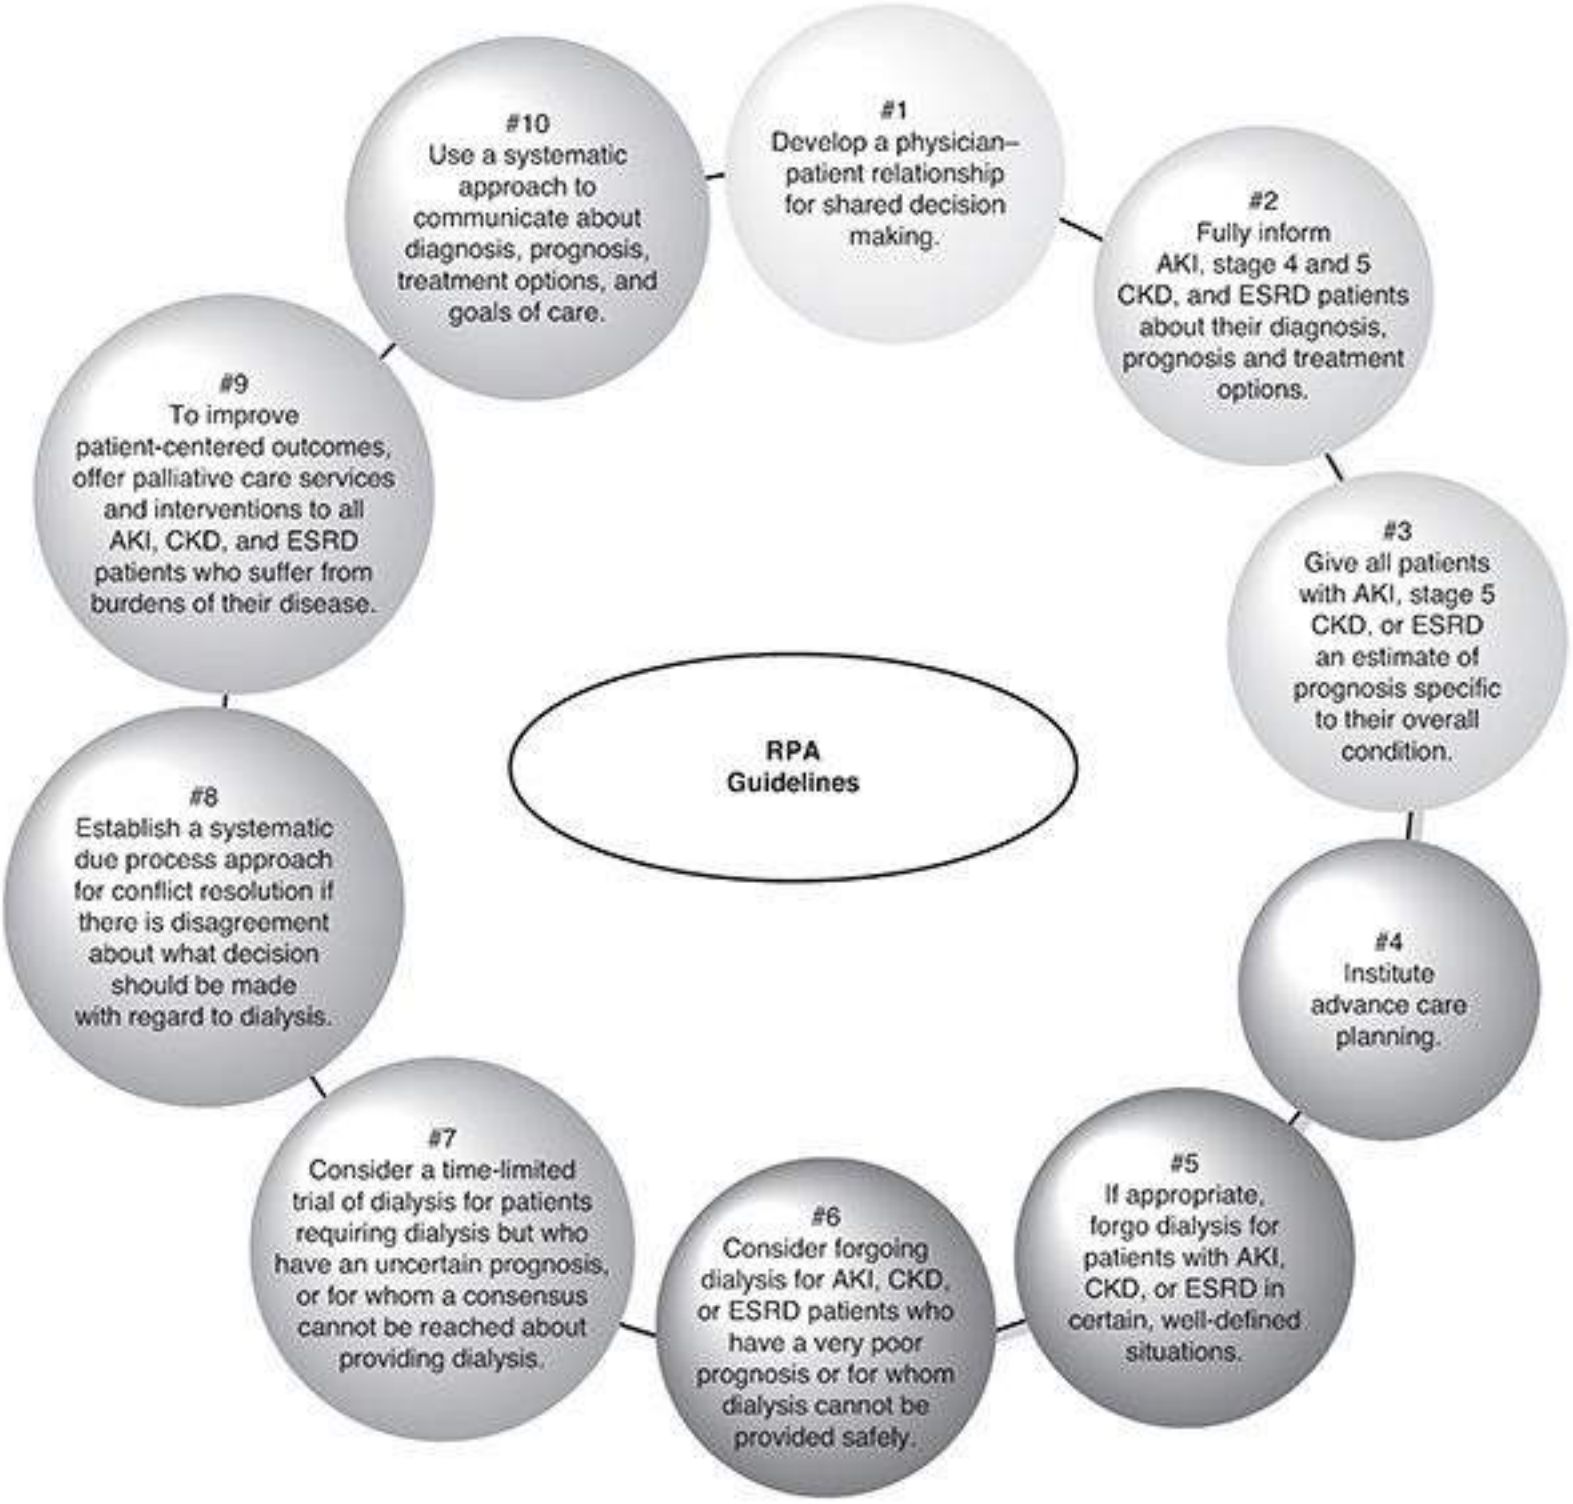

FIGURE 39.5 Revised Renal Physicians Association guidelines.

What Is the Current Evidence for Conservative Management?

Extensive literature survey supports that mostly elderly dialysis patients live longer than those managed

without dialysis (**FIGURE 39.6**) (13).

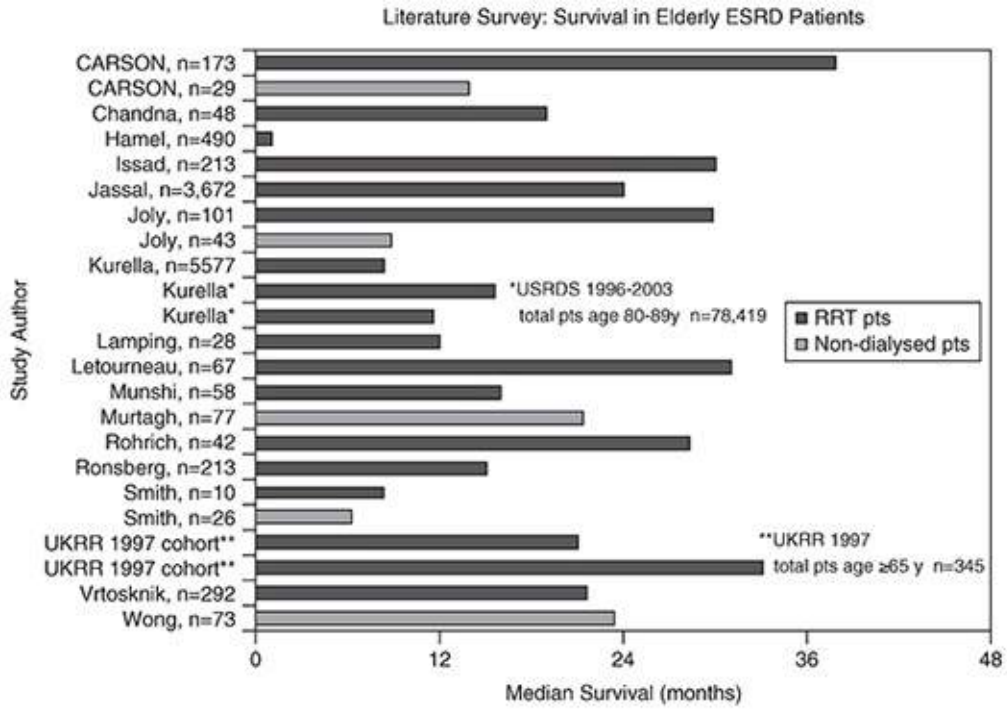

FIGURE 39.6 Summary graph of survival of elderly patients with end-stage kidney disease. [Adapted from Carson RC, Juszczak M, Davenport A, et al. Is maximum conservative management an equivalent treatment option to dialysis for elderly patients with significant comorbid disease? *Clin J Am Soc Nephrol* 2009;4(10):1611–1619.]

Currently, only cohort studies are available addressing the role of conservative management. It would be challenging to conduct a randomized controlled trial. The key issues in this prospective studies at the differences in start time for the dialysis group, rate of decline in kidney function, definitions of comorbidities, functional scoring, presence or absence of a dedicated conservative care clinic, health care system, and quality-of-life information.

Median survival with conservative management ranges from 6.3 to 23.4 months based on current data. This wide range in survival is due to differences in patient characteristics in the cohort studies. For example, the studies with the longest survival recruited patients with the youngest median age (14).

Three cohort studies showed a survival advantage for dialysis patients compared to conservative management. They are summarized as follows in **TABLE 39.3**.

TABLE 39.3 Cohort Studies Demonstrating a Survival Advantage in the Renal Replacement Therapy Group Compared to Conservative Management

	Patient Characteristics		Results and Comments
Carson et al. (13) Prospective cohort study *N* = 202 elderly	Age > or = 70 y divided into		Median survival was 37.8 mo for RRT patients and 13.9 mo for MCM patients (p <0.01). RRT patients had higher rates of hospitalization [0.069 (95% CI 0.068 to 0.070) versus 0.043 (95% CI 0.040 to 0.047) hospital days/patient-days survived] compared with MCM patients. MCM patients were 4 times more likely to die at home or in a hospice (odds ratio 4.15, 95% CI 1.67 to 10.25). MCM had older patients with a modest size group compared to RRT. Interestingly, MCM group survived more than 1 year and were more likely to die in their home or hospice compared to RRT group who spent a greater proportion of days in the hospital.
	MCM	RRT	
	n = 29	*n* = 173	
	Age = 83 y	Age = 75 y	
	CCI = 7.4	CCI = 7.4	
	DM: 13.8%	DM: 29.5%	
Chandna et al. (16) Retrospective cohort study *N* = 844 elderly	MCM	RRT	Median survival from entry into CKD 5 was less in the MCM than in RRT group (21.2 vs. 67.1 mo: p <0.001). A subgroup analysis of age 75 years and older was performed after correcting for comorbidity scores, diabetes, and age. The survival benefit in the RRT group was no longer statistically significant.
	n = 155	*n* = 689	
	Age = 77.5 y	Age = 58.5 y	
	>75 y = 68.4%	>75 y = 11.2%	
	High comorbidity: 49.7%	High comorbidity: 17.3%	
Joly et al. (15) Prospective cohort study *N* = 144	MCM	RRT	Median survival was strikingly larger in the RRT group of 28.9 mo vs. 8.9 mo in the MCM group: p <0.0001.
	Age 84 y	Age 83.2 y	
	Late referral: 51.4%	Late referral: 28.9%	
	DM: 21.6%	DM: 6.5%	
	Social isolation: 43%	Social isolation: 14.7%	

MCM, maximum conservative management; RRT, renal replacement therapy; CCI, Charlson Comorbidity Index; DM, diabetes mellitus; CI, confidence interval.
From O'Connor NR, Kumar P. Conservative management of end-stage renal disease without dialysis: a systematic review. *J Palliat Med* 2012;15(2):228–235.

Carson et al. (13) followed 202 elderly ESKD patients in a prospective study who were offered either conservative management or renal replacement therapy. Although the authors demonstrated a survival benefit in the renal replacement therapy group, but the conservative care group patients were 4 times more likely to die at home or under hospice care. The renal replacement therapy group spent majority of their extended survival time either admitted in the hospital or in an outpatient dialysis unit. The conservative care group survived more than a year and had similar hospital free days as the renal replacement therapy group. Yes, this study demonstrated prolonged survival time in the renal replacement therapy group, but whether that time was "quality time" for the patient and their family members is unknown (13).

Joly et al. (15) followed 144 elderly ESKD patients prospectively from 1989 to 2000. They demonstrated a large survival benefit in the renal replacement therapy group compared to the conservative management (28.9 months vs. 8.9 months). The conservative management group had more socially isolated patients, diabetics, lower Karnofsky scores, and late referrals compared to renal replacement therapy group. Hence, it is not surprising that they have a shorter survival time compared to the renal replacement therapy group (15).

Chandna et al. (16) looked at a retrospective cohort of 844 patients with stage 5 CKD (CKD 5). They demonstrated a median survival benefit in the renal replacement therapy group compared to the conservative management group. However, the conservative management group had higher percentage of

elderly more than 75 years of age with significant comorbidities. After adjusting for age and comorbidities among elderly more than 75 years of age in a subgroup analysis, the statistical difference between the two groups disappeared (16).

Murtagh et al. (17) and Smith et al. (18) have demonstrated almost identical findings in their cohort studies. Dialysis did not demonstrate a significant survival benefit compared to conservative management in the elderly with significant comorbidities, especially ischemic heart disease (17). See **TABLE 39.4** for details.

TABLE 39.4 Cohort Studies Demonstrating a No Survival Advantage in the Renal Replacement Therapy Group Compared to Conservative Management

	Patient Characteristics		Results and Comments
Murtagh et al. (17) Retrospective cohort study *N* = 129 Elderly >75 years	MCM *n* = 52 Median age: 83 y DM: = 25%	RRT *n* = 77 Median age: 79.6 y DM: = 23.4%	Median survival from first known date of GFR <15: 18 mo in MCM group vs. 19.6 mo in RRT group This modest survival benefit is reduced with growing comorbidities and ceases to exist in patients with ischemic heart disease.
Smith et al. (18) Prospective cohort study	MCM *N* = 32	RRT *N* = 10	Median survival was 6.3 mo in CM vs. 8.3 mo in RRT group.

MCM, maximum conservative management; RRT, renal replacement therapy; DM, diabetes mellitus; GFR, glomerular filtration rate; CM, conservative management.

Cohort studies in which dialysis did not demonstrate a significant survival benefit compared to conservative management are as follows (14).

SYMPTOM BURDEN AND QUALITY OF LIFE AS AN OUTCOME

Limited observational data is available regarding symptom burden and quality of life in the elderly patients with advanced CKD. A systematic review identified six studies addressing symptom burden and/or QOL. Memorial Symptom Assessment Scale Short Form (MSAS-SF) and modified version of Patient Outcome Scale Symptoms were more frequently utilized tools to assess symptom burden. Average number of symptoms reported was 6.8 to 17 in patients undergoing conservative management. QOL was assessed by three small studies where both the conservative management group and the comparison group had similar impairment of QOL (14).

Brown et al. (19) studied survival, symptom burden, and QOL as an outcome in a cohort of 467 pre-ESKD patients. One hundred twenty-two patients opted for conservative management, whereas 92 (34%) out of the 273 predialysis clinic comparison group opted for dialysis. The patients in the conservative management group had higher mean age (82 years), dementia, and comorbidities compared to the comparison group (predialysis). They utilized MSAS-SF and Medical Outcomes Study Short Form 36-Item Health Survey (SF-36) to assess symptom burden and QOL. The response rate for the SF-36 for was 56% in the conservative management group and 51% in the predialysis group. The response rate for the MSAS-SF was 45.5 % in the conservative management group and 49% in the predialysis group.

In the conservative group, 57% had stable or improvement in symptom burden toward the end of 12 months and QOL remained stable or improved in 58% of the conservative management group. The

response rates for the two surveys were roughly 50% in both groups. However, they did not resurvey the predialysis clinic patients who opted for dialysis, which may have biased the results. This study reinforces that patients on conservative management can survive more than a year and their symptom can be managed fairly to maintain a QOL.

Concept of Chronic Illness Trajectories to Envision a Clinical Course

Understanding chronic illness trajectories may help nephrologists formulate a care plan addressing the multifaceted needs of the patients and their families. Three kinds of chronic illness trajectories are described: a stepwise decline in functional status in progressive organ failure (CKD), frailty and dementia, and terminal illness.

A stepwise functional decline can occur with each sentinel event. These events could be hospitalizations related to cardiovascular events, infections, vascular access, comorbid conditions, or the primary disease. Each of these events provides a unique opportunity for the nephrologist to reassess the "global picture" and involve the renal palliative care team, if indicated.

Frailty and dementia has been described in the elderly CKD patients. They demonstrate a dwindling low functional status leading to death over a prolonged period.

Lastly, the progressive CKD stage 5 patients managed with conservative care can maintain a steady functional status trajectory, until the last few months of life where a precipitous decline occurs. However, palliative care and hospice services are available during this time frame (20). See **FIGURE 39.7** for details.

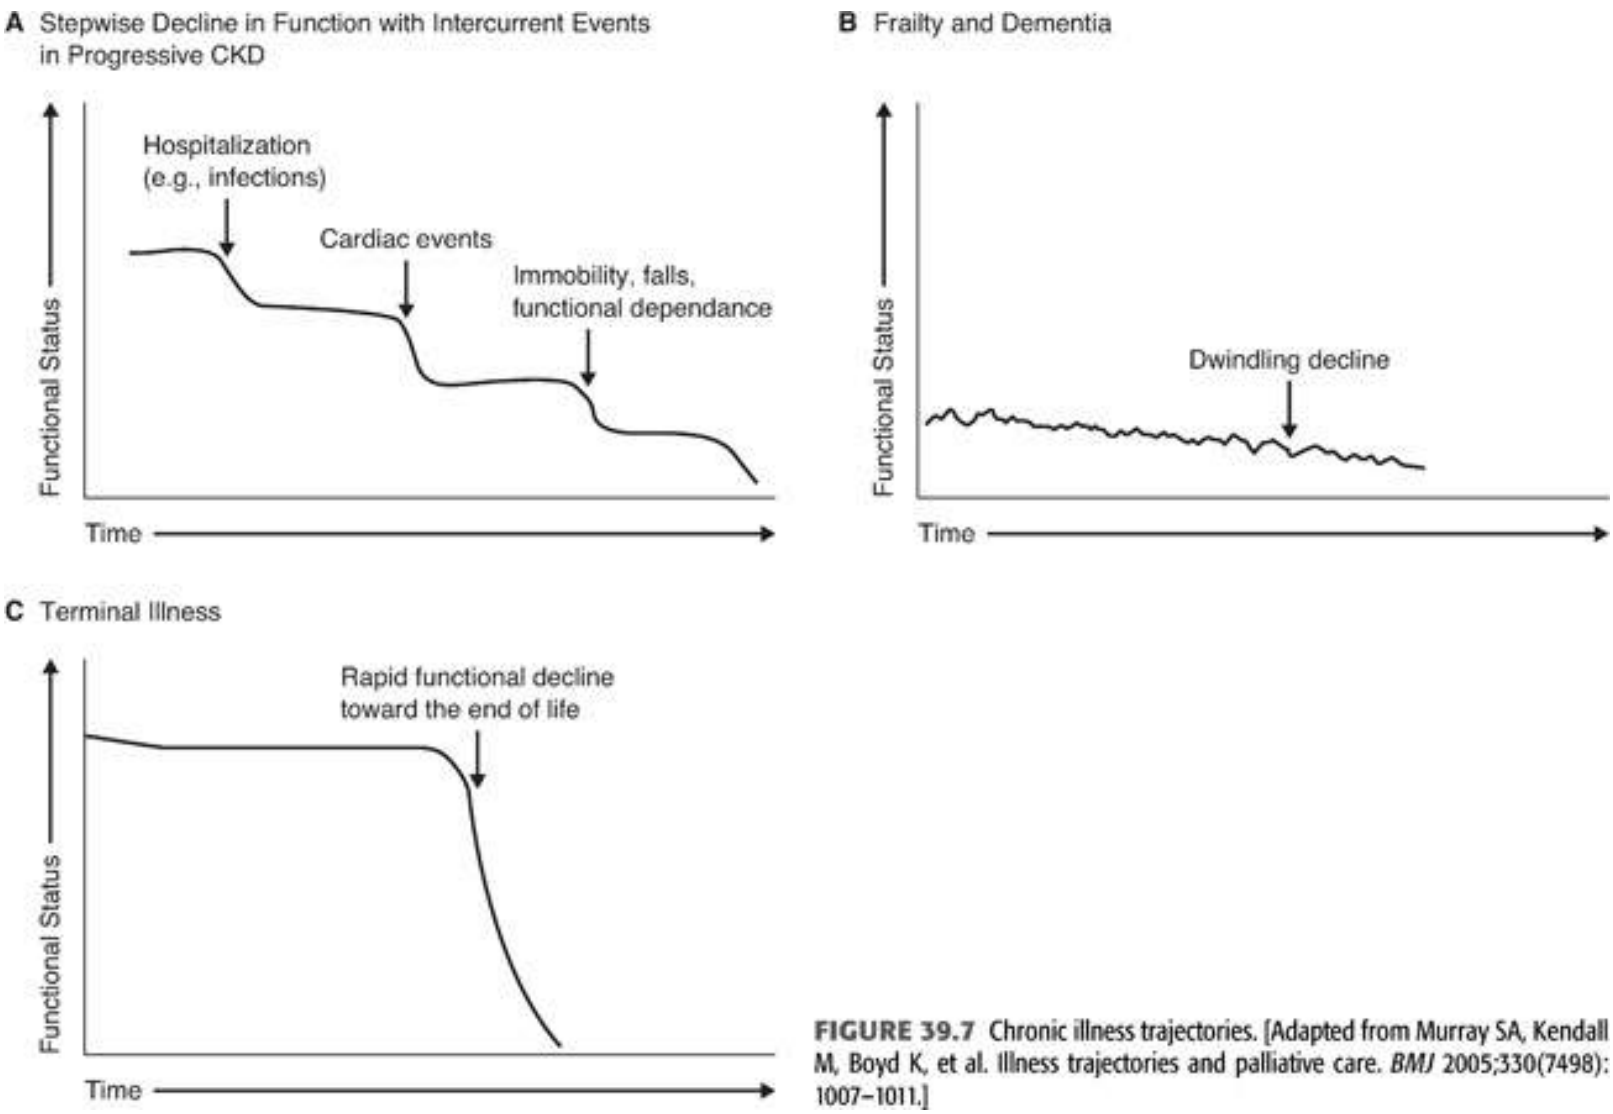

FIGURE 39.7 Chronic illness trajectories. [Adapted from Murray SA, Kendall M, Boyd K, et al. Illness trajectories and palliative care. *BMJ* 2005;330(7498): 1007–1011.]

How to Prognosticate Survival?

The nephrologist also needs to be well equipped with prognostication tools to predict outcomes.

Charlson Comorbidity Index (CCI): Developed in 1987 to predict 1-year mortality among internal medicine patients based on age and comorbidities. It has been validated in 268 dialysis patients over 3-year period in the university hospital to predict patient outcomes. The CCI is strongly predicted admission rates, hospitalization days, inpatient costs, and mortality. Patients with the CCI >8 had the highest mortality of 0.49 per patient-year (21).

Surprise Question (SQ): Cohen et al. (22) developed a short-term prognostic model utilizing prospective data from dialysis clinics in Northeast United States. The derivation cohort had 512 patients, and the validation cohort had 514 in which providers answered an SQ, "Would you be surprised if this patient died in the next 6 months?" A robust area under the curve (AUC) for a 6-month survival in the derivation cohort. It was 0.87 [95% confidence interval (CI) 0.82 to 0.92] in the derivation cohort and 0.80 (95% CI 0.73 to 0.88) in the validation cohort (22). Revised RPA guidelines have developed an integrated prognostic tool that includes patient's age, serum albumin, comorbidities, and the response of the clinician to the SQ. It is available online at http://touchcalc.com/sq (11).

French Renal Epidemiology and Information Network (REIN) developed a 6-month mortality prognostic score in 2,500 dialysis patients more than 75 years of age; a point system scoring was allocated to nine risk factors (**FIGURE 39.8**). They found an overall 6-month mortality of 19%, and age

was not associated with mortality (23).

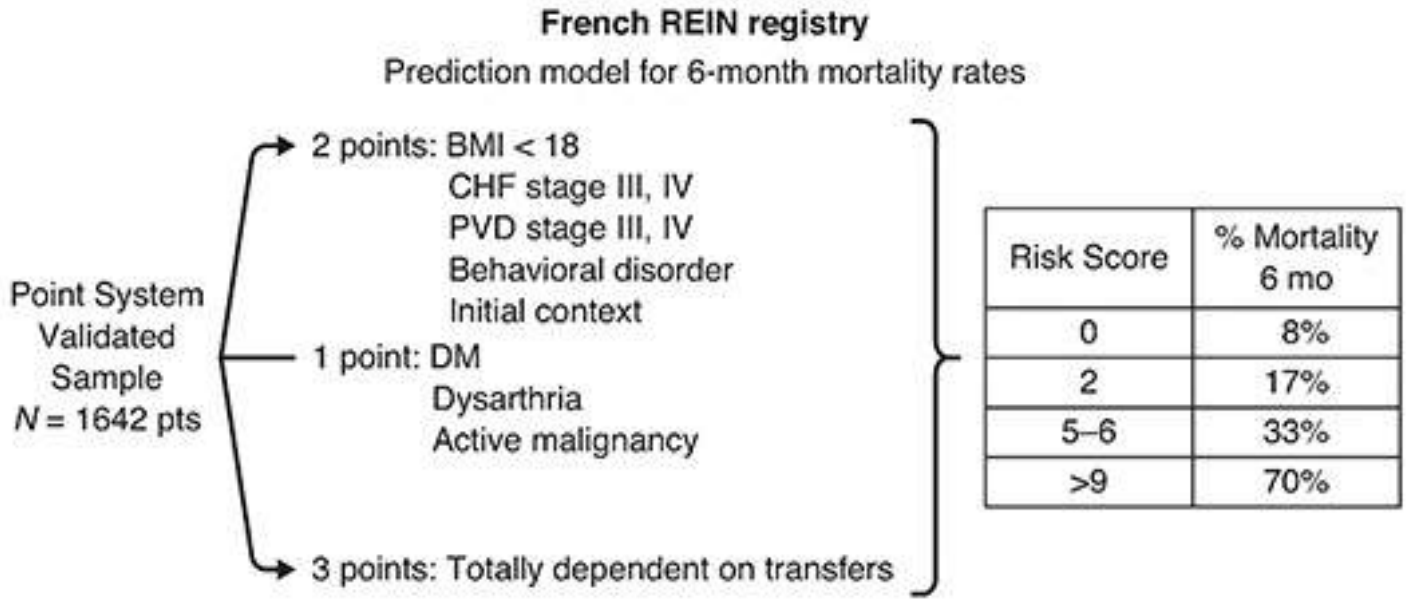

FIGURE 39.8 French Renal Epidemiology and Information Network. BMI, body mass index; PVD, peripheral vascular disease.

RPA guidelines recommend conservative care as an option in elderly CKD 5 patients with two or more of the following predictors of poor survival are present such as high Co-morbidities score of modified Charlson Comorbidity Index > or = 8; poor functional status (Karnofsky performance score < 40); poor nutritional status (serum albumin <2.5g/dl) and if the answer to the surprise question ("Would you be surprised if your patient died within the next year?) is "no". (see **FIGURE 39.5**, Step #6) (11).

CCI: Charlson Comorbidity Index.

Components of Conservative Care or "Active Medical Management"

Conservative care in CKD patients involves advanced care planning, continuing medical management, treatment of symptom burden, patient and family support, and timely hospice referral.

Advanced care planning should be available to all patients, especially if they have CKD stage 4. It involves a patient-focused discussion with the patient and his or her family members. This can be used as an opportunity to name a health care proxy, discuss patient's wishes at the end of life, prognosticate clinical course, determine functional age, and strengthen a doctor–patient relationship.

Continue predialysis medical care such as diet, anemia management, fluid balance, electrolyte and acid–base disturbances, bone mineral disorders, and blood pressure control. Some treatments are modified, such as, if fluid restriction needs to be liberalized, the patient can undergo ultrafiltration to help with fluid balance.

Regardless of the stage of CKD, every patient should receive palliative care. The application of palliative care principles to patients with CKD is called "renal palliative care" (**FIGURE 39.9**). It involves a multidisciplinary team consisting of nephrologists, palliative care specialists, senior renal nurses, counselors, social workers, and hospice workers. They personalize treatment plans, formulate goals, assess functional status, and control symptom burden from ESKD and/or from comorbid conditions, for example, diabetes. They also provide support to the family and the patient with hospice referral, community nurses, social services, and outpatient clinic visits (24,25).

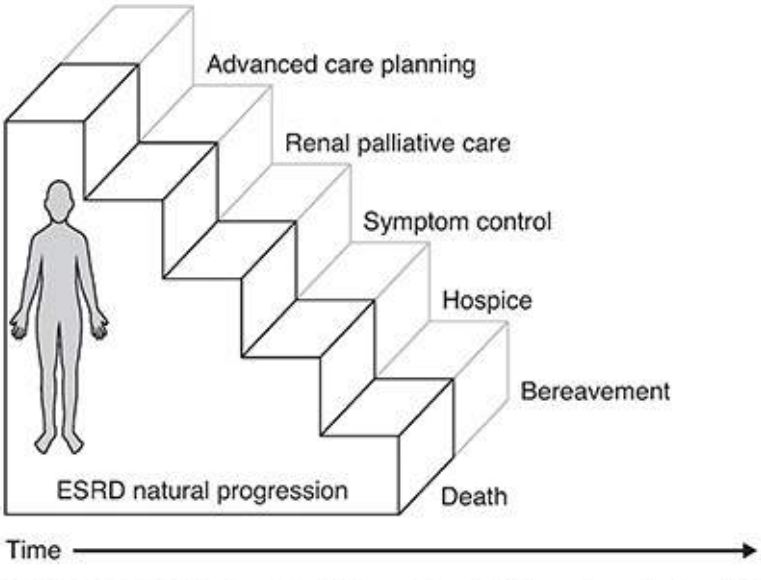

FIGURE 39.9 Patient-centered integrated model of care for end-stage kidney disease.

Summary

- Conduct discussions which are patient-centered and incorporate shared decision making between the patient and his or her family to tailor treatment options based on his or her preferences and goals.
- Discuss the risks and benefits of each treatment and provide prognosis to all patients to help understand clinical course.
- Identify patients who would benefit from conservative care.
- Recognize observational data demonstrating an equal survival benefit among elderly frail patients when treated with conservative management or renal replacement therapy.
- Incorporate advanced care planning and palliative care early.

INDICATIONS AND CONTRAINDICATIONS FOR SPECIFIC THERAPIES

While the first and foremost indication and decision to opt for any particular dialysis modality should be patient preference and lifestyle, there are special circumstances where a particular therapy may be indicated or contraindicated.

Home versus In-Center Dialysis

The decision to perform home dialysis (home HD or PD) versus in-center dialysis is often made to offer better lifestyle and flexibility to patients. A few crucial prerequisites must be met to allow patients to dialyze at home. For all home therapies, adequate physical space has to be available to dedicate to dialysis supplies whether it is peritoneal dialysate bags or home HD set up and dialysate. House pets and small children must be barred from the room during PD exchanges and HD access cannulation.

Also, certain comorbidities or the need for significant assistance may limit the patient's ability to dialyze at home. An extreme example would be patients with advanced cardiac failure on a left ventricular assist device (LVAD), who may only be eligible to dialyze in-center at a dialysis facility qualified to manage such complicated patients. Tracheostomy patients are also candidates for in-center

HD. Many dialysis facilities now have a policy to accept them.

Inability to participate in self-care is a relative contraindication to home therapies, including PD and home HD. The presence of a reliable caregiver may allow exceptions to be made. Significant others may be willing to provide the care, particularly in PD patients. No doubt, this care places a burden on the caregivers that nevertheless they may be willing to undertake. If they do so, a "Plan B" should be in place to spell the caretaker if that person needs a break or develops an illness, called "respite." Plan B for infirm patients might be the creation of an AVF [or even an arteriovenous graft (AVG) in patients >75 to 80 years old] if the family elects to support the PD treatment. The same approach could be used for an intact patient on PD who becomes enfeebled. Because the patient will be treated with PD, there is time to make provision for an angioaccess. This permits the patient to be transitioned to HD either temporarily, to provide relief to the caregiver, or in certain cases permanently.

Psychosis is also a contraindication particular to home HD and PD and would fall under the category of inability to perform sustained, adequate self-care. Uncontrolled psychosis may be a contraindication to any form of dialysis. Other barriers to home HD such as inability or fear of performing cannulation by caregivers can often be overcome with training. It must be noted that as opposed to PD where the patient may be trained to perform therapy independently, home HD requires a caregiver to assist the patient for safety reasons.

Peritoneal Dialysis versus Hemodialysis

PD is a slower, continuous therapy when compared to intermittent HD and may offer hemodynamic advantages in patients with low blood pressures, increased incidence of intradialytic hypotension, and geriatric populations. PD is also the preferred modality of choice for infants and children.

Any patient who prefers PD as the modality of choice, and has no contraindications, should be strongly encouraged to pursue PD. PD may be especially beneficial and particularly indicated in patients with significant residual renal function, where incremental dialysis can be started. The practice of incremental dialysis prescription allows maximizing benefit from the residual renal function, slowly increasing the dialysis dose in an incremental manner over time. This can also be done with HD, especially short daily HD; however, PD just lends itself easier to do this. This sequence of HD initiation may eventually translate into access preservation and possibly offer a mortality benefit for a patient by preserving dialysis access, maximizing options of later treatments, and in turn likely increasing the number of years they can survive on dialysis.

There are a few absolute contraindications to performing PD but many relative contraindications or at least special circumstances where PD can be done with close guidance and special training.

Previous major abdominal surgery may result in excessive scarring and fibrosis. Adhesions may cause PD catheter malfunction due to kinking and obstruction. Morbid obesity may also be a relative contraindication, and individualized decisions must be made in these cases. Part of the challenge in morbid obesity is PD catheter hygiene and concerns with exit-site infections. One way around this particular situation may be a presternal exit site. A colostomy, ileostomy, nephrostomy, or ileal conduit are also relative contraindications due to anatomic manipulation, adhesions, and possibly increased risk of contamination and peritonitis. However, in such circumstances, a presternal catheter may be an option in the highly motivated patient. Severe diverticular disease may be another relative contraindication.

PD can be performed in special populations with support from nephrologists and staff. In Canada,

staff-assisted PD assists maximizes support to these special populations to perform therapy at home, especially for automated PD with cyclers. These populations include the elderly, diabetics, polycystic kidney disease, patients with cirrhosis, and patients with previous abdominal surgeries.

In cases with frequent and recurrent peritonitis, patients should be retrained frequently to eliminate faulty technique and observed closely for future episodes of peritonitis. If this continues to be a recurring or life-threatening issue, certain individuals may have to be transitioned to HD, either home HD or in-center, where dialysis staff would be able to provide treatment care.

Other more common circumstances, which would be limiting to HD, may be limited vascular access. In patients with limited arteriovenous (AV) access options, that is, AVFs and AVGs, PD should be considered and preferred over use of tunneled catheters due to increased incidence of infections and mortality.

In-center HD usually or typically becomes the dialysis modality of choice in urgent or "crash start" situations. This is often with patients who develop AKI and progress to ESKD, or advanced CKD patients who progress to ESKD with no planned access or prior health care.

However, it must be kept in mind that inability to train in performing PD exchanges initially due to uremia may be a relative contraindication to PD, and once the patient is improved on intermittent HD, he or she may be able to transition to PD if this is the patient's preferred modality of choice. An alternative approach would be urgent start PD, where a PD catheter would be placed in the hospital and patient is dialyzed in the hospital or PD unit until he or she is clinically improved from the uremia and able to train for home PD. Urgent start PD is a specialized procedure, and care must be taken to institute the protocol for it. A bowel regimen must be introduced immediately, and the importance of clean bowels emphasized both prior to PD catheter placement, and postoperatively as well. Following placement of the PD catheter, low-volume exchanges (500 to 1,000 mL/exchange depending on the patient's body size) can be initiated in a supine position. Many patients will do well with every 2-hour exchanges with 1.5% dextrose solution to begin. If the patient wishes to ambulate, he or she must do so "empty," that is, after the abdominal cavity has been drained completely.

Again, as discussed earlier, ESKD care has multiple ongoing transition points and decisions, and transitioning from one kind of therapy to another is not always to be considered "therapy failure" and in fact may reflect changing patient preferences that dictate these choices on a continuum.

Short Daily versus In-Center Thrice-Weekly versus Long Dialysis (Nocturnal)

The variation in manner of delivery of HD between short daily, thrice-weekly in-center and long dialysis (nocturnal) is largely impacted by patient preference. There are other factors that may impact the decision toward one therapy or the other.

ESKD and dialysis has been associated with low conception rates and poor pregnancy outcomes, and it is important to discuss these aspects with patients. Longer treatments and more frequent weekly dialysis may impact better pregnancy-related outcomes. Hence, while a switch in modality is not required for pregnancy, increased treatment times and frequency may be beneficial.

Long dialysis, that is, nocturnal therapy offers better phosphorous control, as it allows mobilization of phosphorous from various body compartments including bones and increased phosphorus removal per treatment due to increased session length. This allows patients to liberalize their diets and decreases the pill burden of phosphate binders. In addition, patients who are actively working and choose not to opt for

a home dialysis therapy can benefit from utilizing nocturnal HD, which allows them to have their full next day (**TABLE 39.5**).

TABLE 39.5 Peritoneal Dialysis: Absolute and Relative Contraindications

Contraindications
Previous major abdominal surgery with intra-abdominal adhesions limiting dialysate flow
Ileostomy, colostomy, nephrostomy
Severe diverticular disease
Inability to participate in self-care (physically or mentally) and lack of assistance
Mechanical defects not amenable to surgery that may affect PD or increase infections (omphalocele, large irreparable hernia, bladder exstrophy
Loss of peritoneal function
Relative Contraindications
Severe malnutrition
Morbid obesity (especially in short individuals)
Intra-abdominal foreign body (<4 mo)
Peritoneal leaks and diaphragmatic defects
Intolerance to PD volumes needed for adequate PD
Inflammatory or ischemic bowel disease
Severe diverticular disease or frequent diverticulitis
Abdominal wall or skin infection

PD, peritoneal dialysis.
From the National Kidney Foundation. Measurement of peritoneal dialysis dose. In: *NFK-DOQI Clinical Practice Guidelines for Peritoneal Dialysis Adequacy*. New York, NY: National Kidney Foundation, 1997;S80–S82.

MODALITY TRANSFERS

The initial decision to choose a particular dialysis modality is not immutable. During their course of depurative therapy for ESKD, patients may change modalities. The patients' characteristics that govern their suitability have been described previously. Transition occurs between all renal replacement therapies (**TABLE 39.6**). Transitions to and from transplantation are straightforward: A kidney becomes available or fails, respectively. The rest of this section discusses the reasons for transition between the artificial modalities.

TABLE 39.6 Switching Modalities

Initial Modality	Transition
Hemodialysis (HD)	
In-center HD	Home HD, peritoneal dialysis, transplantation, conservative management
Home HD	In-center HD, peritoneal dialysis, transplantation, conservative management
Peritoneal dialysis	In-center HD, home HD, transplantation, conservative management
Transplantation	In-center HD, home HD, peritoneal dialysis, conservative management

The causes of modality transfers have been described (26–31). The causes of transfer from PD to HD include multiple episodes of peritonitis, loss of adequacy of the peritoneal membrane resulting in poor solute exchange or ultrafiltration failure, leakage including PD fluid causing pleural effusions through diaphragm defects, and social problems. HD patients transfer to PD due to exhaustion of access sites,

cardiovascular instability, intractable hypotension, and personal choice (**TABLE 39.2**).

Implications of Transition

The long-term effects of switching modalities have been examined. A retrospective study or 223 HD patients and 194 PD patients examined the outcome in patients who switched modalities (29). **TABLE 39.7** shows the reasons for transferring.

TABLE 39.7 Reasons for Transfer

From HD to PD (n = 35)	From PD to HD (n = 32)
• Peritonitis/exit-site infection 50%	• Cardiovascular problems 40%
• Access problems 25%	• Adequacy and/or ultrafiltration problems 25%
• Personal choice 23%	• Social problems 14%
• Blood pressure problems 12%	• Extraperitoneal leakage of dialysis fluid 11%

HD, hemodialysis; PD, peritoneal dialysis.

The survival of patients initially receiving PD and switched to HD was better than patients who remained on PD. Patients who switched from PD to HD did not have an improved survival. However, patients who began on PD but later switched to HD had lower mortality than those HD patients who never were on PD. It is known that residual renal function is better preserved in patients who start on PD compared to patients initiated on HD (32–34). Preserved residual renal function enhances solute clearance, and this may confer a survival benefit (35). These findings support a role for integrated care.

Switching from PD to HD often occurs within the first 2 years of therapy and is frequently associated with episodes of peritonitis but does not always result in increased mortality (30). Patients in another study comparing survival of patients who switched from PD to HD to those who remained on PD, it was found that technique failure had an increased risk of mortality that was attributed to episodes of fatal peritonitis (31). An added risk factor was the use of central venous catheters for HD. However, if patients survived more than 60 months after technique failure, there was no adverse effect of switching to HD.

Integrated renal care management includes patients receiving treatments of HD, PD, as well as transplantation for ESKD. A study comparing the outcome of 1,067 maintained on PD to 43 patients transferred to PD following a failed transplant and 245 patients transferred from HD to PD revealed no differences in survival between the three groups (36).

It is reassuring that patients can change modalities if necessary and that their outcomes are favorable. Of course, an individual patient's outcome will be determined by the reason that a patient has to transition to an alternative modality. A need for a colostomy, although not an absolute contraindication to PD, might make HD an attractive option. A patient with severe CHF and hypotension on HD may be better treated by PD. However, the outcome of an individual patient depends on comorbid conditions. For patients who must transfer from PD to HD, plans to create an AVF or AVG should be a priority to minimize the length of time that a central venous catheter is required.

SUMMARY

There have multiple studies comparing survival between HD and PD (37–44). The conclusions of these

studies are conflicting with some favoring HD, others favoring PD, and some showing no differences between the modalities. The statistical methods in these studies differ. In balancing the diverse findings, the experience of the centers that render care is most important. The choice of treatment should ultimately be decided on the lifestyle requirements of the patient. The home therapies offer the most schedule flexibility. In-center thrice-weekly nocturnal HD allows the patient to work. Home HD requires a partner to assist with the treatments. In-center HD is appropriate for those who do not have a partner or who are unwilling or cannot perform PD.

CHAPTER 40

Choosing the Best Dialysis Option in the Patient with Acute Kidney Injury and in the Intensive Care Unit

Ami M. Patel and Beje Thomas

Acute kidney injury (AKI) occurs commonly in the intensive care unit (ICU) inflicting up to a third of the patients (1). The incidence of patients requiring renal replacement therapy (RRT) in the ICU is about 5% to 6% (2). It is well known that AKI is associated with increased mortality, and patients with AKI and multiorgan failure have mortality rates more than 50% (2,3). The use of RRT in AKI has been independently associated with even higher risk of death with mortality rates reaching as high as 75% (3–6). Over the past decade, dialysis-requiring AKI has increased about 10% per year, and the number of deaths associated with it has more than doubled (7). As many as 40% of survivors of AKI are left with stage 3 or greater chronic kidney disease, and approximately 5% remained dialysis dependent at 90 days (2,8,9).

With the lack of effective pharmacologic treatments, the care of the patient with AKI is limited to supportive management, in which RRT plays an integral role. There has been a significant evolution of RRT with the advent of continuous renal replacement therapy (CRRT). Initially, CRRT was offered as a therapy of last resort in the most critically ill patients who were hemodynamically intolerant of intermittent hemodialysis (IHD). As CRRT gained popularity as the dominant form of RRT in the ICU, it has been used for the broader application of extracorporeal blood purification (ECBP) during critical illness. The role of CRRT has been expanded for nonrenal indications, such as a tool for anti-inflammatory therapy and volume control (10).

The goals of this chapter are to characterize different forms of RRTs in the ICU, review the evidence-based literature on the application and the use of RRT in the ICU, and describe the role of RRT in specific disease conditions commonly confronted in the ICU.

TECHNICAL ASPECTS OF RENAL REPLACEMENT THERAPY IN THE INTENSIVE CARE UNIT

This section of the chapter discusses different modalities of RRT in the ICU and review through the calculations for clearance. Also, it reviews forms of anticoagulation for CRRT, dialysis solution, dialysis access, and other technical aspects.

Modes of Renal Replacement Therapy

There are multiple options for RRT that can be used in the treatment of AKI in the ICU. These include conventional IHD; various modalities of CRRT; "hybrid" modalities that combine features of IHD and CRRT, which are known as prolonged intermittent renal replacement therapy (PIRRT); and peritoneal dialysis (PD). **TABLE 40.1** summarizes solute clearance and prescription for each therapy.

TABLE 40.1 Typical Dialysis Prescription for Various Modalities[a]

Type of Therapy	Solute Transport	Duration (h)	Replacement Fluid (mL/h)	Blood Flow (mL/min)	Dialysate Flow (mL/h)	Ultrafiltrate Flow (mL/h)
CVVH	Convection	24	500–4,000	100–300	0	500–4,000
CVVHD	Diffusion	24	–	100–300	500–4,000	0–350
CVVHDF	Convection and diffusion	24	500–4,000	100–300	500–4,000	500–4,000
PIRRT (<12 h) or SLED	Diffusion mostly	6–10	–	100–250	200–400	0–1,000
PIRRT (>12 h)	Diffusion mostly	~20	–	100–300	100–200	0–350
IHD	Diffusion mostly	3–4	–	200–450	400–800	0–1,500

[a]Rates of flow are typical in clinical practice.

CVVH, continuous venovenous hemofiltration; CVVHD, continuous venovenous hemodialysis; CVVHDF, continuous venovenous hemodiafiltration; PIRRT, prolonged intermittent renal replacement therapy; SLED, sustained low-efficiency dialysis; IHD, intermittent hemodialysis.

Intermittent Hemodialysis

Traditionally, nephrologists have used IHD to treat AKI in the ICU. Solute clearance is mainly through diffusion, and volume is removed via ultrafiltration. The principal advantages of IHD include rapid removal of solute and volume, making it ideal for certain clinical scenarios such as drug intoxication and management of severe hyperkalemia. The major disadvantage of IHD is the risk of hypotension, which occurs in approximately 20% to 30% of hemodialysis sessions (11,12). The rapid solute removal and shift in electrolytes can exacerbate hemodynamic instability, causing IHD to be intolerable in critically ill patients. For adequacy, the target Kt/V is 1.2 per treatment or urea reduction ratio greater than 0.7. IHD and PD are discussed in greater detail in other sections of this book.

Prolonged Intermittent Renal Replacement Therapy

This category is also known as extended daily dialysis (EDD). The common form of PIRRT is sustained low-efficiency dialysis (SLED), which uses the same dialysis machine as for IHD, but the therapy is delivered at reduced blood and dialysate flow rate over a longer duration of time, usually over 6 to 10 hours. Typical blood-flow rate is around 200 to 300 mL/min with dialysate flow rate around 200 to 400 mL/min. Also, PIRRT can be delivered longer than SLED with duration around 20 hours. In this situation, blood flow is around 150 mL/min with dialysate flow around 100 mL/min. The major benefits of SLED are the reduced cost and staff time while providing solute removal equivalent to CRRT. Also, SLED may be routinely performed without anticoagulation. In one study, the weekly cost to the hospital was $1,431 for SLED; $2,607 for CRRT with heparin; and $3,089 for CRRT with citrate (13).

Continuous Renal Replacement Therapy

CRRT was developed in the 1980s specifically for the treatment of critically ill patients with AKI who could not tolerate conventional IHD due to hemodynamic instability or when IHD could not control volume and metabolic derangements. The slower clearance and volume removal through CRRT make it the preferred modality in the ICU patient requiring vasopressors. CRRT allows for greater volume removal with better hemodynamic tolerance in patients who have high obligate fluid intake such as more than 4 L/d. Disadvantages for CRRT include the higher cost, increased nursing support, frequent clotting, and risk of underdosing of antibiotics and other medications (**TABLE 40.2**). Medication dosing in CRRT is not well studied.

TABLE 40.2 Advantages and Disadvantages of Continuous Renal Replacement Therapy

Advantages	Disadvantages
Better hemodynamic stability	Not for intoxication and severe hyperkalemia
Capable of greater clearance over time	Expensive
Better volume control for high obligate fluid intake	Increased nursing support
Less effects on intracranial pressure	Increased clearance of antibiotics and medications
	Hypophosphatemia and other electrolyte disturbance
	Frequent clotting
	Limit patient mobility
	Bleeding complication with anticoagulation
	Nutrient losses

From Tolwani A. Continuous renal-replacement therapy for acute kidney injury. *N Engl J Med* 2012;367(26):2505–2514; and Clark EG, Bagshaw SM. Unnecessary renal replacement therapy for acute kidney injury is harmful for renal recovery. *Semin Dial* 2015;28(1):6–11.

The blood circuit for CRRT is commonly a venovenous circuit through a double-lumen, large-bore catheter. There are four options for CRRT: continuous venovenous hemodialysis (CVVHD), continuous venovenous hemofiltration (CVVH), continuous venovenous hemodiafiltration (CVVHDF), and slow continuous ultrafiltration (SCUF) (14,15). **FIGURE 40.1** shows the circuit components in the various forms of CRRT. **TABLE 40.1** summarizes typical dialysis prescription for different forms of CRRT. The usual blood flow is around 200 to 300 mL/min. Increasing blood flow from 100 or 150 mL/min to 200 or 300 mL/min helps increase the efficiency of clearance and reduce the risk of clotting (16).

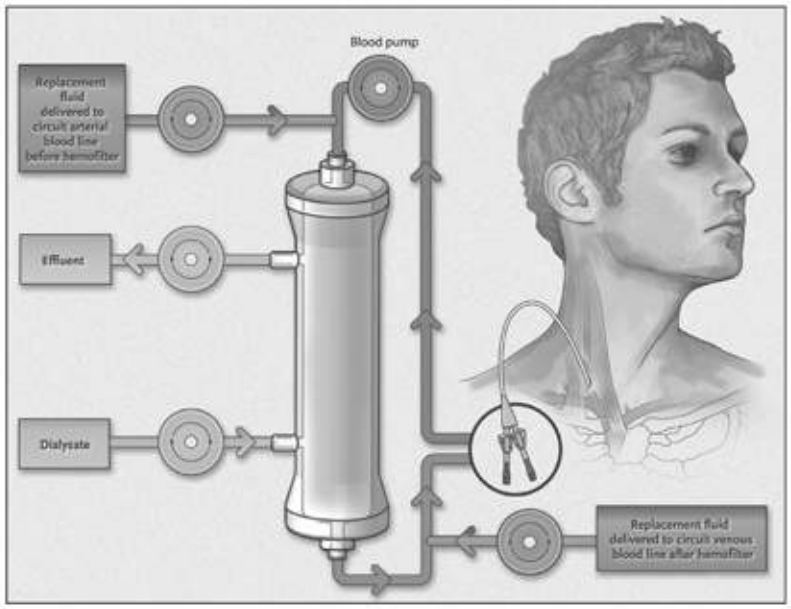

FIGURE 40.1 Circuit components in continuous renal replacement therapy. [Reprinted with permission from Tolwani A. Continuous renal-replacement therapy for acute kidney injury. *N Engl J Med* 2012;367(26):2505–2514.]

Continuous Venovenous Hemodialysis

The primary means of solute clearance is through diffusion. The dialysate flow is slower in comparison to IHD and runs in the opposite direction to the faster moving blood flow in a countercurrent course, allowing for maximal saturation of solutes of the outflow dialysis. Solute removal occurs by concentration gradient between blood and dialysate compartment across a semipermeable biosynthetic membrane otherwise known as the hemodiafilter. Substances such as urea, creatinine, and potassium diffuse down their concentration gradient from the blood to dialysate compartment during hemodialysis, while other solutes, such as bicarbonate, move from the dialysate to blood compartment. The rate of removal of solute through diffusion depends on the size. Smaller molecules diffuse more easily, and larger molecules diffuse slowly and are not as easily removed (14,15).

Continuous Venovenous Hemofiltration

The primary means of solute clearance is through convection. As the blood flows through the hemodiafilter, transmembrane pressure gradient between the blood and ultrafiltrate compartment forces plasma water to be filtered across the hemodiafilter (or also known as hemofilter). The small-sized solutes (such as urea and electrolytes) are removed in the same concentration as the plasma. The volume removed in the ultrafiltrate is replenished by a replacement (or substitution) fluid to prevent excessive fluid removal and volume depletion, thereby diluting the concentration of the plasma solutes. The replacement fluid is infused into the blood compartment either prefilter (also known as predilution), postfilter (also known as postdilution), or both. The rate of solute removal depends on the size of hemofilter pores and the convective force, which allows for larger molecules to be removed in contrast to hemodialysis (14,15).

The downside of using only postfilter replacement is the increased rate of clotting as the blood filters through the hemofilter and becomes increasingly concentrated at the end of the hemofilter with the removal of the ultrafiltrate. Therefore, replacement fluid is usually infused either as all prefilter or as a combination of prefilter and postfilter to reduce the risk of clotting. Common percentages for replacement fluid is 100% prefilter, 70% prefilter with 30% postfilter, and 50% prefilter with 50% postfilter. As the

percentage of replacement fluid is increased postfilter, the risk of clotting rises, which can be ascertained by calculating the filtration fraction. Filtration fraction above 25% indicates a greater risk for clotting, and these calculations are described further in the next section of this chapter. On the other hand, when replacement fluid is given prefilter, the blood entering the filter will become diluted, reducing the maximum solute clearance. For instance, if prefilter replacement fluid is infusing at 40 mL/min and blood flow is at rate of 200 mL/min, the dilution factor will be 200/240 = 83% or there is a 17% dilution. Depending on the solute and dialysis prescription, prefilter replacement reduces clearance by 15% to 20% (17). On a milliliter for milliliter basis, CVVHD is more efficient, removing small-sized solutes in comparison to CVVH with prefilter replacement. However, middle-sized molecule solutes (500 Da to 60 kDa) such as β_2-microglobulin are cleared more effectively with CVVH due convective clearance.

Continuous Venovenous Hemodiafiltration

This combines both CVVHD and CVVH, which is usually with prefilter replacement therapy. There are several types of CRRT machines available, and depending on the machine, it can provide different modalities.

Slow Continuous Ultrafiltration

This is used commonly in patients who need only volume removal but not solute clearance. There is no dialysis or replacement fluid in this mode of therapy; only ultrafiltrate is removed at a slow rate using a hemofilter.

Dialysate Solution

Dialysate and replacement solutions are very similar, and many of the dialysate solutions are being used as replacement fluid off-label. These solutions contain potassium, calcium, magnesium, and glucose in physiologic ranges. There are additional solutions such as varying potassium and calcium baths, which are available for special circumstances. For hyperkalemia, one can use 0 to 2 mEq/L potassium bath. As for the anion buffer, acetate, lactate, citrate, and bicarbonate have all been used, but bicarbonate is preferred (14). Lactate-based solutions are unfavorable because it can cause hyperlactatemia in critically ill patients with liver dysfunction and may be associated with higher episodes of hypotension in comparison to bicarbonate-based (15,18). Acetate-based dialysate fluid has been implicated with contributing to intradialytic hypotension with IHD. Acetate can induce production of nitric oxide, a vasodilator (19). However, recent study showed that acetate-containing solution does not seem to affect hemodynamics because lower amount of acetate is delivered in comparison to the amount delivered in IHD (15,20). Popular dialysate solutions have predominant concentration bicarbonate with low concentration of lactate, usually around 3 mmol/L. Lower levels of bicarbonate are recommended with citrate anticoagulation to avoid severe metabolic alkalosis since citrate is metabolized by liver to bicarbonate.

Vascular Access

Vascular access is absolutely necessary for RRT. However, it must be kept in mind that with ICU patients with AKI, there is the possibility of long-term dialysis, so maintaining the vasculature is important for future dialysis access. There are primarily three forms of access: dialysis catheters (DCs), arteriovenous

fistula (AVF), and arteriovenous graft (AVG). In the various modes of CRRT, the DC is preferred. There is limited data on DCs used in the ICU as most of the data is actually from studies looking at central venous catheters (CVCs) and access in end-stage kidney disease (ESKD) patients. It is questionable if this data is applicable as there are significant differences between the catheters and a patient in the ICU versus a patient in the dialysis unit.

Blood flow through the catheter is a significant factor in determining the dialysis dose provided. This is particularly important in IHD since blood flow tends to be higher in comparison to CRRT, in which dosing is more dependent on the effluent volume. DC dysfunction as defined in various studies as a low blood flow of <150 to 200 mL/min with inadequate dialysis dose delivery and blood flow reduction of more than 20% even after attempts to maintain patency of the DC (21). Early DC dysfunction is usually due to improper catheter placement technique such as cannulating the wrong vessel, catheter tip malposition, or kinking of the catheter. Late DC dysfunction is usually due to thrombosis intrinsic (obstructive thrombosis of the catheter lumen) or extrinsic (thrombosis or stenosis of the blood vessel) to the catheter. The majority of DC catheter dysfunction occurs in the first 10 days but increases the longer the catheter remains inside (21,22). Countermeasures that can be used to increase the blood flow after catheter placement include repositioning the patient, flushing the line with saline, using an anticoagulation (citrate or heparin) dwell in the DC, and reversing the lines. Of course, accurate placement of the DC is important, and this has improved with the use of ultrasound guidance to image the targeted vessel throughout the procedure and x-ray to confirm placement. If all measures fails, then replacing the DC might be the only alternative to provide an adequate dialysis dose. This can be done over a guidewire.

Another complication of DC is infection, which is defined by two separate cultures separated by 120 minutes that grow the same phenotypic organism. One culture is drawn from the peripheral blood and the other from the CVC. The rates of catheter infections have dramatically declined due to various methods aimed at preventing CVC infections in the ICU. These methods include adequate hand hygiene, barrier precautions, prompt removal of catheter when it is no longer necessary, and advancements in dressings. There is a need for large randomized trials before the routine use of antimicrobial locks or antimicrobial catheters can be recommended (22,23).

The options of dialysis access site are the internal jugular (IJ) vein, the subclavian vein, and the femoral vein. The most recent Kidney Disease: Improving Global Outcomes (KDIGO) AKI guidelines present an ungraded recommendation for which vessels to use. In descending order from most to least desired site, right IJ vein, femoral vein, left IJ vein, and lastly, the subclavian veins. The reason for the left IJ vein and both subclavian veins are less desirable are due to the increased risk of the development of central vein stenosis (24). Traditionally, femoral vein access has been attributed to greater infection risk and to restrict patient mobility (23). This has more recently come under scrutiny. Parienti et al. (25) performed one of the first randomized controlled trials on catheter site insertion. They found that the risk for a catheter-related blood stream infection was lower for femoral lines if the body mass index (BMI) was <24.2 and for the IJ if BMI was >28. A meta-analysis reported that outside of patients with a high BMI that there was no significant increase in infection rates between the subclavian or IJ veins versus the femoral vein. The meta-analysis also stated that there was no difference in the deep vein thrombosis rates (26). Both of these conclusions of no significant difference in infectious or thrombosis rates were reported by a recent Cochrane review (27).

The catheter site does also play a role in catheter dysfunction rates and the dose of dialysis delivered to a patient. In the multicenter Cathedia Study, which included 736 patients, there were similar rates of first DC dysfunction between the IJ (11.1%) and femoral (10.3%) veins. It is important to note the side of the DC affected dysfunction rates: the right IJ was 6.6%, the femoral veins 10.3 %, and the left IJ was 19.5%. In regard to dialysis dose, if the desired blood flow is less than 200 mL/min, there is negligible difference between the IJ and femoral veins; however, if the blood flow is over 200 mL/min, the right IJ vein is preferred (28). Remember, the right IJ vein is the most direct and straight route to the superior vena cava (22).

In summary, the first choice of access should be the right IJ vein; remember, an advantage of IJ access is that the patient will be able to mobilize easier (24). The femoral veins should be considered particularly in patients with a lower BMI (<24), high likelihood of long-term dialysis, and if emergent dialysis is needed with inexperienced operator or no ultrasound available. The left IJ vein should be considered if the right IJ and femoral veins are not optimal choices. The subclavian vein is the last resort with the right side being preferable (23).

Anticoagulation

The CRRT extracorporeal circuit's patency and filter lifespan are of critical importance to ensure that there is adequate solute clearance and filtration. A major hindrance to this is clotting in the extracorporeal circuit leading to a discontinuation of therapy (29). It has been shown that when 24 hours of CRRT are prescribed on average without anticoagulation, the patient receives therapy for about 16 to 18 hours. This interrupted treatment results in a higher cost, unnecessary blood loss, and an increased strain on nursing. Hence, prevention of clotting by various methods including anticoagulation is required for the patient on CRRT. In regard to anticoagulation, it is usually necessary for the patient on CRRT, and this is a distinct disadvantage of this modality of RRT. Studies have shown 5% to 50% of patients on anticoagulation with CRRT have bleeding complications. The desired anticoagulant should have certain qualities including providing optimal anticoagulation with minimal systemic side effects including bleeding. It should be readily available, able to be monitored, reversible, and inexpensive (30–32). In this section, we will discuss both nonanticoagulant and anticoagulant strategies to prevent clotting of the CRRT extracorporeal circuit.

The patient's clinical status, characteristics of the extracorporeal circuit, and blood flow all affect the coagulation pathophysiology of the patient. The clinical status can have a procoaguable effect from the pathologic presence of proteins as in antiphospholipid syndrome or secondary to overt inflammation as in sepsis. It is thought that once blood comes into contact with the extracorporeal circuit, there is stimulation of the coagulation system. This includes activation of the intrinsic and extrinsic coagulation systems with thrombin generation, monocytes, and platelets. In an inflamed state, there is diminished activity of the endogenous anticoagulation system with decreased antithrombin, protein C, and tissue factor plasminogen inhibitor. This is due to decreased production and even direct lysis of anticoagulants. Once the clotting starts, usually there is fibrinolysis, but this is impaired as well with the increased activity of plasminogen activator inhibitor. The endothelium's antithrombogenic properties are also lost due to inflammation and oxidative stress. Other causes of clotting are blood flow stasis, hemoconcentration, turbulent blood flow, and contact between blood and air (30,32).

Vascular access obviously affects blood flow. We have gone into further detail elsewhere about

vascular access but will briefly review the type and location of access. There is no significant difference in filter life when comparing the IJ and femoral sites (33,34). However, there is less infectious risk and recirculation with an internal IJ. Femoral catheters tend to kink more particularly in the obese patient. IJ catheters can generate high access pressures when a patient is agitated or coughing. There is some data that show the right side for both catheters are associated with less catheter dysfunction (34). The actual catheter itself should optimally be short and have a wide inner diameter. In addition, staff managing the CRRT extracorporeal circuit should respond to pump alarms in a timely manner, be able to recognize when a catheter is kinked, and properly rinse the filter to minimize the blood-air contact which initiates clotting (32). We will discuss filtration fraction later in this chapter.

We will primarily discuss the use of heparin and citrate for anticoagulation. There are other potential agents available that are not routinely used. These include heparinoids and platelet-inhibiting agents. We will not cover these agents in this section.

Unfractionated Heparin Anticoagulation

Unfractionated heparin (UFH) is the most commonly used anticoagulant. UFH's mechanism potentiates the effects of antithrombin III by a thousandfold, inhibiting thrombin activity and factor Xa. The half-life of UFH is about 90 minutes to 3 hours depending on kidney function. UFH has advantages including physician familiarity, reversibility with protamine, relative short half-life, and ease of monitoring. There are significant disadvantages such as dosing variability, heparin-induced thrombocytopenia (HIT), heparin resistance, and risk of hemorrhage. The incidence of bleeding has a wide range of 10% to 50%. UFH when used is usually as a bolus of 2,000 to 5,000 IU at 30 IU/kg. This is followed by a continuous infusion in the arterial arm of 5 to 10 IU/kg/h to maintain an activated partial thromboplastin time (aPTT) of 34 to 45 seconds or an aPTT of 1.5 to 2.0 times the normal level (31,35).

The reversal agent or antagonist for UFH is protamine. When used in CRRT, protamine is given postfilter at a ratio of 100 between prefilter heparin (IU) and protamine (mg). The protamine–heparin complex is released into the body and broken down by the reticuloendothelial system. The side effects of protamine include hypotension, thrombocytopenia, leukopenia, cardiac depression, and anaphylaxis. Regional anticoagulation using heparin with protamine reversal is cumbersome due to the difficulty in calculating how much protamine is actually necessary. There is also variability in prolonging filter life. Therefore, heparin anticoagulation is commonly applied without the use of protamine. Low molecular weight heparin (LMWH) is not used routinely for CRRT anticoagulation. This is due to an increased risk of bleeding, cost with need to monitor anti-Xa activity, and risk of HIT, and lack of clearance in kidney disease (31). However, even if one is able to perform anti-Xa monitoring, it is not entirely reliable in predicting bleeding complications (10).

Heparin-Induced Thrombocytopenia

Once there is a suspicion for HIT, all heparinoids should be stopped as soon as possible and replaced with alternative anticoagulation. Thrombocytopenia occurs in up to 60% critically ill patients, and when CRRT is initiated, a drop in platelet count by as much as 50% has been reported. The diagnosis of HIT is based on detection of platelet factor 4 antibodies (10,36,37). Another functional assay used as a diagnostic test is the serotonin releases assay. The alternative anticoagulation used in the clinical setting of HIT with CRRT is a direct thrombin inhibitor. The preferred direct thrombin inhibitor of choice in

renal dysfunction without liver failure is argatroban and in those with liver failure, bivalirudin. These agents would treat both the procoagulable state of HIT and provide anticoagulation for the CRRT. An alternative anticoagulation strategy to prevent HIT is to avoid heparin-based agents all together and use citrate anticoagulation (37–39).

Citrate Anticoagulation

Citrate has multiple advantages, namely, avoidance of systemic anticoagulation and no association with HIT. It has been shown to have better filter survival times and less bleeding when compared to heparinoids (40–42). Disadvantages of citrate anticoagulation are metabolic abnormalities, increased complexity, and the lack of universal availability. Citrate solutions and protocols have been reviewed recently. Citrate prevents clotting in CRRT by chelating ionized calcium in the extracorporeal circuit. Calcium is required for multiple steps in the coagulation cascade. There is also thought to be additional antihemostatic and anti-inflammatory properties of citrate. Citrate is infused in the arterial limb (prefilter) of the CRRT proportional to the blood flow. Citrate itself is not measured, but instead, the postfilter ionized calcium is used. The citrate infusion is titrated so that the postfilter ionized calcium is <0.35 mmol/L. This level of ionized calcium is associated with optimal anticoagulation in the extracorporeal circuit and correlates with a citrate concentration of 4 to 6 mmol/L (40,42,43). Citrate has a low molecular weight, high sieving coefficient, and high diffusion/convective clearance so that a major portion of the citrate–calcium complexes is lost in the effluent (44). This would lead to systemic hypocalcemia if not for the calcium infusion postfilter to replace the lost calcium. Calcium chloride or calcium gluconate is used for the calcium infusion. Citrate–calcium complexes that are not lost in the effluent but instead return to the systemic circulation are metabolized to bicarbonate by the skeletal muscle, kidney, and liver. Each citrate–calcium complex yield three molecules of bicarbonate and returns the ionized calcium to the patient (40,42).

Metabolic Abnormalities with Citrate Anticoagulation

The most common metabolic complications of regional citrate anticoagulation are hypocalcemia and metabolic alkalosis (45). We will discuss monitoring of electrolytes in the next section. Intravenous infusion of calcium postfilter is given and adjusted on an ongoing basis to prevent hypocalcemia. In general, with blood-flow rates of about 200 mL/min and effluent rates of 25 to 30 mL/kg/h, calcium supplementation starts at 2 to 3 mmol/h. One has to be cognizant of the replacement fluid/dialysate containing calcium as this could affect the rate of citrate and calcium infusions. The goal for the systemic ionized calcium is 0.9 to 1.2 mmol/L. The other possible etiology of hypocalcemia with citrate infusion is ineffective metabolism and subsequent citrate accumulation seen in liver failure or tissue hypoperfusion (shock). If citrate is not metabolized, then calcium is not released from the citrate–calcium complex. The solutions for this include reducing the citrate infusion, enhancing citrate removal in the effluent (by increasing the replacement fluid or dialysate rate), and switching from citrate- to bicarbonate-based replacement fluid or dialysate. Hypercalcemia also occurs with citrate anticoagulation if there is an excessive replacement with intravenous calcium (40,42).

Another effect of inadequate citrate metabolism is anion gap metabolic acidosis. The management of this is similar as mentioned previously for hypocalcemia in the same clinical setting. Metabolic acidosis is also caused by an imbalance of buffer (citrate and bicarbonate) being delivered to the patient and that

being lost in the effluent. One can increase the amount of buffer by increasing the citrate infusion rate or by decreasing the loss in the effluent by reducing the replacement fluid or dialysate rates. Other options are intravenous bicarbonate infusion or increasing the amount of bicarbonate in the replacement fluid or dialysate.

Metabolic alkalosis as we have mentioned is the second most common complication. This is usually secondary to an excess buffer load or not appropriately matching the CRRT solutions with citrate. An excess buffer load is a result of a higher blood-flow rate, which subsequently infuse citrate at a higher rate. One option is to reduce the amount of citrate entering the circuit by decreasing blood flow or by aiming for a higher ionized calcium goal (i.e., lower citrate level). The other option is to increase the citrate lost in the effluent by increasing the replacement or dialysate flow rates. An important caveat is that there are other sources of citrate in the intensive care setting. Citrate is the preservative for blood products, and so the patient receiving multiple transfusions is also receiving an increased amount of citrate. Another example is acetone in total parenteral nutrition. The other mechanism of metabolic alkalosis is inappropriately high bicarbonate in the replacement fluid or dialysate in a patient receiving citrate. The conversion of the citrate that reaches systemic circulation to bicarbonate must be accounted for when considering the replacement fluid or dialysate. For instance, when starting a patient on citrate who was not previously on anticoagulation with CRRT, one must lower the bicarbonate in the CRRT fluids being used. Another approach to prevent metabolic alkalosis is to use hyperchloremic solutions such as normal saline pre- or postfilter (40,42,45).

Other electrolytes potentially affected include magnesium and sodium. Magnesium is also chelated by citrate but usually does not need replacement as magnesium is found in the dialysate or the replacement fluids. Hypernatremia can result from not adjusting to the sodium load that occurs with citrate anticoagulation. To prevent hypernatremia, it is important to reduce the sodium concentration in the dialysate or the replacement fluids. Hyponatremia is seen if there is an excess of hypotonic fluid being given to the patient or a technical error where the citrate has not been given (45).

Citrate Toxicity and Monitoring

Citrate accumulation and toxicity risks include the patient with liver dysfunction, with severe tissue hypoperfusion (shock), or a large citrate load (multiple blood products). The liver is the main site of metabolism for citrate. Clinically, this is seen with worsening metabolic acidosis and hypocalcemia potentially leading to hypotension and arrhythmias. Typically, electrolytes are monitored frequently when a patient is on CRRT by as much as every 4 to 6 hours. More frequent monitoring could be required for the patient with an increased risk for citrate toxicity (40,42). Citrate itself is not routinely measured but instead the ratio of total-to-ionized calcium (calcium ratio) is used as a surrogate for the citrate level. The accumulation of citrate results in an increased infusion of calcium postfilter leading to a disproportionate rise in total calcium as compared to ionized calcium. The critical cutoff for the calcium ratio is >2.5 indicating that the patient is at increased risk for metabolic complications and citrate toxicity (46). Management of citrate accumulation and toxicity revolves around reducing exposure and increasing the clearance of citrate. This can be done by reducing the blood-flow rate and amount of citrate infused aiming again for higher calcium targets. On the other hand, the clinician can increase clearance by increasing convective or dialysis forces (43).

In high-risk patients, such as those with liver failure, citrate may be used but with caution. Liver indices are not always reliable in predicting metabolic clearance. Better predictors of the liver's ability to metabolize citrate include a prothrombin time ≥33 seconds and a lactic acid level ≥3.4 mmol/L (47,48). Laboratory monitoring should be more frequent as much as every 2 hours and should include the calcium ratio and the pH. We have mentioned citrate toxicity management by decreasing the exposure and increasing the clearance of citrate in this section already. Other available measures to manage metabolic acidosis and hypocalcemia are the systemic infusion of bicarbonate and/or calcium as needed. If acidosis is present, we advise to correct the calcium first as bicarbonate infusion can result in a further drop in ionized calcium level (43).

In summary in deciding which modality of anticoagulation to use for CRRT, it is best to consider the time interval it will be required for, the bleeding risk of the individual patient, and the therapeutic agents available. The clinician must also be aware of the intensity of monitoring and the use of resources required with anticoagulation in CRRT. In the patient that cannot have anticoagulation, it is possible to maintain CRRT with other strategies as we have described (49).

Clearance for Continuous Renal Replacement Therapy

The "dose" of RRT administered is determined by the effluent flow, which comprises of ultrafiltrate in CVVH, the spent dialysate in CVVHD, and both in CVVHDF. It is commonly reported as the effluent flow rate in milliliters per kilogram per body weight. The recommended effluent flow dose is at least 20 to 25 mL/kg of body weight per hour in order to achieve adequate solute clearance (14,50,51). There are often frequent interruptions in CRRT such as procedures and clotting of hemofilter; therefore, effluent flow may need to be increased to account for lost time. In addition, clotting and protein deposition on hemofilter can reduce actual solute clearance (14).

Calculations

Where K is the clearance, Q_E is the effluent rate, C_E is the effluent concentration, and C_B is the blood concentration. K is expressed in mL/min (**EQUATION 40.1**) (52).

$$K = Q_E \times C_E / C_B \qquad (40.1)$$

where Q_d is dialysate fluid rate, Q_R is replacement fluid rate, Q_{net} is the net fluid removal rate, and Q_{uf} is the total ultrafiltration volume. All are reported in mL/min. The effluent rate, which is also known as "dose" of CRRT, can be expressed in mL/h or as mL/kg/h. The recommended "dose" of RRT is at least 20 to 25 mL/kg/h (**EQUATIONS 40.2** and **40.3**) (50–53).

$$Q_E = Q_d + Q_R + Q_{net} \qquad (40.2)$$

$$Q_{uf} = Q_R + Q_{net} \qquad (40.3)$$

where σ is the sieving coefficient. For small molecules, the sieving coefficient approximates to 1. Using urea as the solute, equilibrium is achieved between C_E and C_B since the effluent rate is much smaller than the blood-flow rate and the solute size for urea is small (60 Da) (**EQUATION 40.4**). For instance, effluent rate is usually ranging 17 to 50 mL/min versus blood-flow rate around 200 to 300 mL/min. Therefore, the

sieving coefficient for urea is 1. Another determinant of the sieving coefficient is the pore size of the hemodiafilter. **TABLE 40.3** shows an example of the sieving coefficient of different molecules (54).

$$\sigma = C_E / C_B \qquad (40.4)$$

TABLE 40.3 Sieving Coefficient of Different Molecules in Continuous Renal Replacement Therapy[a]

Molecule	Molecular Weight (Da)	Sieving Coefficients
Urea	60	1.0
Creatinine	113	1.0
Vitamin B_{12}	1,355	1.0
Albumin	65,000	<0.01
Myoglobin	17,000	0.58

[a]The sieving coefficient depends on multitude of factors, including dialysis prescription, characteristics of the molecule, and characteristics of the hemodiafilter membrane. The sieving coefficient is for the AN69 ST membrane for the Prismafex sets.

Diluting factor is used in calculating K for CVVH with prefilter replacement, which reduces the maximum solute clearance per unit volume of replacement fluid in comparison to postfilter replacement (**EQUATION 40.5**). With the infusion of prefilter replacement fluid, the blood entering the hemofilter becomes diluted and as a result, the effluent has a lower concentration of solutes than plasma (52).

$$\text{Dilution factor} = Q_B / (Q_B + Q_R) \qquad (40.5)$$

where FF is filtration fraction, Q_p is plasma flow expressed in mL/min, and Q_B is blood flow expressed in mL/min (**EQUATIONS 40.6–40.8**).

$$FF = Q_{uf} / Q_p \qquad (40.6)$$

$$Qp = (1 - \text{hematocrit})\ (Q_B) \qquad (40.7)$$

$$FF = Q_{uf} / (1 - \text{hematocrit})\ (Q_B) \qquad (40.8)$$

FF is the ratio of the ultrafiltrate to the plasma flow entering the hemofilter (**FIGURE 40.2**). The goal filtration fraction is <25% to reduce the chances of clotting. When FF is ≥25%, there is a greater chance of clotting. Raising the blood flow or reducing the ultrafiltration rate decreases the risk of clotting. Conversely, lowering the blood flow or increasing the ultrafiltration rate increases the risk of clotting. Furthermore, adding prefilter replacement lowers the filter fraction because the prefilter replacement fluid dilutes the plasma flow entering the hemofilter (49). To calculate FF, the prefilter replacement fluid is added to the denominator (**EQUATION 40.9**).

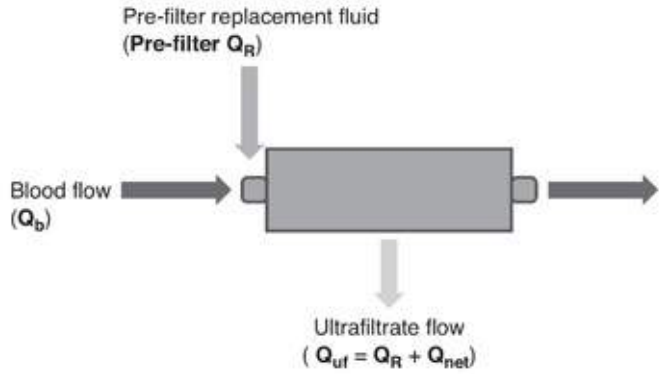

FIGURE 40.2 Determinants of filtration fraction.

$$FF = Q_{uf} / [(1 - \text{hematocrit})\ (Q_B) + \text{prefilter } Q_R] \quad (40.9)$$

Example 1: Continuous Venovenous Hemodialysis

70-kg patient with CVVHD at Q_B 100 mL/min, Q_d 1,500 mL/h. Net fluid removal by CVVHD was 2 L. Hematocrit is 30%; C_E/C_B or σ for urea = 1.

$$K = Q_E \times C_E / C_B \qquad Q_E = Q_d + Q_R + Q_{net}$$
$$= 1{,}500 \text{ mL/h} + 0 + 83 \text{ mL/h}$$
$$= 1{,}583 \text{ mL/h}$$

$$K = (1{,}583 \text{ mL/h})\ (1) = 26 \text{ mL/min}$$

"Dose" is (1,583 mL/h) / 70 kg = 23 mL/kg/h

$FF = Q_{uf} / [(1 - \text{hematocrit})\ (Q_B)]$; $Q_{uf} = Q_R + Q_{net}$

$Q_{uf} = 0 + 2 = 2$ L/d or 1.4 mL/min

FF = 1.4 mL/min / (1 − 0.3) (100 mL/min) = 0.02 or 2%

Example 2: Continuous Venovenous Hemofiltration with Postfilter Replacement

70-kg patient with CVVH at Q_B 100 mL/min, Q_R 1,500 mL/h (postfilter). Net fluid removal by CVVH was 0. Hematocrit is 30%; C_E/C_B or σ for urea = 1.

$$K = Q_E \times C_E / C_B \qquad Q_E = Q_d + Q_R + Q_{net}$$
$$= 1{,}500 \text{ mL/h} + 0 + 0$$
$$= 1{,}500 \text{ mL/h}$$

$$K = (1{,}500 \text{ mL/h})\ (1) = 25 \text{ mL/min}$$

"Dose" is (1,500 mL/h) / 70 kg = 21 mL/kg/h

$FF = Q_{uf} / (1 - \text{hematocrit})\ (Q_B)$; $Q_{uf} = Q_R + Q_{net}$

$Q_{uf} = 1{,}500$ mL/h + 0 = 1500 mL/h or 25 mL/min

FF = 25 mL/min / [100 mL/min × (1 − 0.3)] = 0.36 or 36%

Example 3: Continuous Venovenous Hemofiltration with Prefilter Replacement

70-kg patient with CVVH at Q_B 100 mL/min, Q_R 1,500 mL/h (prefilter). Net fluid removal by CVVH was 0. Hematocrit is 30%; C_E/C_B or σ for urea = 1.

$K = Q_E \times C_E / C_B$ $Q_E = Q_d + Q_R + Q_{net}$

$= 1{,}500 \text{ mL/h} + 0 + 0$

$= 1{,}500 \text{ mL/h}$

Use dilution factor = $Q_B / (Q_B + Q_R)$

Therefore, $K = [Q_E \times C_E/C_B] \times [Q_B / (Q_B + Q_R)]$

$K = (1{,}500 \text{ mL/h}) \times 1 \times (6{,}000 \text{ mL/h}) / (6{,}000 \text{ mL/h} + 1{,}500 \text{ mL/h}) = 1{,}200 \text{ mL/h}$ or 20 mL/min or 17 mL/kg/h

$FF = Q_{uf} / [(1 - \text{hematocrit}) (Q_B) + \text{prefilter } Q_R]$; $Q_{uf} = Q_R + Q_{net}$

$Q_{uf} = 1{,}500 \text{ mL/h} + 0 = 1{,}500 \text{ mL/h}$ or 25 mL/min

$FF = 25 \text{ mL/min} / [100 \text{ mL/min} \times (1 - 0.3) + 25 \text{ mL/min}] =$ 0.26 or 26%

Example 4: Continuous Venovenous Hemodiafiltration

70-kg patient with CVVHDF at Q_B 100 mL/min, Q_R 1,500 mL/h (prefilter), Q_d 1,500 mL/h. Net fluid removal by CVVHDF was 0. Hematocrit is 30%; C_E/C_B or σ for urea = 1.

Total K = K for CVVH + K for CVVHD

K for CVVH = 1,200 mL/h or 20 mL/min or 17 mL/kg/h (see Example 3)

K for CVVHD = $Q_E \times C_E / C_B = (1{,}500 \text{ mL/h} + 0) \times 1 =$ 1,500 mL/h or 25 mL/min or 21 mL/kg/h (refer to Example 1)

Total K = 1,200 mL/h + 1,500 mL/h = 2,700 mL/h or 45 mL/min or 38 mL/kg/h

$FF = Q_{uf} / [(1 - \text{hematocrit}) (Q_B) + \text{prefilter } Q_R]$

$Q_{uf} = Q_R + Q_{net} = 1{,}500 \text{ mL/h} + 0 = 1{,}500 \text{ mL/h}$ or 25 mL/min

$FF = 25 \text{ mL/min} / [(1 - 0.3) \times 100 \text{ mL/min} + 25 \text{ mL/min}] =$ 0.26 or 26%

CLINICAL ISSUES OF RENAL REPLACEMENT THERAPY IN THE INTENSIVE CARE UNIT

There has been substantial advancement in regard to the optimal dosing of RRT through large multicenter, randomized clinical trials. However, the optimal timing of initiation of dialysis remains elusive, and the preferred modality of RRT in the ICU is somewhat controversial. This section of the chapter reviews through the literature discussing the issues surrounding the clinical applications of RRT in the ICU.

Indications for and Timing of Initiation of Renal Replacement Therapy

When first introduced into clinical practice in the 1940 to 1950s, RRT was mainly used to treat late and severe symptoms of kidney disease. Studies published during the 1960s to 1970s showed a worse mortality if RRT was started when blood urea nitrogen (BUN) exceeded 163 to 200 mg/dL versus BUN 93 to 150 mg/dL (55–57). The concept of “prophylactic” dialysis for AKI was first introduced by Teschan et al. (58) more than 50 years ago. They recommended starting dialysis before obvious clinical symptoms or biochemical derangements occur and they theorized that postponing dialysis can cause

"retention of dialyzable substances which interfere with the functions of many cells and tissues," resulting in irreversible damage (58). However, it is difficult to conclude the benefits of preemptive dialysis from older studies since many were observational studies, the study population was younger compared to current, and lastly, many would consider what was claimed to be early start with BUN ranging 90 to 150 mg/dL as rather late for initiation.

The indications for and optimal timing of initiation of RRT in patients with AKI has remained uncertain. There is little debate about initiation of RRT when there is severe volume overload, hyperkalemia, refractory metabolic acidosis, and overt uremic manifestations such as pericarditis. However, when there is no classic indication for RRT initiation, it is debatable whether starting dialysis "preemptively" will improve outcome. Some of the reasons to start dialysis preemptively are to improve volume control, restore acid–base homeostasis quicker, avoid situations for emergent "rescue" dialysis, and remove small middle-sized molecules. **TABLE 40.4** outlines conventional, preemptive, and nonrenal indications for RRT.

TABLE 40.4 Indications for Renal Replacement Therapy

Conventional Indications	Preemptive[a]	Nonrenal Indications[a]
Hyperkalemia	Azotemia	Sepsis/removal of cytokines
Diuretic-resistant volume overload	Disrupted fluid balance	Increased intracranial pressure
Refractory acidosis	Restoration of acid–base homeostasis	Acute respiratory distress syndrome
Uremic manifestations (e.g., pericarditis)	Increased catabolic states (e.g., rhabdomyolysis and tumor lysis)	
Oliguria/anuria	Electrolyte abnormalities	
Some drug intoxication		

[a]Preemptive and nonrenal indications for renal replacement therapy are controversial and are opinion-based.

In this regard, it is worth reviewing key recent studies investigating the role of preemptive dialysis. Using the data from the Program to Improve Care in Acute Renal Disease (PICARD) cohort, which was a multicenter observational retrospective study, Liu et al. (59) analyzed 243 patients who required dialysis for AKI and subdivided the group by the level of BUN when dialysis was initiated. The higher degree of azotemia group was defined as BUN >76 mg/dL, and lower azotemia group was BUN ≤76 mg/dL. After multivariate adjustment for comorbid diseases and for propensity for initiation of RRT, late RRT was associated with a twofold risk of death at 60 days since the diagnosis of AKI (59). In another study, Vaara et al. (60) examined 239 patients who were started on RRT in the ICU using the prospective observational cohort from the Finnish Acute Kidney Injury Study Group. Patients were divided into those who were started on RRT for classic indications versus preemptive initiation. The classic group was further subdivided into delayed, which meant RRT was initiated >12 hours since the indication, versus urgent, which meant that RRT was initiated <12 hours. The crude 90-day mortality rate was 68% for the classic-delayed group, 39% for classic-urgent, and 30% for the preemptive group. The crude 90-day mortality rate was 49.3% for the non-RRT match equivalent to the preemptive group. Although initial studies reported decreased mortality with earlier initiation of renal support, the results are obscured by

multiple limitations such as nonrandomization of groups and probable differences in the indications for initiation. More importantly, these studies did not include the analysis of patients with AKI who did not receive RRT because they either recovered renal function or died (60).

There are a few small-sized randomized controlled trials investigating the optimal timing of RRT. Study by Bouman et al. (61) was a prospective study of 106 critically ill patients with AKI randomized into three groups: early low-volume CVVH at average dose 20 mL/kg/h, early high-volume CVVH at average dose 48 mL/kg/h, and late low-volume CVVH at average dose 19 mL/kg/h. Early group started CVVH within 12 hours of oliguria after optimization of hemodynamics or measured creatinine clearance <20 mL/min on a 3-hour timed collection. The late group started CVVH when BUN was >112 mg/dL, hyperkalemia (K >6.5 mEq/L), or presence of pulmonary edema. There was no observed difference in 28-day survival (74.3%, 68.8%, 75%, respectively, $p = 0.8$) and renal recovery rate. Of the 36 patients who were randomized to the late low-volume group, 4 recovered kidney function and 2 died. This finding suggests that preemptive RRT may be unnecessary in some patients. Nevertheless, the study was underpowered to detect survival differences, and the overall high survival rate of these patients suggests that the study population is not representative of an average ICU.

Another study was an open label, randomized controlled trial of 208 patients with severe AKI in Western India. Patients were randomized to either early-start with serum creatinine >7 mg/dL or BUN 70 mg/dL versus usual-start for clinical indications as determined by the treating nephrologists (62). For the usual-start group, the mean starting BUN was 101 mg/dL and creatinine 10.4 mg/dL. There was no difference in-hospital mortality or risk of chronic dialysis at 3 months. Early-start group had 90-day mortality of 21% versus 12% for the usual-start, with relative risk ratio of 1.67 [95% confidence interval (CI) 0.88 to 3.17, $p = 0.2$]. Overall, dialysis dependence was reported in about 5% of the patients. The time to renal recovery of kidney function was significantly longer in the early-start group by 2 days. Limitations of the study include small sample size and that the study group was not representative of a typical ICU population. About half of the study population had tropical infections and obstetric complications. However, it is worth noting that 17% of patients in the usual-start group recovered kidney function before initiation of RRT (62).

Meta-analysis of 15 studies by Karvellas et al. (63) concluded that early initiation of RRT in ICU patients with AKI may have a favorable impact on survival. It should be recognized that the findings of this study were based on prospective and retrospective studies of varying quality and heterogeneity and that there were only two randomized controlled trials. Observational data showing improved outcomes may reflect inclusion of patients with a lesser degree of organ injury, whose outcomes would have been better regardless of treatment strategy. Some patients with severe AKI recovered kidney function, and if these patients were included in the “late” group, then the mortality for late group would be less. Furthermore, the argument that initiation of RRT early during the ICU stay is associated with increased survival may not be related to timing of initiation but rather due to the characteristics of patients who develop AKI early in the ICU stay compared to those who develop AKI several days or weeks after ICU admission. In addition, several of these studies used BUN as a surrogate marker for the duration of AKI (63). Yet, BUN is an imperfect surrogate marker for time and uremia because urea generation is not constant between patients or even within an individual patient over time.

While in some patients, preemptive RRT may improve outcome, it has been argued that a strategy of

early initiation of RRT might expose patients to the risk of dialysis in those who would recover renal function with conservative therapy alone and may subject patients to further renal damage, delaying renal recovery (64). Repeated episodes of transient intradialytic hypotension can prolong AKI and reduce the chance of renal recovery (65). Although IHD may have higher likelihood of hemodynamic instability (65), episodes of hypotension can also occur with CRRT and SLED (2,66). Additionally, blood contact with dialyzer membrane may incite an inflammatory response that can exacerbate AKI, but this inflammatory stimulus was mostly caused by cellulose dialyzer membranes, which are now infrequently used (67).

Other potential risks of preemptive but unnecessary RRT in patients who would have had renal recovery are shown in **TABLE 40.5**. Patients are exposed to the risk of complications related to vascular access, subtherapeutic levels of essential medications, and electrolyte derangements. Medication dosing in AKI during RRT has been inadequately examined in particular for CRRT and SLED (64). Limited knowledge about proper dosing of antibiotics for CRRT can lead to suboptimal levels of antibiotics, which are potentially lifesaving in septic shock. Another complication of RRT is depletion of essential nutrients and electrolytes such as phosphorus. Hypophosphatemia is a common occurrence in patients on CRRT and has been linked to prolong recovery from critical illness (68).

TABLE 40.5 Risks of Renal Replacement Therapy

Risks	Examples
Hemodynamic instability	Hypotension, arrhythmias
Access-related complications	Bleeding, thrombosis, hemothorax, pneumothorax, air embolus, arteriovenous fistula formation
Electrolyte disturbances	Hypophosphatemia, hypokalemia, hypocalcemia
Anticoagulation-related complications	Bleeding, heparin-induced thrombocytopenia, citrate-induced alkalosis, and hypocalcemia
Impair renal recovery	
Dialyzer reaction	Anaphylaxis
Subtherapeutic levels of essential medications	Antibiotics, antiepileptic drugs
Depletion of micronutrients	Amino acids and proteins, vitamins, and trace mineral
Limit patient mobility	
Hypothermia	

From Clark EG, Bagshaw SM. Unnecessary renal replacement therapy for acute kidney injury is harmful for renal recovery. *Semin Dial* 2015;28(1):6–11; and Finkel KW, Podoll AS. Complications of continuous renal replacement therapy. *Semin Dial* 2009;22(2):155–159.

Based on the available data and literature, there is no consensus about the optimal timing and initiation of dialysis. It is advised to initiate RRT when life-threatening changes in fluid, electrolytes, and acid–base balance occur (69). However, most nephrologists will initiate RRT before the overt complications of AKI occur while considering age, severity of illness, presence of other organ dysfunction, and degree of kidney disease. Our capacity to predict which AKI will worsen and need RRT and which AKI will improve obviating the need for RRT is relatively poor. The clinical decision to start RRT should be based on the overall clinical context, presence of modifiable conditions by RRT, and the trends of laboratory values rather than single BUN and creatinine levels alone (69). Currently, Initiation of Dialysis EArly versus Late in Intensive Care Unit (IDEAL-ICU) study and Artificial Kidney Initiation in Kidney Injury (AKIKI) are two multicenter randomized controlled trials conducted in France investigating the impact of the timing of RRT initiation on outcome (70,71).

Fluid Overload

Fluid overload is a common indication for initiating RRT. Several observational studies have demonstrated that the degree of fluid accumulation in critically ill patients with AKI is linked to adverse outcomes including mortality (72–74). Furthermore, it has been reported that fluid overload at time of RRT initiation has been associated with increased mortality and decreased renal recovery (75,76). Possible explanations for these associations include failure to recognize AKI due to creatinine dilution, direct tissue edema leading to impaired renal perfusion, and increased risk of other complications such as prolonged ventilator-dependent respiratory failure and sepsis (77). It is unknown whether fluid overload is the result of more severe kidney disease or that fluid overload contributes to the cause of kidney disease. Also, higher volume administration may be suggestive of a more severe inflammatory state with greater vasodilation and capillary leak. Future studies are necessary to determine whether fluid overload is directly causing adverse outcomes or merely it is a confounding sign of illness severity (77).

After initial resuscitation, it is important to avoid unnecessary fluid buildup to limit later requirements of fluid removal. Patients should be evaluated routinely for fluid overload, and the rate and final goal of fluid removal must be carefully assessed and frequently reassessed. The rate of removal depends on severity of fluid overload and its complications, expected fluid intake, estimated vascular refilling, and hemodynamic tolerance to fluid removal from the intravascular space. There is no consensus in the method to evaluate fluid balance. The most commonly used methods to calculate fluid balance are monitoring changes in body weight relative to baseline and tallying daily fluid balance. Fluid overload is often defined as greater than 10% increase in body weight relative to baseline. Bioimpedance analysis and relative blood volume monitor may assist in estimating the amount of fluid removal, but these techniques are not commonly utilized (10,78). While there are tools such as pulse pressure variations and passive leg raising to help predict the hemodynamic tolerance to fluid removal, these tools are not perfect. Often, a fluid removal trial (reverse fluid challenge) is the only option left to determine the hemodynamic tolerance of fluid removal with RRT.

The impact of different CRRT fluid management strategies on outcomes has not been studied well. Michael et al. (79) investigated patients retrospectively who developed AKI after stem cell transplantation and showed that maintaining euvolemia with aggressive use of diuretics and early initiation of RRT was associated with increased survival. In the absence of randomized control trials, whether correcting fluid overload with CRRT improve outcomes remains uncertain.

Modality of Renal Replacement Therapy

As mentioned previously, there are multiple modalities that can be used in the treatment of AKI, which include conventional IHD, various modalities of CRRT, PIRRT, and PD. The optimal modality of RRT in ICU has been the subject of ongoing controversy. Among ICU patients treated with RRT, CRRT is the most common initial modality used. In the observational multinational study, Beginning and Ending Supportive Therapy for the Kidney (BEST Kidney), 80% of the patients with AKI in the ICU were initially treated with CRRT, followed by intermittent RRT in 16.9%, and PD and SCUF in 3.2% (2).

Intermittent Renal Replacement Therapy versus Continuous Renal Replacement Therapy

The impact of RRT modality in ICU patients with AKI on long-term kidney function is unknown, and there does not appear to be an effect on mortality. In comparison to conventional CRRT, IHD may hinder renal recovery by conferring greater hemodynamic instability (34). Removing relatively large volume of fluid

in short period of time can cause hypotension and secondary renal ischemia. On the other hand, CRRT allows for more gradual removal of fluid and solutes and has been associated with greater hemodynamic stability. A retrospective cohort study of 2,004 patient pairs by Wald et al. (34) revealed that the risk of chronic dialysis was significantly lower among patients who received CRRT initially versus IHD with hazard ratio 0.75 (95% CI 0.65 to 0.87). This relation was stronger among patients with preexisting chronic kidney disease and heart failure (34). Likewise, Uchino et al. (80) analyzed recovery of kidney function in 1,218 patients who received RRT in the BEST study. Although hospital survival was lower in CRRT group (35.8 vs. 51.9%, $p < 0.0001$), dialysis independence at hospital discharge was more common in CRRT group (85.5 vs. 66.2%, $p < 0.0001$) (80). Another study by Bell et al. (81) from the Swedish Intensive Care Nephrology Group (SWING) reported on outcomes in 2,202 patients from 32 ICU in Sweden who underwent RRT. Mortality at 90 days was around 50% for both groups. Of patients who survived, there was a higher proportion of patients in IHD group who were dialysis dependent compared to CRRT group, 16.5% versus 8.3%, respectively (81). The major limitation of these studies relates to the possibility of residual confounding and, in particular, baseline factors that may have influenced the initial selection of RRT modality according to treatment intention (81).

Currently, randomized controlled trials has not shown that CRRT is superior to IHD in terms of survival and renal survival. There are only few small-sized randomized controlled trials that have investigated the optimal modality. One of the most notable is the Hemodiafe Study by Vinsonneau et al. (82), which was a randomized controlled trial of 360 patients across 21 ICUs in France to either IHD versus CVVHDF. Patients were well matched with regard to severity of illness, with more than 85% of patients requiring vasopressor support and more than 95% ventilator dependence. There was no significant difference in mortality at 60 days with mortality rate of 68% in IHD group versus 67% in CVVHDF ($p = 0.98$). There was no difference in hemodynamic intolerance, number of ICU and hospital days, and renal recovery. After discharge from the ICU, 6 of 61 (10%) patients remained dependent on dialysis in the IHD group compared with 4 of 61 (7%) patients in the CVVHDF ($p = 0.5$). After hospital discharge, only one patient from CVVHDF remained dependent on dialysis. Of note, the average treatment time for IHD in this study was 5.2 hours, which is longer than typical IHD treatment, and IHD was prescribed about three times a week (82).

Another study is the Stuivenberg Hospital Acute Renal Failure (SHARF) study by Lins et al. (83), which was a multicenter randomized controlled trial of 316 ICU patients in Belgium with AKI to either IHD versus CVVH. Patients underwent IHD (or IRRT) daily with each session lasting about 4 to 6 hours. In-hospital mortality was 62.5% in IHD group versus 58.1% in the CVVH group ($p = 0.43$). There was no significant difference in renal recovery and ICU and hospital days (83). A recent meta-analysis by Bagshaw et al. (84), involving nine randomized controlled trials with 1,403 patients, showed that the initial RRT modality did not seem to affect mortality or renal recovery. However, the authors identified numerous issues related to study design, conduct, and quality. They concluded that further high-quality studies, which are suitably powered are needed to address this issue (84).

PIRRT have become an increasingly used modality of RRT in the ICU that theoretically offers advantages of both IHD and CRRT in the ICU. SLED is becoming popular due to the lower cost, and it is the mode of RRT in the ICU of hospital centers without the capabilities of CRRT. The available studies have shown that SLED and CRRT have similar outcomes (85,86). The hemodynamic stability is similar in

both groups. The correction of acidosis is faster, and less heparin is required with SLED (85). Study by Schwenger et al. (86) is a prospective, single-center randomized clinical trial of 232 patients in a surgical ICU, who were randomized to either 12-hour SLED versus 24-hour predilutional CVVH. The target dose of CVVH was 35 mL/kg/h. The 90-day mortality rate was similar between groups with 49.6% in SLED versus 55.6% in CVVH groups ($p = 0.43$). In this study, hemodynamic stability did not differ between groups during the treatment. Interestingly, SLED group had significantly fewer days of mechanical ventilation (17.7 ± 19.4 vs. 20.9 ± 19.8, $p = 0.047$) and fewer ICU days (19.6 ± 20.1 vs. 23.7 ± 21.9, $p = 0.04$). The SLED group required fewer blood transfusions (1,375 ± 2,573 mL vs. 1,976 ± 3,316 mL, $p = 0.02$) and had a considerable reduction in nursing time and support for RRT ($p < 0.001$) which resulted in lower costs (86).

Although many consider CRRT as the preferred therapy in the ICU (87), the predominance of the available evidence does not support a benefit of CRRT over IHD or PIRRT (4,82,84,88–90). Studies suggesting decreased renal recovery raise concern that episodes of intradialytic hypotension can impair recovery of kidney function; however, it should be recognized that the studies showing these findings are predominantly reported in observational studies (34,80,81) and that many of the published randomized trials have not observed this (4,82–84,88).

Hemofiltration versus Hemodialysis

Many clinicians prefer hemofiltration with the preconception that convection can remove middle-sized cytokines and reduce systemic inflammatory response; however, clinical studies have not shown significant and sustained reduction of cytokine concentration or improvement in clinical outcome with hemofiltration. The clearance of cytokines through high-volume CVVH is marginal in comparison to the greater endogenous production. Also, anti-inflammatory mediators are probably cleared, which can theoretically worsen the overall inflammatory state (14,53). The role of hemofiltration in sepsis is discussed in greater detail in the next section of this chapter.

The OMAKI (Optimal Mode of RRT of AKI) study by Wald et al. (91) randomized 78 ICU patients to either CVVH or CVVHD. Both modalities were delivered at 35 mL/kg/h. Mortality (54% CVVH; 55% CVVHD) and dialysis dependence in survivors (24% CVVH; 19% CVVHD) at 60 days were similar. Interestingly, there was a trend toward reduced vasopressor requirements among CVVH group during the first week of treatment (91). Recent meta-analysis by Friedrich et al. (92) concluded that there was no significant clinical benefit of hemofiltration on mortality, RRT dependence, vasopressor use, and organ dysfunction compared to hemodialysis. However, it is important to point out that this study showed that filter survival time was reduced by one-third, on average of 7 hours, with CVVH in comparison to CVVHD. There was a 50% increase in the number of filters despite the use of heparin and predominantly prefilter replacement. Combined with its higher fluid requirements to achieve similar small molecule clearance (need 15% to 20% more) and frequent filter clotting suggest that hemofiltration may consume more resources than hemodialysis (92).

Peritoneal Dialysis

High-volume PD can be an acceptable alternative to IHD and CRRT in the treatment of AKI in the ICU especially in low-resource regions. Because local renal hemodynamics are better preserved without extracorporeal circulation, there is a theoretical benefit of increased renal recovery with PD. PD may be

more physiologic with less inflammation provoked than extracorporeal circulation with exposure to synthetic surfaces of the dialyzer. In the acute setting, PD is often delivered via a flexible catheter and with the use of a cycler. The minimum standardized Kt/V urea should be at least 1.7 per week. The most commonly described complication related to acute PD is peritonitis, which can reach as high as 40%, followed by mechanical complication (93). In a single-center study in Brazil by Ponce et al. (94), peritonitis occurred in 12% after mean of 5 days of therapy and 7% had mechanical complication of catheter.

There are limited studies examining the impact of acute PD on clinical outcomes. Study by Gabriel et al. (95) randomized 120 patients with AKI to high-volume PD (daily Kt/V = 0.65) with IHD (Kt/V = 1.2 per session) provided six times per week. Hospital mortality, renal recovery, and metabolic control were similar in both groups. The PD regimen consisted of 2-L exchanges with 30 to 60 minutes of dwell time, resulting in total PD fluid of 36 to 44 L/d and 18 to 22 exchanges per day (95). These findings are in contrast to study by Phu et al. (96), which randomized 70 patients to high-volume PD versus CVVH. PD regimen was 2-L exchanges with 30-minute dwell time (~70 L/d). Majority of the study patients suffered from severe malaria and other sepsis. The mortality rate was 47% in the PD group compared to 15% in CVVH group ($p = 0.005$). CVVH group had a faster resolution of acidosis. It was postulated that the poor outcome in the PD group was attributed to accelerated growth of malarial parasite due to the presence of high splanchnic blood glucose resulting from the glucose-enriched PD fluid (96). Meta-analysis by Chionh et al. (93) concluded that there was no difference in mortality between PD and ECBP in AKI. There is a need for well-designed studies in this area.

Intensity of Renal Replacement Therapy

There are multiple randomized controlled trials that have provided guidance for dialysis dosing in AKI in the ICU. Initial studies have shown improvement in mortality with higher intensity dosing for CRRT (97). One of the major landmark studies is the United States–based Veterans Affairs/National Institutes of Health Acute Renal Failure Trial Network (ATN) study, which randomized 1,124 patients in the ICU with AKI to high- and low-intensity dosing of RRT. This study categorized the critically ill patients by the Sequential Organ Failure Assessment (SOFA) score to hemodynamically stable and hemodynamically unstable groups (50). The hemodynamically stable group was randomized to IHD three times a week versus six times a week. The hemodynamically unstable group was randomized to either CVVHDF at 35 mL/kg/h versus 20 mL/kg/h or SLED six versus three times a week. The single-pool Kt/V was aimed for 1.2 to 1.4. The rate of death from any cause by day 60 was 53.6% with intensive therapy and 51.5% with less-intensive therapy [odds ratio (OR) 1.09, 95% CI 0.86 to 1.40, $p = 0.47$]. There was no significant difference between the two groups in the RRT duration, renal recovery, and recovery of nonrenal organ failure. Dialysis independence at day 60 in those who survived was around 34% for both groups ($p = 0.75$) (50). Second large study was the Randomized Evaluation of Normal versus Augmented Level (RENAL) Replacement Therapy, which randomized 1,508 patients across 35 ICUs in Australia to postdilution CVVHDF 40 mL/kg/h versus 25 mL/kg/h (51). The 90-day mortality was 44.7% in high-intensity and 44.7% in the low-intensity group. The dialysis dependence at 90 days was reported in 6.8% of survivors in high-intensity versus 4.4% in intensity group (OR 1.59, 95% CI 0.86 to 2.92, $p = 0.14$). There was no difference in renal recovery, ventilator-dependent days, ICU, and hospital days (51).

There are limited studies investigating dialysis dosing in PIRRT. In the ATN study, less than 5% of

the treatments were SLED treatments (50). A study by Faulhaber-Walter et al. (98) conducted a prospective randomized control trial of standard versus intensified extended dialysis in patients with AKI in ICU in a single-center tertiary center. A total of 156 patients with AKI requiring RRT were randomly assigned to receive standard dialysis [dosed to maintain plasma urea levels between 120 and 150 mg/dL (20 to 25 mmol/L)] or intensified dialysis [dosed to maintain plasma urea levels <90 mg/dL (<15 mmol/L)]. No differences between intensified and standard treatment were observed for survival by day 14 (70.4% vs. 70.7%) or day 28 (55.6% vs. 61.3%), or for renal recovery in survivors by day 28 (60.0% vs. 63.0%) (98).

Meta-analysis of 12 randomized or quasi-randomized clinical trials by Van Wert et al. (99) showed no difference in high versus low intensity therapy. High-intensity therapy groups included effluent rates of >30 mL/kg/h, or at least six sessions per week of IHD or SLED compared to standard-dosage therapies which included CRRT with effluent flow rates of <30 mL/kg/h or two to four sessions per week of IRRT (99). The prescribed dose of CRRT should be higher to account for loss time on CRRT due to interruptions. In the ATN study, the dose delivered was 89% of that prescribed for higher intensity treatment (50). In contrast, another study reported that patients received only 68% of their prescribed dose of CRRT (100). The reported prescribed clearance overestimated the actual delivered clearance by 24% (52). This gap was related to decrease in filter function by assessing the FUN/BUN ratio (where FUN is filtrate urea nitrogen). To assess adequacy of CRRT, solute clearance should be measured rather than estimated by the effluent volume. The other major interruptions were related to filter clotting, disconnection for procedures, and change in patient clinical status (52). Study by Overberger et al. (101) showed that IHD and CRRT were the most popularly used modalities of RRT, with SLED and other "hybrid" treatments used in fewer than 10% of patients. IHD was most commonly provided on a thrice-weekly or every-other-day schedule, with only infrequent assessment of the delivered dosage of therapy. Majority of the practitioners did not routinely monitor Kt/V and did not dose CRRT on the basis of patient weight (101).

For IHD or PIRRT, the recommended minimum dose of dialysis is Kt/V of 1.3 per treatment (corresponding to urea reduction ratio >0.7) scheduled three times per week (69). For CRRT, the recommended effluent volume, which is the dialysis dose, is at least 20 to 25 mL/kg/h. In order to ensure the target dose, CRRT dose should be prescribed at 25 to 30 mL/kg/h to account for the interruptions in treatment. The dose of dialysis should be assessed frequently and adjusted to achieve electrolytes, acid-base, solute, and fluid balance (69).

RENAL REPLACEMENT THERAPY FOR SPECIAL CIRCUMSTANCES

Respiratory Failure

Acute respiratory distress syndrome (ARDS) is common in the ICU, and it is characterized by alveolar damage resulting in increased permeability of the alveolar–capillary barrier and accumulation of extravascular fluid. Mortality is high with patients with ARDS, in the range of 25% to 40%, and the predominant causes of death are sepsis and multiorgan failure rather than hypoxemia (102). AKI occurs frequently in patients with ARDS, with reported incidence around 44% in one study (103), and the

presence of AKI raises the risk of mortality to approximately 60% (102). Patients with ARDS are susceptible to fluid retention, which occur through multiple mechanisms. The increased thoracic pressures caused by the positive end-expiratory pressure from the ventilator results in decreased renal perfusion and activation of water- and sodium-retaining hormonal systems (104). Greater fluid retention worsens interstitial edema in the lung parenchyma, compromising lung function and hypoxia. In addition, injured lungs from mechanical ventilation stimulate cytokine release, which can exacerbate AKI, which then reduces cytokine clearance further, resulting in a vicious cycle (102,105,106).

Lung-protective ventilation using low tidal volumes around 6 mL/kg is the mainstay of therapy to improve clinical outcomes (10,107), which can be viewed as “kidney-protective ventilation” (10). In addition, measures aimed to reduce fluid and inflammatory mediators may help improve outcome with ARDS. With fluid overload and ARDS, CRRT may be used to diminish pulmonary edema and allow for less intense ventilator settings, shielding the lung from further injury. Patients are often left with a combined respiratory and metabolic acidosis as a result of permissive hypercapnia from using low tidal volume and kidney disease that often occurs in these patients. In these situations, CRRT can help restore acid–base balance (10).

There is conflicting evidence whether CRRT has beneficial effects beyond fluid removal and metabolic control such as improvement in gas exchange or cytokine removal resulting in enhanced recovery of ARDS. Several studies have shown improvement in outcome with CRRT including the use of high-volume hemofiltration (105,108–110), while other studies have shown unimpressive results (111). A study by Vesconi et al. (109) is a prospective, multicenter observational study comparing more intensive (CRRT ≥35 mL/kg/h, IRRT ≥6 sessions/wk) or less intensive (CRRT <35 mL/kg/h, IRRT <6 sessions/wk). Although there was no difference in mortality, shorter duration of mechanical ventilation was observed among survivors in the more intensive group in addition to shorter ICU stay (109). Timing of dialysis is another matter of debate. A study by Han et al. (105) showed that early initiation of CRRT, defined as within 12 hours of presentation of ARDS, is associated with improvement in oxygenation and shorter duration of mechanical ventilation compared to late initiation of CRRT after 48 hours. However, study by Hoste et al. (111) observed no improvement in oxygenation in 37 patients with ARDS who received CVVHDF with zero fluid balance. This finding suggests that the benefits seen with CRRT in patients with ARDS may be related to reestablishing fluid balance rather than removing inflammatory mediators.

Since clearance of complement and cytokine depends mainly on adsorption and less on convective force (112,113), there may be a role for cytokine-adsorbing hemofilter in the treatment of ARDS. A study by Matsuda et al. (114) showed that there were decreased levels of cytokines and improved survival rate in patients with ARDS complicated by renal failure who were treated with cytokine-adsorbing hemofilter. Further studies are needed to validate the efficacy of cytokine-adsorbing hemofilters.

In cases of severe but reversible cardiopulmonary failure, extracorporeal membrane oxygenation (ECMO) and pumpless CO_2 removal systems (PECLA) are utilized to support lung-protective ventilation strategies and to improve CO_2 removal and respiratory acidosis. ECMO is associated with high incidence of AKI, reaching to 70% to 85%, and those patients who require RRT have even higher risk of mortality, independent of confounding variables. Fluid overload occurs frequently in patients who are on ECMO and is a common indication to initiate RRT in addition for metabolic control. Cumulative fluid overload

is associated with increased mortality, prolonged mechanical ventilation, and ICU stay (75,76). Improvement in fluid balance is associated with enhanced pulmonary function and earlier weaning of ECMO. CRRT is the most common modality used for RRT in ECMO because of its ability to make rapid changes to fluid removal while maintaining hemodynamics. Although fluid overload at time of CRRT initiation was associated with increased mortality, correction of fluid overload did not appear to improve survival (115). In patients who required CRRT, prolonged ECMO duration and higher mortality were observed, but this association may reflect underlying higher severity of illness (116).

There are three principal methods to provide CRRT for patients on ECMO: (a) incorporate an in-line hemofilter, (b) incorporate a traditional CRRT device into the ECMO circuit, and (c) perform CRRT through venous access independent of ECMO circuit (117). In the first scenario, the in-line hemofilter is typically inserted after the pump, which provides forward blood flow to the hemofilter, and before the oxygenator, which can help trap air clot in case of complications (**FIGURE 40.3**). The blood after passing through the hemofilter is returned to the proximal limb of the ECMO circuit, creating a shunt. Because of an existence of a shunt, an ultrasonic probe is attached to arterial return line to measure the actual flow delivered to the patient. The hemofilter blood-flow rate is calculated by subtracting the flow delivered to the patient from the total ECMO blood-flow rate. The hemofilter blood-flow rate can be adjusted by using a stopcock or other flow-restricting device; however, this can result in turbulent flow, increasing the risk of hemolysis and thrombus. Because the hemofilter is designed for high pressure system, it does not work well for diffusion. It is primarily uses convection as its primary means of clearance. The amount of replacement fluid is controlled by an intravenous infusion pump, which is integrated into the circuit. The disadvantages of this circuit are the inaccuracy of fluid removal and absence of pressure monitoring, which can lead to delayed detection of clotting or rupture of filter (117).

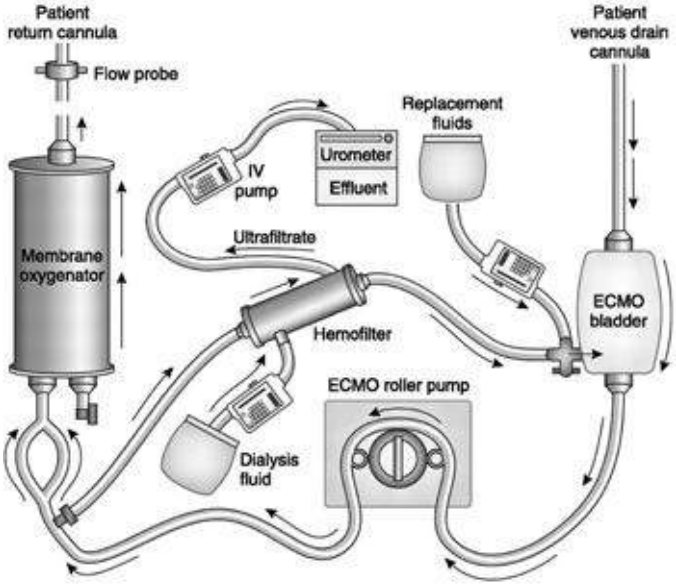

FIGURE 40.3 Using an in-line hemofilter during extracorporeal membrane oxygenation. Renal replacement therapy using an in-line hemofilter during extracorporeal membrane oxygenation (ECMO). As blood comes from the patient via the venous drain cannula, it goes through the ECMO bladder to the ECMO pump, to the membrane oxygenator, and back to the patient via a return cannula. Blood is shunted from the circuit to the in-line hemofilter and returned to the ECMO pump. Fluid (ultrafiltrate) can be controlled using an intravenous (IV) pump. Replacement or dialysis fluid can be used for solute clearance and/or to achieve metabolic control. [Reprinted with permission from Askenazi DJ, Selewski DT, Paden ML, et al. Renal replacement therapy in critically ill patients receiving extracorporeal membrane oxygenation. *Clin J Am Soc Nephrol* 2012;7(8):1328–1336.]

In the second scenario, the CRRT machine is usually connected to the venous limb of the roller-head ECMO circuit before the pump (**FIGURE 40.4**). The blood returns from the CRRT to the ECMO circuit near the venous CRRT connection and before the ECMO (117). If the ECMO pump is centrifugal, it is necessary to integrate the CRRT machine after the pump because of the risk of air entrapment. The reconnection of the return blood from CRRT device should be before the oxygenator to trap air or clots before it return to the patients. Additional anticoagulation is not necessary since the ECMO circuit is heparinized. Furthermore, the life span of CRRT that is part of the ECMO circuit is longer than when it is independent. Also, integration of CRRT provides more accurate assessment of fluid removal (116). The pressure alarms for CRRT may need to be adjusted when incorporating into ECMO. Typically, the access pressure alarms are negative; however, when CRRT is operating in series with ECMO, the positive pressure at the entry point of the CRRT machine will create pressures close to zero or positive. Some machines (including Gambro, Prismaflex, and the Braun Diapact) allow clinicians to adjust alarm while other machines (including NxStage, Fresenius 2008K, and older Gambro Prisma) do not have these capabilities. Alternatively, flow restrictors can be used to reduce the pressure the CRRT circuit; however, this can increase risk for hemolysis and thrombosis (117).

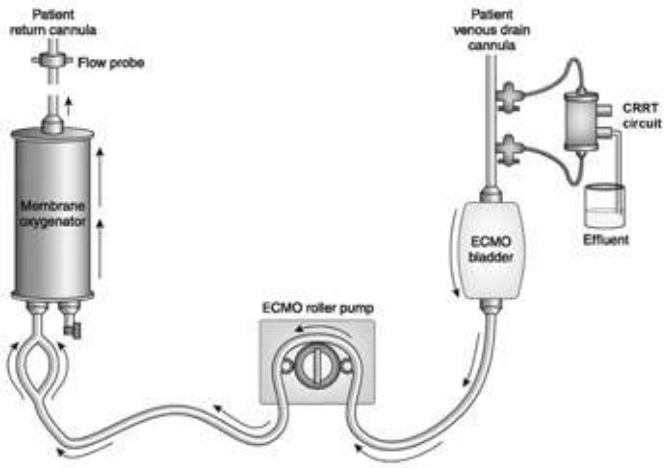

FIGURE 40.4 Incorporating renal replacement machine during extracorporeal membrane oxygenation. Renal replacement therapy (RRT) using RRT machine during extracorporeal membrane oxygenation (ECMO). If the ECMO circuit uses a roller pump, a proportion of the circuit blood comes from the patient via the venous drain cannula and enters the RRT machine where replacement, dialysis, and ultrafiltration occur. Blood from the RRT machine then goes back to the ECMO bladder to the ECMO pump, the membrane oxygenator, and back to the patient via a return cannula. If a centrifugal pump is used, the RRT machine must be connected after the ECMO bladder to prevent air entrapment. [Reprinted with permission from Askenazi DJ, Selewski DT, Paden ML, et al. Renal replacement therapy in critically ill patients receiving extracorporeal membrane oxygenation. *Clin J Am Soc Nephrol* 2012;7(8):1328–1336.]

Since ECMO requires high blood flow to support the circuit, it requires a large-diameter cannula, which poses additional risk to patients. In recent years, studies have looked into low-flow CO_2 removal using a hollow-fiber gas exchanger (**FIGURE 40.5**) (118,119). Conventional CRRT can be used by integrating it into a series after the roller pump (118). Blood flow typically ranges from 300 to 500 mL/min. In a small observational study of 10 ICU patients with ARDS and multiorgan failure by Forster et al. (118), low-flow CO_2 removal improved respiratory acidosis (average reduction of 17.3 mm Hg pCO_2) with a concomitant rapid correction of arterial pH and improvement of hemodynamics with reduction of vasopressors. Low-flow CO_2 did not affect systemic oxygenation, which would require

ECMO in settings of severe hypoxia (118). Although not as effective as ECMO, low-flow CO_2 removal can help reduce tidal volume and potentially benefit patients with severe cases of ARDS.

Low-flow CO_2 removal integrated into a renal-replacement circuit can reduce acidosis and decrease vasopressor requirements. *Crit Care* 2013;17(4):R154.]

Sepsis

Sepsis is the leading cause of death in the ICU, especially when complicated by AKI (120). Cytokine and other inflammatory mediators play a role in the pathogenesis of septic shock and sepsis-related AKI (121). There is correlation between high levels of cytokines and mortality (122). The role of EBCP in removing cytokines and other inflammatory mediators to impact clinical outcomes remain uncertain. Depending on the pore size of the dialyzer membrane, majority of the cytokines that are cleared are water-soluble with midrange molecular weights ranging 5 to 51 kDa (33). **TABLE 40.6** shows the convective removal of selected cytokines and mediators. Since hemofiltration is considered the preferred modality for middle molecule clearance, some experts have argued that CRRT using convective clearances such as CVVH or CVVHDF should be used at higher prescribed doses of 30 to 35 mL/kg/h in the setting of septic AKI (123). However, traditional CVVH has not been shown to significantly reduce plasma cytokine levels and influence clinical outcomes (124). Earlier studies demonstrated an initial reduction in cytokine levels after starting CVVH followed by increase in cytokine levels to baseline within hours (125,126). The initial reduction is attributed to adsorption of cytokines to the hemofilter membrane, which then becomes saturated. Currently, exact timing of RRT has not been defined for sepsis-related AKI, and recent studies have not shown any clinical benefit of early CRRT initiation (124,127). Early application of CVVH at standard dosing of 25 mL/kg/h resulted in greater severity of organ failure in one randomized study of 80 ICU patients (124). A recent retrospective review of 120 ICU patients found no difference in dialysis requirement and mortality in “early” versus “late” start CRRT for septic shock and AKI (127).

TABLE 40.6 Sieving Coefficient of Inflammatory Mediators

Mediator	Molecular Weight (Da)	Sieving Coefficient
AA mediators	600	0.5–0.91
Bradykinin	1,100	–
Endothelin	2,500	0.19
C3a/C5a	11,000	0.11–0.77
Factor D	24,000	–
MDS	600–30,000	–
LPS	67,000	–
LPS fragments	>1,000–20,000	–
TNF-α (trimer)	17,000 (54,000)	0.0–0.2
sTNFr	30,000–50,000	<0.1
IL-1	17,500	0.07–0.42
IL-1ra	24,000	0.28–0.45
IL-6	22,000	–
IL-8	8,000	0.0–0.48
IL-10	18,000	0.0
INF-γ	20,000	–

From Schetz M. Non-renal indications for continuous renal replacement therapy. *Kidney Int* 1999;56:S88–S94, with permission.

There are four main techniques investigated for cytokine removal in sepsis: high-volume hemofiltration, high-cutoff techniques, combined plasma filtration adsorption, and polymyxin B hemoperfusion. There is suggestion that early short-term, high-volume hemofiltration may be a therapeutic value in the treatment of intractable septic shock. Hemodynamic and metabolic response improved in a small prospective study involving 20 patients with refractory septic shock who underwent 4 hours of 35 L of ultrafiltrate, followed by CVVH for 4 days (128). However, other studies utilizing high-volume hemofiltration, as defined as an effluent rate greater than 50 mL/kg/h, failed to show promising results in sepsis (108,129). In the hIgh VOlume in Intensive caRE (IVOIRE) study, 140 ICU patients with catecholamine-dependent septic shock and AKI were randomized to high-volume hemofiltration at 70 mL/kg/h versus standard-volume hemofiltration at 35 mL/kg/h for 96 hours. High-volume hemofiltration failed to improve mortality, hemodynamic profile, or organ function (129). Investigators have also shown that even extra high-volume hemofiltration with doses reaching up to 85 mL/kg/h had no impact on mortality and renal outcomes in sepsis (130). Finally, a recent meta-analysis by Clark et al. (131) of four randomized controlled trials using high-volume hemofiltration, including 470 patients, showed no difference in mortality in addition to renal recovery, vasopressor reduction, and ICU stay. There are complications that can occur with high-volume hemofiltration such as electrolyte abnormalities, excessive antibiotic removal, and micronutrient depletion (131). Based on these findings, no specific recommendations regarding the use of high-volume hemofiltration can be supported for sepsis and septic AKI.

In recent years, high-cutoff membranes with larger pore size have been introduced to remove greater amount of cytokines (132,133). Treatment using high-cutoff membranes has shown enhanced immune cell function and survival in animal models of sepsis (134). In a pilot study by Morgera et al. (135), high-cutoff hemofiltration using a hemofilter with a cutoff point of about 60 kDa had a beneficial effect on reducing norepinephrine requirement in septic patients and was superior to conventional hemofiltration in

clearing interleukin-6 and interleukin-1 receptor antagonist in septic patients. Although high-cutoff hemofiltration has shown greatest cytokine removal in terms of sieving and clearance in comparison to all other approaches, it is associated with greater plasma protein losses including albumin (132,135). Additional studies are needed to determine the efficacy of high-cutoff hemofiltration in sepsis.

Another therapy is coupled plasma filtration and adsorption (CPFA), which allows for removal of large soluble inflammatory mediators. In contrast to high-volume high filtration which removes molecules less than 45 kDa, plasma filtration removes below 900 kDa (123). This extracorporeal circuit consists of a plasma filter, a resin cartridge, and a high-flux dialyzer (**FIGURE 40.6**). The plasma filter separates plasma from blood and then the plasma passes through a synthetic resin cartridge for adsorption. Once the blood is reconstituted, it passes through another filter to remove fluid and small molecular weight toxins. Thus, CPFA and CRRT can function in series. The minimum volume of plasma treated per day should be 10 L, corresponding to a blood flow of 150 mL/min and a filtration fraction of 12% (136). In a small pilot study, CPFA was associated with decreased levels of vasopressors and improved immune function of leukocytes in sepsis (137). In an Italian multicenter study conducted by Livigni et al. (136), 192 ICU patients with septic shock were randomized to CPFA versus standard care. CPFA was performed daily for 5 days, lasting at least 10 h/d (136). The investigators found no statistical difference in hospital mortality (47.3% controls, 45.1% CPFA; $p = 0.76$), occurrence of new organ failures, or ICU-free days for first 30 days. The study was terminated early on the grounds of futility. One possible reason for a negative result was that nearly half of the patients randomized to the CPFA group were found to be undertreated. This indicates the poor feasibility of delivering this therapy. Majority of the centers encountered frequent clotting despite using heparin or citrate anticoagulation to maintain circuit patency. Also, the therapy was expensive. A subgroup analysis showed that those who received CPFA dose >0.18 L/kg/d had a lower mortality compared with controls (OR 0.36, 95% CI 0.13 to 0.99) (136).

A novel therapy undergoing investigation is polymyxin B direct hemoperfusion (PMX-DHP), which was developed in Japan in the 1990s. Polymyxin B is adsorbed to a polystyrene fiber in a hemoperfusion device that is used to bind and remove circulating endotoxin, which stimulate cytokine release in gram-

negative sepsis (138,139). Typical treatment course requires two PMX cartridges, administered 24 hours apart. Each treatment is 2-hour session at a blood-flow rate of approximately 100 mL/min through the circuit, using a standard IHD machine as a blood pump (140). Meta-analysis by Cruz et al. (141) reviewed 28 trials using PMX-DHP for severe sepsis, largely conducted in Europe and Japan, with a total cohort of 978 patients. Although there was heterogeneity among trials, PMX-DHP was associated with improvement in hemodynamics with overall mean arterial pressure increase by 19 mm Hg (95% CI 15 to 22 mm Hg; $p < 0.001$), significantly lower mortality risk (risk ratio 0.53, 95% CI 0.43 to 0.6), and improved oxygenation (PaO_2/FiO_2 ratio) (142). More recently in 2009, Early Use of Polymyxin B Hemoperfusion in Abdominal Sepsis (EUPHAS) is a prospective multicenter randomized controlled trial of 64 ICU patients in Italy with severe sepsis or septic shock who underwent emergent surgery for intra-abdominal infection that compared addition of two sessions of PMX-DHP versus standard therapy. The investigators demonstrated that PMX-DHP was associated with improved blood pressure, reduced organ failure, and improved survival. The absolute risk of death at 28 days improved significantly from 53% in the conventional group to 32% in the PMX-DHP group (adjusted HR 0.36, 95% CI 0.16 to 0.80) (142). The Evaluating the Use of Polymyxin B Hemoperfusion in a Randomized controlled trial of Adults Treated for Endotoxemia and Septic shock (EUPHRATES) trial (ClinicalTrials.gov identifier: NCT01046669) is currently enrolling patients in North America to investigate the safety and efficacy of polymyxin B hemoperfusion in patients with septic shock (140).

At the current level of evidence, the clinical significance of cytokine removal using blood purification technique is unknown (132). High-volume hemofiltration and CPFA have not been associated with significant improvement in clinical outcome in recent trials. Preliminary studies using polymyxin B hemoperfusion has a positive effect on arterial pressure, gas exchange, and mortality, and recent randomized controlled trials hopefully will provide definite conclusions regarding its role in sepsis.

Lactic Acidosis

Lactic acidosis occurs commonly in ICU patients with AKI who are treated with RRT, and it is associated with higher mortality. Up to one-third of the ICU patients have severe lactic acidosis as defined as serum lactate concentration >5 mmol/L and pH <7.35 (143). Lactic acidosis can be classified based on the presence (type A) or absence (type B) of tissue hypoxia. The kidney is the major lactate-consuming organ following the liver. Approximately 25% to 30% of the exogenous lactate is removed by the kidneys primarily through lactate metabolism rather than excretion. While acidosis inhibits hepatic lactic metabolism, the renal contribution to lactate removal increases from 16% at a pH of 7.45 to 44% at a pH of 6.75 to compensate for the hepatic loss of lactic metabolism. Even in the setting of reduced renal blood flow and endotoxemia, the kidney continues to remove lactate from circulation (144).

Initiating RRT for solely due to lactic acidosis with stable serum pH is controversial. Although RRT provides a means to correct severe acidemia from lactic acidosis, RRT is often futile in cases of severe lactic acidosis since many of these patients already have high mortality. After starting RRT, the decreased lactate levels may be related to improvement of clinical situation rather than clearance of lactate by RRT. In addition, even though lactate is cleared through RRT, its clearance is much lower than the mass quantity of lactate produced in severe lactic acidosis. For instance, study by Levraut et al. (145) showed that the median lactate clearance using bicarbonate-buffered CRRT was only 24.2 mL/min compared to median

endogenous clearance of 1,379 mL/min, thereby RRT accounted for <3% of the total body clearance. One should note that this study of lactate clearance was performed using relatively low level of RRT dosing with CVVHDF at Q_B 100 mL/min and Q_d 1,000 mL/h. Further studies are needed examining lactate clearance using different modalities and dosing of RRT. In general, lactate-buffered replacement solution should be avoided to prevent exacerbating hyperlactatemia, and bicarbonate-buffered solution is preferred to restore acid–base balance (144).

Liver Failure and Extracorporeal Liver Assist Devices

AKI occurs frequently in hospitalized patients with decompensated cirrhosis, reportedly around 20% (146). The common etiologies are prerenal azotemia, acute tubular necrosis (ATN), and hepatorenal syndrome (HRS). The pathophysiology in cirrhosis is distinguished by the development of splanchnic vasodilatation causing decreased effective circulating volume, which stimulates the renin-angiotensin-aldosterone system, sympathetic system, and nonosmotic release of antidiuretic hormone. This contributes to hypoperfusion of the kidneys and sodium retention, leading to ascites that is refractory to diuretics and ultimately HRS (147). Mortality in patients with cirrhosis who develop AKI is high especially when RRT is required. Often, these patients are in the ICU due to sepsis and multiorgan failure. CRRT is often employed over intermittent dialysis because many of these patients have hypotension that require ionotropic support and are susceptible for worsening hypotension with fluid removal.

Due to the extremely high mortality associated with AKI in ICU patients with liver failure, the role of RRT is controversial. Dialysis in patients with HRS who are not transplant candidates are unlikely to prolong length or quality of life. One study by Wong et al. (148) reported that the mortality rate was 94% in patients with liver failure who did not receive transplant, and half of these patients died within 8 days of receiving RRT. Discussions about goals of care should occur with the family early on especially when the patient is not considered a transplant candidate and/or the patient has developed severe shock with multiorgan failure, unlikely to survive. In situations where it is unclear if the patient may have renal recovery, a trial of RRT may be offered with the understanding that overall survival in patients with irreversible liver failure without the prospect for liver transplantation is still poor (147).

Extracorporeal liver assist devices (ELADs) can provide temporary liver support in patients as a bridge to liver transplantation or hepatic recovery. In general, ELADs can be categorized into biologic devices, which incorporate either whole animal livers or bioreactors with hepatocytes which provide excretory and synthetic liver function, and nonbiologic devices, which provide no synthetic functions but utilizes EBCP to remove endogenous hepatotoxins. Bioartificial livers currently remain experimental and are not discussed further in this chapter (149).

Recently, nonbiologic ELADs using albumin-based dialysis have been implemented to remove protein-bound substances such as bile acids that accumulate in patients with liver failure. These therapies include single pass albumin dialysis (SPAD), molecular absorbent recirculating system (MARS), and the fractionated plasma separation and adsorption (Prometheus). Since 1993, over 400 patients with liver failure have been treated with MARS worldwide. Treatment with MARS and other extracorporeal blood detoxification therapies result in significant removal of bilirubin, bile acids, tryptophan, short- and middle-chain fatty acids, aromatic amino acids, and ammonia. In addition, nitric oxide, renin, and aldosterone concentration have been reduced after treatment with MARS (150). Clearance rates for

albumin-bound substances vary between 10 and 60 mL/min. Studies have shown the use of albumin-based dialysis has been associated with improvement in hepatic encephalopathy, reduction in intracranial pressure (ICP), decreased level of bilirubin, and increased sodium level (149,151). While few studies showed improved hemodynamics, renal function, and urine output (151,152), others have noted disappointing renal and hemodynamic outcomes with the use of albumin-based dialysis (148,153). In addition, worsening coagulopathy and decrease in platelets were observed in patients with MARS (154). The major downsides of these studies are that all were small scale and none included renal outcomes or survival as their primary endpoint. Larger scale studies are necessary to determine the utility of these modalities.

Both SPAD and MARS are modified dialysis modalities that use albumin-containing dialysate. Toxin-rich blood passes along one side of a semipermeable membrane (that is not permeable to albumin), while albumin-enriched dialysate flows in the opposite direction, allowing for passage of unbound and bound toxins down their osmotic gradient. In SPAD, the albumin-rich dialysate is discarded after circulating through the dialyzer and then replenished, whereas in MARS, it is regenerated by using low-flux dialysis and two different absorbers to wash away or bind the toxins off the albumin.

The MARS system consists of three circuits: blood circuit, albumin dialysate circuit, and a bicarbonate-based dialysate circuit (**FIGURE 40.7**). The albumin dialysate circuit is interposed in between the blood and bicarbonate-based dialysate circuits. The MARS monitor (Teraklin AG, Rostock, Germany) has a single roller pump that pumps the albumin dialysate. This circuit is coupled to either a standard dialysis machine or CRRT machine. Using the standard venous dual-lumen central catheter, the blood leaves the patient and enters the hollow fibers of the MARSFlux filter (Teraklin AG, Rostock, Germany), which is a high-flux polysulfone membrane that is impermeable to albumin. The blood bathes in the albumin dialysate, allowing for exchange for protein-bound substances between the blood circuit and albumin dialysate circuit. Simultaneously, the water-soluble solutes that are nonprotein bound such as uremic toxins diffuse from the blood into the albumin circuit. Thus, the “spent” albumin dialysate leaving the MARS filter is saturated with albumin-bound liver toxins and water-soluble uremic toxins and is then pumped through the hollow fibers of a second dialyzer of either a standard HD or CRRT machine. The “spent” albumin dialysate is bathed in a fresh bicarbonate dialysate, allowing for diffusion of water-soluble uremic toxins into the bicarbonate dialysate circuit. The albumin dialysate leaves the second dialyzer and passes through two sequential columns, charcoal and then an anionic resin, both which help regenerate the albumin (149). The albumin circuit contains about 600 mL of 20% human serum albumin, and because the albumin is constantly regenerated, no additional albumin is required for the circuit. The duration of MARS treatment is typically 6 to 8 hours, and single treatment does not typically exceed 10 hours given the possible risk of albumin becoming a culture medium for bacteria. UFH can be prescribed to prevent the filter from clotting (1,000 to 2,000 IU heparin for priming followed by 250 to 500 IU/h continuous infusion). Both the blood and albumin pump speeds are around 150 to 200 mL/min. The dialysate flow rate can be set <300 mL/min if CRRT is used or 300 to 500 mL/min if a standard HD machine is used (149,150).

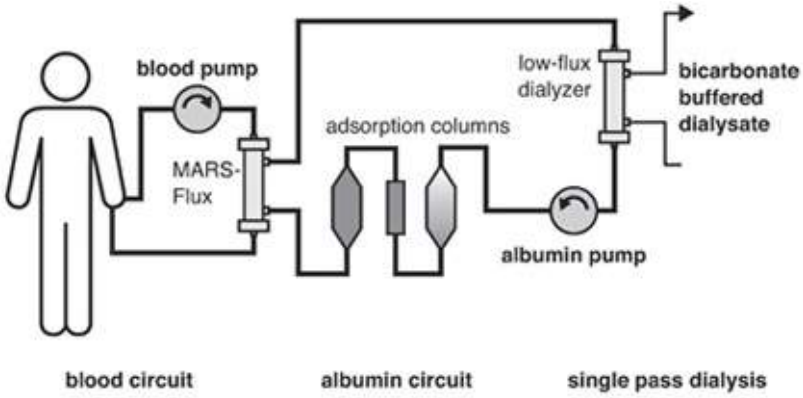

FIGURE 40.7 Schematic drawing of the molecular adsorbent recirculating system (MARS). (Reprinted with permission from Mitzner SR, Stange J, Klammt S, et al. *J Am Soc Nephrol* 2001;12:S75–S82.)

In the case of Prometheus, an albumin-permeable polysulfone filter (AlbuFlow) is utilized. Due to the high sieving coefficient, albumin (68 kDa) easily passes from blood into the secondary circuit. The filtered plasma with albumin-bound toxins flows through one or two adsorbers, which remove the liver toxin, and the purified plasma is returned to the blood side of the albumin filter and back to the patients. A traditional hemodialysis machine can be incorporated in series with the circuit to remove water-soluble toxins (155,156).

MARS and other extracorporeal blood detoxification therapies can be effective in treating patients with fulminant hepatic failure who are awaiting liver transplant or spontaneous liver recovery. Large multicenter controlled trials are necessary to confirm whether these therapies alter the natural course of liver failure including renal and survival outcomes. In addition to its role in patients with liver failure, MARS has been approved by the U.S. Food and Drug Administration for overdose and poisoning as of June 2005. MARS have been used in patients poisoned by paracetamol or *Amanita phalloides* who present with liver failure. ELADs have also been used to promote clearance of drugs that are highly protein bound such as phenytoin, theophylline, and calcium channel blockers (157).

Renal Replacement in Neurotrauma

Patients with ESKD on renal replacement therapy regardless of it being PD or hemodialysis have an increased incidence of intracranial, extradural, and subdural hemorrhage (158). Those patients with increased ICP particularly when on dialysis have a mortality of 80% (159). It is important for the patient to have the appropriate dialysis prescription to help improve a patient's outcome.

An acute brain hemorrhage is a space-occupying lesion in the cranium leading to brain injury. The brain tissue at the center of the injury is most at risk for apoptosis and necrosis. As ICP increases, brain perfusion is hindered, and the physiologic response is for the systolic blood pressure (SBP) to be elevated. In management of this elevated SBP to maintain cerebral perfusion, the BP is only decreased by 15% to 30 % in the first 24 hours (158). Hemodialysis's adverse effects include an elevating ICP with increased cerebral edema or decreased cerebral perfusion with ultrafiltration (160,161).

When hemodialysis is started, there is a rapid clearance of urea from the plasma in the first hour. As this urea is cleared from the plasma, a gradient develops between the brain and the plasma because urea is slow to move out of the brain down its gradient into the plasma. The result is a low serum osmolality versus brain osmolality. Water will go down this osmolality gradient and enter the brain causing cerebral edema. It is important to be aware that the transport of water is much faster than that of urea (158).

There are three parts of the hemodialysis prescription to focus on to prevent worsening cerebral

edema. These are the urea clearance and the concentration of sodium and bicarbonate in the dialysate. The clearance of urea is dependent on diffusion and can be slowed by using a dialysis filter with a smaller surface area, slowing the blood and dialysate flow, and reducing the duration of dialysis. Daily hemodialysis would help as the predialysis urea would be lower so there would be less of a drop in urea concentration each session (162). Serum sodium also affects osmolality. In the patient with elevated ICP, the sodium prescription should be 5 to 10 mEq/L higher than the serum concentration. This is to offset drop in serum osmolality with the rapid loss of urea by increasing serum sodium concentration temporarily thereby raising serum osmolality. The concentration of bicarbonate in the dialysate is supraphysiologic, and so there is a rapid rise in bicarbonate during dialysis. Once the bicarbonate is in the plasma, it is converted to water and carbon dioxide, both of which can rapidly cross cell membranes. This carbon dioxide enters brain tissue causing an intracellular acidosis and increase in osmolality drawing water in and worsening cerebral edema. This can be prevented by using a lower bicarbonate bath of 30 to 32 mEq/L when there is an elevated ICP (158). Most neurotrauma units try to maintain a cerebral perfusion pressure (CPP) of 60 mm Hg. This can be affected by hypotension a frequent complication of routine hemodialysis. Strategies to combat this include increasing dialysate concentration of sodium (about 10 mEq/L above the serum sodium concentration), potassium, and calcium. Another method is cooling the dialysate (163).

If CRRT is available, it is the optimal modality of RRT in the patient with an elevated ICP. There are slower rates of change of urea, bicarbonate, sodium, and other electrolytes decreasing the risk of worsening cerebral edema. CRRT also is associated with less hypotension as compared to intermittent HD (163). In regard to anticoagulation if using CRRT, systemic anticoagulation is avoided. Regional anticoagulation with citrate is possible and can be considered. Obviously, the safest method would be to optimize all other nonanticoagulant-based strategies in the setting of a cerebral hemorrhage (31,164).

CHAPTER 41

Preparing Dialysis Patients for Renal Transplantation

Feras F. Karadsheh, Matthew R. Weir, Charles B. Cangro, and Beje Thomas

Kidney transplantation is now regarded as the treatment of choice for end-stage kidney disease (ESKD). Kidney transplantation has saved over a million life-years in the United States during the last 25 years, with 4.4 life-years saved per transplant recipient (1). A successful kidney transplant reduces the risk of dying for patients when compared with maintenance dialysis and improves the quality of life. Multiple studies comparing patients who have undergone transplantation with those remaining on the waiting list have clearly shown that renal transplantation confers a survival advantage (2–6). This survival benefit was seen in all age groups including the elderly and among African Americans and diabetic patients.

KIDNEY TRANSPLANT TYPES AND THE WAIT LIST

Kidney transplantation procedures can be divided into several types based on the living status of the donor and the potential relationship between donor and recipient. The two major groups include deceased donor renal transplants and living renal transplants. Deceased donor renal transplants are further divided into standard criteria (donor <50 years old), expanded criteria living donor (donor >60 years old or 50 to 60 years old with two of the following, history of hypertension, terminal creatinine >1.5, or died of a stroke), and donation after cardiac death. Living-related transplants may related or unrelated. Deceased donor renal transplantation remains the most common transplant procedure. It is important to note the type of transplant a patient receives has an important impact on patient survival, allograft organ survival, and time spent waiting for transplantation.

There are currently 123,175 people waiting for lifesaving organ transplants in the United States. Of these, 101,170 await kidney transplants. Nearly 3,000 new patients are added to the kidney waiting list each month. (7). However, the number of available organs has been outpaced by the increasing number of patients listed resulting in longer wait times. Patients who entered the waiting list after 2002 had a median waiting time of more than 3 years (8). Approximately 12 people die each day while waiting for a transplant (4). It is no surprise then that patients who have a preemptive transplant (one done before the initiation of dialysis) or spend less than 1 year on the waiting list have shown to have an improved

survival following transplantation (9–11). In particular, the faster the elderly patient is transplanted, the greater the survival benefit as they are more prone to have issues arise and die on the wait list (12). Over the last decade, there have been only marginal increases in the number of deceased donors. In 2006, there were 8,024 deceased donors. This increased to 11,163 in 2013 and to 13,124 in 2014 in part due to expanding the criteria for acceptable donors (7,13). In regard to living donors, the volume of living donation in transplantation peaked in 2006 (1). Recently, there has been a decline of about 13% per year and is more pronounced among blacks, males, younger adults, siblings, and parents (13,14). In absolute numbers, in 2005, there were 6,500 living donations compared to 5,733 in 2013 (7,8).

The United Network for Organ Sharing (UNOS), which is the agency that governs transplant policy and organ distribution, recently in December of 2014 revised the system that matches kidneys from deceased donors with patients needing transplantation. This aimed to extend the length of functioning transplants, to increase the likelihood of receiving a transplant for candidates who are difficult to match, and to make better use of available kidneys through increasing organ usage and reducing the need for repeat transplants. Now, UNOS will calculate the transplant waiting time from the date the patient begins dialysis, even if he or she started dialysis before being accepted for listing at a transplant center (15). This new system gave priority to candidates whom are sensitized and have difficulty finding a human leukocyte antigen (HLA)-compatible donor and allows patients expected to live longer to receive kidneys likely to function longer.

The former standard criteria/expanded criteria donor has been replaced by the Kidney Donor Profile Index (KDPI). The KDPI is calculated as a percentage; it describes how long a deceased donor kidney is expected to function compared to all the kidneys donated in the previous year in the United States. For instance, if a donor kidney has a KDPI score of 85%, then that kidney is expected to have a shorter functional life than 85% of kidneys harvested the year before (i.e., the lower the number, the better). Roughly, a KDPI score of 0% to 20% has a graft survival of about 11 years, 21% to 85% of 9 years, and 86% to 100% of about 6 years. Expanded criteria donor kidneys are thought to be the equivalent of a KDPI score of 85% or higher (15). The group of patients that would be recommended to sign for a kidney with a KDPI of >85% would be a high-risk patient that might not be expected to survive long without a transplant (15).

Transplant candidates are also risk stratified based on their estimated posttransplant survival score. This is calculated using recipient age, diabetes status, history of previous transplantation, and duration on dialysis. Those patients in the top 20th percentile will receive kidneys with a KDPI score of <20%. This is longevity matching so providing kidney allografts expected to survive posttransplant for a longer time with individuals expected to live longer. There is concern this will bias against older recipients (15).

TRANSPLANT OUTCOMES

In deceased donor transplantation, the 1-year allograft survival rates have gradually improved over the last decade and have reached 92% recently. This is not dramatically different from the 96.6% 1-year graft survival for all living donor transplants (13). The truly important differences between deceased donor renal transplantation and living donor renal transplantation emerge with the examination of the long-term graft survival rates. With deceased donor renal transplantation, there is a substantial fall in graft survival over time. By 5 years, deceased donor allograft survival has decreased to 72.1%, whereas living donor

transplant graft survival remains at 84% (13). The results of renal transplantation using kidneys from living unrelated donors such as spouses are similar to those results obtained with living-related donors. With both deceased donor and living donor transplantation, there is a significant effect of HLA matching on allograft survival, particularly in long-term graft survival (**TABLE 41.1**). Five-year allograft survival of a zero-mismatched HLA deceased donor organ is 75%, whereas a six-antigen mismatched deceased donor organ has a 5-year survival of 66% (8). This can be contrasted with a two haplotype matched or (zero antigen mismatch) living donor transplant that has a 5-year survival of 84% (8). In addition to the benefits of living donor renal transplantation on allograft survival, there is a substantial benefit on patient survival as well. Patients who received deceased donor transplants in the last decade had a 10-year survival of 62.4%. This is in contrast to a 78% 10-year patient survival for recipients of living donor transplants (13). The benefits of living donor transplantation for dialysis patients can perhaps best be appreciated by noting that the outcome for both patient and allograft survival with any category of living donor transplant is superior to even well-matched deceased donor transplantation. In addition, patients able to undergo living donor transplantation can have this procedure scheduled on an elective basis and are able to avoid a prolonged period on the transplant waiting lists.

TABLE 41.1 Five-Year Kidney Allograft Survival Related To Human Leukocyte Antigen Mismatch

Mismatch	Cadaveric Donor Survival	Living Donor Survival
0	72%	79%
1	69%	76%
3	65%	71%
6	59%	87%

Historically, the increasing size of the wait list and wait times led to the use of the previously mentioned expanded criteria donor kidneys. Elderly patients receiving these expanded criteria organs have been shown to have improved survival compared with patients who remain on the transplant waiting list (16). These transplants do, however, have a shortened allograft survival compared with kidneys obtained from standard criteria donors.

COMBINED KIDNEY TRANSPLANT PROCEDURES

The kidney transplantation can be combined with other organs, heart, lung, liver, pancreas, and bone marrow. An extensive review of all the combined organ transplants is beyond the scope of this chapter and is reviewed elsewhere in the literature. However, we will focus on the combined pancreas and kidney transplant.

Combined kidney and pancreas transplantation for patients with ESKD and type 1 diabetes has been widely available over the past 15 years. Dialysis patients who have previously received a deceased donor or living donor kidney transplant are also potential candidates for a solitary pancreas transplant. The primary indications for pancreas transplant are type 1 diabetic or a type 2 diabetic with a progressive secondary diabetic complications or a brittle diabetic. The major benefits of kidney and pancreas transplantation are an improved quality of life, freedom from insulin therapy, the potential of avoiding additional secondary complications, and a normalization of fasting glucose with a decrease in the

incidence of hypoglycemic episodes (17–19). The results of studies of secondary complications of diabetic patients undergoing pancreas transplantation are difficult to interpret in light of the fact that most of these patients have had diabetes for up to two decades. Successful pancreas transplantation is associated with normalization of serum insulin responses and a normalization of glycosylated hemoglobin. Glucose counterregulation associated with hypoglycemia improves after pancreas transplantation. The symptom recognition of hypoglycemia is restored, and dangerous episodes of hypoglycemia can be avoided. Diabetic neuropathy has been shown to be stabilized, and in some instances, autonomic and peripheral diabetic neuropathy improves (20). At present, there has been no clear benefit in halting the progression of the advanced diabetic retinopathy following pancreas transplantation. Recurrent diabetic nephropathy in the transplant kidney is prevented by pancreas transplantation and native kidney diabetic nephropathy may improve (21). In addition, some data suggest that combined kidney and pancreas transplantation may be associated with improved patient survival compared with diabetic patients who undergo kidney transplantation alone. Although the potential for significant improvement in outcome for diabetic patients with kidney disease exists, the combined kidney–pancreas transplantation procedure has an increased morbidity compared with kidney transplantation alone. Surgical complications are increased with a significant incidence of wound problems, intra-abdominal infections, recurrent urinary tract infections, and primary technical failure of the pancreas allograft. In addition, successful kidney and pancreas transplantation requires a more aggressive antirejection immunosuppression strategy and results in the increased risk of infection associated with this procedure (22,23). The decision to undergo kidney and pancreas transplantation is perhaps best made by the patient in conjunction with the patient's nephrologist in consultation with a transplant center experienced in pancreas transplantation.

MEDICAL EVALUATION OF THE PATIENT WITH END-STAGE KIDNEY DISEASE

Organ transplantation improves the duration of life for the patient with ESKD (5). This result is in part due to the selection process of healthier individuals but is also related to other issues such as progression of atherosclerotic cardiovascular disease (5). However, in the perioperative period, the relative risk of death is greater in the transplant recipient compared with the same patient remaining on dialysis. Only at the point of 3 to 4 months posttransplantation does the relative risk of death equalize between the patients remaining on dialysis and those receiving a kidney transplant. It is for this reason that a very thorough medical evaluation of each patient must be performed pretransplant to ensure that the recipient is medically and nutritionally stable to undergo the rigors of an elective surgical procedure and be capable of tolerating not only the medications but also various treatments during the posttransplantation course (**TABLE 41.2**).

TABLE 41.2 Contraindications to Transplantation

Active infection
Recent or current malignancy
Severe uncorrectable nonrenal disease
Active substance abuse
Severe psychiatric illness
Pregnancy

The leading causes of death posttransplantation are cardiovascular (24,25). Hence, management strategies for patients with incipient or existing cardiovascular disease remain most important. In addition, issues relating to lung disease, malignancy, preexisting viral infections, and risk for recurrent kidney disease also play an important role in stratifying the risk among candidates and may require specific therapy before transplantation and may influence the strategy for donor selection and even immunosuppression.

Cardiovascular Disease

Cardiovascular disease is the leading cause of death and graft loss after renal transplantation (26). Almost half of deaths with graft function that occur within 30 days of transplantation are due to cardiovascular disease, primarily myocardial infarction (27). Risk stratification before transplantation is critical to avoid perioperative mortality and minimize the risk for long-term morbidity and mortality (28,29). The presence or absence and the extent of cardiovascular disease may also play a role in the decision whether to undergo elective transplantation.

Although there is a large body of literature evaluating cardiovascular risk of nontransplant populations having elective surgery (30), there is limited study of transplant populations despite the fact that they have a substantial increased risk for cardiovascular disease (24,25).

The surgical risk of patients undergoing kidney transplantation is considered intermediate (1% to 5%) (31). All patients' evaluation should start with detailed history, careful physical examination, electrocardiogram (ECG), and chest radiograph.

In 2012, the American Heart Association (AHA) and the American College of Cardiology (ACC) Foundation published their recommendations for evaluation and management for kidney transplant candidates. In addition to ECG, patients with three or more coronary artery risk factors (**TABLE 41.3**) with no active cardiac disease should be considered for noninvasive stress testing (32). The most recent European Renal Best Practice (ERBP) (33) Guidelines on the Management and Evaluation of the Kidney Donor and Recipient published in 2013 recommended performing a standard exercise tolerance test and cardiac ultrasound in asymptomatic high risk patients.

However, to this date, the optimal noninvasive test remains unclear (5).

Most of the available data on the effectiveness of noninvasive screening techniques come from studies examining either dipyridamole, thallium, or sestamibi scintigraphy (34,35), or dobutamine echocardiography (36,37). Myocardial perfusion determination with stress single photon emission computed tomographic (SPECT) imaging has proved to be helpful. If negative, 97% of patients are cardiovascular event-free with 42 months follow-up (38). Although most of the available data with these screening techniques have been in patients without ESKD, some well-defined studies have looked at patients being screened for transplantation (34–37).

Dobutamine stress echocardiography and thallium myocardial perfusion scan both have moderate sensitivity and specificity among kidney transplant candidates (32) and might even have lower accuracy for coronary artery disease (CAD) detection in dialysis patients compared to the general population (39). One systematic review suggested that dobutamine stress echocardiography is superior to myocardial perfusion scintigraphy in detecting CAD in patients who are potential kidney transplant recipients (40). In the non-ESKD population, some investigators have suggested that dobutamine echocardiography was more specific for detecting CAD than dipyridamole sestamibi scanning, whereas the sensitivities of the two tests were very similar (41). However, direct comparisons between these two screening modalities in patients with ESKD are lacking.

Echocardiography by itself is considered a reasonable test for assessing the left ventricular function in kidney transplant candidates (32). However, hemodialysis patients undergo regular hemodynamic changes that also may affect echocardiographic findings (42). Myocardial contrast echocardiography (MCE) was recently identified as a safe and uncomplicated bedside technique with good accuracy for ruling out the presence of a significant coronary artery stenosis in patients with ESKD. MCE may help along with other methods to select candidates for coronary revascularization ESKD patients (43,44).

CT scan is also not recommended for the diagnosis of CAD in dialysis patients because the correlation between coronary calcification and luminal diameter in dialysis patients is less certain than in the general population, since vascular calcification in this population is often the result of medial calcification rather than atherosclerosis (45). Stress cardiac magnetic resonance imaging (MRI) was established as valuable tool for the diagnosis and management of ischemic heart disease (46); however, experience with cardiac MRI in dialysis patients is very limited. In summary, all of these noninvasive tests are less than perfect in predicting angiographically documented coronary disease or cardiovascular events. Many still support coronary angiography as the gold standard (47).

Now, with the median waiting time for a kidney transplant is more than 3 years and can even be several years for some patients, the question of the need to repeat cardiac testing done at the time of listing or the frequency of performing such tests becomes vital. Again, to this date, there are no clear guidelines exit and most centers have their own protocols. The AHA and the ACC Foundation suggest that the usefulness of periodically screening asymptomatic kidney transplantation candidates for myocardial ischemia while on the transplant waiting list to reduce the risk of major adverse cardiac events is uncertain (32). However, an annual ECG is reasonable in all patients waiting for a transplant, and for ESKD patients with moderate aortic stenosis, an annual echocardiogram is also reasonable (32).

National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF/KDOQI) guidelines from 2005 for CAD in dialysis patients recommend for kidney transplantation candidates with normal cardiac stress testing at listing, an annual testing in those with diabetes mellitus or known CAD, testing every 2 years in those classified as “high risk,” and testing every 3 years in others (48) (**TABLE 41.4**). For the optimal cardiac testing method, NKF/KDOQI recommend exercise or pharmacologic stress echocardiographic or nuclear imaging tests (48).

TABLE 41.4 Summary of Suggested Cardiac Evaluation for Kidney Transplant Candidates

Test	At the Time of Listing	Frequency While on the Waiting List
ECG	All patients	Annual
CXR	All patients	N/A
Noninvasive stress test	Patients with three or more coronary artery risk factors[a]	• Annual for DM, known CAD • Every 2 years for high risk patients • Every 3 years for all other patient
Cardiology referral for percutaneous angiography	Patients with: • Angina • Ejection fraction less than 50% • Ischemic left ventricular dilatation • Established exercise induced hypotension	

ECG, electrocardiogram; CXR, chest x-ray; DM, diabetes mellitus; CAD, coronary artery disease.
[a]Refer to **Table 41.3.**

So far, we reviewed the recommendations for initial cardiac testing and follow-up while on the waiting list. As for intervention, the AHA and the ACC Foundation recommend cardiology referral for patients with angina, patients with ejection fraction (EF) less than 50%, patients with ischemic left ventricular dilatation, and patients with established exercise-induced hypotension (**TABLE 41.4**). Patients who appear to have critical lesions should undergo revascularization or angioplasty, stenting, and so forth before transplantation. One study demonstrated that patients randomized to revascularization before transplantation had fewer posttransplant cardiovascular disease events compared with patients managed medically (49). These findings suggest that, in particular, diabetic patients and those with high risk for severe CAD should undergo elective revascularization before rather than after renal transplantation. However, this study was small and, therefore, cannot be generally extrapolated to the whole ESKD population group in large part because morbidity and mortality are increased in dialysis patients who undergo coronary artery bypass surgery compared with non-ESKD patients (50). The decision to perform coronary revascularization before transplantation should be considered in patients who meet the criteria for general population. In some asymptomatic transplant candidates, the risk of coronary revascularization may outweigh the risk of transplantation. These risks must be weighed by the multidisciplinary transplantation team on a case-by-case basis (32). For the choice of the optimal method for coronary revascularization in patients awaiting kidney transplant, coronary artery bypass grafting (CABG) appears to be superior to percutaneous coronary intervention (PCI) in diabetic candidates with multivessel CAD (51).

Perioperatively, patients already taking β-adrenergic blockers before renal transplantation should continue the medication perioperatively and postoperatively. For patients not on β-blockers but who have high cardiac risk (**TABLE 41.3**), it should be considered for initiating β-blockers preoperatively and to be continued postoperatively if no contraindication exists.

In regard to antiplatelets therapy, aspirin therapy should be continued indefinitely after renal transplantation in patients with known CAD, following the same ACC/AHA guidelines for general

population with CAD.

Congestive heart failure is an important clinical consideration as part of the kidney transplant evaluation. Fifty percent of hemodialysis patients have a history of volume overload at some point during their clinical course during dialysis (52), and as many as 20% may have decreased systolic function on echocardiogram (53). However, it is important to note that many patients have left ventricular hypertrophy and diastolic dysfunction with impaired lusitropy. This interferes with ventricular filling during diastole and can ultimately lead to output failure. The rationale for treatment is entirely different depending on ventricular function. Those with systolic heart failure will require preload and afterload reduction, whereas those with diastolic dysfunction will need antihypertensive agents, especially those that slow heart rate and facilitate ventricular relaxation (53). There are no overt contraindications to transplantation in patients with left ventricular hypertrophy or ventricular dysfunction unless the EF is less than 20%. An analysis by Wali et al. (54) indicated that one important factor that reduced the likelihood of improvement in ventricular function posttransplantation was increasing time on dialysis. Consequently, an echocardiogram is an important part of the evaluation. On a positive note, renal transplantation improves ventricular function in most patients with EFs in the 20% to 40% range (54,55).

Reversible causes of myocardial dysfunction should also be identified and treated. Problems related to alcohol abuse, anemia, and hypertension need to be considered. Reversible ischemia also may impair ventricular function.

Cerebral vascular disease is also an important consideration that must be considered as part of the pretransplant evaluation. The increasing age and prevalence of hypertension and diabetes as a cause of ESKD with the associated macrovascular disease increases the likelihood of cerebral vascular disease. Patients with audible bruits or prior histories of transient ischemic attack (TIA) or stroke should have carotid artery Dopplers and consideration for carotid endarterectomy if significant disease is noted. Data from studies in the general population indicate that prophylactic surgery may be effective in selected patients, especially in those with a surgical risk of less than 3% and a greater than 60% diameter reduction on ultrasound or in those patients whose surgical risk is slightly higher, but have more substantial stenoses in the presence of contralateral internal carotid artery stenosis of greater than 75% (56). In addition, whether patients with cerebral vascular disease are symptomatic or not, aspirin prophylaxis should be considered, although there are no data on transplant patients to support its use. In the presence of chronic atrial fibrillation, anticoagulation should be considered for guideline as in the general population (57).

Patients with polycystic kidney disease as a cause of ESKD with a family history of intracranial aneurysms or with a previous episode of intracranial bleeding should undergo computed tomography (CT) scan or MRI to evaluate the presence of intracranial aneurysm (58). Those aneurysms greater than 10 mm should be considered for prophylactic surgical removal to prevent bleeding (59).

Peripheral vascular disease is common in patients with ESKD (60). Its presence may help identify patients who need more careful evaluation of potential CAD or cerebral vascular disease. Because the renal transplant is connected to the iliac vessels, it is important to know the status of vasculature. Disruption of compromised iliac flow with a kidney transplant could render more distal vascular beds to impair blood supply. Some patients may require reconstructive surgery of aortoiliac disease before or at the time of renal transplantation. Consequently, in high-risk patients, lower extremity noninvasive testing

should be considered followed by angiography if there is any question concerning the adequacy of the circulation.

In summary, atherosclerotic cardiovascular disease involving the heart, brain, and peripheral vasculature is one of the most important aspects of the pretransplant evaluation. Careful evaluation of all risk factors, adequacy of treatment, and provision of optimal medical management is necessary. In addition, preoperative evaluation of all possible areas of vascular compromise should be rigorously pursued and surgically corrected if indicated.

Cancer

In the past decade, malignancy has become one of the three major causes of death after transplantation. Malignancies are responsible for 1% to 4% of all deaths in the dialysis population and 9% to 12% of deaths in the renal transplant population (61). Kidney transplant recipients have a 3- to 12-fold increased risk of developing nonlymphoid or solid organ cancers when compared to the general population (62). Consequently, careful pretransplant screening is important to rule out preexisting malignancy prior to transplant. The most important cancers to screen for pretransplant are those that occur with greater frequency in the general population including cancers of the lung, prostate, breast, and cervix, which will be discussed later in greater detail (63). What is not known is whether pretransplant screening may have a benefit in reducing the incidence of posttransplant malignancies. The recommendations for cancer screening in the posttransplant period are mostly extrapolated from the general populations and are consistent with screening guidelines in the general population, with the exception of cervical, skin, colorectal, and renal cancers (64).

Patients with prior episodes of cancer have a waiting period before transplantation because most forms of immunosuppression will likely inhibit surveillance mechanisms that would otherwise counteract the development of a malignancy (**TABLE 41.5**). The Cincinnati Transplant Tumor Registry indicates that 54% of recurrences occur in patients who underwent transplantation within 2 years of treatment, whereas 33% of recurrences occurred in patients 2 to 5 years before transplantation (63). Only 13% of recurrences occurred in patients treated more than 5 years before transplantation. These statistics provide some general consideration in terms of the duration of wait between the time of treatment for cancer and transplantation. Other reports also provide some suggestions (65).

TABLE 41.5 Recommended Tumor-Free Intervals before Transplantation

Malignancy	Time
Basal cell	None
In situ cervical	None
In situ bladder	None
Clark's level 1 melanoma	None
Duke's A colon	None
In situ lobular breast	None
Prostate	2 y
Uterine	2 y
Lymphoma	2 y
Breast	2–5 y
Invasive cervical	2–5 y
Colorectal	2–5 y

Lung cancer is the leading cause of cancer deaths (66). Screening chest x-ray film and a possible

low-dose CT of the lung may be appropriate in high-risk patients with a family history who are smokers. Preferably, every patient who smokes should be made to stop before transplantation.

The overall age of male transplant recipients has risen, and it is important to consider yearly evaluation of prostate-specific antigen (PSA) and digital rectal examination before transplantation, particularly for those older than 50 years (67). This may also be even more important in the African American population in which there is a higher incidence of prostate cancer (68). If identified, it should be treated before transplantation. In the Cincinnati Transplant Tumor Registry, 40% of prostate cancer recurrences occurred within 2 years of treatment (69). However, it should be noted that the death rate associated with remaining on dialysis is often higher than death due to prostate cancer. Some investigators have developed a nomogram, based on PSA, to evaluate this risk (70), so that one can decide on an appropriate time period to delay transplantation.

The overall incidence of cervical cancers in women who received a kidney transplant is at least 2 to 3 times greater than the age- and gender-matched population. For women, a pelvic examination with cervical evaluation and manual examination of the uterus should be part of every workup and should be continued on an annual basis while on the waiting list of a transplant. In regard to human papillomavirus (HPV), studies are currently underway to determine the efficacy of HPV vaccination in women with advanced stage chronic kidney disease (CKD) and ESKD (71).

Cancer of the breast is the most common form of *in situ* cancer in female patients with ESKD after nonmelanoma skin cancer and cancer of the uterine cervix (72). Interestingly, renal transplant recipients appear to have a lower relative risk of breast cancer than the general population. The explanation for this may be due to improved screening or previously unidentified effects of the immunosuppression (73). Factors associated with an increased risk of recurrence posttransplantation include prior nodal involvement, bilateral disease, inflammatory carcinoma, and prior bone metastases (63). Most clinicians would recommend a waiting period of 2 years after treatment and preferably longer (5 years) for most patients given the fact that the recurrence rate may be as high as 23% and mortality associated with it is substantial (63). Biennial mammographic screening for breast cancer is standard practice in the general population. (64). Kidney Disease: Improving Global Outcomes (KDIGO) workgroup did not make a recommendation for or against mammographic screening. However, the European Best Practice Guidelines Expert Group recommended following the guidelines established for the general population (71).

Renal cell cancer is more common in the population with ESKD than in the general population, particularly in younger patients and those with ESKD from toxic, infectious, or obstructive uropathies (74). In addition, uroepithelial malignancies need to be screened for if there is any evidence of abnormalities in urinary sediment. High-risk patients may deserve an abdominal CT scan as part of their pretransplant workup.

Cutaneous malignancy is the most common form of cancer posttransplantation, particularly squamous cell carcinoma (63). Renal transplant patients have a 60- to 250-fold increased risk of developing a nonmelanoma skin cancer, which includes squamous cell carcinoma, basal cell carcinoma, Kaposi’s sarcoma, Merkel cell carcinoma, and adnexal tumors (75). There is a high recurrent rate of nonmelanoma skin cancers that occur over time after renal transplantation despite timely removal of lesions. However, this is rarely a cause of death.

Although the incidence of colorectal cancer in dialysis patients is not increased compared with the general population (76), it remains a common cancer; therefore, screening colonoscopy should be considered in all patients older than 50 years, as would be standard for the general population (72). Kidney transplant recipients appear to have a risk for colorectal cancer comparable to those in the general population 10 to 20 years older, so consideration can be given to routine screening starting at age 40 or 5 years after transplantation (77). Patients with previously treated colon cancer should wait at least 5 years before renal transplantation because the recurrence rate diminishes with time, and mortality from recurrent colon cancer after renal transplantation is very high (63).

Lymphoproliferative disorders are more common in patients with ESKD than the general population (74) and may be substantially higher in renal transplant patients if they are exposed to the Epstein-Barr virus (EBV) *de novo* in the posttransplantation period (78). There is a question as to whether or not prophylactic treatment with acyclovir would be capable of suppressing EBV infection and the likelihood of EBV-associated posttransplantation lymphoproliferative disease (79,80). To date, published reports supporting the potential efficacy of antiviral agents have been retrospective and have been limited by the use of either historical or no specific controls (81). In general, complete medical history and physical examination coupled with standard laboratory screening and judicious use of imaging techniques in higher risk patients should be considered as part of the standard workup. Individual determination of time to wait posttreatment of cancer before transplantation should be made on a case-by-case basis. In general, waiting at least 5 years is preferred for most previously treated cancers.

Pulmonary Disease

Anticipating respiratory complications posttransplantation in the patient with ESKD is no different than would be seen for patients without ESKD facing elective surgery. The primary focus should be elimination of smoking and evaluation of pulmonary function if there is a history of chronic obstructive pulmonary disease or other forms of lung disease that interferes with oxygenation. All patients should be screened with a careful history and physical examination and a chest x-ray film. As mentioned previously, specific focus should be addressed on the smoker because studies in the general population indicate that smokers were 5.5 times more likely to develop pulmonary complications postsurgery compared with those who did not smoke (82).

Endocrine Disease

The endocrine evaluation of a dialysis patient should primarily focus on issues surrounding diabetes, obesity, and ESKD-related bone disease. Diabetes is the leading cause of ESKD, so the proportion of patients on dialysis awaiting a transplant with diabetes is substantial. Patients with diabetes, which is most commonly type 2, have advanced risk for atherosclerotic cardiovascular disease and death (83). Consequently, all diabetic patients need careful focus on evaluation of vascular beds pretransplantation. Retinopathy, neuropathy, autonomic dysfunction, and associated complications from diabetes persist and/or progress during dialytic therapy. Despite greater likelihood of progression of complications of the diabetes posttransplantation, survival is demonstrably improved for diabetic patients with renal transplantation compared with remaining on dialysis (5).

Pancreas transplantation as discussed earlier may also be an appropriate strategy for a patient with type 1 diabetes who requires renal replacement therapy (84). With improving techniques and

immunosuppression, pancreas transplantation has become an accepted therapy for patients with type 1 diabetes with patient survival rates exceeding 90% and rates of insulin independence of more than 80% at 1 year (85–87).

In the ESKD population, a higher body mass index (BMI) is associated with a reduced mortality among dialysis patients (88–90). The average cutoff for BMI for a potential transplant recipient at most transplant centers is 30 to 40. Obesity is associated with increased morbidity and mortality posttransplantation (91). Obese patients have higher rates of delayed graft function, suffer from more surgical complications and wound infections, and will frequently require prolonged hospitalization (88,92,93). Some investigators even suggest obesity is associated with increased graft failure (89), although others disagree (92). Posttransplant diabetes mellitus is more common in obese patients, and some transplant centers even suggest that increased risk of acute rejection and graft loss occurs in obese patients (91,94). In regard to weight loss prior to transplantation, transplant centers generally recommend weight loss through lifestyle and dietary changes. It is important to note that BMI should not only be looked at alone but also the overall body habitus of the patient should be taken into consideration. If a patient does not have central obesity or has a high muscle mass with a high BMI, they might not necessarily need weight loss prior to listing (95). In regard to mode of dialysis and obesity, peritoneal dialysis has not been shown to lead to greater weight gain or limit the opportunity for transplantation compared to patients on hemodialysis (96). Bariatric surgery is not routinely recommended but should be considered on a case-by-case basis particularly with recent advancements in surgical technique (95).

Pretransplant planning for the treatment of metabolic bone disease is important because preemptive strategies may prevent the development of pathologic fractures (97). However, a meta-analysis of clinical trials indicated that vitamin D and bisphosphonate therapy helps bone mineral density but did not reveal evidence of reduction in fractures (98). Patients with ESKD can suffer from high-turnover bone disease because of secondary hyperparathyroidism, low-turnover bone disease resulting from osteomalacia, or variance of both (99,100). Patients may also have dialysis-related amyloid bone disease. Renal transplantation is an effective treatment for most causes of low-turnover bone disease and for dialysis-related amyloid bone disease. However, persistence of hyperparathyroidism after successful renal transplantation is common (101). Therefore, parathyroid hormone (PTH) levels should be checked pretransplant and posttransplantation, and surgical removal may be necessary. However, since the advent of cinacalcet therapy (102), the need for parathyroidectomy has become less common.

Gastrointestinal Disease

The primary gastrointestinal issues in the patient with ESKD revolve around the presence or absence of diverticulosis or diverticulitis or other forms of colonic disease; peptic ulcer disease; gallbladder disease; or chronic liver disease, usually resulting from major hepatitis viruses or gallbladder disease.

Colon disease resulting from diverticulosis or diverticulitis is not uncommon in the patient with ESKD; in many cases, it is due to sedentary lifestyle and the medications predisposing to constipation (103). Although posttransplantation colonic perforation is a morbid and mortal consequence (104), it is unknown how to best diagnose and treat it preemptively. Patients with severe diverticulosis may require partial colectomy pretransplant. However, there is no accepted standard in terms of how to approach this problem. Patients with polycystic kidney disease have an even greater risk for colonic perforation posttransplantation, as high as 5%, which is substantially more than the 0.5% to 2% that is seen in patients

with ESKD receiving renal transplantation, resulting from nonacquired polycystic kidney disease (non-APKD) (105).

Peptic ulcer disease can be a serious complication posttransplantation (106,107). The perioperative use of corticosteroids and infections such as herpes virus, cytomegalovirus (CMV), or Candida markedly increase the risk for gastritis and gastrointestinal hemorrhage. Prior history of peptic ulcer disease should prompt physicians to perform upper gastrointestinal endoscopy and fecal occult blood testing. During endoscopy, screening for *Helicobacter pylori* should be planned (108). With the advent of proton pump inhibitors, the risk of serious complications of gastrointestinal hemorrhage posttransplantation has markedly improved (109). Patients with a history of peptic ulcer disease have a threefold greater incidence of ulceration posttransplantation compared with those patients without a history of peptic ulcer disease (107). However, progressive screening and proton pump inhibitor use largely mitigates this risk.

All patients should have pretransplant screening for gallstones. If evident, the patient should have an elective cholecystectomy pretransplant since there is an increased risk of posttransplant complications, including cholangitis.

Liver disease is a significant cause of late morbidity and mortality among renal transplant recipients (110). In fact, death from liver failure has been reported in anywhere from 8% to 28% of renal transplant recipients (111). Chronic posttransplant liver disease is usually related to viral hepatitis, primarily hepatitis B virus (HBV) and hepatitis C virus (HCV). Serum transaminases should be routinely followed pretransplantation, and if persistently abnormal, a liver biopsy should be obtained. The primary use of the liver biopsy is to screen for cirrhosis and active hepatitis. Renal transplant recipients should be routinely screened for HBV surface antigen and HCV. Patients who are HBV surface antigen positive will also have circulating HBV antigen or serologic evidence of acute viral replication (HBV DNA) and are at increased risk of progressive liver disease posttransplantation compared to seronegative patients (112,113). All patients who are HBV surface antigen negative should receive the recombinant HBV vaccine. Although chronic dosing of lamivudine may help control viral replication in these patients, drug resistance likely limits the long-term effectiveness of this therapy (114,115).

Current guidelines recommend the use of nucleoside analogs (NA) in HBV surface antigen–positive patients preemptively before immunosuppressive therapy, regardless of baseline HBV DNA levels and for 12 months after its cessation. Lamivudine can be used only in patients with low HBV DNA (<2,000 IU/mL) and when a finite and short duration of immunosuppression is scheduled; otherwise, the candidates should be treated with a newer generation NA (116).

HCV-related liver disease is a substantial problem for hemodialysis patients because of its frequency and increased risk of death and graft failure compared to seronegative patients (117–119). Roughly 10% to 20% of hemodialysis patients are positive for HCV. Up to 50% of the cases of liver disease posttransplantation can be attributed to HCV infection (117,118). All transplant candidates should be screened for anti-HCV radioimmunoassay with confirmation testing by radioimmunoblot assay (RIBA). If positive, serum should be tested for HCV RNA to confirm current HCV infection. Serum transaminases can be followed, but a liver biopsy should be strongly considered. Patients with cirrhosis on liver biopsy should, in most instances, remain on dialysis because of an unacceptable increased risk for progressive liver failure posttransplantation (120). One exception is patients with cirrhosis but with a hepatic portal venous gradient below 10, a kidney transplant alone in this situation may be safely performed (121).

Without evidence of cirrhosis, the presence of HCV antibody *per se* should not be a contraindication to transplantation because survival after transplantation is markedly higher than that of HCV patients who remain on chronic HD (122). Patients who are HCV RNA positive may benefit from a course of interferon-α before transplantation (123–126). Ribavirin is contraindicated in the setting of late-stage kidney disease. Thus, it would be preferable for ESKD and kidney transplant patients to have an interferon/ribavirin-free regimen. This is possible with the advent of direct-acting antivirals (DAAs). These drugs are more tolerable and avoid many of the side effects and drug interactions as compared to interferon/ribavirin. However, there presently is no recommended dosage for patients with an eGFR <30 mL/min, ideally an ESKD patient would be transplanted and would have enough renal function to dose DAA. The management of both hepatitis B and C should be done in conjunction with a hepatologist (127). This is also potentially useful to expedite a hepatitis C positive patient's transplant as they can accept a hepatitis C positive kidney and then be treated afterward.

The goal of pretransplantation treatment is to decrease the risk of progressive liver disease and prevent the development of posttransplant HCV-associated renal disease (126). Interestingly, HCV is also associated with an increased incidence of glomerulonephritis and diabetes posttransplantation (128).

The role of immunosuppression on the progression of fibrosis in cases of HCV infection is uncertain in kidney transplant recipients. Actually, there is some evidence that cyclosporine inhibits the replication of HCV *in vitro* (129). It has been routine over the last decade to give HCV-positive transplant candidates HCV-positive donor kidneys (130). Most reported experiences do not suggest that there is any increased risk of progressive liver disease to the recipient in the short term (131). However, long-term observation will ultimately be necessary to demonstrate the safety of this practice. It is important to note that waiting times on the transplantation list are reduced if HCV-positive kidneys are used in HCV-infected recipients (131).

Infections

An important part of the pretransplant evaluation in the dialysis patient is to eliminate infection that may persist posttransplantation and that may become more difficult to treat or possibly become life threatening. A careful history and physical examination are important to identify possible sites of infection such as at the site of hemodialysis or peritoneal dialysis access. Peritoneal fluid should be cultured. A serologic evaluation of past viral exposures is important and may help in the design of proper posttransplantation prophylaxis treatment as well as guide decisions with regard to transplantation of a kidney from an infected donor. Transplant candidates should receive immunizations for known infections that are prevalent before transplantation, such as HBV and any childhood immunizations, that may have been missed. Seroscreening for CMV, EBV, and all the hepatitis viruses is routinely recommended. However, it is not possible to exclude possible infection with other unusual pathogens such as syphilis, strongyloidiasis, toxoplasma, or herpes. Seroscreening for HIV and tuberculin testing should also be routine.

CMV infection, until the development of effective anti-CMV drugs, was a morbid and mortal event that could occur in the transplant recipient. The incidence of CMV disease is generally less than 5% for recipients who do not have antibodies to CMV and who receive kidneys from donors who are antibody negative (132,133). However, the incidence of primary CMV disease among antibody-negative recipients of CMV-positive kidneys is high, on the order of 50% to 75% without specific and effective prophylactic

regimens (132,133). This drops to 15% to 35% when using a prophylactic regimen (134). CMV disease in antibody-positive recipients receiving either positive or negative donor kidneys is approximately 25% to 40% (106,107). Therefore, this illness is frequent in the posttransplant patient and will require careful assessment of the amount of immunosuppression because this directly influences the incidence and severity of CMV disease.

A meta-analysis of controlled clinical trials demonstrated that specific antiviral agents (acyclovir or ganciclovir) were effective in preventing CMV infection in solid organ transplant recipients (135). However, it is important to note that this regimen is associated with side effects and can be expensive. Therefore, judicious and appropriate screening, pretransplantation can help identify those patients who will derive greatest benefit from the investment in prophylactic therapy. There is a concern that ganciclovir- and valganciclovir-resistant CMV strains can develop in patients receiving prophylaxis, which could undermine this therapeutic strategy (136).

Patients with ESKD are at greater risk for mycobacterial disease. This is frequently asymptomatic despite the fact that up to a third of patients with ESKD may be anergic. Purified protein derivative (PPD) testing is recommended so that isoniazid prophylaxis can be used, and performance of a chest x-ray examination can be helpful to rule out the likelihood of active infection. There is no evidence that prophylaxis with isoniazid reduces the incidence of reactivation of tuberculosis after transplantation (137). Despite this, many centers require pretransplant and/or posttransplant isoniazid prophylaxis for patients with a positive PPD skin test.

Peritoneal dialysis patients must be carefully screened for occult tunnel track or peritoneal fluid infections. In particular, *Staphylococcus epidermidis* may cause an occult peritonitis that can flourish once immunosuppression is started posttransplantation. Clinical studies indicate that patients on peritoneal dialysis more frequently develop infections within the first month posttransplantation compared with patients on hemodialysis. More often than not, these sites are located in the abdominal cavity, the surgical wound, or in the peritoneal fluid. Peritoneal dialysis patients with active infections should have transplantation delayed, if at all possible, if they have a history of active or recent peritonitis to ensure that proper therapy can be employed. Documentation of clearing of the infection is appropriate.

Careful evaluation of the dentition is appropriate pretransplantation in all dialysis patients. Periodontal infections and active periodontitis could worsen posttransplantation because of the use of immunosuppressive agents, particularly cyclosporine because it induces gingival hyperplasia (138). Although there are no controlled clinical trials demonstrating that treatment of periodontal disease reduces the likelihood of recurrence posttransplantation, it is appropriate to consider strategies to care for active disease processes before using medications that will stimulate gingival growth and could cover up underlying infectious processes.

Pulmonary infections posttransplantation are an important concern. Some studies suggest that renal transplant recipients develop pneumococcal infections at a rate of approximately 1% per year (139). Pneumococcal immunization is currently recommended for all chronic dialysis patients (140). It is particularly important for those who have been previously splenectomized. Annual immunization with influenza vaccine is also currently recommended for all chronic dialysis patients (140). However, there are no good studies to indicate that influenza is more severe when it occurs in an immunosuppressed transplant patient compared with a dialysis patient. Most childhood vaccinations should be employed

pretransplantation, if they have never been received.

Patients who are HIV positive and have a strong desire for transplantation may be evaluated for transplantation. Data from several large prospective multicenter cohort studies have shown that solid organ transplantation in carefully selected HIV-infected individuals is safe (141). Newer approaches for immunosuppression have made transplantation feasible, and HIV is no longer an absolute contraindication for solid organ transplantation (142,143).

Genitourinary Disease

The patient with ESKD needs a careful examination of the genitourinary tract for a number of important reasons. There may be abnormalities in the drainage system that lead to the original renal dysfunction, such as bladder disease, stones, prostatic disease, or urethral strictures. These underlying abnormalities would need to be identified and corrected before the same urinary tract is used for drainage for the transplanted kidney. For this reason, a careful history and physical examination are needed. Routine recommendation for a voiding cystourethrogram (VCUG) should be considered in patients with a history of genitourinary abnormalities. Up to 25% of pretransplant VCUGs are abnormal in patients with ESKD (144). Most of the time, the abnormalities are minor and do not require surgical correction. Among younger individuals, the likelihood of congenital abnormalities is greater, whereas in older individuals, prostatic hypertrophy either from benign growth or from malignancy is a possibility. In addition, bladder cancer is 1.4 to 4.8 times more common in dialysis patients than in the general population (74). Therefore, any abnormalities on urinalysis should be carefully followed up with either a VCUG or cystoscopy. Urine cytology may also be helpful.

A neurogenic bladder is also an important problem that should be identified pretransplant. Although there are many causes, the most common are due to neurogenic issues usually related to diabetes. Patients may require intermittent catheterization or urinary diversion. In addition, patients with small bladders may need a bladder augmentation procedure or bladder stretching.

Patients with a history of urinary tract infections or stones need careful evaluation to ensure that there are no structural abnormalities that could predispose them to recurrence of these infections posttransplantation. Patients with bladder diverticula, large stones, or infected cysts, such as patients with polycystic kidney disease, may benefit from either unilateral or bilateral nephrectomy to reduce the likelihood of recurrent infection.

Other causes for a nephrectomy could include the identification of a renal cell carcinoma on ultrasound, oversized kidneys resulting from polycystic kidney disease that could impair placement of a new allograft, or possibly an inability to control blood pressure.

Recurrent Kidney Disease

It is important to identify the cause of ESKD in patients being evaluated for a kidney transplant. Almost all causes of kidney disease can recur in the kidney transplant with few exceptions such as polycystic kidney disease, Alport’s syndrome, or toxic nephropathies resulting from drug ingestion. The risk of recurrence for certain kidney diseases can be substantial and possibly lead to graft loss. In those patients who do have recurrent kidney disease, the risk of graft failure is 1.9 times higher than for patients without recurrent disease (145). In large part, the physician’s assessment of the risk of recurrence is difficult because many patients progress to ESKD without proper identification of the cause. In addition, the

incidence of recurrent disease may depend on the length of follow-up, and sometimes the ability to diagnose recurrent disease from chronic allograft nephropathy may be difficult. Registry data are being collected to provide a timely understanding about their risk (146).

Recurrent glomerulonephritis is most commonly seen with focal segmental glomerulosclerosis (FSGS), immunoglobulin A (IgA) nephropathy, and membranoproliferative glomerulonephritis (MPGN). Other glomerulonephritides such as membranous glomerulonephritis, Wegener's granulomatosis, and hemolytic uremic syndrome (HUS) can also recur (**TABLE 41.6**) (117).

TABLE 41.6 Recurrence of Glomerulonephritis after Renal Transplantation

Disease	Histologic Recurrence (%)	Graft Loss with Recurrence (%)
Focal segmental glomerulosclerosis	20–40	40–50
IgA nephropathy	20–40	6–33
Membranoproliferative		
Type I	20–30	30–40
Type II	80–90	10–20
Membranous nephropathy	10–20	0–50
Anti-GBM nephritis	10–25	Rare
Henoch-Schönlein purpura	15–35	Rare
Hemolytic uremic syndrome	10–25	10–40
Lupus nephritis	Rare	Rare

IgA, immunoglobulin A; GBM, glomerular basement membrane.

FSGS recurs in 30% of patients, and, of those that do recur, 40% to 50% will lose their grafts (147,148). Those patients with rapid progression to original ESKD with FSGS are at greatest risk. African Americans and patients with younger age at onset of disease are more likely to have recurrence (149). The strongest predictor, however, is recurrence in a previous transplant. Podocyte effacement is the primary pathologic manifestation of FSGS posttransplant (150). Recently, lots of effort have been put into identifying a factor that is implicated in the pathogenesis of native and recurrent FSGS. FSGS is not viewed as a contraindication to renal transplantation because it is a heterogeneous disease process, and it is impossible to predict who would not be an ideal candidate.

IgA nephropathy can also recur frequently (20% to 40%) (151). Although graft failure can occur in 6% to 33% of patients with recurrent disease (152), a shorter interval between onset and the development of ESKD with IgA nephropathy appears to correlate with the likelihood of recurrence (152). It is also more common to recur in recipients of living related transplants. However, donor source has not affected graft survival in patients with ESKD who underwent transplantation resulting from IgA nephropathy. Graft loss because of recurrent IgA nephropathy is not a contraindication for retransplantation because good long-term graft survival is observed after repeat renal transplantation.

Henoch-Schönlein purpura recurs in 15% to 35% of patients but rarely causes graft failure (153). It usually recurs in individuals with disease that has been recently active. However, occasionally, it can recur in patients who have had no evidence of disease for several years. Most data suggest that a shorter duration of original disease makes recurrence more likely (153). However, only 11% of graft failure can be attributed to recurrent disease despite the fact that histologic evidence of recurrence is common (153).

Patients with MPGN have recurrence rates of 20% to 30% (154). Graft loss may be seen in 40% of patients (154). In patients with type 2 MPGN, the risk of recurrence is approximately 80%; however, graft loss is less common than in type 1 MPGN occurring in approximately 10% to 20% of patients with recurrence (154). It is important to differentiate these idiopathic forms of MPGN from that which occurs secondary to HCV infection. It is also important to differentiate MPGN from chronic rejection by careful histologic evaluation, including immunofluorescence and electron microscopy.

Less common glomerulonephritides include membranous glomerulonephritis, which occurs in 10% to 20% of patients (155). Graft loss may be as high as 50% if patients are followed up for more than 10 years (155). There are no readily identifiable risk factors to determine the likelihood of recurrence.

HUS can recur in 10% to 25% of patients. However, it can be primary (without obvious cause) or secondary (related to the use of calcineurin inhibitors such as cyclosporine or tacrolimus) (156). It has even been reported with the use of antilymphocyte globulin and OKT3 monoclonal antibody (157,158). The older the age of onset of HUS, the shorter the interval for recurrent HUS posttransplantation and the shorter the interval between HUS onset and ESKD. The use of living donors should be contraindicated in these patients because it increases the risk for recurrence (155). The risk for graft failure is substantial. It may be as high as 50% (155). It is reported to be more than 5 times higher than for patients without posttransplant HUS. Strategies to provide necessary immunosuppression, particularly with the need for deceased donors in these patients, are important because most transplant centers would prefer not to use calcineurin inhibitors. Some centers have suggested that the use of prophylactic antiplatelet therapy may help reduce the chances of recurrence. However, there are no data to support this effort.

Antiglomerular basement membrane (anti-GBM) disease may recur in 10% to 25% of patients, although histologic recurrence may be seen in approximately 50% of patients. Anti-GBM antibodies should be documented as undetectable in the pretransplant workup to minimize the likelihood of recurrence.

Patients with ESKD resulting from Wegener’s granulomatosis may also experience a recurrence rate as high as 15% to 50% (159). Data from small uncontrolled studies indicate that patients with recurrent disease can be successfully treated with cyclophosphamide (159). Most centers would recommend waiting until the disease is quiet before transplantation, although there are no data to indicate optimal timing of renal transplantation in patients with this disease process.

Patients with ESKD resulting from systemic lupus erythematosus (SLE) have a low risk of recurrence, perhaps less than 10% (160). However, a recent review indicates it is not rare (161). It is generally recommended that patients not have any evidence of clinical disease before transplantation. It is preferable that the serologic parameters such as complements and antinuclear anti-DNA antibody be normal or at least stable before transplantation. Recurrence that results in graft failure is unusual, and there does not appear to be any effect of prior SLE on patient or graft survival (160).

Unusual causes of ESKD such as oxalosis, cystinosis, Fabry’s disease, and sickle cell disease can recur. Oxalosis is the most important with regard to its recurrence rate, and preferably, the patient should receive a simultaneous liver transplant at the time of the kidney transplant to reduce the likelihood that hyperoxalosis will destroy the transplanted graft.

Amyloidosis can recur in the kidney in approximately one-third of patients posttransplantation (162). If patients have severe multiorgan involvement with amyloidosis, transplantation should be generally

discouraged because their survival is low. However, with primary injury to the kidneys, transplantation should not be precluded. More often than not, the outcome of transplantation appears to be determined by the severity of systemic disease affecting survival rather than recurrence in the allograft leading to graft dysfunction.

Because diabetes is the most common cause of ESKD, it is important to note that both type 1 and type 2 diabetes can recur within the transplanted kidney. For type 1 diabetes patients, this explains the rationale behind simultaneous pancreas and kidney transplantation. In the patients with type 2 diabetes, careful attention should be focused on blood pressure, cholesterol, and glycemic control. In addition, therapeutic strategies incorporating drugs that block the renin-angiotensin system should be used. Although no studies have indicated effects on graft survival using this approach, it has certainly been demonstrated to be effective in patients with type 2 diabetes and kidney disease without kidney transplantation.

Coagulopathies

Patients with a history of recurrent graft clotting on dialysis or deep vein thrombosis should have special attention focused on their clotting studies. Limited studies have attempted to determine the prevalence of coagulation abnormalities among kidney transplant candidates. Patients with SLE may have antiphospholipid antibodies, which may manifest as a lupus anticoagulant, and may have increased thrombotic risk (163). Other clotting abnormalities may also occur. Unfortunately, they may increase the risk for perioperative graft thrombosis. Consequently, a proactive approach is necessary to screen high-risk patients for coagulation abnormalities and to use prophylaxis to prevent clotting.

Psychosocial

A complete psychosocial evaluation should be performed on all prospective transplant recipients at the time of their initial evaluation. The importance of this evaluation is to be sure that there are not psychosocial barriers to transplantation or potential problems with compliance or chemical dependency that could interfere with the complicated medical regimen of posttransplantation. As part of the initial evaluation, the family and social support available to a candidate should be established. Transplant patients require frequent follow-up clinic visits, trips to the laboratory, hospital, and pharmacy. What mechanism does the patient have to get to and from clinic appointments and other locations? What will be the cost of travel to the patient? Does the patient drive, and if not, how will he or she get to and from clinic and local laboratory for blood draws? Identification of those members of the patient's closest contacts who are willing to help the recipient over the long haul is essential. The magnitude of this commitment should not be underestimated, especially when patients are old and have multiple comorbid conditions. Patients may wait years for a deceased donor transplant, so the social support available to each candidate should be updated frequently, perhaps as often as their cardiac status is reviewed. An elderly type 2 diabetic patient who initially was counting on his or her spouse to assist posttransplant will require a much higher level of assistance from the posttransplant team if his or her significant other suffer a major change in health and is no longer available. A significant change in a patient's social support network should not remove him or her from the transplant waiting list; however, early awareness and contingencies need to be identified.

At the time of initial evaluation, an extensive review of a patient's employment history, finances, and

insurance coverage should be undertaken. Transplant social workers are the best members of the health care team to assist each patient select what choices will be the best interest (164). According to the UNOS, the first-year billed charges for a kidney transplant are more than $262,000. Should a patient continue to work and maintain benefits or seek disability? Transplant social workers are uniquely positioned to perform biopsychosocial assessments of individual candidates and identify barriers that individual will face in returning to full employment after transplantation (165). The answer must be individualized for each patient and can best be considered with the help of an experienced transplant social worker.

Language and cultural barriers should be evaluated. If a patient does not speak English, who will accompany the recipient to clinic visits and be available to take phone instruction when the posttransplant team calls with medication changes? Optimal care requires a competent translator accompany the patient to every clinic visit.

Reversible medical causes of cognitive impairment could be identified with a dementia workup such as evaluating thyroid function and obtaining thiamin, vitamin B_{12}, and folate levels. In particular, alcohol and drug abuse must be identified and treated. Underreporting of individuals with substance abuse is common, as patients believe it will mean they will be denied transplantation. Substance abuse may lead to graft loss because of noncompliance (166,167), but if change is undertaken and documented, such patients can be successfully transplanted. Those at greater risk for relapse should be willing to submit to unannounced testing for substance abuse and be able to demonstrate continued abstinence.

Mental illness is common in patients with ESKD. Depression is the most common psychiatric illness in patients with ESKD (168). The stress of a transplant and concern about the viability of the transplant could lead many patients into significant depression that could interfere with the maintenance of proper medical care. Consequently, susceptible individuals should be identified pretransplant so that careful support systems can be used during the transplantation course (169,170).

In the past, mental retardation was considered a contraindication for organ transplantation (171). The concern was that such patients would not be able to comply with the posttransplant medical regimen and so would be doomed to rejection and graft loss. A recent review on the accessibility and success of organ transplantation on patients with mental retardation documented 1- and 3-year survival rates of 100% and 90%, respectively (172). Good compliance with posttransplant regimens was noted and attributed to the presence of supportive family members and caregivers.

Well-managed schizophrenia is generally not considered a transplantation contraindication. Patients who are not well controlled deserve an opportunity for proper treatment before transplantation. Bipolar patients can be successfully transplanted and do well. If a bipolar patient is maintained on lithium pretransplant, the psychiatrist may wish to try alternative medications to control the disease while the patient is on dialysis. Long-term exposure to lithium can lead to nephrogenic diabetes insipidus in 20% of patients who take this medication. Before transplantation, the goal should be to determine if a non–lithium-based regime could control the patient’s bipolar disease. Bipolar patients who can only be managed on lithium can be continued on this medication posttransplant if no other reasonable alternative medication controls the illness. Although lithium is nephrotoxic at high serum concentrations, its toxic effects can be significantly reduced if serum drug levels are kept within therapeutic range. Patients who receive renal transplants have frequent blood draws to monitor immunosuppressant levels, and this

requirement facilitates the frequent monitoring of lithium levels. Bipolar transplant recipients who were only controlled on lithium pretransplant can be maintained on the regimen, questioned frequently about nocturia, and monitored for a concentrating defect. Monitoring of lithium levels will minimize the detrimental effects on the kidney and will offer the recipient the best quality of life and control of the bipolar disorder. Those patients who receive a renal transplant require lithium and develop a concentrating defect may be candidates for treatment with amiloride.

In summary, a careful examination of psychosocial issues is imperative before transplantation because noncompliance is the third leading cause of graft failure (173). Moreover, a poor home situation and financial or social problems could interfere with proper delivery of care and may lead to an adverse outcome posttransplantation.

MANAGEMENT OF PATIENTS ON THE CADAVERIC KIDNEY WAITING LIST

How should the health status of dialysis patients on the UNOS deceased donor kidney waiting list be followed up? Unfortunately, evidence-based guidelines describing the best mechanism to manage the health and psychosocial well-being of patients on the deceased donor renal transplant waiting list have never been published. Knowledge about the correct management of patients on the waiting list for deceased donor kidney transplantation is in its infancy (174). Recognition of the significant death rate and the demonstration that the length of time on the waiting list is an independent determinant of long-term posttransplant prognosis has prompted intense interest in this subject (175).

The Clinical Practice Guidelines Committee of the American Society of Transplantation published the results of a survey, which polled transplant centers in the United States and asked how they managed patients on the deceased donor transplant waiting list (176). Sixty-seven percent (192 of 287) of centers polled responded to the survey. Despite a lack of evidence-based guidelines for the management of dialysis patients awaiting renal transplantation, certain important points merit discussion. During the months and years that a patient is maintained on hemodialysis awaiting a renal transplant, many things may change including demographics, psychosocial support, general medical condition, and cardiovascular status. A regular review and update of these aspects of a patient’s condition should be undertaken to ensure the continued preparedness for transplantation.

The transplant procedure has been described as an urgent surgery performed on an elective population. When a kidney becomes available, time is of the essence. The patient must be easily contacted, and a mechanism to transport the patient to the transplant center must be readily available. Patients undergoing maintenance hemodialysis must be continually reminded to update their telephone numbers and addresses with the transplant center. It should be pointed out to the patient that his or her diligence in this regard will benefit the patient greatly. Notifying the transplant center when a listed patient is going on a prolonged vacation, temporarily residing at an alternative location, or when changing residence will ensure that the patient can be promptly contacted when an organ becomes available. Delay in physically having the patient in the operating room leads to prolonged cold ischemia time, which increases the risk for delayed graft function, may increase the risk of early acute rejection, and overall negatively affects graft survival (177,178).

Many important psychosocial issues change for patients on maintenance hemodialysis. Unfortunately, these issues can be viewed as being of secondary importance compared with the general and more specifically cardiovascular health of potential recipients on the waiting list. Nevertheless, a patient's employment status, marital status, state of residence, insurance coverage, and psychological support mechanisms can all change while on hemodialysis and on the waiting list. Although it is unlikely that any of these issues would directly prevent a patient from receiving a kidney transplant, these issues are important. For example, patients who stop working, graduate from school, relocate to a nearby state, or suffer the loss of spousal support as a result of death or divorce might find themselves nearly destitute in the posttransplant period as they face various challenges. These include the financial cost of medications, repeat hospitalizations, and professional fees during the months and years following transplantation. Currently, maintenance medications for a renal transplant patient approach $15,000 per year. Few, if any, are able to cover these costs out-of-pocket. As a result, every patient should be reminded, while on the waiting list, to seek advice about how changes in psychosocial issues could alter benefits, insurance, and prescription coverage and thereby affect posttransplant life. Dialysis patients on the waiting list and transplant centers should maintain a routine dialogue about such issues. Patients should seek advice from social workers and financial counselors at their transplant center or dialysis unit when contemplating major life changes, such as changing jobs, seeking early retirement, seeking disability, and moving to another state. Ideally, individuals would have all the appropriate information to make the best decision before irreversible loss of coverage or benefits occur.

Ensuring that a patient, who might be on dialysis for several years before transplantation, is medically fit to undergo surgery is a daunting task for many transplant centers. At this time, given the lack of evidence-based data from studies of this population, the recommendation is to follow age-appropriate health maintenance and screening guidelines for colon, prostate, breast, and uterine malignancy (174,179).

Dialysis patients are catabolic, are at risk for malnutrition, suffer recurrent life-threatening infections, and, most significantly of all, live with the atherogenic burden of CKD (180–183).

Strict medical guidelines for the initial listing of patients with renal insufficiency are standard at most transplant centers. Once a patient is listed, however, the frequency with which a patient on dialysis is reevaluated and the integrity of the cardiovascular reserve to permit a safe surgical procedure varies widely (184–186).

Given the importance of appropriate cardiovascular clearance and the often asymptomatic deterioration of cardiovascular function on dialysis, many centers surveyed responded that they closely followed up patients on the waiting list. Most centers (79%) indicated that they screened patients on an annual basis. Of these, 40% employed nuclear perfusion scanning, 33% used exercise thallium scanning, 31% employed dobutamine echocardiography, and only 15% required coronary angiography (176). Unfortunately, these diagnostic studies are less reliable among patients with ESKD. Noninvasive testing for CAD among asymptomatic patients with ESKD is of limited value (187). Unfortunately, the frequency of follow-up assessments required and long-term studies comparing this with gold standard angiographic evidence are lacking. Dobutamine stress echocardiography has a sensitivity of 75% and a specificity of only 71%, compared with angiography when evaluating lesions of greater than 70% stenosis (188). Dipyridamole and thallium imaging has a sensitivity of only 37% and a specificity of only 73% in this population. It does not clearly predict cardiac prognosis among patients with ESKD (189). Efforts to

facilitate communication and to educate patients, primary care physicians, local subspecialists (especially cardiologists), dialysis social workers, and dialysis center staff about the importance of updating the transplant center about changes in demographic, psychosocial, and health issues must be stressed. Most importantly, patients themselves, their nephrologists, and the pretransplant coordinators should work in concert and communicate frequently and freely to maximize preparedness at all times. It has been suggested that regular contact between the patient, nephrologist, and transplant centers, perhaps during site visits to dialysis centers by members of the transplant center team, could serve to educate patients, maintain motivation, diminish a sense of hopelessness, and offer time to reevaluate living donor options.

CHAPTER 42

The Geriatric Dialysis Patient

Yusra Cheema and Wendy Weinstock Brown

The dialysis population in the United States continues to grow, and the elderly constitute the most rapidly expanding segment of this population. Care of the elderly patient with kidney disease is particularly challenging, both because of the increased number of comorbid conditions that tend to be present and because these conditions are superimposed on the anatomic and physiologic changes seen with normal aging (1,2). Many elderly patients do not tolerate rapid changes in volume or electrolytes, and many have impaired or atypical responses to medications; stress; intercurrent illness; and changes in diet, mobility, and environment (2–9). Importantly, age alone should not be a contraindication to renal replacement therapies, especially as not all individuals age biologically at the same rate (6,10–14).

This chapter discusses the incidence, prevalence, and demographics of kidney failure in the elderly; summarizes morbidity and mortality in these individuals; reviews causes of kidney failure in the elderly; and addresses special issues in the elderly kidney failure patient including timing of dialysis initiation, modality choice, dialysis access considerations, and comorbid conditions such as cognitive impairment and depression.

DEMOGRAPHIC CHARACTERISTICS OF THE GERIATRIC POPULATION WITH END-STAGE KIDNEY DISEASE

Incidence and Prevalence of End-Stage Kidney Disease in the Elderly

When the Medicare end-stage kidney disease (ESKD) program was funded in 1973, individuals receiving dialysis comprised the healthiest, most motivated, and youngest segment of the population with kidney failure. The advent of systematic funding of ESKD care in the United States widened the availability of renal replacement therapies and rendered committees judging “Who Shall Live and Who Shall Die” obsolete. Renal replacement therapies have now become available to all segments of the population, including the elderly (15).

Patients older than 65 years represent a rapidly growing segment of the population with ESKD in North America, Europe, Australia, and Japan (10,16–19). This is particularly notable among

octogenarians and nonagenarians (**FIGURE 42.1**). In the United States, from 1995 to 2004, there was a greater than 60% increase in incident dialysis patients 80 years and older, such that in 2004, approximately 28,000 individuals in this age-group initiated dialysis (21). In more recent years, incident cases of ESKD in those aged 75 years and older appear to have plateaued, but the incidence rate remains highest in this age-group (21). However, these oldest old comprise a fraction of the elderly hemodialysis (HD) population; in 2011 to 2012, there were 56,000 incident patients with ESKD 65 years or older, representing 50% of the incident U.S. dialysis population.

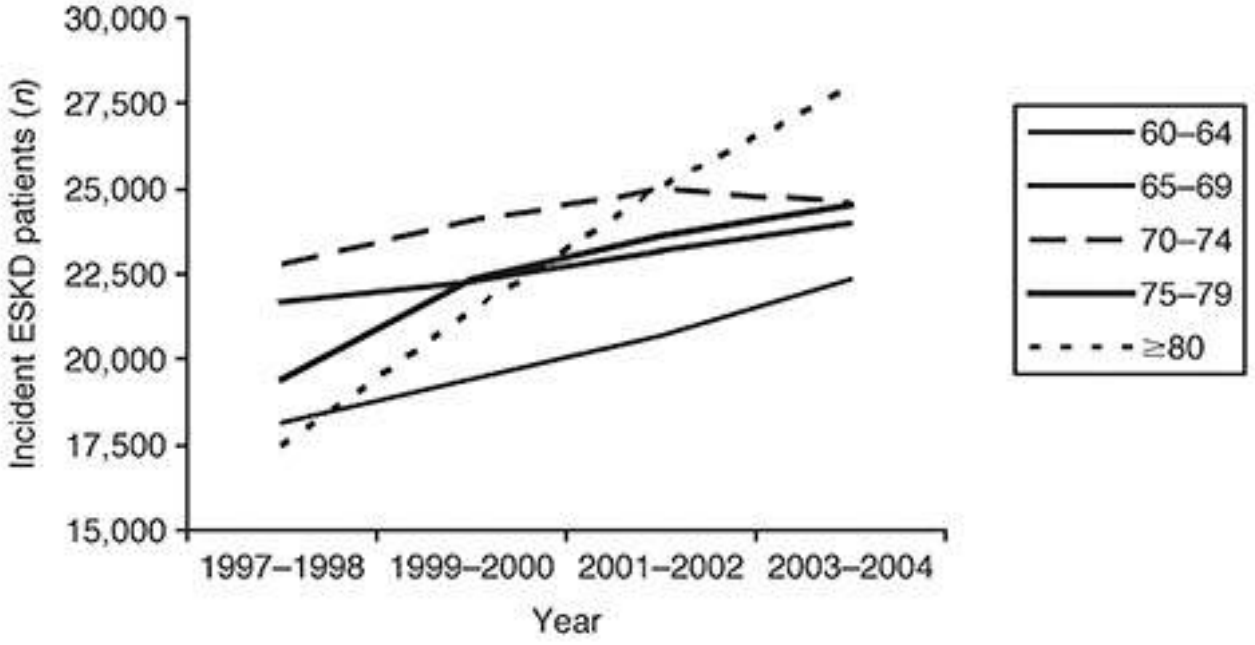

FIGURE 42.1 Incident cases with end-stage kidney disease (ESKD) in the United States among individuals aged 60 years or older (20).

Despite higher mortality rates and lower life expectancy, the rise in the elderly dialysis population in the United States is seen in prevalent as well as incident HD patients. In 2012, there were 244,324 individuals age 65 years and older prevalent in the ESKD program compared with 166,695 patients in 2004. This comprises 38% of prevalent patients with ESKD (includes individuals with a functioning transplant) and 44% of prevalent dialysis patients. The very elderly (over age 75 years) on dialysis numbered more than 94,000 (21% of the dialysis population). Although the rise in the total number of dialysis patients in the United States is apparent in all age-groups, with the prevalent dialysis population increasing from 335,000 in 2004 to 450,000 in 2012, the largest proportional increase (50%) is seen among individuals 75 years and older (**FIGURE 42.2**) (20).

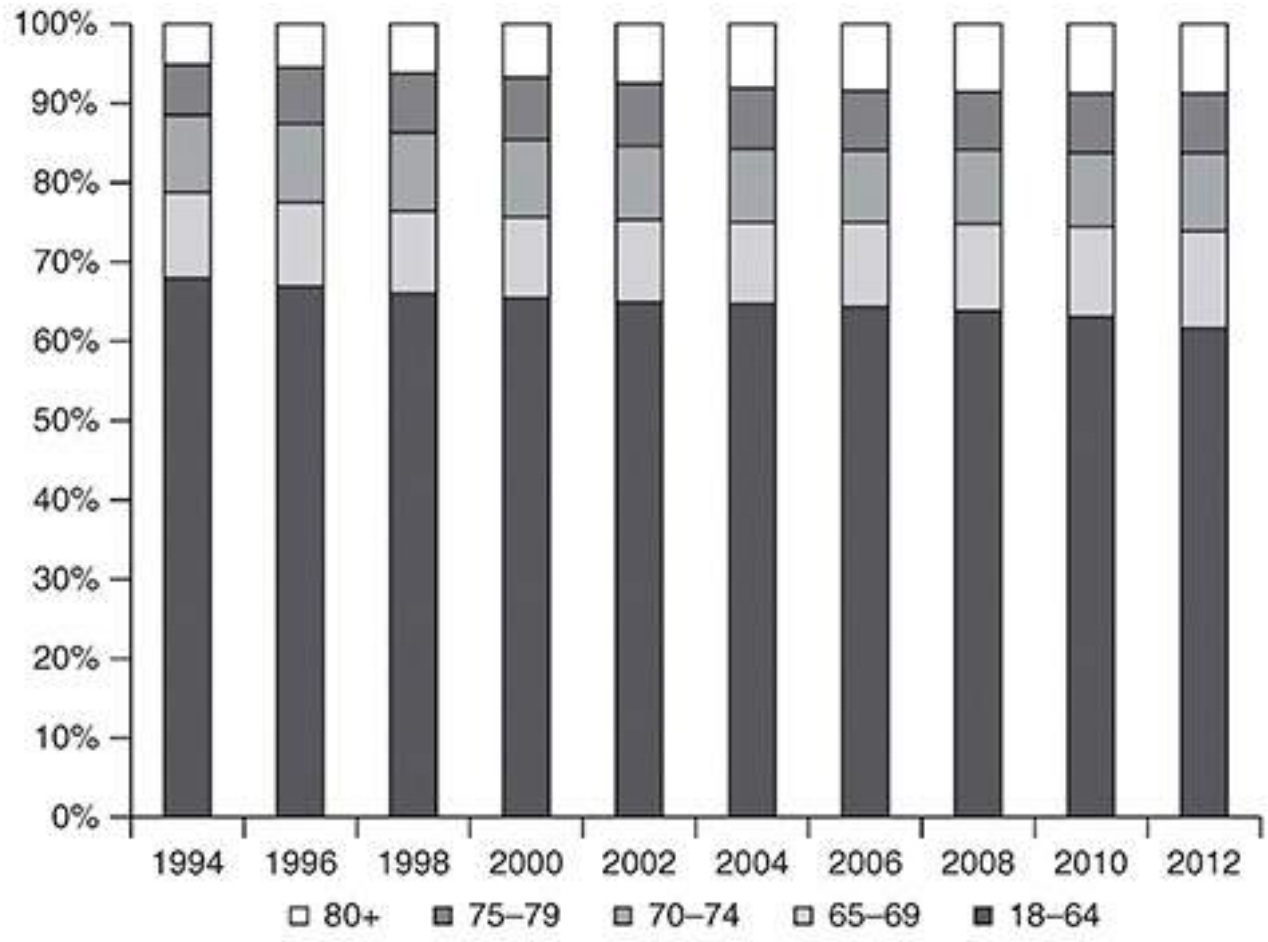

FIGURE 42.2 Prevalence rates of elderly hemodialysis and peritoneal dialysis patients in the United States from 2003 to 2012 as a proportion of the adult dialysis population.

As with younger patients, there remains a disproportionate, *albeit* far less marked, overrepresentation of ethnic minorities in the elderly U.S. population with ESKD. Although African Americans comprise 35.5% of the incident population with ESKD younger than 65 years, they comprise only 22.8% of the population with ESKD 65 years and older and just 17.3% of octogenarians and nonagenarians. A similar pattern is seen for those of Hispanic ethnicity (both African American and non–African American Hispanics), where the proportion of incident Hispanic dialysis patients declines as the population ages from more than 17% in individuals younger than 65 years to 11% among individuals aged 70 to 75 years and fewer than 9% among those 80 years and older (20). The reasons for this demographic shift are not known.

Causes of End-Stage Kidney Disease in the Elderly

Similar to the population as a whole, the most common causes of ESKD in the elderly are diabetes and hypertension. Among individuals 50 to 69 years old, diabetes is the primary cause in 50% and hypertension in 23%. In contrast, hypertension is reported as the primary cause in 38% of incident dialysis patients 70 years and older and in 46% of patients 80 years and older (**FIGURE 42.3**). This pattern is similar for prevalent dialysis patients (**FIGURE 42.3**). Notably, diabetes is increasingly the primary cause of incident ESKD in individuals both older and younger than 70 years (20). Unfortunately, due to the reluctance to biopsy elderly patients, even in the presence of common indications for biopsy including nephrotic-range proteinuria and unexplained kidney failure, elderly patients with treatable causes of kidney failure may go underdiagnosed and therefore untreated (17,22–24). This may explain the

high prevalence of hypertension as the primary cause of kidney failure as this diagnosis is often indicated in the absence of other known causes. Critically, elderly patients with atypical presentations of ESKD should be evaluated for treatable causes of kidney disease just as younger patients are.

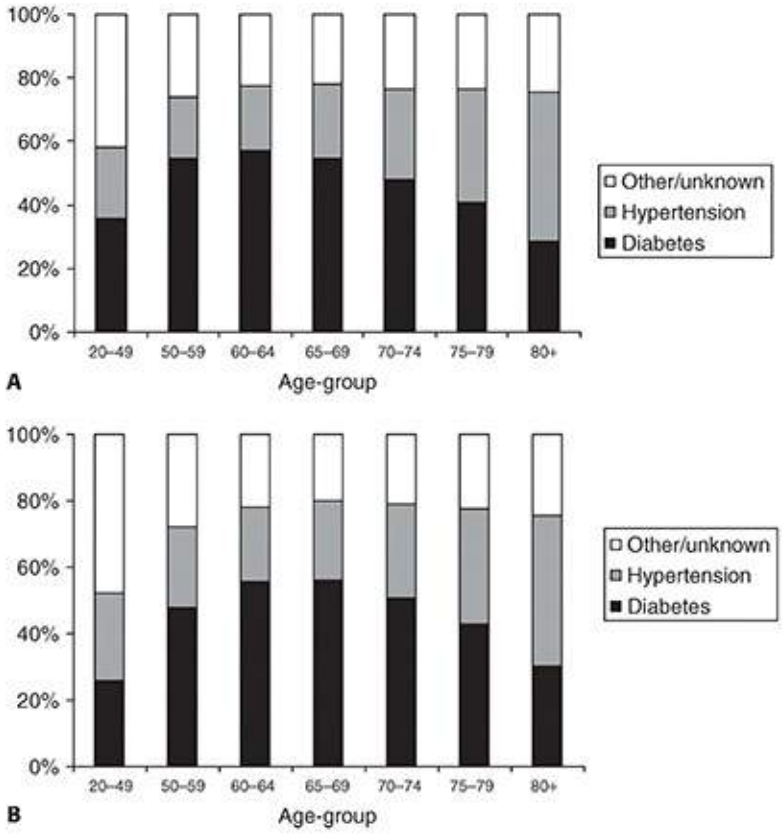

FIGURE 42.3 The primary cause of end-kidney renal disease (ESKD) among incident (**A**) and prevalent (**B**) dialysis patients in 2004. (From United States Renal Data System. *Annual Data Report: Atlas of End-Stage Renal Disease in the United States*. Bethesda, MD: National Institute of Diabetes, Digestive and Kidney Diseases, 2006.)

Mortality in End-Stage Kidney Disease in the Elderly

Although mortality is higher in the elderly ESKD population compared to their younger counterparts, elderly individuals with ESKD do surprisingly well on dialysis. In 2003, median survival was 16 months for individuals aged 80 to 84 years but dropped to less than a year for those 85 years and older. This compared with median survival of 24 months among individuals aged 65 to 79 years initiating dialysis in the United States (25). More recent data from the Dialysis Outcomes and Practice Patterns Study (DOPPS) demonstrates a median survival of 3 years for those patients starting dialysis after age 75 years compared to 6 years for those aged 45 to 74 years old (26).

This pattern is similar in other countries, and, with careful management, many elderly dialysis patients accommodate well to ESKD and maintain reasonably good quality of life (27–30). In Italy, patients initiating dialysis at age 65 years or older (mean 71.3 years) had a survival rate of 82.7% at 1 year and 62.3% at 2 years (31). In Spain, dialysis patients aged 65 to 85 years had the same mortality rate as the age-matched general population (32). A German study of 76 patients starting dialysis after age 80 years reported 1-year survival of 87% and 3-year survival of 52%. They noted improved outcomes linked with duration of predialysis nephrology care (33). In the very elderly dialysis population in Japan, the median survival in those 80 to 84 years old, 85 to 89 years old, and >90 years old was 3 years, 2.5 years, and 0.9 years, respectively (19). In a retrospective analysis from the United Kingdom, patients starting dialysis after age 80 years had 1-year survival of 78.5%, whereas the median time to death for those who pursued maximum conservative therapy for their advanced kidney disease was 6 months. However, these

results may have been skewed by some selection bias (34). Röhrich et al. (35) note that in their practice, there has been a progressive increase in mean survival time for patients who begin treatment when older than 80 years, from 22.7 months before 1990 to 28.3 months after 1990; they opine that this is due to improvements in dialysis techniques, diet, and anemia therapy. Despite these outcomes, a survey of physicians in the United Kingdom conducted in 1996 showed that a previously healthy octogenarian would not be referred for dialysis by 68% of primary care physicians or accepted for dialysis by 28% of nephrologists (36). Given the growth in the elderly dialysis population, it appears that these practices are changing.

Dialysis Modality

Elderly individuals initiating dialysis in the United States overwhelmingly receive HD. Compared to incident patients with ESKD younger than 65 years where 82.8%, 10.0%, and 3.8% initiated renal replacement therapy with HD, peritoneal dialysis (PD), and transplant, respectively, patients with ESKD 65 years and older had rates of 89.8%, 5.8%, and 0.9%, respectively, in 2012. This trend is most marked in the oldest patients with ESKD, where only 4.8% initiated renal replacement therapy with PD (21).

INDICATIONS FOR INITIATION OF DIALYSIS

Chronic Dialysis

The decision to initiate dialysis in the elderly is multifaceted, requiring careful weighing of advantages and disadvantages associated with this lifesaving modality. Unfortunately, many patients are not referred to nephrologists with sufficient time for careful decision making for initiating dialysis or determination of the optimal modality should the patient decide to initiate dialysis therapy. Non-nephrologist physicians may not be aware that elderly patients are candidates for dialysis therapy and may not recognize the severity of their kidney dysfunction, potentially leading to late referral. After adjusting for comorbid conditions, Mignon et al. (37) found that the increased mortality observed in the elderly in the first 3 months of dialysis correlated with late referral. It has been questioned whether earlier initiation of dialysis in the elderly may reduce this excess early mortality, but studies have not been conclusive. Meta-analyses certainly do not support the idea of initiating HD at a higher glomerular filtration rate (GFR), but there may be benefit to starting peritoneal dialysis earlier (24,38,39).

Determining when to initiate dialysis in elderly patients can be challenging due to problems of assessing kidney function in this population and the overlapping symptoms of uremia with other chronic or acute conditions common in the elderly. Decreased protein intake and loss of muscle mass lead to maintenance of the serum creatinine values despite an approximately 10% decrease in GFR per decade after the age of 40 years (40). Estimating equations, such as the Modification of Diet in Renal Disease (MDRD) study equation, are developed to accommodate this age-related change in creatinine generation (41,42). Although used widely, the MDRD equation tends to overestimate GFR in the elderly and recently has been shown to be less accurate than the newer Chronic Kidney Disease-Epidemiology Collaboration (CKD-epi) and Berlin Initiative Study (BIS) equations (43). In addition, GFR-estimating equations cannot account for accelerated muscle loss that may occur with very frail or sick patients and therefore tend to overestimate actual GFR in such patients. Cystatin C, a filtration marker that is not generated from muscle, has been posited to be a better marker than creatinine, especially in the elderly. However, we now know

that there are non-GFR determinants of cystatin C levels, making its utility as a sole filtration marker similar to that of serum creatinine. The most accurate GFR estimation equations in the elderly appear to be those that include both serum cystatin C and creatinine measurements (43).

In addition, symptoms often attributed to uremia are commonly seen in other chronic conditions in the elderly. Porush and Faubert (16) evaluated the signs and symptoms present before initiation of maintenance dialysis in 118 elderly patients. The most common symptoms were anorexia and weight loss (61%), generalized weakness (58%), encephalopathy (49%), and nausea and vomiting (41%), many of which are seen in other diseases. Some potential indications for a trial of dialysis in the elderly are listed in **TABLE 42.1**. There are several reasons why nephrologists may not initiate dialysis in an elderly person. In particular, it may be appropriate not to initiate dialysis in patients with dementia given the need for cooperation to safely deliver adequate dialysis.

TABLE 42.1 Indications for a Trial of Dialysis in the Elderly

Uremia
Potentially reversible acute renal failure
Unexplained dementia or cognitive impairment
Unexplained worsening of congestive heart failure
Personality change
Irritability, irascibility, or newly subdued demeanor
Adult failure to thrive
Change in sense of well-being

Acute Dialysis

The effect of age as an independent risk factor for development, mortality, and prognosis in acute kidney injury (AKI) has been well established (44–51). In a study of critically ill patients, there was a 20% greater rate of AKI in those patients greater than 75 years compared with the age-group of 18 to 54 years (52). An analysis of Medicare data showed that for the years 1992 to 2001, the overall incidence rate of AKI was 23.8 cases per 1,000 discharges, with rates increasing by approximately 11% per year. Older age, male gender, and African American race were strongly associated (p <0.0001) with AKI (53). Subsequent data has demonstrated a further increase in incidence of AKI across all ages and races from 2000 to 2009 (52). As advanced age is a strong risk factor, this increase in AKI to some extent is explained by the overall growth in the elderly population (44,51). Other contributing factors include higher incidence of comorbidities such as hypertension, cardiovascular disease, and chronic kidney disease (CKD), in addition to exposures such as surgery, sepsis, and nephrotoxic medications (44,45,54).

In addition to age, prognosis in AKI appears related to the presence of comorbid conditions, cause of the acute illness, oliguria, requirement for dialysis, and number of nephrotoxic events (44,45,47,54–57). In the analysis of Medicare patients described earlier, the in-hospital mortality rates were 15% and 33% in discharges with AKI diagnostic codes as the principal and secondary diagnosis, respectively, compared to 5% without a diagnosis code for AKI. Death within 90 days of hospital admission was 35% and 49% in discharges with AKI as the principal and secondary diagnosis, respectively, compared to 13% in discharges without AKI (46). Among cases of AKI, mortality was greatest in the oldest patients (52,58). In critically ill patients with AKI, in-hospital mortality was 24% versus 13.9% when comparing the oldest patients (>75 years) to the youngest (<54 years). This trend continued to the 90-day point with mortality rates of 35.7% versus 17.2% in the oldest versus youngest groups (52). In terms of renal

recovery, a meta-analysis of 17 studies demonstrated advancing age to be a negative predictor of renal recovery (59). Kane-Gill et al. (52) noted an overall renal recovery rate at 90 days of 31%, but patients aged 18 to 54 had a 15.8% higher rate of recovery compared with those over age 75 years.

There is frequently reluctance to initiate dialysis in an elderly individual with AKI and multiple medical or psychosocial disorders because of the fear of committing the patient to chronic long-term dialysis or because of ethical concerns (60). In fact, despite the highest incidence of AKI, patients over age 75 years are least likely to receive renal replacement therapy (RRT) (52). However, while elderly survivors of AKI seem to require more time for total recovery and recover function less completely, dialysis should not be automatically withheld. These patients should be involved in a shared decision-making process with the nephrologist and a trial of dialysis should be considered following a discussion of overall prognosis, comorbidities, functional status, and perceived risks and benefits of RRT (45,60–62).

CHOOSING A RENAL REPLACEMENT THERAPY MODALITY

Hemodialysis versus Peritoneal Dialysis

As in younger populations, factors affecting the selection modality for treatment of ESKD in the elderly include patient or physician preference, availability of trained personnel, proximity to a dialysis center, concurrent illnesses or comorbid conditions, and specific contraindications to a particular modality. Potential advantages of PD in the elderly include better preservation of renal function, avoidance of large volume or electrolyte shifts leading to improved cardiovascular stability, allowance of a more liberal diet, avoidance of vascular access, decreased transportation time, and ease of travel and holiday times (63). Patients who tolerate HD poorly because of cardiovascular disease or difficulty with vascular access also may do better with PD (64,65), whereas HD may be a better choice for patients with inguinal or abdominal hernias, diverticulitis, compromised peritoneal surface area secondary to abdominal surgery or adhesions, abdominal aortic aneurysm, morbid obesity, or physical or psychosocial inability to perform PD (9). Many patients find PD more compatible with an independent lifestyle and desire active participation in their treatment, whereas others find the responsibility of self-care overwhelming. There may be age bias in this selection process (66).

There are conflicting reports as to the survival advantage of one modality over another in elderly patients. In a small European study of patients older than 70 years, the annual mortality rates in PD versus HD were similar (26.1 vs. 26.4 deaths per 100 person-years) (67). However, other analyses in the United States have suggested increased mortality rates for those on PD, particularly among the elderly and those with diabetes (68–70). A study of 1,041 patients beginning HD and PD in 81 dialysis clinics in 19 U.S. states showed an increased risk for mortality for PD patients after the first year of dialysis with no difference based on patient age (71). Recent large cohort studies have provided more clarity on the issue. In an analysis of all incident dialysis patients between 1996 and 2004 in the United States, Mehrotra et al. (72) demonstrated no significant difference in risk of death between those treated with HD or PD in the cohort of patients beginning dialysis after 2002. The increased mortality that had previously been seen in PD patients decreased over time, suggesting that advances in PD have seemingly closed this survival gap

between HD and PD. In concordance with prior studies however, the subset of diabetic patients over age 65 years continued to have an increased risk of death with PD (72). In a large study of all incident dialysis patients in the United States, Weinhandl et al. (73) used a propensity-matching scheme to compare HD versus PD survival given the inability to have a true randomized trial. Their results support the finding of decreased survival with PD versus HD in patients >65 years of age, diabetics, and those with cardiovascular disease (73). It has been suggested that poor nutritional status in diabetic PD patients may account for increased mortality (74). Excess mortality for elderly PD patients is relevant in consideration of appropriate treatment modality and must be included in the equation along with considerations of comorbidity, quality of life, distance from center, and other issues.

Peritoneal Dialysis in the Elderly

In the United States, 8.1%, 6.4%, 5.9%, and 4.9% of dialysis patients aged 20 to 44 years, 45 to 64 years, 65 to 74 years, and older than 75 years are on PD compared to 49.7%, 60.2%, 70.0%, and 86.1% on HD (20). Other countries have a higher use of PD, likely in part, due to geographic and financial considerations. In Hong Kong, Mexico, and New Zealand, for example, 74%, 49%, and 33% of patients are on PD, respectively (20). In most countries, PD use decreases as patients age, especially for the older-than-75-year age-group; exceptions are New Zealand and Iceland, where 60% and 47% of patients aged 75 years or older were treated with PD as of 2004 (75). Worldwide use of home HD also decreases dramatically with age; in-center HD is the predominant modality for dialysis patients older than 65 years (**FIGURE 42.4**) (75).

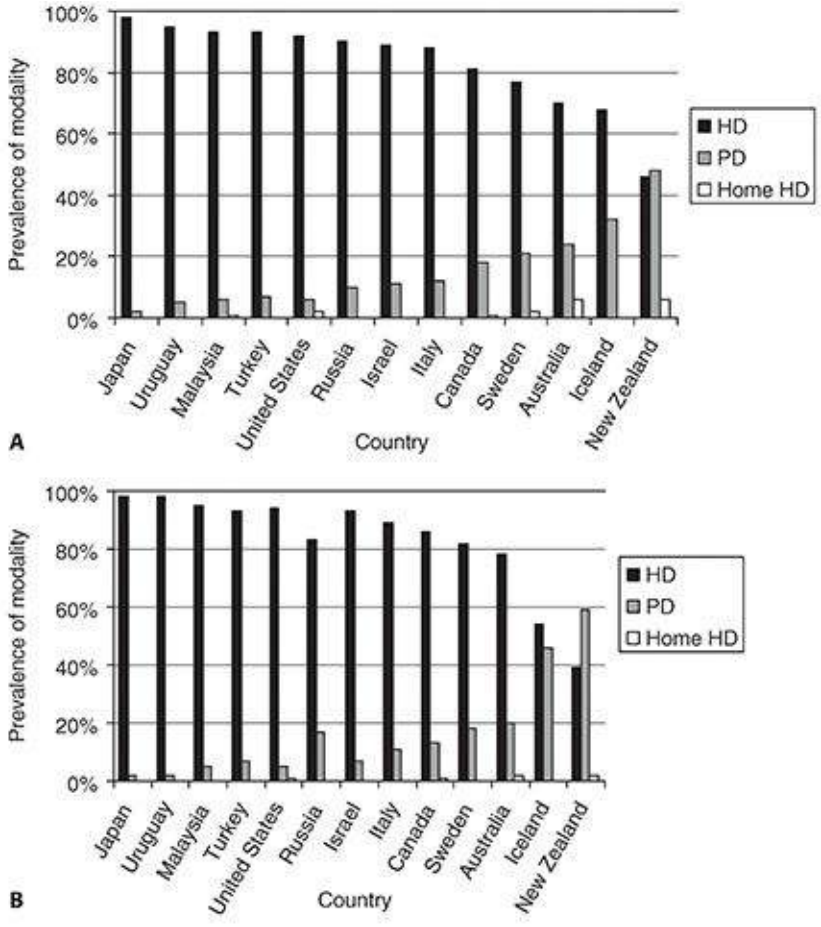

FIGURE 42.4 Dialysis modalities among elderly individuals by country among individuals aged 65 to 74 years **(A)** and older than 75 years **(B)**. HD, hemodialysis; PD, peritoneal dialysis. (From United States Renal Data System. *Annual Data Report: Atlas of End-Stage Renal Disease in the United States*. Bethesda, MD: National Institute of Diabetes, Digestive and Kidney Diseases, 2006.)

As a home-based modality, PD may help elderly patients with ESKD maintain independence (63). Additionally, in patients with excessive volume gains, hemodynamic instability, or limited vascular access options, PD may be the most desirable ESKD treatment modality for medical reasons. Unfortunately, many elderly patients may perceive limitations in their ability to perform PD; reasons include decreased strength and manual dexterity, vision problems, limitations in mobility, and anxiety. Another limitation, not often considered, is storage space for dialysate and potentially for a cycler; this may assume greater importance in the elderly who often have limited housing options. Finally, assistance from a family member or paramedical staff may be essential (76). Automated PD, such as continuous cyclic peritoneal dialysis (CCPD), or intermittent peritoneal dialysis (IPD) may be a good option for the elderly patient who requires assistance with dialysis, particularly when the assisting spouse or children work during the day (63,77–79).

A recent retrospective cohort study in France analyzed data from all incident PD patients between 2002 and 2010. In comparing those requiring assisted PD (PD performed with assistance of a health care technician, community nurse, or family member) versus self-care PD, they found a lower risk for transfer to HD (80). Those patients requiring assisted PD were generally older (mean age 78 years vs. 56 years), had a higher Charlson Comorbidity Index, and were found to have a higher risk of death attributed to the aforementioned differences between these groups. A cost analysis of this French system found PD, even when requiring assistance, a cheaper alternative to in-center HD (81). In Hong Kong, a comparison of elderly patients on assisted chronic ambulatory peritoneal dialysis (CAPD) and those performing self-care CAPD noted no difference in patient survival, technique survival, or peritonitis-free period between these groups. Two-year survival was 88% in the self-care group and 95% in the assisted group with technique survival rates of 84.7% and 80.9%, respectively (82). In a recent study in Toronto, Canada, when home care assistance was available, only 20% of the elderly population had contraindications to PD, and 59% of those eligible accepted it (83). These experiences suggest a role for assisted PD to safely and effectively increase utilization of PD among the elderly.

Home Hemodialysis in the Elderly

In recent years, there has been increased international interest in home HD as an alternative to both PD and in-center HD. Several nonrandomized studies have shown improved morbidity and mortality, although the magnitude of the advantages may differ on method of delivery (84–86). Home HD requires a high level of functional status and independence by the patient as well as appropriate physical space, support, and resources (84,86). Given the multiple comorbid conditions and common frail status, many elderly patients may not be eligible for this therapy.

In the United States in 2012, 0.4% of dialysis patients aged 65 to 74 years and 0.3% of patients aged 75 years and older chose home HD as their first modality; this is comparable to the very low level of home HD use in other age-groups in the United States (20). Worldwide, the proportion of individuals using home HD declines as the population ages (75,87). Agraharkar et al. (85) suggest that staff-assisted home HD may be an appropriate short-term option for debilitated or terminally ill patients, particularly when ambulance transportation is required. A financial analysis performed in 2002 revealed that staff-assisted home HD was less costly than either in-hospital HD or outpatient HD with ambulance transportation, with a week of staff-assisted home HD costing $1,200 and a week of in-center HD with ambulance transportation costing $2,640 (United States).

Transplant as a Modality for Kidney Replacement in the Elderly

Although low, transplant rates among the elderly have been steadily rising. In 1990, only 1.9% of all transplants in incident ESKD patients occurred in those over the age of 65 years, while in 2002, this number had increased to 7.7%. According to 2012 United States Renal Data System (USRDS) data, 16.6% of incident ESKD patients receiving transplants were between the ages of 65 and 74 years, and 2% were 75 years or older (20).

Recent reports have recognized the benefits of kidney transplantation for carefully selected older patients (88–90). Although elderly transplant recipients have a higher mortality rate than younger patients, they also have a 41% lower risk of death than age-matched patients on the transplant waiting list (89,90). In a 2005 study, the expected survival for dialysis patients over the age of 70 years was 8.2 years for those who received a kidney transplant compared to 4.5 years for those that remained on the wait-list (91). Wolfe et al. (89) showed that the risk of death decreases below the waiting list group by 148 days after transplant in the elderly as compared to 95 days for patients aged 40 to 59 years. Owing to reduced life expectancy in older adults, death with a functioning graft occurs in 50% of patients older than 65 years, and most grafts last throughout the life of the transplant patient (88,91,92).

Given the heterogeneous population of older patients with ESKD, it may be a challenge for medical providers to decide which patients to recommend for transplant evaluation. Decision to refer a patient for transplant evaluation should be made on an individual basis, independent of age (27,93–96). As in younger patients, kidney transplantation evaluation should be performed to identify conditions that may interfere with surgery, recovery, or the patient's survival after surgery. Advanced peripheral vascular disease and cardiac disease are the most common barriers to kidney transplantation in the elderly. In addition, smoking and obesity may be more important relative contraindications for the elderly (88).

As the population with ESKD has increased, the supply of kidneys has not met demand (88). Practices in the United States and internationally have evolved to meet this demand by creating the expanded criteria donors (ECD) list, a full description of which is beyond the scope of this chapter (88). Port et al.'s (97) analysis of U.S. kidney transplant recipients from 1995 to 2000 shows that it takes 1.5 years for patients to achieve better outcomes from ECD kidneys than from dialysis alone, and Ojo (98) demonstrates that an ECD kidney transplanted to recipients older than 65 years results in 3.8 years of projected additional life span. A recent study by Molnar et al. (99) demonstrated that ECD kidneys were significant predictors of mortality in nonelderly patients (<70 years old), but in the elderly population, there were similar patient and graft survival outcomes when comparing ECD versus non-ECD allografts. It is recommended to use ECD kidneys in older patients, especially those with diabetes, who are shown to have increased benefit from reduced waiting time and may have shorter life expectancies, thereby maximizing the benefit of ECD kidneys (88,89,100).

DIALYSIS TECHNICAL CONSIDERATIONS

Hemodialysis Vascular Access

Following the publication of the first National Kidney Foundation (NKF) Clinical Practice Guideline on vascular access in 2001 (101), the 2005 Fistula First initiative in the United States was promoted as a means to "substantially improve the health of Americans who need kidney dialysis or transplantation"

(102). Although fistula rates in the United States increased subsequent to these campaigns, much of this rise is attributable to a precipitous drop in arteriovenous graft (AVG) use with a much more modest decline in catheter use. From 1997 to 2013, fistula prevalence increased from 24% to 68% with a decline in AVG use from 49% to 18% and catheter use from 27% to 15% (103). This has led to a call for a "catheter last" rather than just a "fistula first" strategy (104).

Despite success in increasing fistula prevalence, little progress has been made in reducing catheter use among incident HD patients. In an analysis of the DOPPS from 2012 to 2014, 67% of patients in the United States initiated HD with a catheter, 28% with a fistula, and 5% with an AVG (103). More concerning is the relatively low rate of conversion to use of a graft or fistula, particularly among the elderly. In a report from Centers for Medicare & Medicaid Services ESKD Clinical Performance Project, among individuals who initiated with a catheter, 59% were still catheter dependent, while 15% had transitioned to a fistula and 25% to a graft after 3 months. Critical within this report is that, in adjusted analyses, individuals younger than 50 years had a twofold increased likelihood of converting to arteriovenous fistula (AVF) use compared with patients older than 75 years [odds ratio (OR) 2.14, 95% confidence interval (CI) 1.40 to 3.28], whereas patients between 65 and 74 years of age were 39% more likely to convert to AVG use than continue to use a central venous catheter compared with patients older than 75 years (OR 1.39, 95% CI 1.01 to 1.92) (105).

In this section, the advantages, disadvantages, and special issues associated with permanent vascular access methods in the elderly HD patient are discussed.

Fistulas

Multiple recent studies have focused on the question of ideal HD vascular access in the elderly as there are notable differences in this population compared to younger counterparts. Because of the high prevalence of diabetes, chronic hypertension, and both atherosclerosis and arteriosclerosis, the vascular substrate for access creation is certainly less satisfactory than that in younger patients (106). Not surprisingly, fistulas are less prevalent and catheters are more prevalent in elderly U.S. dialysis patients (**FIGURE 42.5**).

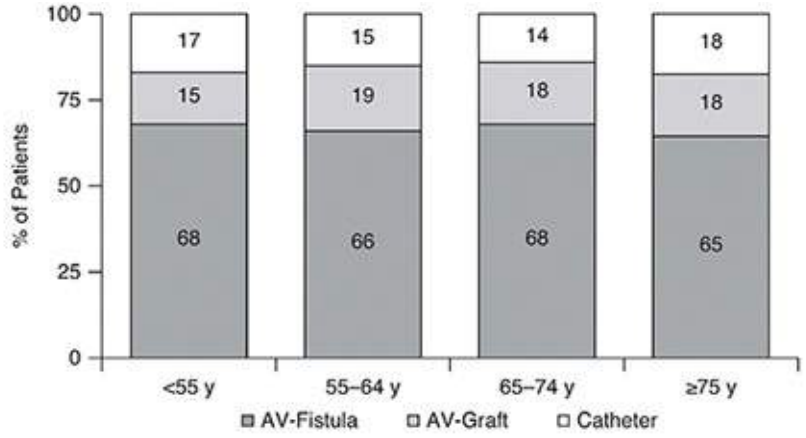

FIGURE 42.5 Vascular access use among a cross-section of U.S. prevalent patients by age. (From Pisoni RL, Zepel L, Port FK, et al. Trends in US vascular access use, patient preferences, and related practices: an update from the US DOPPS Practice Monitor with international comparisons. *Am J Kidney Dis* 2015;65:905–915.)

Current Kidney Disease Outcome Quality Initiative (KDOQI) recommendations suggest that a fistula should be placed at least 6 months before the anticipated start of HD treatments. This time frame is suggested to allow for both initial access evaluation as well as additional time for revision to ensure that

a working fistula is available at initiation of dialysis therapy (107). In general, a working fistula must have the following characteristics: blood flow adequate to support dialysis (generally greater than 600 mL/min); a diameter greater than 0.6 cm, with location accessible for cannulation and discernible margins to allow for repetitive cannulation; and a depth of approximately 0.6 cm (ideally, between 0.5 to 1.0 cm from the skin surface). Determination of whether a fistula is likely to function may take up to 2 months, and adequate maturity for cannulation as much as 4 months, particularly with upper arm access in individuals with small veins at baseline. Not unexpectedly, the primary failure rate of fistulas may be higher in elderly patients and further attempts at fistula creation may be needed, resulting in a longer duration from initial fistula creation to successful fistula use. It is easy to foresee that this process may take a year or more, even with a dedicated access team. Does this mean that fistula creation should occur even earlier in the elderly? On an individual patient level, it makes sense—the earlier the fistula creation, the more attempts can be made to obtain successful access. However, particularly in the elderly, the earlier a fistula is created, the more likely it is that a patient will die of other causes before requiring dialysis (108). The competing risk of death increases with increasing age; Lee et al. (109) found in a cohort of 3,418 elderly (>70 years old) CKD patients who had predialysis access created, 67% started dialysis within 2 years. However, when stratified further by age, 69% of those aged 70 to 74 years initiated dialysis within 2 years with only 12% dying before requiring dialysis, while for those over the age of 85, 21.9% died before requiring dialysis with 60% initiating dialysis within the 2-year follow-up period (109). Furthermore, a recent study evaluating the optimal timing of fistula placement in the elderly concluded that there appears to be little benefit of placing access more than 6 to 9 months prior to anticipated need to start dialysis. The likelihood of initiating dialysis with a functioning fistula increased with fistula creation greater than 3 to 6 months prior to starting dialysis but plateaued after the 6- to 9-month range. In addition, the number of interventional access procedures increased over time, greatest in those who had fistulas placed >12 months predialysis (110). In another study of individuals 75 years and older, the number of access surgeries needed to allow one elder to initiate dialysis with a functioning fistula ranged from 8 to 12 procedures when surgery was performed at a GFR of 25 mL/min/1.73 m^2 or lower to two to three surgeries at a threshold of 15 mL/min/1.73 m^2 within a 6-month time frame (108).

A large study of fistula placement in an elderly population retrospectively evaluated access success among 196 patients aged 65 years and older and 248 patients younger than 65 years (111). There was a 64.8% primary and 75.1% cumulative fistula patency at 1 year among patients 65 years and older. This was comparable to that seen in younger patients. However, fistulas in the elderly group were more likely to have maturation failure with a relative risk of 1.7 compared to the <65 group. It is notable that analysis by anatomic type showed better survival of radiocephalic fistulas in the younger cohort, which had been described previously (112).

Fistula success can be maintained in an elderly population. Although Leapman et al. (113) demonstrated only 40% patency rates at 1 year among patients 70 years or older, many others reported better results. Wing et al. (114) reported 80% 1-year fistula survival in individuals older than 65 years, whereas Berardinelli et al. (112) described 78% 3-year patency for upper arm fistulas and 57% patency for forearm fistulas. Konner et al. (115) describe excellent 1-year primary access survival of first AVFs for nondiabetic patients 65 years and older (73% for women, 77% for men) and diabetic patients 65 years and older (78% women, 81% men) with use of either forearm AVFs or perforating vein or nonperforating

vein fistulas at the elbow.

Grafts

Prosthetic grafts have a higher stenosis rate and a higher infection rate than AVFs (see Chapter 3) (106). The most common cause of graft loss is uncorrected stenosis with associated thrombosis (116). This is probably not different in the elderly. As in younger patients, it is vital to look for underlying cause(s) of thrombosis and try to correct them (16,106,117). Although KDOQI guidelines favor active access monitoring of AVGs, small studies have failed to show a consistent benefit in graft survival.

Tunneled Catheters

An indwelling central double-lumen cuffed catheter or twin single-lumen tunneled cuffed catheters may be the preferred intermediate or long-term access for some patients (118,119), in particular, those individuals who lack adequate vessels for fistula or graft creation, individuals with limited life expectancy, and individuals prone to steal syndrome with severe high-output heart failure unable to tolerate AVFs or grafts; these situations are all more common in the elderly than in younger patients.

One Strategy for Access in Geriatric Dialysis Patients

There are no clinical trials to guide therapeutic decisions for dialysis access in the elderly. Numerous studies have found that survival among incident dialysis patients with a functioning AVF is superior to that with a catheter or graft; however, survival with a graft is far superior to that with a catheter (**FIGURE 42.6**) (120). A large recent analysis of outcomes in elderly patients (>67 years old) based on predialysis access placement found no significant mortality difference between those patients who had a fistula placed as initial access versus those with AVG placement (121). When stratified further by age, it appeared there was a survival benefit for those ages 67 to 79 years with initial fistula placement compared with those with an AVG, but this disappeared in those greater than 80 years old. Importantly, of those with a fistula as their predialysis access, only 50.7% initiated dialysis with an AVF, the remainder required catheter placement. In those with an AVG as predialysis access, only 25.4% required conversion to catheter at time of dialysis initiation. This increased conversion to catheter use likely limits the prior benefits associated with “Fistula First” in the elderly. Another key variable as described by O’Hare et al. (108) is that many elderly individuals either do not progress to kidney failure or die before requiring dialysis. On the basis of clinical experience, observational data, and KDOQI guidelines, the authors favor the approach presented in **TABLE 42.2** for individuals receiving care before kidney failure, taking into consideration life expectancy and expected time until dialysis will be required. This strategy should allow for at least one revision in the setting of primary access failure and allows the surgeons to progressively work their way up the arm. Finally, although a forearm access may not become usable for dialysis, often times in the setting of inflow stenosis, early creation may facilitate more rapid maturation of an upper arm outflow vein, especially when anastomosed to the larger caliber upper arm brachial artery.

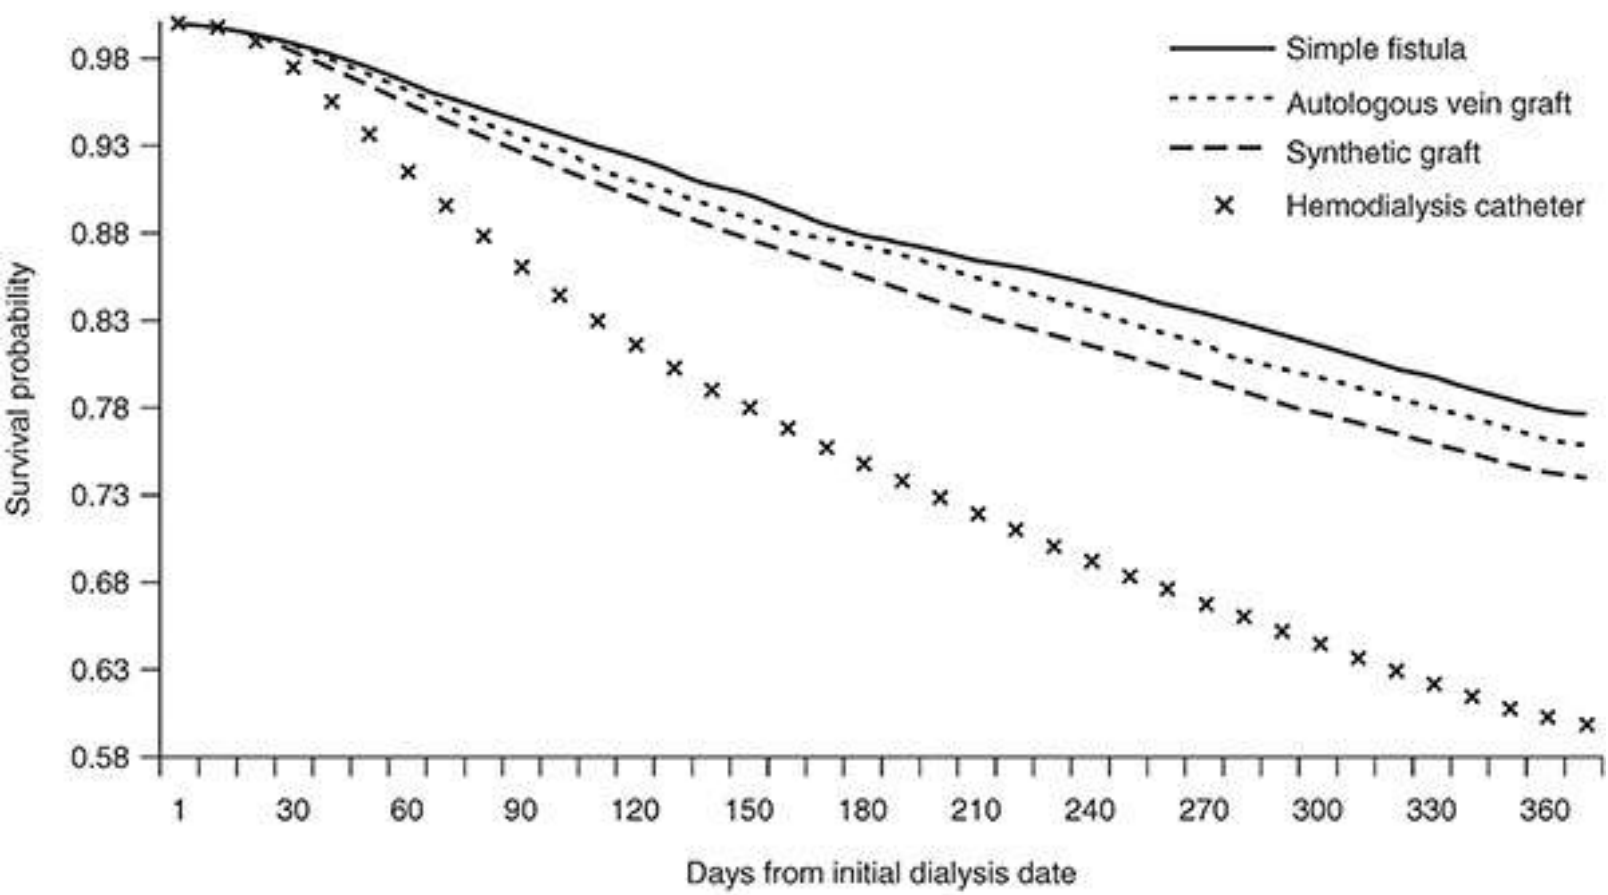

FIGURE 42.6 Survival probability by dialysis access type at initiation among Medicare recipients in 1995, 1996, and 1997: age 67 years and older, adjusted for age, race, sex, year, blood urea nitrogen (BUN), creatinine, albumin, diabetes, and time since access placement. [Xue JL, Dahl D, Ebben JP, et al. The association of initial hemodialysis access type with mortality outcomes in elderly Medicare ESRD patients. *Am J Kidney Dis* 2003;42(5):1013–1019.]

TABLE 42.2 Strategies for Vascular Access in Elderly Individuals with Stage 4 to 5 Chronic Kidney Disease

For all patients
1. Nephrology referral by onset of stage 4 CKD (eGFR <30 mL/min/1.73 m^2)
2. Discussion of modality choice at onset of stage 4 CKD

For patients referred before need for renal replacement therapy
1. Ultrasonographic artery and vein mapping of both arms to facilitate a hemodialysis access plan
   a. If unsuccessful, contrast venography can be considered.
   b. Use very low volume of contrast and premedication.
2. Avoidance of venipuncture in the designated extremity based on vein mapping
3. Assessment of life expectancy (no tools available at this time to assist)
   a. Poor life expectancy (<2 y); place AV graft ~3–4 months before expected dialysis initiation, preferably a forearm loop graft in the nondominant arm
   b. Good life expectancy (≥2 y); place AV fistula at least 1 year before expected dialysis initiation, beginning with a forearm fistula if the vessels are viable

For incident or prevalent elderly dialysis patients with a catheter for access
1. Ultrasonographic artery and vein mapping of both arms or contrast venography to facilitate a hemodialysis access plan
2. Avoidance of venipuncture in the designated extremity based on vein mapping
3. Assessment of life expectancy (no tools available at this time to assist)
   a. Poor life expectancy (<1–2 y); place AV graft, preferably a forearm loop graft in the nondominant arm
   b. Good life expectancy (≥1–2 y); place AV fistula, beginning with a forearm fistula if the vessels are viable

CKD, chronic kidney disease; eGFR, estimated glomerular filtration rate; AV, arteriovenous.

A similar approach can be taken in elderly individuals initiating dialysis with a catheter, especially as it was demonstrated in a *post hoc* analysis of Hemodialysis (HEMO) Study data that changing vascular access type from a catheter to a fistula or graft was associated with a substantially lower risk for mortality compared with continuous use of a catheter, whereas changing from a fistula or graft to a catheter was associated with more than a twofold greater death rate compared with patients who used a fistula or a graft throughout the study (122). A strategy for incident or prevalent elderly dialysis patients with a catheter for access is also summarized in **TABLE 42.2**. The rationale behind these time frames is that the median survival of an AVG for individuals initiating dialysis with a functioning graft is more than 1 year (123), indicating that in individuals with limited life expectancy, it may be a beneficial trade-off to have higher initial success rates as seen with grafts than higher long-term access survival rates seen with a fistula.

Peritoneal Dialysis Access and Performance

Catheter Survival

In the early days of CAPD experience (1982), Ponce et al. (124) found decreased 2-year peritoneal catheter survival (67% vs. 78%) and increased pericatheter dialysate leakage (42.3% vs. 26.9%) in patients older than 60 years compared with younger patients. They hypothesized that the difference was secondary to “loose abdominal walls.” Because more than 90% of dialysate leaks occurred within the first week of insertion (catheters were used immediately) and leakage resolved if the catheter was not

used for 1 to 2 weeks, catheters are usually inserted 2 to 3 weeks before use, with temporary HD if necessary, until the insertion site is completely healed. If it is necessary to use the catheter earlier, small frequent exchanges are employed with the patient in the supine position, gradually increasing in volume once integrity has been established (10).

Contrary to earlier findings, recent studies support the finding that catheter survival is either equivalent or improved in older versus younger patients (65,125,126). Kim et al. (127), in a retrospective multiyear comparison of peritoneal catheter survival with arteriovenous access, found greater long-term peritoneal access than arteriovenous access patency, particularly in diabetic patients and the elderly. Gentile (125) observed fewer catheter-related complications in elderly patients than in younger patients.

Peritonitis

Several large studies reveal no differences in peritonitis rates between young and old PD patients (10,65,125,126,128–130). Nissenson et al. (126), in a large two-center study, reported that after 1 year of CAPD, 60% of patients younger than 60 years were free of peritonitis versus 65% of the patients older than 60 years. At 3 years, the figures were 38% and 46%, respectively, and at 7 years, 30% and 38%. Nolph et al. (128) found an increased incidence of peritonitis in bedridden patients, although there was no increase in exit-site and tunnel infection rates or catheter replacements. A recent study evaluated first year outcomes in incident peritoneal dialysis patients and reported the highest rate of peritonitis among those aged 55 to 65 years old (43 per 100 patient-years) with lower rates in those younger than 55 and older than 65 years (131). See Chapter 37 for further discussion of peritonitis in CAPD patients.

Exit-Site and Tunnel Infections

There is little difference in exit-site infection rates (10,128), tunnel infections (65,128), or dialysate drainage pain in young versus elderly CAPD patients (10,132).

Adequacy

Poor adequacy may be related to poor drainage. This may be commonly caused by constipation in the elderly and can be treated with laxatives or catheter reinsertion. There are no reports as to differences in membrane characteristics by age.

Automated Peritoneal Dialysis

The use of automated or assisted PD can facilitate the use of this therapy even in patients with apraxia, cognitive difficulties, or even a person with disability treated either at home or at a nursing home.

SPECIAL SITUATIONS IN THE ELDERLY DIALYSIS PATIENT

Compliance with Therapy

There are little data evaluating compliance with dialysis prescriptions and lifestyle among the elderly. Recently, however, a recent large retrospective study of over 180,000 HD patients found that missed treatments were more frequent among younger patients (133). Avram et al. (134) describe a positive

correlation between increased age and lower intradialytic weight gain, lower serum creatinine, and lower urea generation rate for both HD and PD patients, whereas McKevitt et al. (135) noted that dialysis patients aged 60 years and older demonstrated good compliance with potassium restriction, fair to good compliance for serum phosphorus, and fair to poor compliance with fluid restriction. Many factors may influence compliance among the elderly. These include cognitive impairment, visual impairment, depression, and social support. Therefore, individualized approaches to compliance and social support for the elderly dialysis patient, including evaluation of physiologic and psychosocial factors are essential for dialysis success (135–137).

Infection

Abnormalities of Immune Function with Aging

The altered immune status of uremia (138,139) is complicated in many elderly patients by similar changes in the immune system that may occur with aging, including increased susceptibility to infection and malignancy (140), and abnormalities in lymphocyte function and cell-mediated and humoral immunity (141,142). Whether there is a specific interaction with age, such that the double hit of uremia and aging synergistically enhances the risk of infection, is unknown. Whereas an older Israeli study found that infection was the most common cause of death in patients beginning dialysis at age 80 years or older, USRDS data reveal that, among prevalent U.S. dialysis patients aged 75 years and older, cardiovascular disease was 4 times more often the cause of death than infection from 2010 to 2012 (20,143).

Manifestations of Infection in the Elderly

In addition to changes in immune responsiveness, the presentation of infection in elderly patients is often subtle (see Chapter 37). The elderly patient may not manifest fever or leukocytosis, and even severe processes like acute abdomens may have less apparent manifestations. Similarly, elderly dialysis patients may manifest occult infection in subtle ways, including anorexia, apparent depression, vague feelings of malaise, apparent development of dementia, or decreased ability to cope with the usual activities of daily living. Occasionally, the only indication of infection is an increase in predialysis blood urea nitrogen (BUN) levels without any apparent change in clinical status (144). Notably, urinary tract infections are common in the elderly but may be overlooked as a potential source in dialysis patients (145,146). Successful treatment of infection is generally associated with a return to the previous level of function.

Nutrition

Nutrition and Outcomes

It is particularly important to emphasize adequate nutrition in the older dialysis patient. The presence of protein-energy wasting and serum albumin levels have been shown to be independent predictors of mortality in dialysis patients (147). Both serum albumin and prealbumin predict hospitalization and mortality due to infection (148). Whether reduced nutritional indices are a marker of infection or indicate individuals predisposed to infection is unknown, although Kalantar-Zadeh and Kopple (149) postulate the existence of a “malnutrition inflammation complex syndrome” in maintenance dialysis patients with protein-energy malnutrition that predisposes to illness and infection and leads to poor quality of life and increased morbidity and mortality.

Strategies to Enhance Nutrition in Elderly Dialysis Patients

Some causes of nutritional impairment and strategies to enhance good nutrition in elderly dialysis patients are listed in **TABLE 42.3** (150). Many of these strategies are self-explanatory. Patients who are disabled or living alone may benefit from programs such as meals-on-wheels, which deliver one or two prepared meals per day to the patient's home and can accommodate a prescribed diet. Home assistance services that provide aides to prepare meals, shop for groceries, and/or provide companionship can be very helpful. Patients with poor intake may benefit from liberalized diets at the expense of permitting higher potassium and/or phosphate levels. The benefit of oral intradialytic nutritional supplementation remains controversial, but more recent observational data demonstrate an association between protein supplementation and reduced mortality, irrespective of serum albumin levels (151). Patients with diabetic gastroparesis may benefit from metoclopramide, 5 to 10 mg orally administered 30 minutes before meals. Zinc deficiency can occur in dialysis patients and may be associated with dysgeusia; supplementation may enhance the taste of food (152). Megestrol acetate can stimulate appetite in selected patients (153). Good oral hygiene is also very important. It is difficult for elderly patients to eat properly if they have sore gums, poor dentition, or poorly fitting dentures. Depression and constipation, both of which inhibit appetite, must also be treated. Finally, a thorough review of the patient's medication list may reveal a large number of prescribed pills. Consolidating or eliminating unnecessary and less necessary medications may be associated with improved appetite.

TABLE 42.3 Nutrition in Elderly Dialysis Patients

Challenges	Strategies
Dialysis associated	
• Loss of nutrients by dialysis	Multivitamin formulated for dialysis
• Catabolism	High protein diet and supplements
Common comorbid conditions	
• Impaired absorption	Assess medications
• Gastroparesis	Promotility agents
• Dentition	Dental care
• Constipation	Bowel regimen (sorbitol, lactulose, senna)
Food security	
• Low income	Meals on wheels, and so forth
• Access to food	Involve friends and family in care
• Food preparation	Common dining Home services
Other	
• Anorexia	Assess and treat depression
• Dysgeusia	Adequate dialysis Megestrol and other appetite stimulants Consider reducing dietary restrictions, zinc supplementation

Pruritus

Pruritus is one of the most common and distressing cutaneous symptoms of CKD. CKD-associated pruritus may be difficult to differentiate from pruritus caused by nonrenal comorbidities frequently associated with CKD, such as liver and thyroid disease (154). In the Japanese Dialysis Outcomes Practice Patterns Study (JDOPPS) (1999–2008), pruritus was associated with a 22% higher mortality risk; unlike prior studies, this effect was not attenuated after adjusting for sleep quality measures, likely

indicating that the systemic adverse effects of pruritus are not completely mediated by sleep abnormalities (155). Pruritus was also associated with significantly lower mental and physical quality of life scores. In the JDOPPS, older age was a modest but significant risk factor for dialysis-associated pruritus.

First-line treatments include topical therapies such as emollients, particularly those with a high water content, capsaicin creams, and potentially bath oil containing polidocanol. Other topical therapies include bathing less frequently using tepid rather than hot water and increasing ambient humidity with vaporizers or humidifiers. Many systemic medications, including antihistamines (diphenhydramine or hydroxyzine), gabapentin, and opioid (κ-receptor) agonists, have been successfully used to treat CKD-associated pruritus, but the sedative effects of these medications may cause confusion in elderly patients.

Chronic Pain and Pain Management

Chronic pain and management of that pain is a major problem in the elderly dialysis patient. As expected, pain is a common symptom experienced by dialysis patients, relating both to underlying medical conditions like osteoarthritis common in all elderly individuals and also related to conditions more common in CKD, including bone pain in hyperparathyroidism, frequent medical procedures, neuropathy, and cramping related to the dialysis procedure itself (156).

The dialysis population is likely both understudied and undertreated for chronic pain. Reasons for this may include severity of comorbid conditions as well as a justified concern with use of certain medications in dialysis patients. This often results in worsened quality of life and life expectancy. Chronic pain has also been associated with increased likelihood of abbreviated HD sessions and hospitalizations (157). Two recent studies focused specifically on pain in HD patients. A Canadian study found that chronic pain was present in more than 50% of HD patients and that approximately 20% had multiple causes of pain (158). Most remarkable was that pain management was described as ineffective in 75%, and almost 30% of patients were not receiving any analgesic therapy. A second study evaluated the efficacy of the analgesic ladder published by the World Health Organization for the treatment of pain in dialysis and found that adequate analgesia could be obtained in 96% of patients with a stepwise escalation of analgesic therapies but critically noted that pain management was significantly more difficult in the elderly (159). Both these studies used multiple classes of medications for pain management.

On the basis of this limited literature, several items can be extracted: (a) pain is common in ESKD and affects quality of life; (b) pain may be multifactorial; (c) pain control can be accomplished in ESKD with minimal side effects; (d) pain can and should be measured in ESKD and serial assessments can assist treatment; and (e) although there are few absolute contraindications to pain medications in ESKD, there are many precautions in their use. In particular, medications should be dosed appropriate for kidney function and titrated as tolerated.

Bleeding Risk and Anticoagulation Therapy

Despite limited data, major bleeding events are felt to be fairly common in dialysis patients, particularly in the elderly (see Chapter 5). Chester et al. (28) found evidence of gastrointestinal bleeding in 22% of elderly HD patients older than 70 years compared with 7% of younger controls, whereas Porush and Faubert (16) found that gastrointestinal bleeding accounts for 18% of hospital admissions in elderly dialysis patients. The potential causes of increased bleeding risk are manifold but are most notable for (a) platelet dysfunction in uremia; (b) nonsteroidal anti-inflammatory drug and aspirin use for pain

management; (c) heparin use during HD; (d) systemic absorption of heparin from catheter-locking solutions; and (e) use of anticoagulation therapies, including warfarin, aspirin, and clopidogrel, to treat comorbid conditions.

Despite the frequency with which anticoagulation therapies are used in the dialysis population, little is truly known about their safety, efficacy, and appropriate use. Warfarin remains the most commonly used agent for systemic anticoagulation, although multiple antiplatelet agents are also in use, in particular aspirin and clopidogrel. Newer anticoagulants such as direct thrombin inhibitors have not been studied in dialysis populations and are not recommended for use currently (160). In the general population, warfarin is indicated for use in individuals with deep venous thromboses, pulmonary embolus, and other severe thrombotic disease; however, its most common use is for stroke prophylaxis in atrial fibrillation. Although current practice favors use of warfarin for thromboembolism prevention in the elderly with atrial fibrillation, recent data stress the bleeding risks. Among individuals between ages 65 and 80 years, risk of major bleeding is 4.7 episodes per 100 person-years, whereas for those aged 80 years and older, the risk is 13.1 per 100 person-years; this risk is highest at initiation of anticoagulation therapy (161). Dialysis patients have reasons to be both at increased bleeding risk as well as increased thrombosis risk, making treatment decisions in atrial fibrillation particularly challenging. In the absence of randomized trials, meta-analyses of retrospective and observational studies provide the best clues to date. In trials chiefly looking at maintaining access patency (for which anticoagulation with warfarin has proved unsuccessful to date), major bleeding episode rates associated with warfarin ranged from 10 to 54 events per patient-year (162). These rates are approximately twice as high as those of HD patients receiving either no warfarin or subcutaneous heparin alone and far exceed rates seen in the elderly nondialysis population. DOPPS data in patients with atrial fibrillation demonstrated an increased risk of stroke in those dialysis patients on warfarin (compared to dialysis patients with atrial fibrillation without anticoagulation) across all age-groups but more so in those over 75 years old (160). A cost–utility analysis used this and other published data to estimate the utility of using aspirin, warfarin, or neither for thromboembolism prophylaxis in dialysis patients with atrial fibrillation. Aspirin and warfarin both prolonged survival compared with no treatment (0.06 and 0.15 quality-adjusted life-years, respectively). Aspirin was associated with an incremental cost-effectiveness ratio of $82,100 per quality-adjusted life-year, whereas warfarin provided additional benefits at an additional cost of $88,400 for each quality-adjusted life-year gained relative to aspirin (163). This study did not specifically examine the elderly. Given the available data, it is not clear that the benefit of anticoagulation for stroke prevention in dialysis patients with atrial fibrillation outweighs the risk; the decision to anticoagulate remains a very individualized one, particularly in the elderly.

Dementia, Depression, and Neuropathies

Cognitive Impairment and Dementia

Cognitive impairment describes a spectrum of mental function extending from subtle alterations to severe dementia and loss of executive functions (see Chapter 33). The two most common causes of dementia in adults are Alzheimer’s disease and vascular dementia. The prevalence of dementia in North America was estimated at 6.9% in 2010 with incidence rates ranging from 3.1 per 1,000 patient-years in individuals aged 60 to 64 years to as high as 175 per 1,000 patient-years among individuals 95 years or older (164).

About 60% to 80% of these cases are related to Alzheimer's disease, whereas most non-Alzheimer's cases are related to vascular causes. Although more subtle than overt dementia, mild cognitive impairment that does not meet the definition for dementia is also a major public health problem, with a prevalence in individuals aged 65 years and older of 20% or higher (165).

Several studies have examined cognition in HD patients. One investigation found that 70% of patients demonstrated significant cognitive impairment (166). Additionally, dialysis patients had significantly more brain atrophy and cerebrovascular lesions than age-matched controls (167). Murray et al. (168) evaluated 338 prevalent HD patients aged 55 years and older from Minnesota and diagnosed 73% with either moderate or severe cognitive impairment, 14% with mild impairment, and only 13% with no cognitive impairment. In further evaluation of a subset of this cohort, these researchers noted an association between time of testing and cognitive performance, such that cognitive performance during the dialysis procedure itself was inferior to that just before dialysis or on the day between dialysis sessions (169). Another study in a cohort of prevalent HD patients in Boston found that despite relatively well-preserved scores on the Mini Mental State Examination, cognitive impairment was prominent and primarily subcortical in nature; this pattern is consistent with small vessel cerebrovascular disease (170).

Accordingly, several studies have found that dialysis patients are at greater risk for covert or silent ischemic brain disease, defined as infarcts on cranial imaging that are not associated with a clinical syndrome consistent with an acute stroke. These silent infarcts are common in older adults in the general population, and their presence predicts incident dementia, additional strokes, and cognitive and physical decline (171–173). Dialysis patients are particularly high risk, with 5 times greater prevalence in HD patients compared to those without kidney disease (174). Dialysis patients with subclinical infarcts also have a fourfold increased risk of acute vascular events compared to those without subclinical infarcts in adjusted analyses (175). Similar findings were recently noted in a PD population in Korea, where there was a 68.4% prevalence of silent ischemic brain disease. This high prevalence is striking given that this population was relatively young (mean age of 48 years) and nondiabetic and compared with a prevalence of 17.5% in an age- and sex-matched nondialysis hypertensive control population (176).

In summary, cognitive impairment in dialysis patients impacts both quality of life and the ability to make crucial social, economic, and health-related decisions that affect physical and emotional well-being, including obtaining a kidney transplant. Newer data even suggest an association between decreased cognitive function (particularly executive function and memory) and increased mortality in dialysis patients (177). Because of the complexity of medical and dietary regimens among dialysis patients, clinicians must recognize individuals who will experience difficulty with treatment plans and choices. Whether the dialysis process itself contributes to cognitive impairment, possibly by inducing cerebral ischemia or cerebral edema through intravascular volume loss and fluid shifts, or the high prevalence of cognitive impairment reflects the very high burden of comorbid conditions, including diabetes and cardiovascular disease, is currently unknown (178).

Depression

In recent years, more attention has been paid to the relatively common comorbidity of depression in dialysis patients. It has been estimated that almost 40% of dialysis patients exhibit depressive symptomatology (179). Multiple studies and meta-analyses in recent years have looked at the impact of depression on outcomes in dialysis patients. Although it is challenging to differentiate depression as a

cause versus a situational consequence of medical comorbidity, several large studies have demonstrated an association between presence of depressive symptoms and increase in mortality of up to 50% among dialysis patients (179). In one study of patients on a transplant waiting list, depression was associated with worse dialysis compliance (180), and in another study of HD patients, the number of depressive symptoms was directly associated with lower quality of life (181). Although therapy has not been adequately explored, one small Korean study suggests that the combination of antidepressant medication and supportive psychotherapy can successfully treat depression and improve nutritional status in chronic HD patients with depression (182). Unfortunately, there are very little data focusing specifically on elderly dialysis patients and no adequately powered trials looking at depression treatment and outcomes in this population.

Cardiovascular Disease

A full discussion of cardiovascular disease in the geriatric dialysis population is beyond the scope of this chapter and is discussed in Chapters 16 and 17. Of note, elderly individuals may have more autonomic dysfunction and thereby diminished ability to tolerate ultrafiltration during the HD procedure (183). See Chapter 18 for particular problems with dialysis hypotension and selection of the proper dialysate. The elderly represent a dialysis group that is particularly fragile in this regard and may benefit from techniques to minimize intradialytic hypotension including avoidance of low-calcium baths, cool dialysate, and midodrine and consideration of PD.

As in HD patients, volume status and fluid intake must be monitored in PD patients, and patients must be educated about the importance of adjusting their PD prescription to allow for fluid losses from sources such as diarrhea, vomiting, fever, or perspiration. If hypotension is secondary to poor cardiovascular status, performing small frequent exchanges with a cycler and keeping the abdominal cavity empty during the day may be considered. Meticulous attention to weight gain or loss and adequate salt intake are also important.

SPECIAL SITUATIONS IN THE ELDERLY PERITONEAL DIALYSIS PATIENT

There is a higher incidence of inguinal hernias, fluid leaks, and vascular ischemia of the lower extremities in older PD patients as compared with younger patients (10,184).

Hernias

Inguinal or abdominal hernias may be aggravated by decreased abdominal muscle tone. Kyphosis in the elderly patient may be associated with widening of the diaphragm and subsequent development of a hiatal hernia (10). Hernias may be aggravated by the stress of carrying 2 L or more fluid in the abdominal cavity. Hernias should be repaired, as in a younger patient. If surgical repair is not feasible, it may be possible to continue PD by doing small volume exchanges with a cycler while the patient is recumbent.

Back Pain

Back pain and musculoskeletal disorders in elderly PD patients may be related to decreased abdominal muscle tone, preexisting back pain or lumbar disk disease, obesity, or weight of dialysate in the

abdominal cavity (185). Patients may benefit from exercises to strengthen back and abdominal muscles that do not increase intra-abdominal pressure and from training in body mechanics—for example, squatting to pick up an object rather than bending over. If back pain continues to be a problem, patients can learn to perform low-volume exchanges with a cycler at night while keeping the abdominal cavity empty during the day (186). If back pain persists despite these measures, the patient may need to switch to HD.

Constipation

Constipation is more common in elderly patients and is a particularly important problem in elderly PD patients because it may interfere mechanically with dialysate drainage. Recommendations include the use of sorbitol or other nonstimulant cathartics, adequate fluid intake, and avoidance of medications that interfere with bowel function.

DIALYSIS IN A NURSING HOME SETTING

As the dialysis population ages and becomes more debilitated, more patients may require skilled nursing care on a temporary or permanent basis (187). In 1997, 0.4% to 0.6% of nursing home patients were on dialysis, and in 1999, it was reported that more than 4.8% of dialysis patients lived in nursing homes (90% HD and 10% PD) (188,189). Patients with ESKD in nursing homes have many concomitant chronic diseases, with higher rates of diabetes mellitus, coronary artery disease, cardiovascular disease, peripheral vascular disease, and amputations compared to the noninstitutionalized population with ESKD. They also have a high rate of physical and cognitive impairments. A recent meta-analysis demonstrated an 80% decline in functional status for ESKD patients in a nursing home setting by 12 months after dialysis initiation; cognitive function declined by 90% over the same time frame. Although many of the included studies were small and observational in nature, the 1-year survival rate from nursing home admission for dialysis patients ranged 26% to 42% (187).

Nursing homes can aid patients by reducing hospitalization time and providing rehabilitation programs, social stimulation, and comprehensive care. However, there are significant challenges to caring for patients with ESKD in a nursing home, including difficulties with transportation and multiple chronic diseases that require specialized knowledge for appropriate management requiring consultation with specialists. Therefore, many nursing homes refuse to admit patients with ESKD because of the extra challenge of caring for them (188). In the early 1990s, Schleifer (190) found that almost half of 197 nursing homes contacted in the Philadelphia area accepted patients with ESKD, 19% of whom were treated with PD and the rest with HD, 18% of the nursing homes refused patients with ESKD, and 34% had never been asked; current data are not known. Reasons given for not accepting patients with ESKD included lack of nurse training, transportation problems, inadequate physician coverage, administrative objection, and financial concerns.

Nursing home residents have several modality options: in-center HD, staff-assisted “home” HD in the nursing home, or PD. In-center HD has the advantage of providing treatment in a specialized facility with trained technicians. However, time spent away from the nursing home may interfere with rehabilitation, social interaction, and meals, and transportation to dialysis facilities may be uncomfortable, inconvenient, and costly. USRDS data from 2004 indicate that 44% of dialysis patients in

nursing homes are unable to ambulate necessitating either ambulance or wheelchair-accessible transportation to get to dialysis facilities (189).

Staff-assisted home HD is less commonly used than in-center HD because it requires nursing home investment, training of nursing home staff, and partnerships with a nephrology unit. Reddy et al. (189) conducted a study of 271 staff-assisted home HD patients and assessed patient survival from entry into the nursing home program. Results showed that survival was 82% at 1 month, 64% at 3 months, 38% at 6 months, and 26% at 12 months, with a median survival of 4.1 months, compared to median survival of 3.4 years for the general HD population.

PD is a good option for use in nursing homes that are willing to take on the responsibility of delivering the dialysis. Carey et al. (191) developed an educational program to train personnel in 10 community-based extended care facilities to care for PD patients who required temporary or permanent placement. Over a 5-year period, 1-month, 6-month, and 1-year patient survival rates were 90%, 50%, and 40%, respectively, with short-term rehabilitation patients having significantly better survival than long-term nursing home residents. In a study by Anderson et al. (192), technique survival rates were 94%, 86% and 79%, at 1 month, 6 months, and 1 year, respectively. Peritonitis rates were slightly higher than in noninstitutionalized patients (10.4 per 100 patient-months vs. 7.4 per 100 patient-months) but overall were comparable with National CAPD Registry data. A Toronto-based group recently published their experience instituting PD programs at three local nursing homes. They found peritonitis rates similar to the community at 1 episode every 40.3 treatment months, mean patient survival of 34.4 months, and a 5.3% transfer rate to HD (193).

ETHICAL ISSUES IN ELDERLY DIALYSIS PATIENTS

As the dialysis population expands, ages, and becomes more infirm, and the societal cost of the Medicare ESKD program continues to grow (194), many ethical dilemmas arise.

Access to End-Stage Kidney Disease Treatment

Do elderly dialysis patients have equal access to treatment or is age a reason for denial of treatment (194–196)? Up until quite recently, most discussions focused on age discrimination in initiation of dialysis. Most essayists on the subject were fond of quoting Berlyne's letter regarding dialysis age discrimination in the United Kingdom (197), and other reports have noted ESKD treatment age inequality in other European countries (32,198). In a survey of French nephrologists nearly two decades ago, 90% refused patients 75 years and older if they were not independent and did not have a supportive family (24). However, there are increasing questions about the appropriateness of biomedicalization at the end of life, as it relates to dialysis and other medical interventions. These are fitting given the success of the medical interventions to extend life but often in the absence of independence and quality of life. Consideration should also be made to the allocation of scarce financial resources, the constant pressure to reduce health care costs, and the national debt (194,199–204). Given its disproportionate consumption of Medicare dollars, dialysis will most certainly be a target for health care reform in coming years. Whether access to RRT will once again be limited by age criteria remains to be seen (204). Societal expectations will have a clear impact on these decisions. While less than 5% of patients with CKD in the United States elect not to start dialysis, this number is approximately 15% in United Kingdom and Canada.

Decisions to initiate dialysis should be made on an individual patient basis and ought to consider treatment goals, physiologic and chronologic age, and equitable access in addition to allocation of resources and cost (205). Appropriateness of the therapy should be reevaluated with major changes in the medical condition of the individual. Solutions to these difficult ethical questions will never be easy, and they require the utmost respect for the individual, great compassion for the patient and family, and a considerate health care provider.

Quality of Life and Rehabilitation

Elderly patients with ESKD seem to segregate into two populations. The first group of elderly patients adjusts to dialysis very well and seems satisfied with the lifestyle. Some of these patients appear to enjoy the increased social interaction of thrice-weekly visits to the dialysis unit. Some investigators have found an unusually high level of life satisfaction among the elderly dialysis patients (206), and others note that older patients frequently appear satisfied with a lifestyle that might be unacceptable to a younger patient (28,207). On the contrary, the second group of patients has more comorbidity and less functional capacity. These are the patients who have higher rates of depression. A survey of Canadian patients, mean age 68 years old, with ESKD reported that 60.7% regretted their decision to start dialysis after a mean of 27 months of treatment (208). This is also reflected in the increasing rate of death following withdrawal of dialysis, currently representing the second leading cause of death after cardiovascular disease in patients with ESKD (208).

There is a wide variability reported in the quality of life assessments in elderly dialysis patients. This may not be surprising given that the elderly dialysis population is heterogeneous, and the assessments themselves are subjective. Different outcomes reported in various studies may reflect differences in physician and patient–family treatment goals, patient selection, rehabilitation needs, support services, and attitude. A recent study of Canadian elderly dialysis patients found that although elderly dialysis patients' mental health and satisfaction with their lives is often as good as or better than those of younger dialysis patients and their peers, they have higher rates of depression and impaired physical functioning (209). Loos et al. (210) reported that older patients with ESKD have a lower quality of life than elderly patients with chronic disease but without ESKD; however, predialysis care of older patients with severe CKD improved quality of life.

A high quality of life and good emotional and mental state may be related to independence and lack of symptoms. (63). Indeed, geriatric dialysis patients suffer from as much as 50% decreased functional capacity compared to age-matched healthy subjects (211). In a study of nursing home residents initiating dialysis, only 13% maintained their predialysis level of functional status after 12 months (212). It has therefore been suggested that rehabilitative programs may be able to maintain or improve quality of life and increase level of functioning. This was recently demonstrated in a report of the first 3 years of an inpatient geriatric HD rehabilitation program in Toronto. In the 164 patients cared for, 69% were ultimately discharged home and 82% met at least one of their rehabilitation goals (213).

Special attention should be given to the quality of life and well-being of the caregiver for these elderly dialysis patients. Belasco et al. (214) surveyed elderly and nonelderly dialysis patients and their caregivers in Brazil and concluded that while all caregivers had lower scores in most dimensions (including functional capacity, physical capacity, and mental health), caregivers of elderly patients had significantly decreased mental health scores compared to caregivers of younger patients. Caregivers of

elderly HD patients had lower social aspect, pain and vitality scores, and had more weekly hours of care; caregivers of elderly PD patients had lower overall scores than HD patients and suffered from lower Mental Component Summary and Karnofsky Index scores. They recommended that professionals provide training and counseling to caregivers, starting from the beginning of dialysis treatment (214).

Discontinuation of Dialysis

Withdrawal from dialysis has been a cause of death in dialysis patients ever since the availability of dialysis for chronic uremia. In recent years, there have been more formalized recommendations from the ESKD Working Group funded by the Robert Wood Johnson Foundation, and consensus guidelines have been published by the Renal Physicians Association/American Society of Nephrology (215). Currently, withdrawal from dialysis is the second leading cause of death amongst patients with ESKD over the age of 75 years (20).

Patients who do withdraw from dialysis therapy should be offered care to provide a “good death; that is, one that is free from pain, brief, peaceful, occurring in the presence of loved ones, and at the place of one’s choice” (216). There are several barriers to good end-of-life care in dialysis patients. **TABLE 42.4** describes barriers and proposed solutions. Nephrologists and dialysis units need to incorporate end-of-life care from other disciplines and work with local palliative care and hospice services. Although hospice enrollment of ESKD patients has been increasing, these services remain underutilized for dialysis patients. This is in part related to the fact that hospice services often refuse patients who continue dialysis therapy and also due to an overall lack of education of patients on palliative and hospice options on the part of the dialysis providers.

TABLE 42.4 Barriers and Solutions to Good Palliative Care for Patients with Chronic Kidney Disease and to Hospice Care for Dialysis Patients

Barriers	Solutions
Doctors are uncomfortable and do not discuss end-of-life issues with patients and family.	Train doctors on communication skills and "breaking bad news."
Patients have not told their physician and family what their wishes are.	Advanced care planning (breaking bad news skills)
Patients and family have fears and misperceptions about end-of-life care and hospice.	Education and discussion surrounding these issues
Patients and family do not have a clear understanding of their prognosis.	Frank discussions of prognosis (breaking bad news skills)
Poor system management, particularly pain	Emphasis on symptom management in nephrology practice and dialysis units Better training in fellowship Research into best practices
Patient and family lack knowledge concerning withholding and withdrawal of dialysis.	Patients and family should have a clear understanding from the earliest contacts concerning the option of withholding and withdrawal of dialysis and what they may expect if they choose either option
Renal team: lack of knowledge about hospice	Educate on national and local coverage issues.
Local hospice: lack of knowledge about ESKD-specific issues	Awareness of local hospice services, establish relationship with local hospice services Education of local hospice
CMS national policy: confusion on the meaning of coverage in ESKD and "related" diagnosis section of the hospice manual	Work with CMS to clarify this confusion. Consider change in regulations through Congress.
CMS regional coverage: lack of uniformity on interpretation of national coverage rules in ESKD	Work with CMS to develop uniformity in local coverage decision.

ESRD, end-stage kidney disease; CMS, Centers for Medicare & Medicaid Services.
From Germain MJ, Cohen LM, Davison SN. Withholding and withdrawal from dialysis: what we know about how our patients die. *Semin Dial* 2007;20(3):195–199.

A recent study compared do not resuscitate (DNR) orders and rates of withdrawal from 208 dialysis facilities in France, Germany, Italy, Japan, Spain, the United Kingdom, and United States who were participating in the DOPPS (217). The United States had the highest rate of DNR (7.5%) and rate of withdrawal from HD (3.5 per 100 patient-years). There was a small increased risk for DNR status with age (OR of 1.16 per 10 years, $p = 0.03$).

Although decisions to withhold or withdraw dialysis are very difficult and have generated a complex legal and ethical literature (218,219), consideration of established ethical principles may make decisions somewhat easier (**TABLE 42.5**).

TABLE 42.5 Ethical Principles for Withholding and/or Withdrawing Dialysis

Self-determination/autonomy
Benefit versus burden
Futile therapy
Conflict between physician and family

Self-determination and Autonomy

The first issue to be considered is whether the patient is competent to make a decision to withdraw a life-sustaining technology. Is there evidence of dementia or psychiatric disorder, or is the patient's judgment clouded by depression, pain, medication, or metabolic derangement? Can the patient understand the choices involved and consequences of any decision? If the patient is truly competent, then he or she has the right to make an informed decision regarding medical care (218,220); recent survey data suggest that

ESKD patients want to be involved in this process and have conversations with their nephrologists about prognosis and end-of-life care (221). The American College of Physicians Ethics Manual (222) suggests that if the patient is not competent, the order of priority for decision making should be advance directives, substituted judgments, and the best interests of the patient.

Since 1991, the Patient Self-Determination Act has given adults the capacity to make medical decisions for themselves and the right to make decisions today about health care treatment they would want to receive in the future; it is now widely recommended that HD patients be encouraged to write advance directives. In a survey of dialysis units in London and Ontario, only 50% of HD patients had considered their wishes in regard to cardiopulmonary resuscitation (CPR), mechanical ventilation, and withdrawal of dialysis (223). In a survey of Canadian patients, only 38% had completed an advanced directive (208). Physicians and other dialysis staff need to be familiar with the concepts and legal ramifications of advance directives, durable powers of attorney, and living wills and be willing and able to discuss them when indicated. The patient's family or significant other may be asked to assist in the decision making and must know they are basing that decision on the patient's best interests, on prior advance directives made by the patient when competent, or on knowledge of what the patient would have wished given the circumstances (218,224).

Understanding the dynamics of the patient–family relationship may also be necessary. Decisions may be made for various reasons, including the best interest of the patient, financial interest, guilt because of the family member's limited contact with the patient, or a misunderstanding of role and process. If the caretaker or physician is uncomfortable with the decision to withhold or withdraw dialysis, he or she may wish to refer the patient to another physician.

Benefit versus Burden

Is the patient likely to benefit from dialysis? In this situation, age is not an appropriate independent criterion (218). Each patient must be evaluated individually for medical and psychological suitability for dialysis and whether dialysis is technically possible. Recently, some have recommended use of prognostic calculators to aid in this assessment. The "surprise" question has been demonstrated to be quite powerful in mortality prediction—"Would you be surprised if Mr. X died within the next 6 months?"—especially when combined with serum albumin levels and age (225).

A nephrologist is not ethically or legally obligated to offer dialysis if treatment would not benefit the patient. Hirsch et al. (226) suggest that dialysis is inappropriate for patients with poor prognoses, including those with multiple organ system failure; nonuremic dementia; metastatic, refractory malignancy; or irreparable and debilitating neurologic disease. When dialysis is appropriate, the patient and/or family member may believe that dialysis poses a burden to the patient that outweighs potential benefit, either because of the process or because of its impact on quality of life (218,224). Understanding why the patient and/or family considers dialysis burdensome is important because it may be possible to modify treatment or even initiate dialysis on a trial basis for a patient who fears dialysis but does not actually know what it is like. Also, the patient's environment or support system can perhaps be adjusted in a way that makes dialysis more tolerable or desirable.

Can Dialysis be a Futile Therapy?

Dialysis may be viewed as a futile therapy—prolonging death rather than sustaining life. For example, a

patient may be facing imminent death from terminal cancer or may be comatose with irreversible brain damage. Removing a life support such as dialysis would not "cause" the patient's death but rather allow it to occur naturally. Kilner (218) refers to this as *passive facilitating*.

Conflict between Physician and Family

When the physician and family cannot agree on the best course of action for a patient, several options are available. These options may include review by an ethics committee or the courts or transfer of the patient to another physician or hospital. It is generally preferable for these discussions to remain among medical staff, patient, and family rather than resorting to the courts. Ethics committees provide a forum for discussion rather than dictate medical decisions (222).

Adequate and clear communication is the most important factor in resolving conflicts regarding terminal care, not only between physician and family but also among all the health professionals involved in the care of the patient. Roberts et al. (227), in a study of the impact of withdrawal of dialysis on surviving relatives, noted that the relatives were most disappointed when physicians failed to tell the truth; were too optimistic; continued dialysis too long; and/or were unwilling to discuss withdrawal, alternatives, and implications.

Cardiopulmonary Resuscitation

A study of CPR performed in an HD unit in Montreal, Canada, between August 1997 and December 2004 showed an incidence rate of 0.012% with a 30-day survival of 79% (228). As expected, CPR during dialysis treatment is associated with better outcomes due to likelihood of electrolyte disturbances that are more readily correctable. On the contrary, survival at 6 months for hospitalized dialysis patients undergoing CPR has been estimated at a dismal 3% (229). When dialysis patients were surveyed regarding their attitudes toward CPR in multiple studies, 65% to 87% of patients reported that they would request CPR (229). Perceptions and preferences tended to be similar to those of nondialysis elderly patients. Poor health status and increasing illness severity seemed to influence likelihood to decline resuscitation. Age was not a factor in decisions to refuse respiratory support or dialysis, although older dialysis patients were more likely to have thought about it. Ultimately, most dialysis patients would like to take part in shared medical decision making with their nephrologist and are open to discussions regarding end-of-life care (208).

CHAPTER 43

Current Outcomes for Dialysis Patients and Improving Quality of Care for Dialysis Patients

Brent W. Miller

Dialysis has evolved from a mostly failed attempt to keep patients with acute kidney injury alive until recovery of kidney function in the 1940s to a small-scale attempt to keep relatively young and healthy patients with chronic kidney disease alive in the 1960s to the widespread, lifesaving, and life-preserving therapy it is today for a broad spectrum of patients with kidney failure.

Despite this positive trajectory, the current state of dialysis therapy still produces insufficient gains in quality of life, morbidity, and mortality. Furthermore, the cost of this therapy has attracted aggressive scrutiny so that any improvement in medical outcomes must also be cost-neutral or even save money (1).

This chapter reviews the current state of dialysis outcomes, potential outcome measurements other than mortality and quality processes that may improve the patient experience, and the involvement of regulatory bodies and payers in outcome measurement.

CURRENT OUTCOME DATABASES

United States Renal Data System

In 1988, the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) awarded a contract for formation of a national end-stage kidney disease (ESKD) registry. This resulted in the formation of the United States Renal Data System (USRDS) (2). When an incident patient begins dialysis treatment in the United States, a Centers for Medicare & Medicaid Services (CMS) 2728 Medical Evidence Report is completed and submitted to the appropriate End-Stage Renal Disease (ESRD) Network (see following text). A similar process occurs when a dialysis patient dies with CMS 2746 ESRD Death Notification Form. This data is then blindly combined with other CMS data such as Medicare part A, B and D claims from care of dialysis patients.

An annual report based on this data is published and readily available online in many formats. Researchers with expertise can purchase the database and separately analyze the data for their own

academic purposes.

The accuracy and integrity of the USRDS data, while widely assumed, has only been examined cursorily. Two studies in 1992 demonstrated a >90% accuracy of most data points obtained from patients (3,4). However, other studies raise concerns. In one study on erythropoiesis-stimulating agent (ESA) use in 8,033 patients at the Department of Veteran Affairs, the sensitivity of accuracy for predialysis ESA use recorded on the 2728 form was 57% (5). Another study of 1,105 incident dialysis patients showed a sensitivity of 0.59 in reporting the 17 comorbid conditions on the 2728 form with significant underreporting (6). Finally, the inaccuracy of the Death Notification Form was demonstrated during the Hemodialysis (HEMO) trial where the major source of misclassification was the frequent use of "unknown cause of death" and "other heart conditions" on the Death Notification Form (7).

Dialysis Outcomes and Practice Patterns Study

The Dialysis Outcomes and Practice Patterns Study (DOPPS) is an international, prospective, observational study beginning in 1996 and divided in multiple time periods ("phases") that examines multiple patient outcomes (8). Over 200,000 patient-years patients in over 600 hemodialysis centers have been included in the data analysis in the first five phases, and the annual reports are available in a variety of formats and online. In 2013, peritoneal dialysis collection began for Peritoneal Dialysis Outcomes and Practice Patterns Study (PDOPPS) (9).

Large Dialysis Organizations

In the United States, over 60% of patients undergo dialysis therapy in outpatient facilities owned and operated by one of two large corporations. With the introduction of computers and large-scale database management software, hundreds of millions of data points can be analyzed regarding ESKD (10). These databases can be used to measure various clinical outcomes and suggesting where and how clinical attention may be needed (11–13).

The recruitment of the Large Dialysis Organization (LDOs) to perform structured, nonclassically randomized trials, so-called "large pragmatic trials" may help answer clinical questions in a more timely and less costly manner than the current NIDDK process. The first of these trials in dialysis will examine the effect of 4.25 hours of hemodialysis versus usual care in incident hemodialysis patients (14,15).

GOVERNMENT MEASURES

End-Stage Renal Disease Quality Incentive Program

In 2008, the United States Congress passed the Medicare Improvements for Patients and Providers Act, which directed the Secretary of Health and Human Services to establish quality incentives for providers of dialysis (1). The incentive chosen was avoidance of a payment reduction from CMS of up to 2%.

New quality targets are chosen each year according to a deliberate process with some public input (**TABLE 43.1**). Although the inclusion of quality measurements, better patient care, and safety and implementation of best clinical practices has been widely praised, the particular choices of quality measures have been controversial. From a global perspective of caring for a complex patient, intense concentration on a few specific measures may distract from other important functions of the dialysis center and clinician. Second, some of the measures chosen have questionable scientific rationale and

could potentially harm patients or at best have no effect if implemented aggressively. For example, in 2012, avoiding a hemoglobin less than 10 g/dL has no basis in literature, and earlier studies demonstrated that the use of ESA may have harmful side effects (16). Furthermore, urea reduction ratio (URR) as an absolute measure of dialysis adequacy had been abandoned by most practitioners by 2012 because of its lack of considering ultrafiltration, dialysis time, residual kidney function, and the other 12 dialysis treatments during the month in addition to marginal evidence that small solute clearance alone corrects the uremic syndrome. To put it bluntly, ESKD patients were not suffering and dying in 2012 for lack of hemoglobin values between 10 and 12 g/dL and a URR ≤65%.

TABLE 43.1 Summary of End-Stage Renal Disease Quality Incentive Program Performance Measures to Avoid Payment Reductions in Years 2012–2018

2012	2013	2014	2015	2016	2017	2018
Hemoglobin >12 g/dL	Hemoglobin >12 g/dL	Hemoglobin >12 g/dL	Hemoglobin >12 g/dL	Hemoglobin >12 g/dL		
Urea reduction ratio ≥65%	Urea reduction ratio ≥65%	Urea reduction ratio ≥65%	Urea Kt/V	Urea Kt/V	Urea Kt/V	Urea Kt/V
Hemoglobin <10 g/dL		% of arteriovenous fistulas and catheters	% of arteriovenous fistulas and catheters	% of arteriovenous fistulas and catheters	% of arteriovenous fistulas and catheters	% of arteriovenous fistulas and catheters
			National Healthcare Safety Network (NHSN) reporting to Center for Disease Control and Prevention (CDC)	Bloodstream infections in hemodialysis patients	Bloodstream infections in hemodialysis patients	Bloodstream infections in hemodialysis patients
			Administration of Patient Experience of Care Survey	Administration of Patient Experience of Care Survey	Administration of Patient Experience of Care Survey	Administration of Patient Experience of Care Survey
			Serum calcium and phosphorus reporting	Hypercalcemia	Hypercalcemia	Hypercalcemia
			ESA dose reporting	ESA dose reporting	ESA dose and hemoglobin reporting	ESA dose and hemoglobin reporting
				Serum phosphorus reporting	Serum phosphorus reporting	Serum phosphorus reporting
					Standardized readmission ratio	Standardized readmission ratio
						Pain assessment and follow-up
						Clinical depression screening and follow-up
						Health care personnel influenza vaccination

For further details and explanations see www.cms.gov. ESA, erythropoiesis-stimulating agent.

Dialysis Facility Compare

Utilizing electronic data derived from Medicare claims and electronic data submitted directly from

dialysis centers (Consolidated Renal Operations in a Web-enabled Network or CROWNWeb), CMS annually gives each dialysis facility a “star rating” from 1 to 5 based on the attainment of certain measurable outcomes. These ratings are posted online and also required to be visible in each dialysis center.

While trying to attain the laudable goal of providing dialysis patients a system to judge their care similar to the way they would choose a restaurant or buy a pair of shoes, the current methodology has raised concerns. First, the system does not measure attained outcomes but rather separates each variable along a curve. Thus, there will always be 10% of dialysis centers with a 1-star rating and 10% of facilities with a 5-star rating regardless of the actual metrics obtained. Second, as providers aggressively react to the few metrics, the separation between a 1-star rating and a 5-star rating may be clinically insignificant. For example, the difference in Kt/V values and hypercalcemia percentages are a few percentage points in the high 90s. Lastly, some physicians may overreact to the metrics with unintended consequences.

End-Stage Renal Disease Networks

In 1978, the United States Congress authorized the establishment of ESRD Network Organizations to support the ESKD program. Currently as of 2015, there are 18 networks with contracts awarded by CMS. The ESRD Network Organization is responsible in its geography for collecting data for the ESKD program, improving the quality of care, addressing patient grievances, and providing technical support to patients, dialysis providers, and other health care professionals and organizations involved in the care of ESKD patients. However, even the well-intentioned programs of the ESRD Networks can go awry such as the Fistula First Initiative which had some unintended consequences of patients likely having catheters in place longer while waiting for multiple fistula surgeries and maturation (17,18).

Randomized Controlled Trials in Dialysis

Given the multiple clinical issues in patients with kidney failure requiring dialysis therapies, the field would seem a frequent target of innovative clinical studies. Alas, this has not been the case and, furthermore, patients on dialysis or even with moderate chronic kidney disease are often excluded from other trials with diverse disease states.

Additionally, many of the interventions suggested by numerous observational studies in ESKD patients have been shown to not be effective when rigorously and formally tested. Applying conclusions broadly from nonrandomized trials has led to errors in clinical practice. One prominent example of this was the Canada-USA (CANUSA) study in peritoneal dialysis where the failure to account for the impact of residual renal function over time led to recommendations of targeting of Kt/V urea >2.1 in thousands of patients who were previously doing fine and potentially led to more glucose exposure and an early technique failure (19,20).

Despite the lack of many ongoing or planned clinical trials to improve care to the ESKD patient, there is a recognition of the continued scope of the problem. In 2012, the U.S. Food and Drug Administration announced an innovation challenge with ESKD and received 32 proposals from which 3 were selected including a vascular access device, an implantable artificial kidney, and a wearable artificial kidney (21).

Clinical Guidelines

The combination of outcome measurement and expert opinion has led to the formation of various guidelines for managing ESKD patients (**TABLE 43.2**). While these well-meaning endeavors can lead to a standardization of therapy and particularly attention on substandard performance, unintended consequences can potentially lead to worse outcomes. One of the better known examples of this is the KDOQI anemia management guidelines (22).

TABLE 43.2 Various Dialysis Clinical Practice Guidelines

Guideline Name	Author Organization
Kidney Disease Outcomes Quality Initiative (KDOQI)	National Kidney Foundation
Kidney Disease Improving Global Outcomes (KDIGO)	KDIGO
Renal Physicians Association (RPA) Clinical Practice Guidelines	RPA
Center for Disease Control and Prevention (CDC) Guidelines	CDC
Canadian Society of Nephrology Guidelines	Canadian Society of Nephrology
The British Renal Association	The Renal Association
Kidney Health Australia–Caring for Australasians with Renal Impairment (KHA-CARI) Guidelines	KHA and Australian and New Zealand Society of Nephrology
European Best Practice Guidelines	European Renal Association and European Dialysis and Transplantation Association

Roles of Medical Director in Outcomes

Over the last decade, the legal responsibilities of the nephrologist who assumes the role of the medical director of the dialysis center have been better defined. The quality of care and continuous improvement in the quality of care is one of these tasks. To succeed in this role, more endpoints need to be considered than the quality incentive program (QIP) or 5-star measures and a more vigorous process enacted than simply reviewing computer-generated laboratory and spreadsheet summaries provided monthly by the corporate management.

An entire field of study has evolved in dialysis about continuous quality improvement (CQI), quality assurance (QA), and quality assurance process improvement (QAPI) (23). Much of this attention has focused on the high infection rate and its concomitant morbidity and mortality in ESKD.

The medical director should act as the leader of a multidisciplinary team at the local level to address specific patient-focused problems in the dialysis center. Monthly meetings of this group seem most effective with attendance monitored and minutes of the meeting being taken. The process should be data-driven with measureable outcomes and relevant, feasible performance criteria. A rudimentary understanding of quality improvement principles such as Pareto analysis, Deming principles, and the use of fishbone diagrams may help. One author suggests a mnemonic of "SMART:" specific, measurable, achievable, realistic and timely, while the Institute of Medicine has suggested safe, effective, patient-centered, timely, and equitable (24,25).

What Are the Desired Outcomes in Dialysis Therapy?

The intersection of a serious chronic disease state, an immense economic burden borne largely by one payer and a provision of the majority of dialysis therapy by two large multinational corporations has focused the attention of outcomes on a small number of measures that shift the focus away from an individual patient. Nissenson (26) has proposed shifting the focus back to the patient and what each patient's goals are for their dialysis therapy within a reasonable framework of clinical medicine. This type of action seems to have as much a chance as succeeding as any bold national proposal. In my practice, this is often expressed to the patient as my desire to turn the disaster of kidney failure into an annoyance of dialysis therapy rather than a new disaster.

CHAPTER 44

The Business of Nephrology

Robert Provenzano

When Medicare was established in 1965, it did not provide coverage for individuals with end-stage kidney disease (ESKD). At that time, kidney failure was considered a fatal disease, as treatment was not available outside a limited number of academic centers. In 1972, Congress passed the Social Security Amendments of 1972. Under this Act, Congress extended coverage to individuals who were younger than 65 years old, had ESKD, and had worked long enough to qualify for Social Security. This coverage became effective July 1, 1973 (1).

At that time, a typical “nephrologist” (as most did not formally train in nephrology but rather had “an interest” and served as a local expert) was on staff at one hospital, rounded in one dialysis facility, and saw office patients in one clinic. He or she was in solo practice or at most shared a small practice with one or two others. There were no thoughts of running their “business” as they were making a good living with robust reimbursement for their much needed, unique skills; slowly but surely this all changed. Reimbursement, in real and adjusted dollars, began to decrease as patient numbers and costs rapidly exceeded projections and nephrologists responded consistent with their training: They worked harder, saw more patients, and rounded at more hospitals and more dialysis facilities, trying to maintain their lifestyles and incomes. The most recent Renal Physicians Association (RPA) Benchmarking survey reports all nephrologists are now on staff at more than one hospital, 27% at four to six hospitals, and 85% round at four or more dialysis facilities in addition to 68% seeing patients in more than three offices (clinics). The average number of ESKD they care for has increased year over year and now stands at 68 patients per nephrologist (2). How this has impacted patient care, safety, quality, or satisfaction can be debated, but to be sure things would need to change as this model was and is unsustainable. This workload is now compounded by recent and expanding regulatory requirements including meaningful use (MU), physician quality reporting system (PQRS), and electronic medical record (EMR) requirements.

BUSINESS AS USUAL

The majority of physicians have little to no formal training in business or business principles. As mentioned earlier, this was not necessary or relevant to running a successful practice. With robust reimbursement for skills learned in medical school and honed in residency and fellowship training, most practices had no business structures. Practices consisted of what I call a *Marcus Welby* (3) structure, front office staff answering phones, checking patients in and out, and medical assistants placing patients in rooms and billing staff. There were no business processes, protocols, measures of practice success, nor the expertise needed to keep abreast of the increasingly complex billing and coding requirements. Governance structure often rested with the most senior rather than most capable physician and rarely did nonphysician business savvy employees participate. Data collection, either on patient-centric information or on basic business metrics, was nonexistent. Inefficiency was the standard. Patient care was rendered one on one, by the physician, delivered to each patient as they were seen. Little focus on education, prevention, or population health was present. Marketing was by reputation alone or word of mouth and was more often based on who you were rather than your capabilities. Your "success" in the eyes of a hospital administrator was solely predicated on your ability to admit as many patients as possible. From a purely business perspective—this is a receipt for disaster, one that has now come due.

CHANGING TIDE

As noted above, since 1972 when Congress passed the Social Security Amendments allowing for coverage of ESKD for all patient services irrespective of age, the number of patients and costs incurred in their care has increased dramatically. Most recent United States Renal Data System (USRDS) data reports that ESKD patients make up 1% of Medicare beneficiaries and consume 5.6% of all Medicare dollars (4). Anemic reimbursement updates over the past 20 years have resulted in ESKD provider consolidation that successfully drove economies of scale in a fee-for-service (FFS) world (5). Although there have been substantial and complex changes in reimbursement under this model, most recently moving to a partially bundled payment model, the end result was business survival favored large integrated providers with the top two now representing over 70% of all ESKD patients in the United States. Predictably, their market power influences payers: Centers for Medicare and Medicaid Services (CMS) and legislators, in ways not available/accessible to the average nephrologist. These realities are influencing the business of the practice nephrology in ways never envisioned before.

If the previous paragraph represents the "macrocosm" of the business of nephrology, the "microcosm" of nephrology (nephrology practices) has also been impacted by the economic impact of legislation passed to influence rising overall health costs. In 2008, Congress passed the Patient Protection and Affordable Care Act (PPACA) (6). This legislation was a game changer for all of health care impacting how hospitals, insurers, and health care providers rendered care and ran their businesses. Forgoing the dominant FFS payment model for a value-based reimbursement (VBR) model, this legislation, as yet unproven in its benefits, has placed disproportional burdens on medical practices challenging the practice models, or lack thereof, on which they were built.

The PPACA granted a windfall of power to hospitals via accountable care organizations (ACOs). ACOs, population risk vehicles, have driven hospital consolidation into mega-health care systems to mitigate this risk. Physicians, faced with little to no ability to compete in this space, quickly became hospital employed, primary care first, followed by high-revenue subspecialists (oncology, cardiology,

orthopedics) all who recently saw their outpatient procedure reimbursement gutted, destroying practice models that had sustained them for years. The hospital strategy is to create seamless care models over wide geographies and manage risk by serving large populations while controlling and directing physician care, hoping to link this to higher care quality and therefore—value.

Although one may quibble over the details or the wisdom of this approach, given how the PPACA is constructed, this scenario is predictably rapidly gaining ground.

Given these realities, the practice of nephrology, or better stated, the business of practicing nephrology must rapidly digest this information and access its business options to survive.

ACCESSING YOUR BUSINESS

The first step in the process of remaining competitive in a changing reimbursement environment is to better understand your business. **TABLE 44.1** provides some critical questions you should ask yourself. But basically, you need to do a SWOT (strengths, weaknesses, opportunities, threat) analysis (7). Although beyond the scope of this chapter, a SWOT analysis is a simple, powerful, and insightful business tool. Block off time, without distraction, to list as many ideas for each category as you can.

TABLE 44.1 Accessing Your Business

What services do you provide?
Where do your business/referrals come from?
What or who is your competition?
What are the risks facing you?
What are your payment sources?
Do you know your costs?
What is your hospital planning?
Are you growing?

There are several items that you will identify in your SWOT analysis worth focusing on; a few high-level items are discussed here.

One item is the practices' internal business structure. How is your practice managed? What is the governance structure? How are decisions made, and by whom? Who operationalizes change within the practice? Is it measured? Without a strong governance structure, the ability to rapidly implement change is limited and will negatively impact any meaningful and necessary change.

What business reports are available? How often are they produced? Who produces them? What information are they providing to you? Do you have business partners? Hospitals, dialysis providers, large primary care provider groups? Are you nurturing these relationships?

Understanding the importance of these questions will be critical for the practice to be credible to outsider providers, in recruiting new physicians, to make decisions quickly and nimbly, and to develop and implement process changes in how clinical services are provided.

Another item to consider is, where do your business/patient referrals come from? In the past, direct relationships with referral sources ruled. That pattern has been rapidly eroded. For the most part, your primary care referral sources no longer round in the hospital, a major source of patient referrals; rather, they outsource this work to hospitalists to better focus on their outpatient patient care. Hospitalists remain a moving target with high turnover, making development of a referral relationship with them challenging; often, there is a generational separation from you, and they tend to be looking for very specific renal services from your practice. Are you meeting that need? Also, direct relationships with insurers/payers

are becoming more common and are often tied to risk contracts.

In the broadest sense, you should determine exactly what services you offer. **TABLE 44.2** lists a few. Importantly, do you know what it costs to provide these services? If you do not know what it costs you to deliver, let us say, CKD stage 4 care, in your office, how can you negotiate payment from insurers? Or how can you render that service more economically? Developing a list of services and understanding their costs will serve you well in measuring, marketing, and reporting outcomes.

TABLE 44.2 Services Offered

Chronic kidney disease (CKD) care
Kidney stones
ESKD care (peritoneal, in-center, home, nocturnal)
AKI management
Hypertension
Glomerulonephritis management
Apheresis
Management of CKD/AKI in pregnancy
Management of autoimmune disorders
Vascular access services
Ultrasound services
Laboratory services

ESKD, end-stage kidney disease; AKI, acute kidney injury.

According to the RPA's (2) 2014 Benchmarking survey, 40% to 50% of a nephrologist's income comes from ESKD care and medical directorships, 30% from hospital work, and the remainder from the office. Each of these "business lanes" needs to be separately analyzed for growth, profitability, and sustainability.

The following sections describe details on nephrology-specific business care lanes that can be a focus of your practice analysis with conclusions drawn specifically to the VBR future for all of health care.

PRACTICE CLINICAL AND BUSINESS STRUCTURES

Nephrology practices are structured in three clinical and four business domains. The clinical domains include hospital services, dialysis services, and office/clinic practice. The business domains include these three plus ancillary nephrology services. Ancillary services traditionally include research, laboratory services, dialysis facility joint ventures or direct ownership, real estate, and vascular access centers, each with their own unique reimbursement and business challenges and are beyond the scope of this chapter. The ability of practices to participate in ancillary services varies from practice to practice and is heavily weighted on practice size, patient density, financial resources, and the practice leaderships' desire to expand into other areas.

The financial viability of the four business domains has historically been predicated on FFS and therefore high patient volumes and market share. Each domain existed in isolation resulting in the fragmented delivery of renal services and, excepting ESKD, had little quality oversight and was innately inefficient.

As mentioned earlier, the PPACA is influencing all of these domains and must be considered in your business planning moving forward.

FINANCIAL MODELS

The best example of a mature business/economic model of renal care is that of ESKD. For greater than 30 years, a focus on ESKD care has created precise financial models. Ease of identifying patients with ESKD, incident rates, defined payment for treatment, known hospitalization, and mortality rates have all allowed this medical industry to prosper and grow. Much less focus and data exists for CKD patients who have been, for all intents and purposes, an FFS payment model. Valid arguments have been made that without viable financial models for CKD patients, providers, out of financial necessity, will continue to apply disproportional resources to ESKD. The PPACA changed the focus in all of health care, targeting health care value rather than care volume. This game changing concept was best summed up by then CMS director, Donald Berwick, in his "triple aim of care": improvement in the health of populations, improvement in the experience of care, and reducing health care costs (8). This creates an incentive to move the FFS CKD payment system to a value care model that may be linked to the totality of renal care potentially inclusive of ESKD care.

Creating a "value-based" model around kidney disease offers us an opportunity to uniquely offer to patients the benefits of Dr. Berwick's triple aim of care. Unfortunately, our kidney care systems remain fragmented, and this creates real barriers that must first be surmounted to move forward in a meaningful way. Additionally, the capital investments necessary for this metamorphosis to occur is out of reach of most practices, necessitating the consideration of strategic partnerships for participation in this model of care. The reality remains though, that the future of the practice/business of nephrology will be linked to this expectation and any considerations of altering your practices' business model must take this seriously.

END-STAGE KIDNEY DISEASE CARE

ESKD care is, for the most part, provided by organized for-profit and not-for-profit providers in partnership with nephrologists (clinical care, medical directorships, and/or joint venture relationships). The greatest proportion of the practice income emanates for ESKD care, and therefore, much attention should be paid here as this income stream is under threat.

Medical directors fee contributes substantially to the practices' income. CMS estimates that the roles and responsibilities contracted for these services consume approximately 25% of a nephrologist's time. Therefore, the number of agreements one can provide will be under scrutiny, and this fact should be considered in their allocation within the practice.

Nephrologists are currently paid on an FFS model for incremental monthly clinical care (one visit, two to three visits, and four visits per month); this changed from the traditional monthly capitated payment not tied to frequency of visits in 2005 (9). The greater the number of patients under your care and the more efficiently you can deliver that care, the more financially successful the practice. This very model incentivizes increasing the volume of ESKD patients rather than delivering "upstream" value-based care that may negatively impact ESKD incident rates. Although it may seem counterintuitive, achieving and maintaining high ESKD patient volume is critical in a VBR model as more patients buffer the practices' ability to accept risk contracts. Therefore, continued efforts at growth must not be ignored.

However, providing ESKD services in an economically viable manner include careful analysis of the number of patients, the number of dialysis facilities served, the geographic placement of these facilities,

and travel time to each (**TABLE 44.3**). This "process of care" is under increased pressure as payments are now starting to be tied to risk models (see the following text), and the ability of physicians to render care personally is in question. Use of physician extenders to provide the noncomprehensive care visits and field questions from dialysis care staff frees the nephrologists' time to focus on other practice business needs and should be considered. Recall, the ESKD population under the practices' care has a specific quantifiable income *and* cost. These should be determined and monitored as a business metric.

TABLE 44.3 End-Stage Kidney Disease Considerations

Patient number
Facility number
Geographic distribution/windshield time
Risk contract exposure
Use of extenders
Cost of delivering care

END-STAGE KIDNEY DISEASE SEAMLESS CARE ORGANIZATIONS

End-stage kidney disease seamless care organizations (ESCOs) are the first disease-specific ACO model designed by CMS to identify, test, and evaluate new ways to improve care for Medicare beneficiaries with ESKD (10). This "award" is predicated on the "bet" that the ACO model of care will be successful and seems reasonable given the knowledge gained by the ESKD care community in the demonstration projects and special needs programs for the past 10 years. Challenges remain in the details for risk/payment in ESCO, but the broad strategy has been accepted. ESCOs must have more than 350 Medicare beneficiaries; they must entail a joint venture between a dialysis provider and nephrologists (with the option to include a third Medicare provider/supplier). Savings versus a historical benchmark will shared with CMS (with up to 75% going to the ESCO) predicated on defined quality measures. This is the first economic model that substantially puts the nephrologist in a position of impacting care delivery. Directing care from more expensive sites of service [hospital, emergency room (ER), dialysis clinic] to less expensive venues, when appropriate (nephrology offices), may deliver savings.

These provocative economic models set the stage for not only a closer more collaborative relationship between dialysis providers, nephrologists, and hospitals on ESKD patients but also, and more importantly, the critical opportunity to focus upstream to influence care and management of transitional CKD patients (CKD stage 4/5) as impacting/improving these patients care [education, arteriovenous fistula (AVF) placement, conservative management, home modalities] may positively influence the risk and outcomes of incident ESKD patients in an ESCO.

HOSPITAL SERVICES

Fully approximately 30% of a nephrology practice income is earned via hospital-rendered care (2). The number of services a practice provides (**TABLE 44.1**) and business considerations (**TABLES 44.2** and **44.4**) enhances the volume of care they are invited to provide in the hospital setting. Under the current FFS payment system, patients with advanced CKD present to the hospital with other immediate critical

health problems. They may develop acute kidney injury (AKI) and recover or have an accelerated progression to ESKD. One of the largest sources of incident ESKD patients continues to emanate from the hospital. Similarly, hospitalized patients with previously undiagnosed CKD are newly identified and require care in nephrologists' offices following discharge. While the FFS diagnosis-related group (DRG) payment models are defined and predictable, there are no strong incentives to identify at risk patients and apply processes of care to avoid AKI, move the patients efficiently through the hospital stay, or ensure proper handoffs and follow-up posthospitalization to decrease readmissions. Nephrologists receive FFS payment incenting them to freely admit patients and accept daily payments. To be fair, there are many regulatory barriers that prevent alignment of incentives among care providers adding to this problem. One of the intents of accountable care organizations (below) is to align incentive toward a value-based system rather than FFS. This, along with ESCOs could go a long way to improve this fragmented system and must be considered in your business model. This alignment allows your practice to take a leadership role within the hospital to help develop newer care models focused on integrated kidney care. Nephrologists are in a pivotal role with the ability to bridge fragmented care linking dialysis facilities, hospitals, and their practices.

TABLE 44.4 Hospital Services

Number of hospital(s) served?
Nephrology services offered?
Cost of your services?
Your position in hospital/partnerships?
What are your hospitals plans? ACO? Pay for performance?

ACO, accountable care organization.

ACCOUNTABLE CARE ORGANIZATIONS

The PPACA created risk vehicles known as accountable care organizations (ACOs) (6). The stated goal is alleviating regulatory barriers to encourage an integrated system of care, thereby delivering higher care value. By doing so, Congress has thrust health care into a full-risk model of care placing hospitals/hospital systems in a unique position of responsibility for the cost and outcomes of all patients within their networks. This has resulted in rapid and significant mergers and acquisitions of hospitals into mega-systems of care. Although this may address the problem of care fragmentation, it does not address the operational realities of assembling all the pieces necessary to deliver value. To accomplish this, it became necessary for hospitals/ACOs to seek out relationships with physicians in a manner not seen since health maintenance organizations (HMOs) of the 1980s. Through employment of care networks, primary care and relevant subspecialties were assembled into care panels to integrate care based on disease avoidance, early disease identification, or specific models of care for those with chronic disorders.

Hospitals'/ACOs' initial focus on primary care physician employment to secure a patient base was followed by arrangements with higher revenue-generating subspecialists (cardiology, oncology, and others). Nephrologists do not fall into this high revenue-generating category and therefore have not been a high target. Nephrologists have reasonable concern that system "savings" generated by this model of care may not trickle down to them given the perceived impact they have on overall ACO revenues. ESCOs offer a more reasonable renal risk model with stronger alignments than general ACOs will or can. Nevertheless, this process is still ongoing and as yet unproven in its overall impact on economic value or

improvement in population health.

It is critical to mention at this point that to effectively deliver health care "value," ACOs must first ensure patient volume to offset risk; this reality is also true of ESCOs. This has resulted in aggressive marketing campaigns to consolidate/grow hospital networks. Additionally, the PPACA has created incentives to blur the lines between insurers and traditional brick and mortar hospitals with both morphing into the other. How this process matures remains unknown and will need to be monitored closely but must be carefully considered as hospitals are exerting much pressure on physicians to service their patients and the high cost of ESKD patients is on their radar.

CHRONIC KIDNEY CARE

Outpatient (office-based) CKD care, patients identified with CKD by their primary care providers are referred to nephrologists for diagnosis and treatment plans, remains mired in an FFS payment system that has been eroded yearly based on real inflation-based dollars (**FIGURE 44.1**). Previous attempts at "disease management" of CKD care have failed for a variety of reasons: poor alignment of incentives across the care continuum, regulatory barriers, underpowered EMR, and analytics to name a few (11). Although FFS payment models for outpatient care are defined, the reimbursement does not sustain the costs of providing that care. This creates financial incentives that favor cross subsidization of office CKD care with income from hospital and ESKD care. Therefore, transition of patients to ESKD and liberal use of hospital care remains lucrative, and prevention of ESKD or hospital avoidance is not, clearly poorly aligned physician incentives.

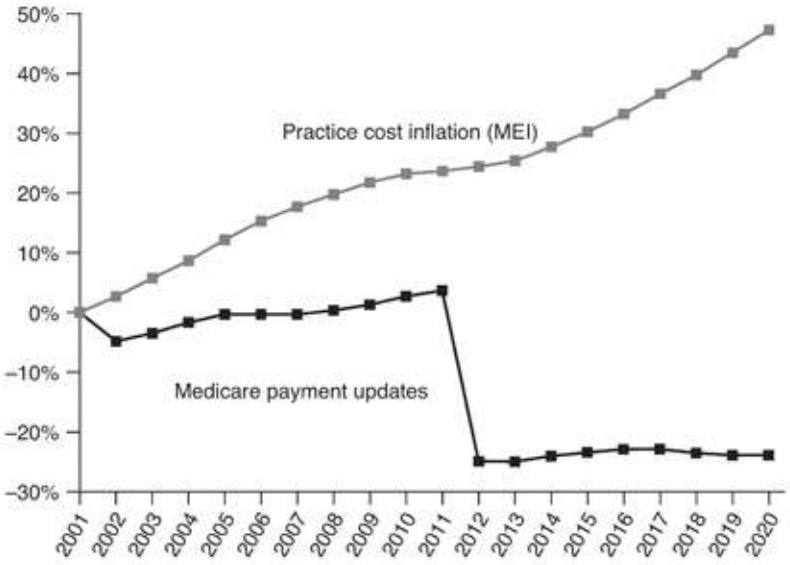

FIGURE 44.1 Disparity over time of practice cost inflation versus Medicare payment updates. (Data from 2011 Medicare Trustees Report, with adjustments based on 2012 Medicare physician payment schedule Final Rule. Prepared by American Medical Association, Economic and Health Policy Research, January 2012.)

The challenge for providers of kidney care is how to unite these three foci of care in a manner that improves patient outcomes and provides an attractive financial model for the practice and other stakeholders.

In the short term, the volume model can be sustained only by finding more efficient ways to manage increased patient volumes and to improve practice business efficiencies. You must challenge your current delivery model. The American Society of Nephrology (ASN) recently reported on nephrology manpower

data suggests a shortage of nephrologists in the market (12). I would posit that there are plenty of nephrologists but with poor clinical deployment. Expanded use of physician extenders in the ESKD space coupled with their use in the office can improve outcomes and lower costs. A nephrologist can see new patients, determine the working diagnosis and treatment plan, and then turn the ongoing care and management to their physician assistant or advanced practice nurse under the guidance of defined CKD guidelines. This obviously frees up the nephrologists time to spend in more critical areas of the practice. This model of care is starting to gain traction and has been successful. In the long term, the economics of CKD will be more closely, if not entirely, tied to broader care models through ACOs, ESCOs, or other yet undetermined economic vehicles.

If one accepts that ESCOs or other risk models will be the economic future of kidney care, then several issues must be addressed in preparation.

REDEFINING KIDNEY CARE DELIVERY

If one accepts the triple aim of care as earlier referenced and espoused by CMS, then three points will help guide you in the process of practice restructure:

- Allocate resources to deliver population-level care in your areas of core competency.
- Leverage economies of scope and scale to allow these same resources to fund care.
- Develop and implement key programs to further improve outcomes.

Restructuring/retooling how a practice delivers quality kidney care, development and implementation of predictable, incremental CKD processes of care (CKD stages 3, 4, and 5), measurement, aggregating and reporting of quality metrics, development of robust integrated EMR systems, and challenging the "minds-set" of all nephrologists will all be necessary.

Structural changes will include processes allowing patients to be seen within 72 hours of hospital discharge, ER avoidance strategies, the capacity to see new/urgent outpatient referrals in a timely fashion, and developing robust business metrics, such as how much does it cost to deliver CKD, ESKD, and hospital care? (**FIGURE 44.2**)

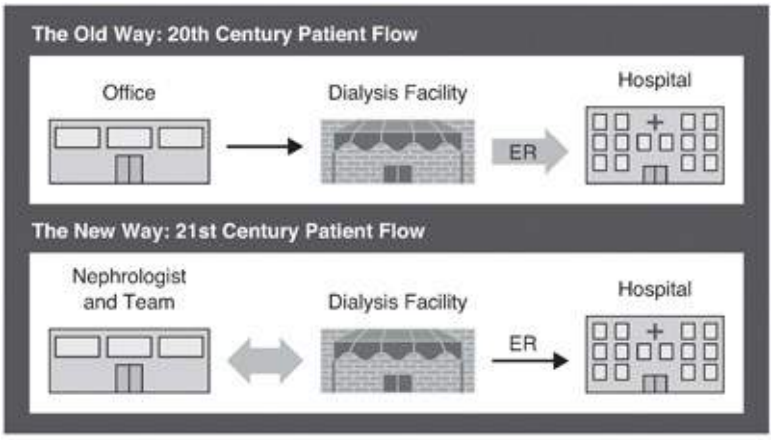

FIGURE 44.2 Patient flow. Arrow size represents volume of patients.

These changes are critical to remain viable in a value-based care system and must be addressed. If a practice does not have the resources or expertise to provide answers, outsourcing your back office management to professionals will add great value to your practice as well as allow you to focus both on care and strategic goals going forward.

Additionally, hospital care will no longer be a passive process. Rather, avoiding unnecessary hospitalizations and readmissions, moving patients through their hospital stay in an efficient manner, and creating a posthospital care process will become critical.

Lastly, relationships with providers are evolving. Hospital via ACOs and dialysis providers via ESCOs will be looking for practices sensitive to value-based care. They are aware of the changes required in broader care models and are taking steps to partner with forward thinking nephrologists in meaningful ways. Practices must consider these strategic partnerships as business opportunities.

Focused goals will include presenting healthier incident patients to dialysis providers, determining who actually benefits from dialysis (elderly vs. conservative CKD management) and which method of dialysis is suited for which patient. Dialysis facility care models will be more intense and specific. Low-hanging opportunities in vascular care, diabetes management, immunization, and so on will have direct financial implications.

CONCLUSION

The “business of nephrology” does not and can no longer exist in isolation. Rather, the financial viability of practices will necessarily be linked to broader risk pools that may include ESKD. A level of practice sophistication with a broad focus and strategy including strategic partnerships will drive the economic future of kidney care. Practices large enough to accept risk will have an advantage; smaller practices are aligning in legal vehicles, independent practice associations (IPAs), or merging to maintain relevance; and many practices are now looking to divest their practices to dialysis providers or hospital systems to fully align incentives. Ultimately, each practice must determine the best business strategies to make upfront capital investments to reap any longer term, as yet, poorly defined, economic returns.

Services, cost, data, process, and patient satisfaction will drive CKD care in the future. Practices’ viability will be determined by developing CKD stage-specific, focused clinical processes with the ability to track, aggregate, analyze, and report outcomes.

Practices will need to take into consideration integrated care requirements including rapid patient assessments and reporting, timely follow-up posthospitalization, ER strategies, efficient use of physician extenders, as well as care models driven by predictive analytics.

Applying high-level practice management will allow your practice to become the business that it is. Revenue cycle management, accounts receivable, denial rates, coding and auditing, personnel management, and credentialing must all be performed in the most economical manner with measurable returns.

Despite a shift to value-driven care, volume of care is still a necessity to weather the financial costs incurred for this transition. Delivering high-volume, high-quality care while moving to value care requires efficiencies in care previously not required.

It remains too early to judge the success or failure of these new economic models, but early results from pioneer ACOs have shown some added value, defined as improved selected clinical metrics and financial savings. Additionally, nephrologists have always led in the delivery of value-based care, and although much will need to change, integrating the delivery of kidney care into a broader risk pool may prove economically attractive for many practices.
