This work is provided "as is," and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based on healthcare professionals' examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data, and other factors unique to the patient. The publisher does not provide medical advice or guidance, and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made, and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used, or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

LWW.com

To all my mentors, and friends, at the University of Santo Tomas Faculty of Medicine and Surgery in Manila, Philippines; Mercy Hospital & Medical Center in Chicago, Illinois; and Northwestern University Feinberg School of Medicine in Chicago, Illinois; who have in one way or another influenced and guided me to become the physician that I am.

To all the medical students, interns, and residents at University of Illinois at Chicago/Advocate Christ Medical Center whom I have taught or learned from, especially those who eventually decided to pursue nephrology as a career. . . .

To my parents and my brothers, without whose unwavering love and support through the good and bad times, I would not have persevered and reached my goals in life. . . . Most especially to my two lovely and precious daughters, Anastasia Zofia and Isabella Ann, whose smiles and laughter constantly provide me unparalleled joy and happiness, and my very loving and understanding wife Michelle, who has always been supportive of my endeavors, both personally and professionally, and who sacrificed a lot of time and exhibited unwavering patience as I devoted a significant amount of time and effort to this project. Truly, they provide me with motivation and inspiration.
- EVL

For my wonderful wife, Duffy, and my three amazing children, Ryan, Courtney, and Kerry, who have generously shared me with my career as a caregiver for patients with kidney disease, I am eternally grateful.
- MRW

CONTENTS

Contributing Authors
Preface

SECTION I

Technical and Procedural Considerations in Hemodialysis

1 Choice of the Hemodialysis Membrane
Jay I. Lakkis and Matthew R. Weir

2 Dialysate Composition in Hemodialysis and Peritoneal Dialysis
Peter Noel Van Buren and Biff F. Palmer

3 Hemodialysis Vascular Access
Dirk M. Hentschel, Stephen J. Bander, and Steve Schwab

4 Anticoagulation Strategies during Hemodialysis Procedures
William J. Dahms, Jr.

5 Measuring Hemodialysis Using Solute Kinetic Models
Andrew I. Chin and Thomas A. Depner

6 Hemodialysis Adequacy and the Timing of Dialysis Initiation
Sharmeela Saha and Jay B. Wish

7 High-Efficiency and High-Flux Hemodialysis
Thomas A. Golper, Rafia Chaudhry, Iheanyichukwu Ogu, and Gerald Schulman

8 Long and Daily Hemodialysis
Andreas Pierratos

9 Home Hemodialysis
Brent W. Miller

10 Continuous Dialysis Therapeutic Techniques
Piyush Mathur, Celina Cepeda, and Ravindra L. Mehta

11 Renal Replacement Therapy—Wearable and Implantable Therapies
Edward R. Gould and William H. Fissell

SECTION II

Technical and Procedural Considerations in Peritoneal Dialysis

12 Adequacy of Peritoneal Dialysis
John M. Burkart

13 Causes, Diagnosis, and Treatment of Peritoneal Membrane Failure
Shweta Bansal and Isaac Teitelbaum

14 Peritoneal Dialysis–Related Infections
William Salzer

SECTION III

Clinical Considerations in the Evaluation of Dialysis Patients

15 Hypertension in Dialysis Patients
Arjun D. Sinha and Rajiv Agarwal

16 Left Ventricular Dysfunction and Valvular Heart Disease in Dialysis Patients
Sean P. Martin, Sean W. Murphy, and Patrick S. Parfrey

17 Coronary Artery Disease and Sudden Cardiac Death in Patients with End-Stage Kidney Disease
Wajeh Y. Qunibi, L. Richard A. Lange, and William L. Henrich

18 Hemodynamic Stability and Autonomic Dysfunction in End-Stage Kidney Disease
Biff F. Palmer and William L. Henrich

19 Oxidant Stress in End-Stage Kidney Disease
Ravinder K. Wali

20 Immune Dysfunction and Low-Grade Persistent Inflammation in Uremia
Gabriela Cobo, Juan Jesus Carrero, Bengt Lindholm, and Peter Stenvinkel

21 Hepatitis and Human Immunodeficiency Virus Infections in End-Stage Kidney Disease Patients
Ruth Berggren

22 Endocrine Disorders in Dialysis Patients
Yin Oo, Naim Maalouf, and R. Tyler Miller

23 Gastrointestinal Complications in End-Stage Kidney Disease
George T. Fantry, Seema Patil, and Donna S. Hanes

24 Chronic Kidney Disease-Mineral Bone Disorder in Patients with End-Stage Kidney Disease
Wajeh Y. Qunibi

25 Acid–Base Considerations in End-Stage Kidney Disease
F. John Gennari and Dana Negoi

26 Respiratory Disorders in End-Stage Kidney Disease
Vibhu Sharma and Michael Achilles Markos

27 Malnutrition and Intradialytic Parenteral Nutrition in End-Stage Kidney Disease Patients
Joel D. Kopple, Anuja Shah, and Kamyar Kalantar-Zadeh

28 Disorders of Hemostasis in Dialysis Patients
Federica Mescia, Miriam Galbusera, Paola Boccardo, and Giuseppe Remuzzi

29 Treatment of Anemia in Patients with End-Stage Kidney Disease
Yaakov Liss and Jeffrey S. Berns

30 Neurologic Complications Associated with Dialysis and Chronic Kidney Disease
Imran I. Ali and Noor A. Pirzada

31 Diabetes Management in a Patient with End-Stage Kidney Disease
Andrew Kowalski, Ruchita Patel, Armand Krikorian, and Edgar V. Lerma

32 Pregnancy in the Chronic Dialysis Patient
Lakshmi Kannan and Janani Rangaswami

33 Acquired Cystic Kidney Diseases in Dialysis Patients
Judy K. Tan, Jonathan Silverman, and Edgar V. Lerma

SECTION IV

Drugs and Intoxications

34 Quality of Life and Rehabilitation in Dialysis Patients
Daniel Jay Salzberg and Fathima Konari

35 Prescribing Drugs for Dialysis Patients
Ali J. Olyaei and William M. Bennett

36 Extracorporeal Treatment of Poisoning and Drug Overdose
Wajeh Y. Qunibi

SECTION V

Dialysis in the Pediatric Population

37 Chronic Dialysis in Children
Bradley A. Warady, Kathy L. Jabs, and Amy L. Skversky

38 Acute Dialysis in Children
Susan R. Mendley

SECTION VI

Dialysis in Specific Circumstances

39 Depurative Modality Options
Tushar Chopra, Iheanyichukwu Ogu, Rafia Chaudhry, Thomas A. Golper, and Gerald Schulman

40 Choosing the Best Dialysis Option in the Patient with Acute Kidney Injury and in the Intensive Care Unit
Ami M. Patel and Beje Thomas

41 Preparing Dialysis Patients for Renal Transplantation
Feras F. Karadsheh, Matthew R. Weir, Charles B. Cangro, and Beje Thomas

42 The Geriatric Dialysis Patient
Yusra Cheema and Wendy Weinstock Brown

43 Current Outcomes for Dialysis Patients and Improving Quality of Care for Dialysis Patients
Brent W. Miller

SECTION VII

Business of Dialysis

44 The Business of Nephrology
Robert Provenzano

PREFACE

The first edition of *Principles and Practice of Dialysis* was published in 1994. The practice of dialysis has evolved substantially since that first edition.

As in previous editions, the fifth edition carries on the tradition of prior editions to achieve a balance between scholarship, clarity, and practicality. The text is written by several acknowledged experts with a view to providing clinical direction built on a platform of the best scientific and clinical evidence. In this edition, we welcome contributions from new authors as well as new topics (home hemodialysis, wearable artificial kidney, respiratory disorders in dialysis patients, dialysis and reproduction, cystic kidney diseases in dialysis patients) and have reworked each chapter to reflect the changing nature of modern dialysis practice.

From personal experience, we are cognizant that for a variety of reasons, the majority of readers would read only one or a few chapters at any given time. In this vein, we considered that each chapter would complement each other yet be complete in itself. Therefore, in this multiauthored text, it is unavoidable to have some overlap in the information presented in a few chapters. However, we feel that this was necessary to provide sufficiently complete information on a particular topic.

This book would not have been possible were it not for many people. First, we would like to thank all of our wonderful contributing authors who have spent countless hours in producing high-quality, up-to-date information. We express our sincere gratitude for their openness to this collegial collaboration, which has been a truly rewarding learning experience for us. We also thank the staff of Wolters Kluwer who helped us in this production, most especially Leanne Vandetty, our Product Development Editor; and Kel McGowan and Julie Goolsby, our Acquisitions Editors.

We are indebted to our teachers and mentors who devoted their own time to educate and train us. We thank all the medical students, residents, and fellows who in one way or another have given us the inspiration to persevere in this profession. Mostly, of course, we are grateful to our patients who are and have been instrumental in our education. On behalf of all the contributors to this book, we sincerely hope that our efforts will contribute to relieving suffering.

It is the wish of all the authors and staff associated with this book that it will continue to serve as a valuable reference and guide for busy practitioners and for trainees at all levels. It is through the accomplishment of these missions that we trust dialysis therapy will improve so that the quality of life for all of our patients with kidney disease may improve.

WILLIAM L. HENRICH, MD, MACP
EDGAR V. LERMA, MD, FACP, FASN, FNKF

CHAPTER 1

Choice of the Hemodialysis Membrane

Jay I. Lakkis and Matthew R. Weir

Although renal replacement therapy (RRT) has been successful at simulating the kidneys' capacity for solute regulation and volume management, significant limitations persist, which continue to challenge the successes of this therapy when compared to normal kidney physiology. In hemodialysis (HD) therapy, the most prevalent form of RRT (>90%) in the United States (1), both ultrafiltration and solute clearance are driven at the level of the dialysis membrane. In addition to dialysis time and frequency, solute clearance remains an integral part of the ongoing quest to establish the optimal dialysis dose and to set clearly defined adequacy measures that correlate with survival, less chronic inflammation, better nutritional status, and improved well-being. Some of the byproducts of this pursuit are a plethora of techniques and mathematical models that simulate target solute kinetics (e.g., urea, index Kt/V) and the continuing development of newer high-performance membranes (HPM) and dialysate solutions to improve clinical outcomes.

The dialysis membrane is manufactured from semipermeable compounds, which may be geometrically designed in coil (1946) (2), parallel-plate (1948), or most commonly hollow-fiber (1956) structure (**TABLE 1.1**), then stabilized mechanically into a potting compound (e.g., polyurethane), and finally encased in a housing material (e.g., polypropylene or polycarbonate). This design creates a barrier between the blood and the dialysate during HD while allowing a bidirectional exchange of solute (e.g., potassium from blood to dialysate and bicarbonate in the opposite direction); the major mechanisms that govern solute clearance in HD are diffusive transport, convective transport, and adsorption. The ideal dialysis membrane is perfectly biocompatible with no proinflammatory effects, achieves the desired ultrafiltration and the highest clearance of all uremic toxins, is associated with the most optimal nutritional status, and does not result in any short-term or long-term complications.

TABLE 1.1 Choice of Dialysis Membrane

Geometric design Hollow fiber Parallel plate Coil	Hollow fiber is the most widely used.
Chemical composition Cellulosic, unmodified, regenerated Cellulosic, modified, substituted Synthetic, noncellulosic	Free hydroxyl groups on surface of unmodified cellulosic membranes contribute to blood–membrane interactions and degree of bioincompatibility. Hydrophobicity of a membrane enhances adsorptive capacity.
Solute clearance: efficiency Low efficiency High efficiency	Efficiency is measured by K_oA urea and can be increased by increasing membrane surface area. • Low efficiency K_oA urea <500 mL/min • High efficiency K_oA urea >600 mL/min
Solute clearance: flux Low flux High flux Super high flux	Flux is measured by β_2-MG or water clearance and can be increased by increasing membrane pore size/permeability. • Low flux: $K_{\beta_2\text{-MG}}$ <10 mL/min or $K_{UF} \leq 12$ mL/h/mm Hg • Medium flux: $K_{\beta_2\text{-MG}}$ 10–20 mL/min • High flux: $K_{\beta_2\text{-MG}}$ >20 mL/min or K_{UF} >12 mL/h/mm Hg • Super high flux: $K_{\beta_2\text{-MG}}$ >50 mL/min, clearance high MW cutoff up to 65 kDA
Biocompatibility Biocompatible Bioincompatible	Inflammation: anaphylatoxins, granulocyte activation, cytokines Thrombogenicity Worse nutritional status Accelerated atherosclerosis and cardiovascular disease Erythropoietin resistance Deposition of β_2-MG fibrils and dialysis-related amyloidosis Sterilization technique
Performance Low performance High performance	High-performance membranes are very highly biocompatible, have enhanced adsorptive capacity, and clear solutes with a high MW cutoff very close to the native kidney, for example, low MW proteins.

K_oA, membrane permeability-area coefficient; K, clearance; β_2-MG, β_2-microglobulin; K_{UF}, ultrafiltration coefficient; MW, molecular weight.

SOLUTE AND WATER TRANSPORT ACROSS A DIALYSIS MEMBRANE

The net clearance of any specific solute, or of water, from a patient's blood at the end of a dialysis treatment is the sum total of a complex interplay between diffusive transport, convective transport, and adsorption, all of which are in turn determined by solute properties, membrane characteristics, solute concentration gradients, transmembrane pressure (TMP) gradients, blood and dialysate flow rates, ultrafiltration rate, patient's hematocrit (Hct) and protein concentrations, and temperature. These processes are described in this section.

Solute Classification by Molecular Weight

A small molecular weight (SMW) solute is one whose molecular weight is less than 500 Da. Examples include most nitrogen-based solutes such as creatinine and urea, lactic acid, cholesterol, most vitamins (A, B_1, B_2, B_3, B_5, B_6, B_7, B_9, C, D_2, D_3, E, K_1, K_2, K_3), and all electrolytes (**TABLE 1.2**).

TABLE 1.2 Clinically Relevant Solutes and Their Molecular Weights

Molecule	Formula	MW Da	Molecule	Formula	MW Da
Albumin	–	66,500	Lambda free light chain (dimer)	–	45,000
β_2-Microglobulin	–	11,815	Magnesium	Mg(2+)	24.305
Bilirubin	$C_{33}H_{36}N4O_6$	584.66214 (CID: 5280352)	Myoglobin	–	17,200
Calcium	Ca(2+)	40.078	Phosphate	–	134
Carbon dioxide	CO_2	44.0095 (CID: 280)	Phosphorus	P(3−)	30.973761
Chloride	Cl(−)	35.453	Potassium	K(+)	39.0983
Cholesterol	$C_{27}H_{46}O$	386.65354 (CID: 5997)	Sodium	Na(+)	22.9898
Creatinine	$C_4H_7N_3O$	113.11788 (CID: 588)	Urea[a](1)	CH_4N_2O	60.05526 (CID: 1176)

MW, molecular weight.
[a]National Center for Biotechnology Information. PubChem Compound Database; CID.

A middle molecular weight (MMW) solute is a solute with a molecular weight between 500 Da and 15 kDa. Examples include β_2-microglobulin (β_2-MG), cystatin C, vitamin B_{12}, inulin, hemoglobin (Hb) and myoglobin, and bilirubin (**TABLE 1.2**).

A large molecular weight (LMW) solute has a molecular weight greater than 15 kDa. Examples

include albumin, immunoglobulins, kappa and lambda free light chains, and ferritin (**TABLE 1.2**).

Diffusion

Diffusion is a mass transfer process that describes the transport of matter from one part of a system to another as a result of random molecular motion triggered by thermally induced agitation; in HD, such transport occurs between the blood and the dialysate across the semipermeable dialysis membrane from a region of high concentration to a region of low concentration. This is best represented by Fick's first law of diffusion:

$$J_{Diffusion} = dn/dt = -D \cdot A \cdot \Delta C / \Delta X$$

where $J_{Diffusion}$ (dn/dt) is flux in mol/s, D is diffusion constant in cm^2/s, A is membrane surface area in cm^2, ΔC is the concentration gradient in moles/cm^3, and ΔX is thickness of the barrier to diffusion in cm. Since flux remains positive while the concentration gradient is dissipating, a minus sign is added to D.

For a specific dialysis membrane, D and ΔX are constant at any preset temperature, and thus, the above equation can simplified as follows:

$$J_{Diffusion} = -K_o \cdot A \cdot \Delta C$$

where K_o is the overall mass transfer coefficient in cm/min. If rearranged, $K_o = (J_{Diffusion} / A) / -\Delta C$ = flux per unit area / driving force of the concentration gradient; furthermore, this can be rewritten as $(J_{Diffusion} / A) = -\Delta C/(1 / K_o) = -\Delta C / R_o$, which can be read as mass transfer per unit area = driving force / resistance to transport. For any specific solute to diffuse from the blood to the dialysate, the total resistance R_o would be the sum of the resistance to move from the bloodstream to the blood surface of the membrane R_B, the resistance to move across the dialysis membrane R_M, and the resistance to move from the dialysis side of the membrane to the dialysate R_D: $R_o = R_B + R_M + R_D$ (3). R_B can be minimized by the maximization of the blood-flow rate Q_B and shear rate, R_D can be attenuated by increasing the dialysate flow rate Q_D, and R_M can be optimized by an even packing density of the membrane fibers and spacer compounds during production.

In intermittent HD, diffusion is the major process for small solute clearance; is governed by concentration gradients; and depends mainly on membrane surface area and thickness, blood-flow rate, dialysate flow rate, and temperature (4). Q_B is usually slower than Q_D and as such has the greatest impact on diffusive solute clearance; at a Q_B of 400 mL/min, any increase in the Q_D above 600 mL/min will only offer a mediocre increase in diffusive solute clearance (5).

Convection

Convection is a mass transfer process that describes the bulk transport of molecules within fluids where transport is dependent upon factors such as changes in hydrostatic or osmotic pressure and membrane porosity; in HD, this is represented by a solute following the bulk transport of water (solvent drag phenomenon) during ultrafiltration triggered by a positive TMP. Said bulk transport follows Poiseuille's law for hydrodynamic flow, which describes laminar flow of a Newtonian fluid through a pipe (e.g., hollow fiber); Newtonian fluids, such as water, have a constant viscosity in time and at different rates of shear stress.

$$Q = dV/dt = \pi \cdot \Delta P \cdot r^4 / 8 \cdot \eta \cdot L$$

where Q is the volume flow rate under laminar flow conditions, ΔP is the pressure drop across a pipe, r is the radius of the pipe, η is the viscosity coefficient (a constant that is dependent on temperature but independent of the speed of flow), and L is the length of the pipe.

However, blood does not obey Poiseuille's law, owing to its being a non-Newtonian viscoelastic fluid with cells, which can deform, and proteins, both of which make its viscosity variable at different Hct and protein concentrations. Viscosity would be at its highest when the blood-flow rate and the shear rate applied are at their lowest (4). For blood flowing in a laminar fashion across a hollow-fiber dialysis membrane under preset condition that makes its viscosity constant, convection is reflected by the Hagen-Poiseuille equation:

$$\Delta P = (8 \cdot \eta \cdot L \cdot Q_B) / (N \cdot \pi \cdot r^4)$$

where ΔP is the pressure gradient across the dialysis membrane, η is the blood viscosity, L is the length of the dialyzer membrane, Q_B is the blood-flow rate, N is the number of hollow fibers in a dialyzer, and r is the radius of the hollow fiber.

Thus, convective clearance across a dialysis membrane is better achieved with a higher pressure gradient ΔP along the length of the dialysis membrane, a higher blood viscosity η which is dependent on Hct, a higher blood-flow rate Q_B exceeding 300 mL/min, a smaller diameter of individual hollow fibers.

Convective clearance can be represented by the following equation:

$$J_{Convection} = SC \cdot Q_F$$

where SC is the apparent solute sieving coefficient and Q_F is the ultrafiltration rate (6).

In HD, convective solute transport is driven by TMP and ultrafiltration (Q_F) and accentuates diffusive transport; convective transport gains greater clinical significance as the solute's molecular weight increases (7) and is the cornerstone of therapies such as hemodiafiltration (HDF) (8).

Adsorption

Adsorption refers to solute removal via solute deposition, predominantly low molecular weight proteins (LMWPs), and adhesion to the dialysis membrane. An initial phase of competitive adsorption of high molecular weight proteins (HMWPs) to the inner layer of the dialysis membrane occurs until saturation is reached; this process results in a surface biofilm consistent of HMWP such as albumin, globulins, and fibrinogen. A second dynamic and slower phase of adsorption involves LMWP, such as β_2-MG, cytokines, and anaphylatoxins, and involves the inner layers of the dialysis membrane and is completely dependent on membrane porosity and charge-dependent selective permeability (9). Synthetic membranes have a higher adsorption clearance than cellulosic membranes owing in part to their higher hydrophobicity and porosity; examples include polysulfone, polyacrylonitrile (PAN), and polymethylmethacrylate (PMMA) (10).

Clearance

The clearance of any specific solute is the sum total of its diffusive clearance, convective clearance, and adsorptive clearance. Clearance K = solute mass removal rate per unit time / plasma solute concentration. Based on prior discussion, solute clearance can be increased in the majority of instances by maximizing

Q_B and Q_F.

Membrane Efficiency

Membrane efficiency refers to SMW solute permeability, most commonly, urea. It is the capacity of any one specific membrane to clear any one specific solute from the blood when other HD variables are preset, namely, blood-flow rate (Q_B) and dialysate flow rate (Q_D); urea has been traditionally the solute of choice to report efficiency in the dialysis membrane industry.

Efficiency is determined by a membrane's surface area and its solute permeability and is quantitatively measured by the membrane permeability-area coefficient K_oA, where K_o is the mass transfer coefficient and A is the membrane's surface area (11). As mentioned earlier, most dialysis membrane manufacturers report the values for K_oA measurements for urea when all other dialysis conditions are preset *in vitro*, namely, the Q_B, the Q_D, the ultrafiltration rate Q_F, dialysate temperature, and blood percent Hct. The K_oA of a membrane indicates its urea clearance when Q_B and Q_D are infinite.

In vivo membrane efficiency may fall short of the *in vitro* performance due to blood-to-dialysate flow mismatch; for example, this may be caused by a higher blood viscosity on the luminal side of the membrane and thus affecting the blood-flow distribution, or to an uneven fiber density in a heterogeneously packed hollow-fiber membrane, thus affecting the dialysate flow distribution and resulting in a decreased dialysate flow velocity in the more densely packed areas, usually in the center, and a higher flow velocity in the less densely packed areas (4). Synthetic membrane fibers are usually distributed in an undulated or rippled pattern and thus result in a lesser blood-to-dialysate flow mismatch than the straight and unevenly packed fibers seen in cellulose membranes (12). It is also worth noting that the performance of many membranes is reported by the manufacturer based on an Hct of 32%, and higher *in vivo* values may also affect dialyzer efficiency (13,14). When *in vitro* experiments use a fluid other than blood, the manufacturer's reported efficiency or K_oA tends to overestimate the *in vivo* values; for instance, the Hemodialysis (HEMO) Study Group reported an *in vivo* K_oA at 80 ± 7% (SD) of the *in vitro* values (p <0.001) in the 1,208 patients with arteriovenous accesses at first use and at a Q_D of 500 mL/min, and this further declined to 74.8 ± 6.6% when other variables were accounted for, namely, effects of Q_D and reuse number (11).

Synthetic and asymmetric membranes also tend to be more efficient due to a lesser resistance to water and solute transport conferred by their lower membrane thickness when compared to homogeneous and symmetric membranes (15).

Membrane Flux

Membrane flux refers to MMW solute permeability. This measure of permeability by molecular size cutoff is routinely reported in reference to a specific MMW or high molecular weight (HMW) solute, most commonly β_2-MG and less commonly vitamin B_{12} or inulin.

Current dialysis membranes in order of permeability are high-cutoff membranes or super high-flux membranes > high-flux membranes > low-flux membranes.

Membrane flux has also been reported as a membrane's capacity at ultrafiltration, or water flux, the major determinant of convective solute clearance across the membrane. The measure of the ultrafiltration

capacity of a membrane, and thus its designation as low or high flux, is based on the ultrafiltration coefficient (K_{UF}):

$$K_{UF}\ (mL/min/mm\ Hg) = \text{water flux / transmembrane pressure} = Q_F / (P_B - P_D)$$

where Q_F is the ultrafiltration rate in mL/min, and $P_B - P_D$ refers to the TMP gradient between the blood and the dialysis compartments. K_{UF} is measured *in vitro* by the ultrafiltration of bovine blood at different TMPs (16). K_{UF} is naturally dependent on membrane permeability to water, and thus, pore size is the major determinant of membrane flux; a membrane with larger pore sizes has the advantage of higher rates of water flux and a higher ultrafiltration capacity as well as a better removal of HMW solutes than membranes with smaller pore size.

Both parameters used to report membrane flux, MMW solute clearance and ultrafiltration capacity (K_{UF}), correlate well as membrane performance measures (17).

Internal Filtration and Backfiltration

Internal filtration/backfiltration (IF/BF) is the phenomenon that describes the automatic and uncontrolled convective transport of solute with water from the dialysate compartment to the blood compartment when the driving force of filtration is dissipated under countercurrent flow conditions; this occurs when the oncotic pressure balances the hydrostatic pressure due to the high ultrafiltration rate characteristic of high-flux dialyzers (18). During a typical HD treatment with a high-flux membrane, the ongoing balance between hydrostatic and oncotic pressures along the membrane results in an ongoing process of IF/BF even when the ultrafiltration rate is nil; it is estimated that 6 to 8 L are internally filtered and backfiltered during a 4-hour treatment when no ultrafiltration is prescribed.

Theoretically, this IF/BF may result in the transport of bacterial byproducts or inflammatory mediators from a contaminated dialysate to the patient's blood and result in bioincompatibility of the membrane; thus, it is recommended that ultrapure dialysate be used with high-flux HD to avoid potential proinflammatory effects (19).

This IF/BF phenomenon contributes to an automatic, uncontrolled form of convective solute transport, a convection-enhanced or IF-enhanced HD with its own internal hemodiafiltration (iHDF) component and without a replacement solution. IF/BF promotes MMW and LMW solute clearance, such as β_2-MG, and LMWP clearance, in a process that is dependent on the IF flow rate Q_{IF}, which can be augmented by increasing Q_B (20–22). Several membrane developers have used this same phenomenon in the development of a newer generation of iHDF membranes that enhances the clearance of aforementioned solutes. A quantifying mathematical model has also been developed (23).

Dialysis Membrane Biocompatibility

Biocompatibility refers to the magnitude of the reaction of the human body upon exposure of blood to the dialysis membrane, triggering a cascade of events and generating a proinflammatory status, via activation of cellular and humoral immunity, and/or a thrombogenic effect. Thus, a hypothetically perfect biocompatible membrane would not trigger any human response (immune or thrombogenic or otherwise) and a bioincompatible membrane would mobilize all components of the immune and coagulation systems among others. For example, membranes made of the naturally abundant, unmodified cellulose

polysaccharide (a D-glucose linear homopolymer ($C_6H_{10}O_5)_n$) (24) are among the least biocompatible membranes and, while at one point of time were the most widely used dialyzer membrane worldwide, have since been discontinued in 2006 and largely replaced by more biocompatible synthetic membranes, largely made of polysulfone (25).

CLASSIFICATION OF DIALYSIS MEMBRANES

There is no one classification of dialysis membranes by geometric design, chemical composition, efficiency, flux, or biocompatibility. With the continued development of newer membranes, there is a considerable overlap when considering all these criteria (**TABLE 1.1**).

Classification of Dialysis Membranes by Geometry, Design, and Structure

Coil Dialyzers have the highest resistance for solute mass transport from the blood to the dialysate (16) and are mostly of historical interest at this time.

Parallel-Plate Dialyzers have a lesser resistance for solute mass transport from the blood to the dialysate (16).

Hollow-Fiber Dialyzers have the lowest resistance for solute mass transport from the blood to the dialysate (16) and are the most widely used all over the world. Cross-sectionally, hollow-fiber dialyzers may be symmetric or asymmetric. Symmetric fibers are homogenous in cross-section with similar pore sizes across all layers. Asymmetric fibers are designed with a thin inner layer on the blood side of the membrane, which is the major determinant for solute permeability, and a thick outer supporting layer (the stroma) with larger pores toward the dialysate side of the membrane. The internal distribution of the hollow fibers plays an important role in its performance, and as mentioned earlier, asymmetric design is associated with less blood-to-dialysate flow mismatch (12).

Classification of Dialysis Membranes by Chemical Composition/Material

Dialysis membranes may be made of unmodified or regenerated cellulose, synthetically modified cellulose (SMC), or synthetic polymers (**TABLES 1.1** and **1.3**). Polymer-based synthetic membranes became commercially available in the 1970s and have since dominated the dialysis membrane industry; they tend to have higher performance, are more biocompatible, and their availability in high flux made it possible for patients to have a shorter HD time without jeopardizing dialysis adequacy (26). It must be noted though, that a dissociation between solute and water flux for membranes of any specific composition makes any simplified model of flux/composition classification almost impossible.

[m]K_{UF}: Measured with bovine blood, hematocrit = 32%, protein 60 g/L, at 37°C.
[n]K_{UF}: Measured with bovine blood, hematocrit of (32 ± 3) % and a protein content of (60 ± 5) g/L.
[o]Sieving coefficient for vitamin B_{12} – inulin – β_2-MG – albumin. Typical values measured with Polyflux 170H dialyzer, with hematocrit of (32 ± 3) % and a protein content of (60 ± 5) g/L.
[p]K_oA: Q_B = 200 mL/min, Q_D = 500 mL/min, Q_F = 0 mL/min.

Unmodified or Standard Cellulose

The first described dialysis membrane was made of collodion, a polymer of cellobiose, an unmodified cellulose-trinitrate derivative (27); cellulose comprises 90% of cotton and 50% of wood and is as such the most abundant of all naturally occurring organic compounds. It is this low-flux membrane that Adolf Fick and Thomas Graham, among other scientists, used to lay out the principles of HD in the 19th century and early 20th century to selectively separate SMW solutes from blood through the process of diffusion (28). In 1914, a team of scientists led by Abel (29) developed and tested the first efficient *in vivo* dialysis system in a living animal at Johns Hopkins University School of Medicine, and in 1924, the first human HD was performed in a uremic patient by George Haas in 1924 at the University of Giessen in Germany (30,31).

Unmodified cellulose membranes are mechanically stable, have symmetric fibers, and are homogenous in cross-section with similar pore sizes across all layers; they are also hydrophilic enabling lower membrane thickness (6 to 15 μm dry thickness) (15,25), have small pores, and as such a good efficiency/performance on LMW or small solute diffusive clearance. However, they have a low flux with a K_{UF} of <10 mL/h/mm Hg and perform poorly on middle-molecule clearance (molecular cutoff clearance of 5,000 Da; e.g., β_2-MG); this, along with their bioincompatibility, driven by a high degree of alternative complement pathway activation as a result of complement protein interaction with the free cellulose hydroxyl moiety (25), eventually led to their replacement and the development of more biocompatible

membranes with better clinical performance measures and clinical outcomes.

Regenerated Cellulose

Regenerated cellulose is obtained from cellulose that has been liquefied, purified, and extruded and changed by physical, rather than chemical, treatment such as cellophane, rayon, and viscose; their chemical structure remains identical to cellulose. One prototype dialysis membrane manufactured from regenerated cellulose is Cuprophan (CU, manufactured by Membrana); other examples include cellophane and cuprammonium rayon. In 1947, Cuprophan flat sheets were established as wrapping foil, and by 1965, the first flat sheet HD membranes were developed, but it was only in 1966 that Cuprophan was used in the world's first industrially manufactured artificial kidney. Regenerated cellulose membranes replaced collodion because they offered better performance at the time and were more stable mechanically; they also had the same advantage of a low membrane thickness owing to their strong hydrophilic characteristics (15).

Modified Cellulose

Substituted Cellulose

This membrane is made by the chemical treatment of cellulose, for example, with acetic acid, where acetate replaces the free hydroxyl groups on the surface of the cellulose molecule. The replacement of the hydroxyl group decreases the availability of free nucleophilic moieties and is thought to reduce complement protein binding and activation and hence enhance biocompatibility (25).

A prototype of substituted cellulose membrane is cellulose triacetate (molecular formula $C_{40}H_{54}O_{27}$; molecular weight: 966.84056 g/mol) (32) (e.g., CT190G, Baxter Healthcare Corp, Deerfield, IL) where there is a total replacement of all hydroxyl groups with acetate; other examples include cellulose acetate, cellulose diacetate, and cellulose hydrate. When replaced with acetate, there is an increase in membrane porosity and hence water and solute permeability; furthermore, the substituted cellulose triacetate membrane is highly hydrophobic and the absence of swelling decreases the membrane thickness (15,16). The cellulose triacetate dialysis membrane is the most biocompatible of all cellulosic membranes has a similar biocompatibility to that of the polysulfone membrane (16).

Semisynthetic Cellulose

This modification aims at replacing the free surface hydroxyl group with a bulky moiety that sterically hinders blood–membrane interactions. One prototype of modified semisynthetic membranes is Hemophan (manufactured by Membrana), in which a synthetic material, diethylaminoethyl (DEAE), is mixed with liquefied cellulose during its regeneration for membrane formation. This membrane retains the high-efficiency characteristics of the unmodified cellulose membrane and is available in low flux and high flux and has an affinity to bind anions, such as heparin and phosphate, and hence a decrease in thrombogenicity and phosphate clearance when compared to nonmodified cellulose membranes (33) but no change in phosphorus kinetics when compared to synthetic membranes (34).

Other examples of semisynthetic cellulose membranes include benzyl-modified cellulose (SMC, Membrana GmbH, Wuppertal, Germany), polyethylene glycol-grafted cellulose (AM-BIO, Asahi Medical Co, Ltd, Tokyo, Japan), and vitamin E (Excebrane, Asahi Medical Co, Ltd, Tokyo Japan).

Noncellulose Synthetic

Synthetic membranes are manufactured with a noncellulosic polymers but are more often than not alloys or copolymers of more than one polymer; this latter point is extremely important for the accurate interpretation of the physical and chemical properties of any synthetic membrane, especially that membrane nomenclature may be often misleading as it refers to only to one of the polymers used.

The first synthetic dialysis membrane was developed in the early 1970s and was a PAN membrane, namely, AN69 (Gambro, Lakewood, CO; Hospal, Meyzieu, France), an alloy of the acrylonitrile and sodium methallyl sulfonate polymers; at the time, the rationale was to develop a membrane with a high ultrafiltration coefficient for high-flux HD and hemofiltration (35).

Currently, the majority of dialysis membranes in use are synthetic. Of the synthetic membranes used, 93% are polymers from the polyarysulfone family with 71% being polysulfone and 22% being polyethersulfone (36).

Prototypes of noncellulose synthetic dialysis membrane include polysulfone (molecular formula: $C_{27}H_{26}O_6S$; molecular weight: 478.55674 g/mol) (32) (e.g., F80A, Fresenius, Lexington, MA) which is the most widely used membrane, polyarylethersulfone (PAES) or polyethersulfone [molecular formula: $(C_{12}H_8O_3S)_n$; molecular weight: $(232.258)_n$ g/mol], polyacrylonitrile (PAN) [molecular formula: $(C_3H_3N)_n$; molecular weight: $(53.06262)_n$ g/mol] (32) (e.g., AN69), polycarbonate [molecular formula: $(CO_3^{ï2})_n$; molecular weight: $(60.0089)_n$ g/mol] (32), polyamide (molecular formula: $C_{18}H_{35}N_3O_3$; molecular weight: 341.4888 g/mol) (32), PMMA membranes [molecular formula: $(C_5H_8O_2)_n$; molecular weight: $(100.11582)_n$ g/mol] (32), and poly(vinyl alcohol-co-ethylene) (EVOH) (linear molecular formula: $(CH_2CH_2)_x[CH_2CH(OH)]_y$). Synthetic membranes are thicker than cellulose membranes (35 μm or more dry thickness) (25), their fibers may be symmetric (AN69, PMMA) or asymmetric (polysulfone, polyamide) with various structures (sponge- or fingerlike) of the supportive stromal layer (16). During the polymerization process of predominantly hydrophobic synthetic membranes, such as polysulfone, polyamide, and polyethersulfone, a wetting hydrophilic agent polyvinylpyrrolidone (PVP, a widely used pharmaceutical excipient) is added to enhance the overall membrane's hydrophilic properties making its clinical use feasible; PVP also promotes the alloyed membrane's porosity and also determines membrane integrity upon reuse.

Bioactive Membranes

Bioactive membranes are synthetic or cellulosic membranes, which are coated with a bioactive compound such as heparin or vitamin E, with a hypothetical intent to decrease thrombogenicity or oxidant stress in these two instances.

Classification of Dialysis Membranes by Flux and Water Ultrafiltration Coefficient

Membrane flux is measured by the permeability of the membrane to water and other molecules typically β_2-MG.

Low-Flux Membranes

The HEMO study defines such a membrane as one with low permeability to β_2-MG and a mean clearance

<10 mL/min (17). The U.S. Food and Drug Administration (FDA) describes a low-flux "conventional" membrane as one with an *in vitro* permeability to water molecules K_{UF} equal or less to 12 mL/h/mm Hg (37).

High-Flux Membranes

The HEMO study defines such a membrane as one with high permeability to β_2-MG and mean clearance >20 mL/min and a K_{UF} of more than 14 mL/h/mm Hg (17). The FDA describes a high-flux "high-permeability" membrane as one with an *in vitro* permeability to water molecules K_{UF} of more than 12 mL/h/mm Hg (37).

Super High-Flux or High-Cutoff Membranes

These membranes have the ability to clear LMW solutes, naturally larger than β_2-MG, such as LMWP including protein-bound uremic toxins. These membranes can clear solutes with a molecular weight cutoff very close to the native kidney and as high as 65,000 Da; they have the ability to clear cytokines in sepsis syndromes, myoglobin in rhabdomyolysis, and kappa and lambda free light chains in multiple myeloma and other plasma cell dyscrasias and dysproteinemias (38,39).

In Japan and for health insurance reimbursement purposes, dialysis membranes are stratified into five different classes based on their β_2-MG clearance (mL/min), when Q_B is set at 200 mL/min, Q_D is set at 500 mL/min, and Q_F is set at 10 mL/min, as follows: type I <10, 10 ≤ type II <30, 30 ≤ type III <50, 50≤ type IV <70, and type V ≥70. As such, types IV and V are super high-flux dialyzers (40,41).

Classification of Dialysis Membranes by Efficiency

A dialysis membrane whose K_oA urea <500 mL/min is considered a low-efficiency membrane and one whose urea KoA >600 mL/min is considered a high-efficiency membrane. Membrane efficiency increases with increasing membrane surface area, optimizing Q_B and Q_D, and a dialysis access capable of providing the prescribed blood-flow rate. Since the potential for augmentation of Q_B, Q_D, or access is quite limited, high-efficiency membranes have traditionally been higher surface area membranes, usually more than 1.5 m^2.

Classification of Dialysis Membranes by Performance

The performance of a dialysis membrane is based on its solute clearance effectiveness and its biocompatibility. An HPM would have the following features: (a) ability to clear target solutes including MMW and LMW uremic toxins, such as β_2-MG and LMWPs; (b) larger pore size and high molecular weight cutoff, thus enhancing its convective clearance capacity, the pore sizes ought to be highly uniform and with minimal variability resulting in a shaper sieving coefficient cutoff and augmented clearance of LMWP-bound uremic toxins (while minimizing albumin losses) as well as MMW and LMW uremic toxins with clearances approaching those of the native kidney; (c) enhanced adsorptive capacity; and (d) superb biocompatibility profile.

The Japanese Society of Dialysis Therapy (JSDT) favors an HPM pore size that is permissive of albumin losses of less than 3 g during one treatment (Q_B 200 mL/min; Q_D 500 mL/min) to enhance albumin turnover (12,40,42,43).

FACTORS INFLUENCING CHOICE OF MEMBRANE AND COMPARISON OF CLINICAL OUTCOMES

Geometric Design

Coil dialysis membranes have been associated with a higher incidence of intradialytic hypotension than parallel-plate and hollow-fiber dialysis membranes (44). Hollow-fiber dialysis membranes were associated with less thrombocytopenia and a higher mean postdialysis platelet count (93% of predialysis platelet count) when compared to parallel-plate dialysis membranes (postdialysis platelet count 69% of predialysis platelet count) (45). There was no statistically significant difference in the blood levels of anaphylotoxins C3a, C4a, and C5a or their des-Arg forms as measured by radioimmunoassay between patients who were dialyzed with parallel-plate or hollow-fiber membranes (46). In contrast, Lins et al. (47) studied the effects of dialysis membrane geometry on platelet count, whole blood activated coagulation time, heparin dose requirement, and complement C3a activation; they found no statistically significant differences between hollow-fiber and parallel-plate Cuprophan dialyzers for any measure at any time.

Currently, the overwhelming majority of dialysis membranes are manufactured in hollow fiber; as such, geometric design hardly plays any significant role in choosing the desired membrane.

Membrane Biocompatibility

The continuing advances in the design of dialysis membranes, aiming to manufacture the perfectly biocompatible dialysis membrane for patients on maintenance HD, can be viewed as yet another application of “Primum non nocere” or “first, do no harm.” Membrane and dialysis biocompatibility may have various clinical implications, some known and others not, that include patient’s well-being, inflammatory status, nutritional status, and degree of thrombogenicity among others.

Well-described aspects of bioincompatibility include (a) an enhanced chronic inflammatory status resulting from the activation of the alternative complement system with subsequent activation of granulocytes and release of cytokines, (b) enhanced thrombogenicity resulting in blood loss and worsening anemia or blood-to-dialysate flow mismatch and reduced uremic toxin clearance, (c) erythropoietin resistance, (d) declining nutritional status and loss of muscle and body mass, (e) accelerated atherosclerosis and cardiovascular disease, and (f) deposition of β_2-MG fibrils resulting in dialysis-related amyloidosis (DRA) (10,48,49). These aspects will be discussed below.

Inflammation

Activation of the alternative complement pathway during HD with a bioincompatible membrane is triggered by the spontaneous production of C3b, covalent bonding of C3b to the free nucleophilic groups on the dialysis membrane, limiting the C3b-binding of inhibitory regulatory factor H and favoring its binding to activating regulatory factors (e.g., factor B), and an amplification positive feedback loop perpetuated by the generation of C3-convertase which in turn results in more C3b production. The end result is the extracorporeal production of anaphylatoxins C3a, C4a, and C5a in the dialysis membrane, which induce granulocytes to release cytokines such as interleukin 1 (IL1), interleukin 6 (IL6), and tumor necrosis factor (TNF). C5a upregulates platelet adhesion molecules, binds and activates granulocytes

(neutrophils and monocytes) and lymphocytes, and induces neutrophil degranulation with release of lysosomes and reactive oxygen species creating a state of oxidative stress which in turn results in lipid and protein peroxidation and toxic-radical induced endothelial cell activation leading to vascular injury and atherosclerosis. The activated granulocytes in the dialysis circuit are removed immediately upon their return to the circulation, resulting in a transient granulocytopenia in the first half hour after starting HD. In addition to C5a-induced granulocytopenia, C5a-induced pulmonary hypertension/pulmonary dysfunction has been described in patients dialyzed with older less biocompatible membranes, mostly unmodified cellulose (9,50–52). First-use syndrome, an anaphylactoid reaction, is mediated by activation of the complement pathway (53).

Activation of the classical and the lectin complement pathway has also been reported but is thought to play a minor role.

The water affinity of the dialysis membrane has been associated with different degrees of biocompatibility with hydrophilic membranes showing greater degrees of complement activation than hydrophobic membranes (16); similarly, chemical composition plays an important role in the degree of biocompatibility with some surface moieties readily accessible for covalent bonding with C3b (e.g., hydroxyl OH, ammonia NH_3) triggering a stronger immune response.

Other important factors that influence biocompatibility and trigger a proinflammatory response include the purity level of the dialysate water, especially with high-flux dialysis membranes where BF is known to occur, and the use of chemicals. In the absence of ultrapure dialysate, bioincompatibility has been described with various scenarios such as dialysate bacterial products and endotoxins backfiltering into the bloodstream where they trigger a potent inflammatory response.

Similar reactions may be observed with leaching of chemicals into the bloodstream, such as residues of ethylene oxide (ETO) used to sterilize the membrane leaching from the polyurethane potting compound and triggering an anaphylactoid reaction (54–57). Chemicals applied for reuse such as formaldehyde have also been described to result in hypersensitivity reactions (58).

Spallation due to insoluble solutes entering the bloodstream, as has been described with silicone released from the tubing of the blood pump under mechanical stress and triggering inflammation with clinical manifestations such as hepatitis, granuloma formation, and hypercalcemia (25,59,60).

An atypical presentation of a polysulfone membrane hypersensitivity was recently described in a patient with recurrent fevers during and posthemodialysis, with a negative infectious workup (61).

Thrombogenecity

Upon the extracorporeal flow of blood through the dialysis membrane, some plasma proteins immediately adsorb to the inner layer of the membrane creating a secondary membrane, a biofilm. This biofilm is thought to play a key role in the degree of activation of the immune and coagulation systems. Since membranes with hydrophobic surfaces enhance this adsorption process, they are generally associated with a higher degree of thrombogenicity (16). The binding of fibrinogen (factor I) to the inner surface of the dialysis membrane activates the coagulation cascade and results in its conversion of insoluble fibrin which in turn upregulated platelet activation and aggregation, the end result being blood clotting and increased thrombogenicity; to offset this rise in thrombogenicity, most dialysis patients receive some form of anticoagulation during dialysis. This protein biofilm may also adversely affect the diffusive and

convective clearance of various solutes across the membrane. On the other hand, it has been suggested that this biofilm may limit complement activation in some cases and, as mentioned earlier, plays an essential role in the clearance of some LMWP. No cellulose of synthetic membrane has been proven to our knowledge to avoid this aspect of bioincompatibility triggered by blood–dialyzer interaction (10,25).

Since a dominantly hydrophilic inner surface of a dialysis membrane promotes complement activation, whereas a hydrophobic surface favors thrombogenicity, there seems to be a theoretical benefit to biocompatibility offered by a balanced combination of hydrophilic and hydrophobic microdomains. Clinical examples include the benzyl SMC membrane, polycarbonate/polyether membrane, and other synthetic membranes (16).

A hypersensitivity reaction has been well described in HD patients who were taking angiotensin-converting enzyme inhibitors (ACEIs) and dialyzed with negatively charged membranes, such as AN69. In the first few minutes after blood flows through the dialysis membrane, the anionic surface binds and activates coagulation factor XII (Hageman factor) triggering a chain reaction that culminates in the production of bradykinin. Since ACEI also inhibit kininase II, the enzyme responsible for the degradation of kinins, bradykinin levels may increase more than 100-fold and the anaphylactoid reaction ensues (62). Thus, it is advised to avoid anionic dialysis membranes, especially AN69, in patients who are taking ACEI. This has led to the development of a modified AN69 membrane, the AN69-ST, the surface of which is treated and coated with polyethylenimine to prevent such hypersensitivity reactions (63).

Composition/Material

Membrane composition and biocompatibility are closely interconnected. There is an abundance of publications that evaluate the impact of dialysis membrane composition on biocompatibility and performance measures. For example, Chiappini et al. (64) reported that cellulose membranes were associated with higher mortality and morbidity when compared to middle- and high-flux biocompatible membranes; morbidity was reflected by a worse nutritional status, higher levels of inflammatory marker C-reactive protein, and higher pre- and postdialysis levels of β_2-MG. Maintenance HD with a Cuprophan membrane was associated with a higher rate of cystic bone lesions and bone amyloidosis than with an AN69 synthetic membrane (65).

However, unfortunately, there are not many large randomized controlled trials that have evaluated the impact of the material and composition of the dialysis membranes on clinical measures. In a Cochrane Database meta-analysis, MacLeod et al. (26) analyzed data from 32 randomized and quasi-randomized controlled trials, which evaluated impact of the dialysis membrane composition (synthetic vs. cellulose/modified cellulose) on various clinical measures in patients with end-stage kidney disease (ESKD) on HD. They found no difference in mortality rates or dialysis-related complications; synthetic membranes were associated with the most favorable albumin (regardless of flux) and lipid profile (high-flux only), while cellulose membranes were associated with a significantly higher urea reduction ratio (URR) than synthetic and modified cellulose membranes. β_2-MG levels seemed to be lower with high-flux synthetic membranes but the heterogeneity between trials (number of patients, membrane flux) rendered the data insufficient to make any reliable conclusions. The authors noted that the clinical trials included were heterogeneous and that the numbers of patients included in many of the trials with outcome measures were low.

Flux

β_2-MG is the only MMW solute, LMWP that has been associated with adverse complications due to the deposition of β_2-MG fibrils in the joints and juxta-articular structures, bones, and gastrointestinal viscera of patients with ESKD. Higher flux membranes have resulted in lower pre- and posthemodialysis β_2-MG blood levels and the amelioration of these clinical manifestations (66–70); however, whether enhanced β_2-MG clearance translates into improved survival in this population remains to be proven.

Hyperphosphatemia has been associated with higher mortality rates in patients on RRT (71,72). High-flux dialysis has been shown to provide better control of phosphorus control than low-flux dialysis but less than HDF (73–77).

Similarly, anemia is associated with increased mortality and morbidity in this patient population. The use of high-flux dialysis in 48 erythropoietin-hyporesponsive patients (dose ≥200 IU/kg/wk) resulted in lower erythropoietin requirements (p <0.001) and improved anemia markers (p <0.001) as well as greater reductions in β_2-MG and phosphorus levels when compared to low-flux dialysis (73). However, Badve et al. (78) conducted a systematic review of two clinical trials to evaluate the efficacy of intervention in the management of erythropoietin-resistant anemia, including high-flux dialysis, highlighted the absence of any randomized controlled trials powered enough to make evidence-based recommendations in favor of any specific intervention.

Koda et al. (67) reported improved survival, lower predialysis β_2-MG levels and risk for carpal tunnel syndrome in a retrospective analysis of among 819 patients who were switched from conventional low-flux to high-flux dialysis.

In the HEMO study, a randomized controlled trial, Eknoyan et al. (17) noted that high-flux membranes did not improve survival or reduce morbidity when compared to low-flux membranes in their primary data analysis, despite the fact that the high-flux membranes resulted in a clear improvement in both urea and β_2-MG clearances. Of interest, secondary analysis showed a possible trend toward a decrease in cardiovascular mortality and hospitalizations in the high-flux membrane group and a possible benefit in women and patients with higher dialysis vintage (>3.7 years) (79).

Similarly, the Membrane Permeability Outcome (MPO) Study Group found no statistically significant survival benefit among 738 incident HD patients randomized to use high-flux and low-flux membranes over a follow-up period of 3 to 7.5 years (80). High-flux membranes were associated with a statistically significant higher survival rates among patients whose serum albumin levels were less than or equal to 4 g/dL; subgroup analysis revealed that there was a possible survival benefit in diabetics as well.

Finally, Palmer et al. (81) conducted a Cochrane Database meta-analysis which included 33 randomized and quasi-randomized controlled trials which evaluated the impact of membrane flux in 3,820 HD patients on all-cause mortality, cause-specific mortality (cardiovascular mortality, infection-related mortality), and hospitalization. Membrane flux did not have any effect on all-cause mortality, infection-related mortality, or hospitalizations; however, high-flux membrane resulted in a 17% reduction in cardiovascular mortality, thus preventing three cardiovascular deaths for each 100 patients treated with high-flux HD for 2 years.

There was no difference between online hemodiafiltration (OL-HDF) and high-flux HD in regard to blood pressure, serum albumin, erythropoietin resistance index, bone, and mineral parameters in a

retrospective cohort of 858 patients followed over 18 years, but there was a reduction in mortality rates in patients treated predominantly with HDF (82). Similarly, in a cohort of 906 maintenance HD patients, those who received postdilution OL-HDF had a reduction in all-cause mortality risk by 30% (NNT 8), of cardiovascular mortality by 33%, and of infection-related mortality by 55%, and in intradialytic hypotension when compared to high-flux HD (83). In contrast, Ok et al. (84) did not find any survival benefit between OL-HDF and high-flux HD except when replacement volumes exceeded 17.4 L. OL-HDF is also hypothesized to improve vascular endothelial function and decrease vascular stiffening and inflammation (85); it has also been associated with a more favorable left ventricular ejection fraction and phosphorus control (74). There are no randomized controlled prospective studies that we know of yet to confirm the superiority of HDF.

The European best practice guidelines on HD strategies recommend the use of high-flux synthetic membranes to avoid long-term complications such as dialysis-related amyloidosis and accelerated cardiovascular disease and to improve phosphate and anemia control (86).

Effect on Residual Kidney Function

The raison d'être of high-performance dialysis membranes, with their high flux and excellent biocompatibility, may generate a hypothesis that they are associated with a better preservation of residual kidney function, owing to their attenuated proinflammatory profile.

Biocompatible high-flux polysulfone membranes are associated with better preservation of residual kidney function than cellulose membranes (87).

However, Hakim et al. (88) reported no statistically significant difference in residual renal function among 159 incident hemodialysis patients who were randomized for HD with a low-efficiency biocompatible dialysis membrane or a low-efficiency bioincompatible dialysis. Similarly, Richardson et al. (89) failed to show any difference in residual kidney function at 7 months in 177 HD patients randomized to a medium-flux modified cellulose triacetate membrane (SF170E, Nipro, Osaka, Japan) or a high-flux polysulfone membrane, Fresenius (HF80LS, Bad Homburg, Germany).

Nutritional Status and Protein Loss

Protein malnutrition (serum albumin <3.5 g/dL) is a known clinical manifestation in patients with ESKD on maintenance HD. Over a period of 18 months, the effect of membrane biocompatibility on various surrogates of nutritional status was evaluated in 158 incident HD patients; dialysis with a biocompatible membrane as opposed to a bioincompatible membrane was associated with an improved dry weight ($p < 0.05$) and an earlier and more significant increase in serum albumin levels (90).

Tayeb et al. (91) reported improved serum albumin levels in patients with protein malnutrition, who were switched from a cuprammonium to a more biocompatible polysulfone dialysis membrane ($p < 0.002$).

In a prospective cohort of 138 maintenance HD patients, middle- and high-flux dialysis were associated with improved nutritional indices, C-reactive protein, pre- and postdialysis β_2-MG, and survival when compared to low-flux dialysis (62).

A decline in body mass index has been associated with increased mortality in maintenance dialysis patients (92–94). Thus, it has been hypothesized that a dialysis membrane that decreases protein loss and associated loss of muscle mass may be associated with enhanced survival. Masakane (70) reports

preservation of body and muscle mass, and lower protein loss, in patients who were dialyzed with an ethylene vinyl alcohol copolymer (EVAL) membrane when compared with a PMMA membrane; similar results were observed when predilution OL-HDF was sued with a polysulfone membrane.

Membrane Bioactivity

No study has shown improved survival with any of the available bioactive membranes such as vitamin E– or heparin-coated membranes.

Vitamin E

Several small studies, however, have pointed the favorable outcome of vitamin E–coated membranes on oxidative stress and biocompatibility, thought to be mediated by the binding of vitamin E to oxygen free radicals in the fiber lumen (95). Examples of such antioxidant activity included prevention of erythrocyte oxidative stress (96,97) and reduction of asymmetric dimethylarginine (ADMA, an endogenous inhibitor of nitric oxide synthase) (98) upon treatment with vitamin E–coated polysulfone membrane. In a prospective randomized Japanese trial, which followed 305 patients from 48 different centers, there was no difference in the erythropoiesis resistance index (ERI = total weekly ESA dose / Hb) at 1 year of follow-up between patients who were dialyzed with a vitamin E–bonded polysulfone and an uncoated polysulfone membrane (99).

In a systematic review, Huang et al. (100) reported that vitamin E–coated membranes may decrease ERI but failed to find any definitive benefit with respect to anemia, nutritional status, lipid profile, or atherosclerosis.

Heparin

The HepZero study is a multinational prospective open-label randomized controlled trial of 251 HD patients, who were randomized to dialyze with a heparin-grafted membrane (HGM), a polyacrylonitrile sodium methallyl sulfonate copolymer (Evodial, Gambro-Hospal, Meyzieu, France), or no-heparin HD with saline flushes or predilution HDF (control group); HGM membrane was noninferior but not superior to saline flushes (101). This provides a reasonable therapeutic alternative to HD patients who are at high risk for bleeding (102).

Sterilization Methods

Dialyzer membranes may be sterilized by the manufacturer in various ways such as gas chemical sterilization with ETO, autoclave or steam heat sterilization, and gamma ray or electron beam irradiation.

Different sterilization techniques did not affect small solute clearances but altered vitamin B_{12} clearance due to membrane shrinkage during the process (103).

Steam sterilization had more favorable biocompatibility surrogate measures when compared to ETO, such as white blood cell and platelet counts, anaphylatoxin levels (C3a and C5a), and polymorphonuclear neutrophil elastase plasma concentration (104).

Yamashita et al. (105) reported improved solute clearance in super high-flux dialyzers which underwent sterilization as compared to no sterilization at all. Kiaii et al. (106) reported that patients who received dialysis with an electron beam sterilized dialyzer had an odds ratio of 3.57 of developing thrombocytopenia on HD, defined by a decline in platelet count exceeding 15%.

Golli-Bennour et al. (107) reported improved viability of endothelial cell and less lipid peroxidation in 10 patients when steam sterilization was used as compared to gamma ray or ETO sterilization.

Dialysis Membrane Reuse

The effect of reprocessing and reuse of the dialysis membrane has been a topic of continued controversy. During reuse, the dialysis membrane is reprocessed with germicides and disinfectants; examples include formaldehyde, hypochlorite, glutaraldehyde, peracetic acid, heated citric acid, Renalin, and bleach.

Reuse is more common in the United States and reached a peak in 1997 when 82% of dialysis facilities implemented a reuse policy and has been declining since (39% in 2005) (108); most European countries and Japan implement no-reuse policies. The rationales for membrane reuse has varied and examples include improved biocompatibility, reduced cost, reduced nonbiodegradable waste production and a more favorable environmental impact (part of a green dialysis or eco-dialysis). On the other hand, concerns over effect of mortality, a possible promotion of the proinflammatory status, infections, and leaching resulting from improper reprocessing procedure with chemicals and germicides, and loss of functional membrane surface area have been described (109,110).

The use of formaldehyde to reprocess less biocompatible membranes, such as unmodified cellulosic membranes, has been associated with less complement activation and neutropenia, owing to the continued saturation of membrane receptors with C3b during the first use (111). In contrast, bleach is capable of effective removal of the C3b from its binding sites resulting in effects similar to first use all over again after each reuse (112).

A systematic review of 14 studies found no difference in mortality between single-use dialysis membrane and reuse (average number of reuses 2.54 to 15) among 956,807 patients with ESKD on HD (113).

There remains an increased risk with reuse inherent to the reprocessing technique with chemical disinfectants and outbreaks of bloodstream infections or sensitivity reactions continue to be reported continually (114).

Environmental Considerations

Biomedical waste from single-use dialyzer membrane poses a huge environmental burden and takes several forms; it has been estimated that in 1997 when reuse was its peak, single-use dialysis membranes alone generated 17 to 18 million pounds of waste (110,115).

CONCLUSIONS

There has been great progress in HD membrane technology. This has eliminated many of the concerns about biocompatibility. Moreover, advances in flux, minimizing protein losses, and enhancing clearance, while reducing the need for anticoagulation requirements has helped improve the clinical care.

CHAPTER 2

Dialysate Composition in Hemodialysis and Peritoneal Dialysis

Peter Noel Van Buren and Biff F. Palmer

Patients with end-stage kidney disease (ESKD) depend on dialysis to maintain fluid and electrolyte balance. In both hemodialysis and peritoneal dialysis, solutes diffuse between blood and dialysate such that, over the course of the procedure, plasma composition is restored toward normal values. The makeup of the dialysate is of paramount importance in accomplishing this goal. This chapter reviews recent developments on how the dialysate can be manipulated to improve patient tolerance and outcome. Individualizing the dialysate composition is likely to gain increasing importance given the advancing age and increasing number of comorbid conditions found in ESKD patients.

DIALYSATE COMPOSITION IN HEMODIALYSIS

In most outpatient settings, patients receive hemodialysis using dialysate prepared in bulk and delivered via a central delivery system so that the composition of the dialysate is the same for all patients. Although most patients tolerate the procedure when administered in this fashion, many patients suffer from hemodynamic instability or symptoms of dialysis disequilibrium. One strategy to improve the clinical tolerance to dialysis is to adjust the dialysate composition according to the individual characteristics of the patient.

Dialysate Sodium

As dialysis has evolved, there has been continued interest in adjusting the dialysate sodium (Na) concentration in an attempt to improve the tolerability of the procedure. In the early days of dialysis, fluid removal was accomplished by a process of osmotic ultrafiltration. High concentrations of glucose were placed in the dialysate in order to create an osmotic driving force for fluid removal, as the coil dialyzers utilized at the time were unable to withstand high transmembrane hydrostatic pressures. In order to prevent the development of hypernatremia as water moved from plasma to dialysate, the Na concentration in dialysate was purposely set low, usually in the range of 125 to 130 mEq/L. With the development of

more resilient membranes capable of withstanding high transmembrane pressures, osmotic ultrafiltration was replaced by hydrostatic ultrafiltration. Initially, a low dialysate Na concentration continued to be used in order to avoid the problems of chronic volume overload such as hypertension and heart failure. With the institution of shorter treatment times, volume removal became more rapid and symptomatic hypotension emerged as a common and often disabling problem during dialysis. It soon became apparent that changes in the serum Na concentration, and more specifically changes in serum osmolality, were playing a role in the development of this hemodynamic instability. Subsequent studies demonstrated that raising dialysate Na to between 139 and 144 mEq/L was associated with improved hemodynamic stability and general tolerance to the procedure (1,2).

The importance of a stable plasma osmolality in maintaining hemodynamic stability was first suggested when the hemodynamic profiles of ultrafiltration were compared to diffusional solute clearance. Ultrafiltration alone (the removal of iso-osmolar fluid by exerting a transmembrane pressure across the dialyzer) decreases cardiac output primarily due to a reduction in the stroke volume but is accompanied by an increase in peripheral vascular resistance such that arterial pressure is maintained. By contrast, diffusional dialysis results in a fall in arterial pressure while peripheral vascular resistance remains the same. With conventional dialysis (ultrafiltration and dialysis), less volume removal can be achieved before hypotension occurs as compared to ultrafiltration alone. The primary and characteristic difference between these two processes with respect to plasma osmolality is that plasma osmolality remains relatively constant during ultrafiltration but declines during dialysis due to the rapid intradialytic fall in plasma urea.

The decline in plasma osmolality during regular hemodialysis favors a fluid shift from the extracellular space to the intracellular space, thereby exacerbating the volume-depleting effects of dialysis. In animal studies, both conventional dialysis and sequential ultrafiltration dialysis result in an ultrafiltrate volume which is less than the decrease in extracellular fluid volume consistent with a shift of fluid into the intracellular compartment (3). In addition, during sequential ultrafiltration hemodialysis, this shift only occurs during the diffusive phase. With the advent of high clearance dialyzers and more efficient dialysis techniques, this decline in plasma osmolality becomes more apparent as solute is more rapidly removed.

Use of a low dialysate sodium concentration would tend to further augment the intracellular shift of fluid, as plasma tends to become even more hyposmolar consequent to the movement of sodium from plasma to dialysate. Older studies that employed maneuvers designed to minimize the decline in plasma osmolality such as infusing hypertonic mannitol, placement of high concentrations of dextrose in the dialysate, or placement of glycerol in the dialysate found that hemodynamic stability became comparable to that seen with ultrafiltration. While maneuvers to minimize the decline in plasma osmolarity using mannitol or glycerol can optimize hemodynamic stability during hemodialysis (4,5), the main and, perhaps the most physiologic, approach adopted to reduce the extent of change in the osmolality of body fluids during dialysis has been to increase the sodium concentration of the dialysate. Indeed, numerous investigators have now demonstrated that hemodynamic tolerance to dialysis is improved when the dialysate sodium concentration is increased to at least 135 mEq/L.

The mechanism by which raising the dialysate Na concentration improves hemodynamic stability is depicted in **FIGURE 2.1**. As discussed previously, a high dialysate Na concentration has been shown

effective in maintaining a relatively constant plasma osmolality, thereby minimizing intracellular water movement during dialysis. In this regard, Van Stone et al. (6) measured changes in body water compartments as a function of low or high dialysate sodium concentrations in a group of dialysis patients in which 2-kg volumes were removed. With a low dialysate sodium (7% lower than serum sodium concentration), there was a dramatic decrease in extracellular water and a 21% decline in plasma volume while intracellular water increased. Use of a high dialysate sodium (7% greater than the serum sodium concentration) resulted in proportional decreases in intra- and extracellular water, and plasma volume only fell by 13%. By preventing a decrease in plasma osmolality, the higher sodium dialysate leads to mobilization of fluid from the intracellular space, resulting in better preservation of plasma volume. These findings have been confirmed by more recent studies utilizing bioimpedance measurements to study changes in body fluid compartments (7). As the dialysate-to-plasma Na gradient increases, there is a greater contraction of the intracellular fluid compartment. The shift of fluid into the extracellular fluid space increases the hydrostatic pressure of the interstitium, thus increasing the capacity for vascular refilling during volume removal resulting in a reduced frequency of hypotension and cramps.

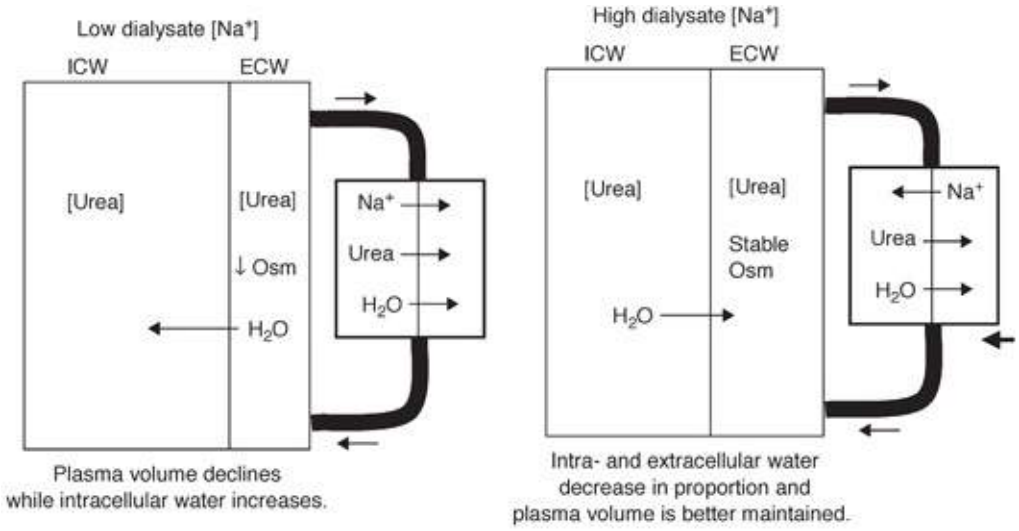

FIGURE 2.1 Use of a low sodium dialysate is more commonly associated with intradialytic hypotension. In the initial period of dialysis, the extracellular urea concentration falls, creating an osmotic driving force for water movement into the cell due to the higher intracellular urea concentration. This drop in extracellular osmolality and movement of water into the intracellular space is exacerbated in the setting of a low dialysate Na concentration. As a result, plasma volume falls and the risk of hypotension increases. A high sodium dialysate helps to minimize the development of extracellular hyposmolality allowing for better refilling of the intravascular compartment. Plasma volume remains better preserved and the risk of hypotension is reduced. ICW, intracellular weight; ECW, extracellular weight.

A high Na dialysate may also more favorably influence compensatory mechanisms involved in maintaining peripheral vascular resistance during volume reduction. Decreased plasma osmolality has been associated with impaired peripheral vasoconstriction during volume removal possibly due to an inhibitory effect of hyposmolality on afferent sensing mechanisms. This effect would compound the tendency toward hemodynamic instability, as many chronic dialysis patients have baseline abnormalities in autonomic function. In addition, central nervous system abnormalities due to cellular swelling are more likely to result during low osmolality dialysis, potentially further impairing autonomic function. A low Na dialysis solution has also been shown to increase prostaglandin E_2 levels. This prostaglandin has venodilatory properties that could lead to venous pooling, thus contributing to hemodynamic instability (8).

The primary concern with use of a higher dialysate Na concentration is the potential to stimulate thirst and cause increased weight gain and poor blood pressure control in the interdialytic period. Studies

addressing this issue confirmed that a higher dialysate Na modestly increased interdialytic weight gain. However, this excess weight was found to be readily removed with improved tolerance to ultrafiltration (1).

More recently, there has been interest in varying the concentration of Na in the dialysate during the procedure to minimize the potential complications of a high Na solution while retaining the beneficial hemodynamic effects. A high dialysate Na concentration is used initially with a progressive reduction toward isotonic or hypotonic levels by the end of the procedure. This method allows for a diffusive Na influx early in the session to prevent the rapid decline in plasma osmolality resulting from the efflux of urea and other small molecular weight solutes. During the remainder of the procedure, when the reduction in osmolality accompanying urea removal is less abrupt, the lower dialysate Na level minimizes the development of hypertonicity and any resultant excessive thirst, fluid gain, and hypertension in the interdialytic period.

Several studies have compared the hemodynamic and symptomatic effects of a dialysate in which the Na concentration is varied during the procedure to that in which the Na concentration is fixed. Dumler et al. (9) used a dialysate Na of 150 mEq/L during the initial 3 hours of dialysis at the time of ultrafiltration; the dialysate Na was decreased to 130 mEq/L for the last hour. The control group was dialyzed against Na concentration fixed at 140 mEq/L. Use of the high/low Na hemodialysis was associated with a smaller decline in systolic pressure as well as fewer symptomatic hypotensive episodes.

Other investigators have varied dialysate Na according to a Na gradient protocol in which the Na is set to decrease from a high to a low level over the course of a dialysis session. Raja et al. (10) and Daugirdas et al. (11) found no measurable benefit. Acchiardo and Hayden (12) found a reduction in hypotensive episodes, and Sadowski et al. (13) had similar results in young patients. The linear and step Na modeling programs have been found to be better in lowering the risk of intradialytic headache as compared with the exponential program. The linear program was the only individual program that alleviated interdialytic cramps; the most striking reduction in the risk for posttreatment hypotension occurred with the step program.

Differences in the incidence of symptomatic hypotension during dialysis or in the degree of interdialytic weight gain between the fixed or variable Na protocols have been difficult to demonstrate. Levin and Goldstein (14) studied a group of patients who were specifically selected because of the frequent occurrence of symptoms on dialysis such as headaches, cramps, and light-headedness. In a crossover trial, these patients were assigned either to a fixed Na dialysate and a constant rate of ultrafiltration or to a gradient protocol in which the initial Na concentration and ramping pattern were individually adjusted to minimize thirst. Use of the patient-specific Na gradient profiles was associated with improvement in all patients with headache and in 70% of patients with light-headedness. Most patients reported an increase in thirst, but there were no differences in interdialytic weight gain or in predialysis and postdialysis mean arterial pressure. Using a more general dialysis population, Sang et al. (15) compared a linear or step Na gradient (155 to 140 mEq/L) protocol with a fixed Na dialysate (140 mEq/L). In this study, Na modeling was associated with a significant reduction in cramps and symptomatic hypotension. However, these benefits were followed by increasing thirst, fatigue, and weight gain between dialysis sessions as well as a higher predialysis blood pressure. The authors concluded that only 22% of patients had a significant benefit from the modeling programs. Finally, a study by Movilli et

al. (16) found improved blood volume preservation by using a pattern of high to low Na change (160 to 133 mEq/L); the changes in blood pressure were similar between this high to low variation and conventional dialysis.

In summary, the available data suggest that in most chronic dialysis patients, changing the dialysate Na during the course of the treatment offers little advantage over a constant dialysate Na of between 140 and 145 mEq/L. The inability to clearly demonstrate a superiority of Na modeling may be due to the fact that the time-averaged concentration of Na was similar in many of the comparative studies. For example, a linear decline in dialysate Na from 150 to 140 mEq/L will produce approximately the same postdialysis serum Na as occurs when a dialysate Na of 145 mEq/L is used throughout the procedure. In addition, the optimal time-averaged Na concentration whether administered in a modeling protocol or with a fixed dialysate concentration is likely to vary from patient to patient as well as in the same patient during different treatment times (17). This variability is supported by studies demonstrating wide differences in the month-to-month predialysis Na concentration in otherwise stable dialysis patients (18).

Nevertheless, in selected patients, Na modeling may be of benefit (**TABLE 2.1**). Patients initiating dialysis with marked azotemia are often deliberately dialyzed to decrease the urea concentration slowly over the course of several days to avoid the development of the dialysis disequilibrium syndrome. The use of a high/low Na dialysate in these patients may minimize fluid shifts into the intracellular compartment and decrease the tendency for neurologic complications. Na modeling may also be beneficial in patients suffering frequent intradialytic hypotension, cramping, nausea, vomiting, fatigue, or headache. In such patients, the modeling protocol can be individually tailored to minimize increased thirst, weight gain, and hypertension. Combining dialysate Na profiling with a varying rate of ultrafiltration may provide additional benefit in particularly symptomatic patients (19). Use of this combined approach may be of particular benefit in ensuring hemodynamic stability in patients with acute kidney injury in the intensive care unit (20).

TABLE 2.1 Indications and Contraindications for Use of Na Modeling (High/Low Programs)

A. Indications
• Intradialytic hypotension
• Cramping
• Initiation of hemodialysis in setting of severe azotemia
• Hemodynamically unstable patient (as in intensive care unit setting)
B. Contraindications
• Intradialytic development of hypertension
• Large interdialytic weight gain induced by high Na dialysate
• Hypernatremia

When prescribing a Na gradient protocol, it is important to monitor the patient for evidence of a progressive increase in total body Na. In some patients, a high/low Na protocol can lead to large interdialytic weight gain or cause intradialytic hypertension (**TABLE 2.1**). Such adverse effects are more likely to occur when the time-averaged Na concentration is greater than the patient's predialysis serum Na concentration (21). In this setting, use of a low dialysate Na during the terminal phase of the procedure does not guarantee negative Na balance. In hypertensive patients, adjusting the protocol to achieve negative Na balance may be of therapeutic benefit in the long-term control of blood pressure. In this regard, Flanigan et al. (22) recently compared a fixed dialysate Na of 140 mEq/L to a gradient protocol in

which the dialysate Na was lowered in an exponential fashion from 155 to 135 mEq/L and then held constant at 135 mEq/L for the final half hour of the procedure. Ultrafiltration was discontinued during the final half hour of the session. Use of the variable Na dialysate permitted a 50% reduction in the dose of antihypertensive medications without significant changes in predialysis blood pressure or interdialytic weight gain. Although not specifically measured, use of the terminal low Na period may have caused a decrease in the total body exchangeable Na, thus accounting for improved blood pressure control in Na-sensitive patients. A recent report from a single dialysis facility also described a beneficial effect on blood pressure when the dialysate Na was simply lowered from a set value of 141 to 138 mmol/L (23). As in the study by Flanigan et al. (22), this effect occurred in the absence of a change in interdialytic weight again consistent with a volume independent effect.

Profiled hemodialysis is a recent attempt to make the dialysate Na even more patient specific. This technique is based on a mathematical model in which baseline patient characteristics are used to construct a patient-specific Na profile dialysate before each treatment. Initial experience with this procedure has shown improved cardiovascular hemodynamics when compared with a fixed dialysate Na concentration despite the same total mass of Na being removed (24).

In dialysis patients, interdialytic Na and water loads vary from one patient to another and from treatment to treatment. Water balance can be achieved by making total ultrafiltrate volume equal to interdialytic weight gain. Current research is focusing on ways in which the dialysate Na concentration can be adjusted to more accurately match intradialytic Na removal with interdialytic Na intake. The ability to achieve zero Na balance would enhance the ability to control hypertension in the interdialytic intervals and minimize the risk of hypotension during the dialysis procedure.

The ability of dialysis to accurately regulate fluid balance has become highly refined over the years (although choosing the target dry weight and reaching it are more problematic). A similar accuracy in the maintenance of Na balance requires that the dialysate Na concentration be individualized such that with each treatment, a constant end-session plasma Na concentration is reached. If over time end-dialysis weight and plasma Na concentration are kept constant (assuming no change in Na distribution volume), one can assume that the patient will be in Na balance. As currently practiced, the dialysate Na concentrations whether fixed or varied are not chosen with the primary aim of achieving Na balance. This approach risks a pathologic excess in the total Na mass, which over time can lead to clinical manifestations of volume overload such as hypertension or congestive heart failure.

To properly calculate the dialysate Na concentration required to maintain Na balance, measurement of the patient's plasma water Na concentration at the beginning of the treatment is required. Given the linear correlation between the conductivity of dialysate and its Na content, conductivity measurements can be used as a surrogate of Na concentration. Locatelli et al. (25,26) have recently described the use of a biofeedback system that allows for the automatic determination of plasma water and dialysate conductivity such that blood sampling can be avoided. With these measurements, along with session time, desired weight loss, and expected end-treatment plasma water conductivity, the dialysate conductivity is automatically adjusted to achieve the prescribed final plasma water conductivity. Application of this conductivity kinetic model to patients treated with a variant of hemodiafiltration has allowed for near zero hydro-sodium balance to be achieved. At the same time, cardiovascular stability was improved (25). Newer technologies capable of repetitive measurements of plasma water and dialysate conductivity will

allow for the dialysate Na to be adjusted throughout the procedure (27).

With increased ability to individualize the dialysate Na concentration, one can envision a scenario in which a patient initiated on hemodialysis is initially treated with a dialysate Na concentration designed to achieve negative Na balance. Once the patient becomes normotensive or requires minimal amounts of antihypertensive medications, the dialysate Na can be adjusted on a continual basis to ensure that Na balance is maintained. However, a universal approach to prescribing the dialysate sodium relative to the serum remains controversial. Recent epidemiologic data show that, similar to the nondialysis population, lower serum sodium levels (measured predialysis) are associated with increased mortality (28). Despite the known effects on weight gain from high dialysate sodium, large dialysis cohort data show that use of a lower dialysate sodium is actually associated with further increase in mortality compared to higher dialysate sodium (29) among those patients with the lower tertile of serum sodium (<137 mEq/L). Identifying the appropriate dialysate sodium requires consideration of numerous factors including intradialytic symptoms and interdialytic habits. Achieving the optimal total body Na content will likely become just as important as determining an accurate dry weight.

Dialysate Potassium

In most chronic outpatient dialysis centers, there is little individualization of the dialysate potassium concentration. Rather, most patients are dialyzed with a potassium bath that is prepared centrally and delivered with a concentration fixed at 1 or 2 mEq/L. When using a fixed dialysate potassium, it is difficult to predict the exact amount of potassium that will be removed in a given dialysis session. Typically, one should not expect more than about 80 to 100 mEq of potassium removal even with the use of a potassium-free dialysate. In addition, there will be marked variability in the amount of potassium removed from patient to patient despite similar predialysis potassium levels and dialysis regimens. This variability can be explained by the fact that potassium movement from the intracellular to the extracellular space and ultimately into the dialysate is influenced by several patient-specific factors.

The removal of excess potassium by dialysis is achieved by the use of a dialysate with a potassium concentration lower than that of plasma creating a gradient favoring potassium removal; its rate is largely a function of this gradient. Plasma potassium concentration falls rapidly in the early stages of dialysis, but as the plasma concentration falls, potassium removal becomes less efficient. Because potassium is freely permeable across the dialysis membrane, movement of potassium from the intracellular space to the extracellular space appears to be the limiting factor in potassium removal. Factors that importantly dictate the distribution of potassium between these two spaces include changes in acid–base status, tonicity, glucose and insulin concentration, and catecholamine activity (**TABLE 2.2**).

TABLE 2.2 Factors Affecting Potassium Removal during Hemodialysis

A. Shifts K into cell thereby ↓ dialytic K removal
• Exogenous insulin
• Glucose containing dialysate versus glucose-free dialysate
• β-Agonists
• Correction of metabolic acidosis during dialysis
B. Shifts K to extracellular space or impairs cell K uptake thereby ↑ dialytic K removal
• β-Blockers
• α-Adrenergic receptor stimulation
• Hypertonicity

↓, decrease; ↑, increase.

The movement of potassium between the intracellular and extracellular space is influenced by changes in acid–base balance that occur during the dialysis procedure (30). Extracellular alkalosis causes a shift of potassium into cells, whereas acidosis results in potassium efflux from cells. During a typical dialysis, there is net addition of base to the extracellular space, which promotes cellular uptake of potassium and therefore attenuates the removal of potassium during dialysis. The degree to which potassium shifts into the cell is directly correlated with the bicarbonate concentration of the dialysate (31). However, with routine dialysis, the change in blood pH is of small magnitude and the effect on potassium removal is not profound. By contrast, dialysis in patients who are acidotic will result in less potassium removal because potassium is shifted into cells as the serum bicarbonate rises. Wiegand et al. (32) described five patients in whom the serum potassium concentration decreased during dialysis even though the dialysate potassium concentration was higher than the original serum potassium concentration. The decline in potassium concentration occurred in association with a marked rise in the pH. In one patient, the decline in potassium concentration was of such a magnitude that she became quadriplegic and developed respiratory failure. There appears to be no difference in potassium removal whether acetate or bicarbonate is chosen as the dialysate buffer.

Insulin is known to stimulate the cellular uptake of potassium and can therefore influence the amount of potassium removal during dialysis. This effect of insulin was demonstrated in studies comparing potassium removal using glucose-containing and glucose-free dialysates (33). The use of a glucose-free dialysate was found to result in greater amounts of potassium removal when compared with the use of a glucose-containing bath. The use of a glucose-free dialysate would be expected to result in lower levels of insulin. However, another study showed little difference in intradialytic or postdialysis serum potassium levels between high and low glucose baths in diabetic and nondiabetic patients, suggesting that neither increased serum glucose (seen in both groups) or increased insulin (seen in nondiabetics) were sufficient to make a clinically significant change potassium removal (34).

Changes in plasma tonicity can affect the distribution of potassium between the intracellular and extracellular space. Administration of hypertonic saline or mannitol is sometimes used in the treatment of hypotension during dialysis. These agents would be expected to favor potassium removal during dialysis because the resultant increased tonicity would favor potassium movement into the extracellular space. There are no studies addressing whether there is any significant clinical benefit with this approach.

β-Adrenergic stimulation is known to shift potassium into cells and lower the extracellular concentration. Inhaled β stimulants have been reported to be effective in the acute treatment of hyperkalemia, so such therapy before dialysis may lower the total amount of potassium removed during

the dialytic procedure. Allon and Shanklin (35) found that the cumulative dialytic potassium removal was significantly lower in patients who were treated with nebulized albuterol 30 minutes before the procedure as compared with patients in whom the albuterol treatment was omitted.

Alterations in serum potassium concentration during dialysis can conceivably have important effects on systemic hemodynamics. A decrease in serum potassium concentration during hemodialysis would be predicted to increase systemic vascular resistance. Hypokalemia has been shown to increase resistance in skeletal muscle, skin, and coronary vascular beds, possibly through effects on the electrogenic Na-K pump in the sarcolemmal membranes of vascular smooth muscle cells. In addition, decreased serum potassium concentration may enhance the sensitivity of the vasculature to endogenous pressor hormones (36).

Despite the potential for hypokalemia to increase systemic vascular resistance, Pogglitsch et al. (37) found the incidence of hypotensive episodes were, in fact, reduced when supplemental potassium was administered during the final 30 minutes of dialysis. One explanation for this seemingly paradoxical finding rests on the known interaction between hypokalemia and the autonomic nervous system. For example, hypokalemia has been found to be associated with dysautonomia in patients with hyperaldosteronism (38). It is reasonable to speculate that in patients with advanced kidney disease, who already have a propensity for autonomic insufficiency, a fall in plasma potassium may uncover or cause impairment in sympathetic responses (39).

In support of this suggestion, Henrich et al. (40) found that hypokalemic dialysis was accompanied by a fall in plasma catecholamine concentration as compared with dialysis in which serum potassium concentration was held constant. Moreover, despite similar reductions in blood pressure, the isokalemic dialysis group had a significant increase in heart rate after dialysis, whereas the hypokalemic group demonstrated no significant change. Further studies are needed to investigate the effects of fluctuations in serum potassium concentration during dialysis on the autonomic nervous system.

Changes in serum potassium concentration during dialysis may also influence systemic hemodynamics through effects on myocardial performance. Dialysis is associated with an increase in contractility, which can be attributed to an increase in ionized serum calcium. Increased ionized calcium is most closely related to improved ventricular contractility, but modifying effects of concomitant decreases in potassium may also be important. Haddy et al. (41) have demonstrated that the inotropic effect of increased serum calcium concentration is enhanced by simultaneous decreases in plasma potassium concentration. In this regard, Wizemann et al. (42) found that improvement in myocardial contractility during a series of isovolemic dialysis maneuvers was related to a simultaneous increase in plasma calcium and decrease in plasma potassium concentration. In the presence of an elevated plasma potassium concentration, a high plasma calcium concentration failed to exert a significant inotropic effect.

An increase in peripheral vascular resistance secondary to the development of hypokalemia could have potential detrimental effects on dialysis efficiency. This decrease in efficiency would result from decreased blood flow to urea-rich tissues such as skeletal muscle and in effect increase the amount of body wide recirculation. In support of this possibility, Dolson and Androgue (43) found that a dialysate potassium concentration of 1.0 mmol/L as compared with 3.0 mmol/L resulted in lower values for both the urea reduction ratio and Kt/V in 14 patients with ESKD. By contrast, Zehnder et al. (44) found no effect of dialysate potassium on dialysis adequacy. Although more studies are needed in this area, it is

likely that any effect of a low dialysate potassium concentration to decrease dialysis adequacy is small in magnitude. In addition, increasing the dialysate potassium concentration to improve dialysis adequacy will increase the risk of hyperkalemia during the interdialytic period.

Most patients dialyzed with a fixed potassium dialysate tolerate the procedure well and do not suffer from complications of hypokalemia or hyperkalemia. Nevertheless, there are clinical conditions in which an individualized dialysate potassium concentration may be useful. Patients with underlying heart disease, particularly in the setting of digoxin therapy, are prone to arrhythmias, as hypokalemia develops toward the end of a typical treatment. Additionally, low dialysate potassium has been shown to unfavorably alter the QTc interval (a marker of risk of ventricular arrhythmias) (45).

Setting the dialysate potassium concentration to a higher value in any patient at risk for arrhythmias is not without risk. In an analysis of more than 80,000 maintenance hemodialysis patients, predialysis serum potassium values between 4.6 and 5.3 mEq/L were associated with the greatest survival, whereas values <4.0 or ≥5.6 mEq/L were associated with increased mortality. Use of a higher dialysate potassium concentration was associated with increased mortality in patients with predialysis potassium values ≥5.0 mEq/L (46). A separate case-control study found the use of a low potassium dialysate (<2.0 mEq/L) as an independent risk factor for the specific occurrence of in-center sudden cardiac arrest. Patients with cardiac arrest who were on low potassium dialysate were noted to have lower predialysis serum potassium than the control patients on low potassium dialysate (47). Altogether, when considering the risk for cardiac death or mortality, predialysis serum potassium should help guide the decision of the dialysate potassium with caution to avoid excessively high or low serum potassium levels. The use of variable dialysate potassium levels during a single treatment results in less QTc abnormalities compared to fixed levels, but it is uncertain if this would translate into overall better outcomes (48).

With these considerations in mind, Redaelli et al. (49) have studied the effects of modeling the dialysate potassium concentration in such a way as to minimize the initial rapid decline in the plasma potassium concentration (**FIGURE 2.2**). Patients with frequent intradialytic premature ventricular complexes were dialyzed using a dialysate with a fixed (2.5 mEq/L) potassium or one with an exponentially declining potassium (from 3.9 to 2.5 mEq/L), which maintained a constant blood to dialysate potassium gradient of 1.5 mEq/L throughout the procedure. In the fixed dialysate group, the blood to dialysate potassium gradient decreased over the treatment from 3.0 to 1.4 mEq/L. The variable potassium dialysate decreased premature ventricular complexes, a finding most evident during the first hour of the procedure. The total drop in the serum potassium concentration was no different between the fixed and variable potassium dialysates.

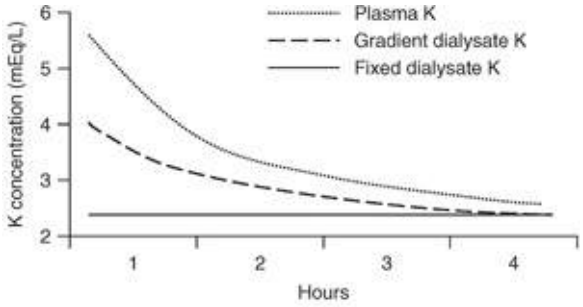

FIGURE 2.2 Hypothetical representation of the plasma-to-dialysate K gradient over time comparing a fixed versus a ramped K dialysate. The decline in the plasma K concentration is most rapid in the early stages of the hemodialysis procedure particularly when utilizing a fixed dialysate K. This more rapid decline is due to the initially large concentration gradient between the plasma and dialysate. The rapid decline can be attenuated by utilizing a ramped K dialysate, which acts to minimize the initial and thereafter maintain a constant plasma-to-dialysate K concentration gradient.

In summary, because of kinetics of potassium movement from the intracellular to the extracellular space, one can expect only up to 70 to 90 mEq of potassium to be removed during a typical dialysis session. As a result, one should not overestimate the effectiveness of the dialytic procedure in the treatment of severe hyperkalemia. The total amount removed will exhibit considerable variability and will be influenced by changes in acid–base status, changes in tonicity, changes in glucose and insulin concentration, and catecholamine activity. Given the tendency for the plasma potassium to rise in the immediate postdialysis time period, the most efficient way to remove excess potassium stores would be to prescribe 2- to 3-hour periods of dialysis separated by several hours. Studies examining the hemodynamic effect of potassium fluxes during hemodialysis are limited. More importantly, deliberate alterations in dialysate potassium concentration to affect hemodynamic stability would not be without risk. Use of low potassium dialysate concentration may contribute to arrhythmias, especially in those patients with underlying coronary artery disease or those taking digoxin. On the other hand, use of dialysate with high potassium concentration may predispose patients to predialysis hyperkalemia. In patients who are at high risk for arrhythmias on dialysis, modeling the dialysate potassium concentration to maintain a constant blood to dialysate potassium gradient throughout the procedure may be of clinical benefit (**FIGURE 2.2**).

Dialysate Buffer

Acetate Buffer

The early use of bicarbonate as the base in dialysis solutions required a cumbersome system in which CO_2 was continuously bubbled through the dialysate to lower pH to prevent the precipitation of calcium and magnesium salts. As a result, in the early 1960s, acetate became the standard dialysate buffer used to correct uremic acidosis and to offset the diffusive losses of bicarbonate during hemodialysis. Over the next several years, reports began to accumulate linking routine use of acetate with cardiovascular instability and hypotension during dialysis. In particular, critically ill patients undergoing acute hemodialysis, especially with the use of large surface area dialyzers, were found to exhibit vascular instability when exposed to acetate in dialysis fluid. Given these observations, bicarbonate-containing dialysate began to reemerge as the principal dialysate buffer especially as advances in biotechnology made the use of bicarbonate dialysate less expensive and less cumbersome to use. Because acetate is still used as the principal dialysate buffer in some centers, the following paragraphs compare the clinical effects of acetate and bicarbonate dialysate.

During a routine dialysis in which acetate is used as the buffer, there are large fluxes of both acetate and bicarbonate across the dialyzer with little overall net gain in base. Because the acetate dialysate lacks bicarbonate, there is diffusion of actual bicarbonate from the blood into the dialysate. In addition, potential bicarbonate is lost from the blood in the form of organic anions such as citrate, lactate, pyruvate, BETA-hydroxy-butyrate, and acetoacetate because these anions diffuse across the dialyzer and into the dialysate (50). The pH of blood exiting the dialysis cartridge does not fall because CO_2 diffuses from the blood as well. Despite this large efflux of potential and actual bicarbonate from the body, there is a net gain of alkali because of the greater influx of acetate as it diffuses from the dialysate into the blood. Acetate is normally metabolized in muscle to acetyl coenzyme A (CoA). Acetyl CoA is then metabolized in the Krebs cycle to CO_2 and water with formation of one bicarbonate molecule for each molecule of acetate metabolized. The metabolism of acetate to carbon dioxide can contribute up to 40% of the total energy expenditure during dialysis (51). In addition, acetate-containing dialysate is associated with significant increases in the plasma concentration of ketone bodies. The accelerated ketogenesis and the extra caloric burden seen with acetate dialysate does not appear to be associated with an impairment in glucose utilization or change in plasma insulin during the procedure.

Chronic hemodialysis patients metabolize acetate at a reduced rate as compared with control patients (39). Decreased rates of metabolism of acetate to bicarbonate can potentially result in accumulation of acetate. This accumulation of acetate is magnified with use of dialyzers with large surface areas that allow for transfer of acetate to the plasma compartment at rates greater than a patient's ability to metabolize it. The consequent increase in blood concentration of acetate has been associated with nausea, vomiting, fatigue, and, more importantly, hemodynamic instability.

There are a number of mechanisms by which acetate might predispose to vascular instability (**TABLE 2.3**). Acetate, possibly by its conversion to adenosine, has vasodilatory properties that can directly decrease peripheral vascular resistance. In addition, acetate might increase venous capacity leading to a decrease in cardiac filling (52). These vasodilatory effects of acetate are further augmented through the release of interleukin-1. Interleukin-1 has vasodilatory properties and its activity is increased from 8 to 12 times normal by standard acetate hemodialysis (53).

TABLE 2.3 Mechanisms by which Acetate Buffer Contributes to Hemodynamic Instability

- Directly decreases peripheral vascular resistance (in ~10% of patients)
- Stimulates release of the vasodilator compound, interleukin 1
- Induction of metabolic acidosis through bicarbonate loss through the dialyzer
- Associated with arterial hypoxemia and increases in oxygen consumption
- Possible myocardial effects of acetate

In addition to direct vasodilatory properties, incomplete acetate oxidation can lead to acid–base changes that can adversely affect hemodynamics. Metabolism of acetate to bicarbonate in an amount less than the diffusive losses of bicarbonate through the dialyzer will result in a decreased concentration of serum bicarbonate. A decrease in serum bicarbonate concentration can result in mild metabolic acidosis that may take 2 to 3 hours after dialysis to correct. Such loss of bicarbonate through the dialyzer contributes to vascular instability in addition to any direct vascular effects of acetate.

Arterial hypoxemia occurs with the use of acetate dialysate and may also contribute to vascular instability. During acetate dialysis, there is diffusive loss of soluble carbon dioxide from blood to dialysate. In an attempt to maintain normal blood carbon dioxide concentration, pulmonary hypoventilation occurs resulting in hypoxemia. In addition, metabolism of acetate leads to an increase in oxygen consumption further exacerbating any decrease in oxygenation. In susceptible individuals, acetate may provoke subendocardial ischemia by deleteriously affecting myocardial oxygen balance (54).

Despite the association of acetate with a higher frequency of symptoms in some studies, there is a poor correlation between symptoms and signs and blood acetate concentration. In an attempt to reconcile this discrepancy, Vinay et al. (55) studied a large population of dialysis patients and concluded that true acetate intolerance only occurred in about 10% of the dialysis population. The patients found intolerant were unable to metabolize acetate optimally and were predominately female. Because muscle is the primary site of metabolism of acetate, a reduced muscle mass often found in females might account for the reduced metabolism of acetate. Similarly, malnourished and elderly patients may be more predisposed to acetate intolerance by such a mechanism.

During conventional hemodialysis with acetate, the vasoconstrictive response to hypovolemia is masked by the vasodilatory tendency induced by the diffusive nature of the therapy. It is unclear, however, whether inability to vasoconstrict during conventional hemodialysis is related to use of acetate or rather a fall in serum osmolality. In this regard, several studies have found that vascular instability with acetate dialysis is generally improved with use of a higher Na dialysate concentration. In addition, substitution of bicarbonate for acetate as the base constituent in the dialysate has been purported to markedly improve symptoms on dialysis. It has been difficult to prove, however, whether bicarbonate dialysate can independently further improve hemodynamic and symptomatic tolerance to hemodialysis especially when a higher dialysate osmolality is used. Wehle et al. (56) found no added benefit of bicarbonate over acetate particularly if dialysate Na was increased to 145 mEq/L. Henrich et al. (57) in a comparative study of acetate and bicarbonate dialysis using a dialysate Na concentration of 140 mEq/L demonstrated strikingly similar hemodynamic responses. In a later study, Velez et al. (58) noted that with high Na dialysates (141 mEq/L), no detectable differences between bicarbonate and acetate were found with respect to cardiac output, mean blood pressure, or orthostatic tolerance to standing after dialysis. With use of a dialysate Na of 130 mEq/L, however, bicarbonate dialysate was associated with greater stability of blood pressure on standing after dialysis.

Controversy exists as to the overall effects of acetate and bicarbonate buffers on ventricular performance. Administration of sodium acetate as a bolus injection in dogs results in marked decreases in myocardial contractile force and blood pressure (59). However, if given as a continuous infusion, no definite depression of myocardial function is observed. Aizawa et al. (60) compared the effects of acetate and bicarbonate hemodialysis on cardiac function using phonocardiography. Left ventricular function was depressed to a greater extent with acetate than after bicarbonate dialysis.

The negative inotropic effect attributed to acetate has been contested by other reports in which sodium acetate was found to increase ventricular performance. Nitenberg et al. (61) using angiographic techniques studied left ventricular function in seven patients with plasma acetate concentrations comparable to that found during sodium acetate hemodialysis. An increase in cardiac index, ejection fraction, and maximum velocity of circumferential fiber (VCF) shortening not attributable to alterations in

heart rate, preload, or afterload was demonstrated after sodium acetate infusion. Mansell et al. (62) noted that patients who developed hyperacetatemia during regular dialysis were still able to maintain an increased cardiac output. Schick et al. (63) studied nine patients in a double-blind, crossover manner and demonstrated improvement of left ventricular mean VCF of equal magnitude with both acetate and bicarbonate hemodialysis. Ruder et al. (64) performed a double-blind, crossover study of 36 patients comparing acetate and bicarbonate hemodialysis with respect to baseline left ventricular function. In patients with depressed VCF, hemodialysis with either buffer resulted in improvement of ventricular function with mean VCF significantly higher after bicarbonate dialysis as compared with acetate. In patients with normal VCF, only bicarbonate dialysis produced significantly better ventricular function. In contrast, Leunissen et al. (65,66) found increases in VCF in patients with normal left ventricular function with either acetate or bicarbonate dialysis. In patients with compromised left ventricular function, only bicarbonate dialysis resulted in significant increase in VCF.

The disparity of results in studies of effects of dialysate composition on cardiac function may in part results from failure to distinguish effects of volume removal. In this regard, Nixon et al. (67) demonstrated that dialysis with acetate with or without volume removal produced an increase in contractility. Mehta et al. (68) performed isovolemic dialysis and found that mean VCF improved to the same extent with both acetate and bicarbonate dialysis. Anderson et al. (69) studied left ventricular performance with two-dimensional echocardiography in five patients under three different cardiac filling volumes before and after a standard isovolemic hemodialysis. Cardiac performance as assessed by VCF improved comparably with acetate or bicarbonate under conditions of increased or decreased preloads.

In summary, many years of experience with acetate as the principal buffer in dialysate has not borne out concerns that acetate would be associated with long-term adverse consequences. In most chronic stable dialysis patients, cardiac function is improved with acetate or bicarbonate-containing dialysate. Under conditions in which a dialysate Na of more than 140 mEq/L is used, bicarbonate offers no apparent hemodynamic advantage over acetate. By contrast, use of a bicarbonate bath may provide more hemodynamic stability than acetate under conditions of a low Na dialysate concentration (less than 135 mEq/L) or in patients who are truly acetate intolerant. In addition, bicarbonate-containing dialysate improves platelet function to a greater extent than acetate and may be less arrhythmogenic in susceptible patients. In either case, it should be pointed out that as high-efficiency and especially high-flux dialysis becomes more widely used, acetate-containing dialysate will become a thing of the past. The increased clearance seen with these procedures would allow the rate of influx of acetate to exceed the maximal rate of metabolism such that acid–base balance could not be maintained.

Bicarbonate Buffer

Bicarbonate is now the principal buffer used in dialysate. Producing bicarbonate dialysate requires a specifically designed system that mixes a bicarbonate concentrate and an acid concentrate with purified water. The acid concentrate contains a small amount of either lactic or acetic acid and all the calcium and magnesium. The exclusion of these cations from the bicarbonate concentrate prevents the precipitation of magnesium and calcium carbonate that would otherwise occur in the setting of a high bicarbonate concentration. During the mixing procedure, the acid in the acid concentrate will react with an equimolar amount of bicarbonate to generate carbonic acid and carbon dioxide. The generation of carbon dioxide

causes the pH of the final solution to fall to approximately 7.0 to 7.4. This more acidic pH as well as the lower concentrations of calcium and magnesium in the final mixture allow for these ions to remain in solution. The final concentration of bicarbonate in the dialysate is generally fixed in the range of 33 to 38 mmol/L (**FIGURE 2.3**).

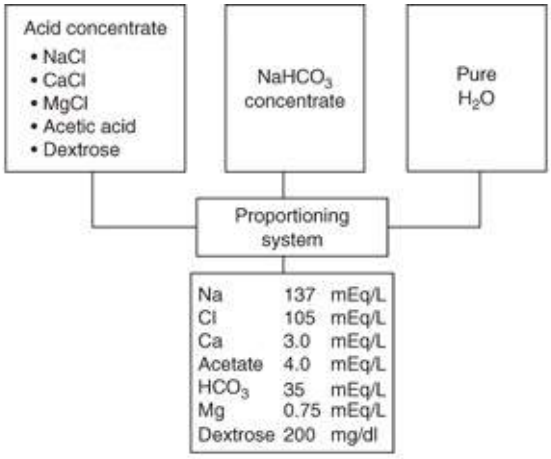

FIGURE 2.3 Components of the dialysate circuit in which bicarbonate serves as the buffer source.

The use of a bicarbonate dialysate is associated with a number of potential complications (70). The liquid bicarbonate concentrate can be responsible for microbial contamination of the final dialysate largely because the bicarbonate concentrate is an excellent bacterial growth medium. This complication can be minimized by short storage time as well as filtration of the concentrate during the production procedure. Use of a bicarbonate cartridge can further minimize this complication. This device allows for the bicarbonate concentrate to be produced on-line by passing water through a column containing powdered bicarbonate. The concentrate is produced and proportioned immediately before mixing with the acid concentrate. Hypoxemia may occur during bicarbonate dialysis when high concentrations of bicarbonate are used. This complication appears to be the result of suppressed ventilation secondary to the increase in pH and serum bicarbonate concentration. In addition, excessively high levels of bicarbonate in the dialysate may result in acute metabolic alkalosis causing mental confusion, lethargy, weakness, and cramps.

The factors that determine bicarbonate requirements in hemodialysis patients include acid production during the interdialytic period, the removal of organic anions during the hemodialysis procedure, and the buffer deficit of the body. Because these factors are likely to vary from patient to patient, there is increasing interest in individualizing the dialysate bicarbonate concentration. The optimal level of dialysate bicarbonate would be a concentration low enough to prevent significant alkalosis in the postdialytic period and yet be high enough to prevent predialysis acidosis.

Maintaining a predialysis total CO_2 concentration of greater than 23 mmol/L can be achieved in most patients by individually adjusting the dialysate bicarbonate concentration. Oettinger and Oliver (71) found that 75% of patients exceeded this level with a dialysate bicarbonate concentration of 42 mmol/L. Use of this high bicarbonate dialysate did not result in progressive alkalemia, even in patients beginning the study with a normal predialysis total CO_2 using a standard bicarbonate dialysate concentration of 36 mmol/L. In addition, the high bicarbonate dialysate did not cause hypoxia or hypercarbia or alter the predialysis calcium, ionized calcium, or phosphorus.

Using high bicarbonate dialysate may improve nutrition, bone metabolism, and hemodynamic

stability. Graham et al. (72) examined protein turnover in a group of chronic dialysis patients in whom dialysate bicarbonate concentration was increased from 35 to 40 mmol/L; supplemental oral bicarbonate therapy was given to two patients whose predialysis total CO_2 (tCO_2) concentration did not exceed 23 mmol/L. The mean tCO_2 concentration increased from 18.5 to 24.8 mmol/L during the high bicarbonate dialysate. Correction of the acidosis was associated with a significant decrease in protein degradation as suggested by leucine kinetic studies. In a similarly designed study, these investigators found an increase in the sensitivity of the parathyroid glands to calcium in patients using a dialysate bicarbonate concentration of 35 or 40 mmol/L (73). With regard to hemodynamics, increasing the bicarbonate concentration to 32 mmol/L is associated with a reduced incidence of both symptomatic and asymptomatic hypotension when compared to a bath bicarbonate concentration of 26 mmol/L (74).

Another strategy that may be effective in improving the acidosis of chronic dialysis patients is to use citric acid in place of acetic acid in the acid concentrate. In a recent study of 22 patients, use of citric acid decreased the number of patients with a predialysis bicarbonate concentration less than 23 mEq/L from 14 to 7 (75). Use of the citric acid dialysate was also associated with an increased delivered dose of dialysis, an effect postulated to be due to improved membrane permeability resulting from citrate's local anticoagulant effect. Improved membrane permeability with greater diffusive flux of bicarbonate from dialysate to blood or metabolism of citrate to bicarbonate in liver and muscle is the most likely explanation for the improvement in bicarbonate concentration.

Despite the positive effects of high bicarbonate dialysate concentrations listed above, it is unclear what specific serum bicarbonate or dialysate bicarbonate to target. Some epidemiologic data show that mild predialysis acidosis (serum bicarbonate 19 to 22 mEq/L) can be tolerated without an increase in mortality or hospitalization, while more severe acidosis (serum bicarbonate less than 17 mEq/L) should be avoided (76), but another large study adjusting for markers related to inflammation and malnutrition shows that, in fact, metabolic acidosis (serum bicarbonate <22 mEq/L) predicts increased mortality (77). While replicating the finding that acidosis is associated with higher mortality, another observational study identified that higher prescribed dialysate bicarbonate concentrations were associated with increased mortality (78). Major limitations of these studies include their observational nature. Consequently, it is important to correct overt metabolic acidosis in hemodialysis patients, but caution is advised in raising the predialysis serum bicarbonate too high.

Dialysate Magnesium

The usual concentration of magnesium in the dialysate is 0.5 to 1.0 mEq/L and is only rarely manipulated. In an attempt to minimize the development of hypercalcemia associated with the use of calcium-containing phosphate binders and vitamin D, there has been interest in using magnesium-containing compounds as a phosphate binder. The use of oral magnesium requires the use of a low magnesium dialysate concentration to avoid the development of hypermagnesemia. Depending on which magnesium salt is used, this strategy has had variable success (79).

Use of oral $Mg(OH)_3$ in association with a magnesium-free dialysate had little or no effect on phosphate and increased mean serum magnesium to 4.3 mg/dL. In addition, diarrhea was a frequent side effect. More favorable results have been reported with oral $MgCO_3$. O'Donovan et al. (80) reported good control of the serum phosphorus level using oral $MgCO_3$ and a magnesium-free dialysate. On this

regimen, diarrhea was mild and transient and the serum concentration of magnesium did not change. More recently, Kelber et al. (81) examined the feasibility of using a magnesium-free dialysate in the setting of high-efficiency dialysis. Despite the use of oral $MgCO_3$, patients developed severe muscle cramping that was immediately relieved by adding magnesium back to the dialysate. It was determined that measured magnesium removal exceeded the estimated predialysis extracellular fluid magnesium pool. By contrast, a dialysate magnesium of 0.6 mg/dL in combination with oral $MgCO_3$ was well tolerated.

Use of this later regimen was then examined in a prospective randomized crossover study (82). Patients were studied while taking $MgCO_3$ and one-half the usual dose of $CaCO_3$ along with a dialysate magnesium of 0.6 mg/dL and again while ingesting $CaCO_3$ given in the usual dose with a dialysate magnesium of 1.8 mg/dL. There was no difference in the serum concentrations of phosphorus, calcium, or magnesium between the two phases of the study. In addition, the $MgCO_3$-low $CaCO_3$ regimen permitted a greater amount of intravenous calcitriol to be used without the development of hypercalcemia. It was concluded that use of oral $MgCO_3$ as a phosphate binder and a low dialysate magnesium concentration may be a useful strategy in patients who develop hypercalcemia during treatment with calcitriol and $CaCO_3$.

Dialysate Calcium

The calcium concentration in the dialysate can be varied extensively according to the individual needs of the patient (**TABLE 2.4**). The most common concentrations used are 1.25, 1.5, and 1.75 mmol/L corresponding to 2.5, 3.0, 3.5 mEq/L and 5.0, 6.0, 7.0 mg/dL, respectively. In earlier times, a higher end dialysate calcium concentration (typically 3.5 mEq/L) was widely used to provide a net flux of calcium into the patient. The substitution of calcium for aluminum phosphate binders and the wider use of high doses of intravenous 1,25 $(OH)_2$ vitamin D made the likelihood of hypercalcemia more common leading to a progressive lowering of the dialysate calcium concentration. For example, using a dialysate calcium concentration of 2.5 mEq/L, Slatopolsky et al. (83) was able to control the serum phosphorus in 21 patients with calcium carbonate at an average daily dose of 10.5 g with no instances of hypercalcemia. Despite the enthusiasm for use of low calcium dialysate, some recent studies have emphasized that such an approach requires careful monitoring to ensure that the patient does not develop negative calcium balance or worsening secondary hyperparathyroidism. Argiles et al. (84) found that serum immunoreactive parathyroid hormone (iPTH) levels increased significantly in patients treated with a 2.5 mEq/L dialysate calcium bath compared with a control group of patients dialyzed with a dialysate calcium of 3.0 mEq/L. This increase in iPTH occurred despite 2.4-fold more oral $CaCO_3$ ingested in the low dialysate calcium group. Although the increase in oral calcium intake was not sufficient to prevent the stimulation in iPTH, subsequent treatment with 1,25 $(OH)_2$ vitamin D was effective in reversing the rise in iPTH levels.

TABLE 2.4 Considerations when Individualizing Components of the Dialysate

Dialysate Component	Advantage	Disadvantage
Na: Increased	More hemodynamic stability Less cramping	Dipsogenic effect, increased interdialytic weight gain, chronic hypertension
Decreased (rarely used)	Less interdialytic weight gain	Intradialytic hypotension and cramping more common
Ca: Increased	Suppression of PTH; promotes hemodynamic stability	Hypercalcemia with vitamin D and Ca containing phosphate binders
Decreased	Permits greater use of vitamin D and calcium-containing phosphate binders	Potential for negative calcium balance, stimulation of PTH, slight decrease in hemodynamic stability
K: Increased	Less arrhythmias in setting of digoxin or coronary heart disease; less rebound hypertension	Limited by hyperkalemia
Decreased (ramped dialysate K ideal, prevents rapid initial decline in plasma K)	Greater dietary intake of K with less hyperkalemia, improvement in myocardial contractility	Increased arrhythmias; may exacerbate autonomic insufficiency
HCO_3: Increased	Corrects chronic acidosis, thereby benefits nutrition and bone metabolism	Postdialysis metabolic alkalosis
Decreased	Less metabolic alkalosis	Potential for chronic acidosis
Mg: Increased	Less arrhythmias, hemodynamic benefit	Hypermagnesemia
Decreased	Permits use of Mg-containing phosphate binders	Hypomagnesemia
PO_4 (rarely added to dialysate)	Treats or prevents hypophosphatemia in malnourished, chronic disease state, overdose setting, daily dialysis	Hyperphosphatemia

PTH, parathyroid hormone.

Similar results were reported by Fernandez et al. (85) in a group of patients sequentially dialyzed against a 3.5 mEq/L and then 2.5 mEq/L calcium bath. While on the low calcium dialysate, there was a significant increase in both serum iPTH as well as serum alkaline phosphatase levels. These changes occurred despite the fact that oral calcium carbonate was administered at doses ranging from 3 to 6 g/day while on the low calcium dialysate. As determined by clearance studies, the authors suggested that the low calcium dialysate resulted in negative calcium balance that, in turn, contributed to the worsening hyperparathyroidism. Furthermore, the maintenance of a normal serum calcium concentration noted in the study occurred at the expense of PTH-induced calcium mobilization from bone. Using measurements of total and ionized calcium in serum as well as in spent dialysate, Argiles et al. (86) have confirmed that a 2.5 mEq/L calcium dialysate is associated with negative calcium balance. Based on the potential of a 2.5 mEq/L dialysate calcium to cause negative calcium balance and to worsen secondary hyperparathyroidism, these authors now use a dialysate calcium of at least 3.0 mEq/L in most chronic dialysis patients (87).

The potential effect of a low dialysate calcium concentration to stimulate PTH release may have utility in patients with low bone turnover. Adynamic bone disease is becoming progressively more common in patients on maintenance hemodialysis. In patients clinically diagnosed with this entity, use of a dialysate calcium concentration of 1.25 mmol/L was found to increase serum PTH and total alkaline phosphatase to a greater extent than a dialysate calcium concentration of 1.75 mmol/L (88). The authors concluded that a low dialysate calcium concentration may be a therapeutic option in patients with this form of metabolic bone disease.

Another variable to consider in choosing a dialysate calcium concentration is the effect on hemodynamic stability during the dialysis procedure. Higher dialysate calcium concentrations may

minimize intradialytic hypotension in patients with ejection fraction of less than 40% as well as other patients prone to intradialytic hypotension (89,90). In patients prone to intradialytic hypotension who are at risk for hypercalcemia, dialysate calcium profiling can be used as a strategy to improve hemodynamic stability and yet minimize the potential for hypercalcemia (91). In one study, patients were dialyzed for 4 hours in which the dialysate calcium concentration was set low (1.25 mmol/L) for the first 2 hours and then increased to 1.75 mmol/L for the last 2 hours (92). Use of the varying dialysate calcium concentration was associated with greater hemodynamic stability as compared with a fixed dialysate calcium concentration of either 1.25 or 1.5 mmol/L. This hemodynamic benefit was accomplished via an increase in cardiac output. At the end of 3 weeks, there was no difference in the predialysis ionized calcium concentration between the three groups.

Changes in serum calcium concentration may influence blood pressure through alterations in either systemic vascular resistance or the determinants of cardiac output or both. In an attempt to determine the physiologic mechanisms for calcium-induced changes in systemic arterial pressure, Fellner et al. (93) studied hemodynamic variables that determine arterial blood pressure as a function of changes in dialysate calcium concentration. Eight patients underwent hemodialysis three times within a single week with dialysate calcium concentrations of 1.0 mEq/L, 3.5 mEq/L, or 5.0 mEq/L. As in previous studies, changes in blood calcium concentration correlated directly with blood pressure. In addition, higher levels of calcium augmented left ventricular stroke volume and cardiac output while leaving total vascular resistance unchanged. It was concluded that alterations in blood calcium concentration affected blood pressure primarily through changes in left ventricular output rather than in peripheral vascular tone, and these findings have been replicated in a subsequent crossover study (94).

In addition to changes in ionized calcium concentration, hemodialysis leads to alterations in several factors that could conceivably be responsible for the observed changes in ventricular function. Henrich et al. (95) performed a series of dialysis maneuvers to determine the contribution of dialyzable toxins, ionized calcium, and acidemia to left ventricular performance during routine hemodialysis. The dialysate of each maneuver was adjusted to produce three effects: (a) isovolemic dialysis in which neither ionized calcium nor bicarbonate was allowed to increase (this procedure tested the effects of uremic toxin removal), (b) isovolemic dialysis during which ionized calcium increased but bicarbonate was held constant, and (c) isovolemic dialysis in which bicarbonate increased but ionized calcium was kept constant. Echocardiographic studies showed that left ventricular end-diastolic and end-systolic volumes decreased and ejection fraction and VCF increased only in the procedure in which plasma ionized calcium increased. This study suggested that the rise in ionized calcium is a major element in the observed improvement in myocardial contractility. Similar findings were recently reported by Lang et al. (96). Using dialysates differing only in calcium concentration, myocardial contractility was shown to correlate directly with plasma-ionized calcium. The mechanism by which increases in ionized calcium seen during hemodialysis lead to enhanced ventricular function is not known.

Despite the favorable effects on hemodynamics, there is a concern that long-term use of a high dialysate calcium concentration may contribute to adverse effects on the cardiovascular system by promoting vascular calcification. A higher dialysate calcium concentration has been linked to progression of aortic calcification and increases in arterial stiffness (97,98).

A final consideration to undertake in the selection of dialysate calcium is the rare occurrence of

arrhythmias including sudden cardiac death. One case-control study evaluating more than 43,000 prevalent hemodialysis patients over the course of 4 years identified low dialysate calcium (<2.5 mEq/dL) as an independent risk factor for the occurrence of in-clinic cardiac arrest (47). Further analysis established that a larger dialysate to serum calcium gradient had linear relationship with the risk for cardiac arrest (99). These retrospective studies should heighten the awareness that independent of bone and mineral disease, there are some risks involved with excessively low dialysate calcium.

In summary, the dialysate calcium concentration has implications with regard to metabolic bone disease, hemodynamic stability, and long-term effects on vascular calcification. The most recent National Kidney Foundation Kidney Disease Outcome Quality Initiative (NKF-K/DOQI) guidelines recommend a dialysate calcium concentration of 1.25 mmol/L as being a useful compromise between optimization of bone health and reductions in cardiovascular risk (100). However, as with the other dialysate constituents, the calcium concentration should be individually tailored to the patient. In patients who are prone to intradialytic hypotension, a higher dialysate calcium concentration may be of benefit. On the other hand, the use of a lower calcium concentration in the dialysate will allow increased doses of 1,25 $(OH)_2$ vitamin D to be utilized to reduce circulating levels of PTH with less fear of inducing hypercalcemia. This issue may be of importance given recent data suggesting vitamin D improves survival in dialysis patients (101). Further research is needed to define the optimal mix of dialysate calcium concentration, dose of vitamin D, amount of calcium- and non–calcium-containing phosphate binder, and use of the calcimimetic agent cinacalcet.

Dialysate Phosphate

In patients with mild to moderate hyperphosphatemia, hemodialysis has been estimated to remove 250 to 325 mg/day of phosphorus when extrapolated to an average week (102). Because a diet that provides adequate protein may provide approximately 900 mg of phosphorus daily, it follows that dialysis cannot provide adequate control of phosphate by itself. Rather, management of hyperphosphatemia requires a combination of dietary restriction, oral phosphate binders, and dialysis.

The limited ability of dialysis to remove phosphorus is primarily related to the kinetics of phosphorus distribution within the body and not inadequate clearance across the dialyzer. In a typical dialysis session, the rate of phosphorus removal is greatest during the initial stages of the procedure and then progressively declines to a low constant level toward the end of the treatment (**FIGURE 2.4**). This decline is due to the decrease in plasma concentration and the slow efflux of phosphorus from the intracellular space and/or mobilization from bone stores. Although dialysis membranes differ with respect to plasma clearance of phosphate, it is the slow transfer of phosphorus to the extracellular space where it becomes accessible for dialytic removal that is the most important factor limiting phosphorus removal (103).

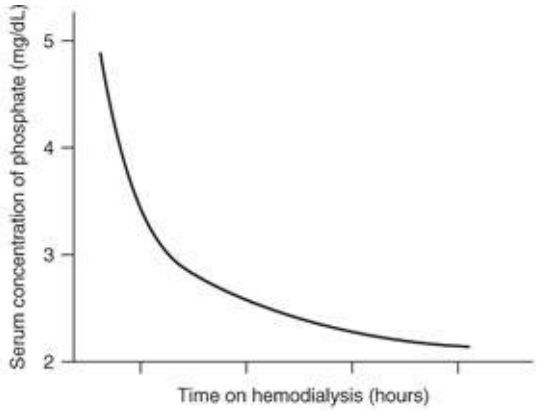

FIGURE 2.4 Plasma inorganic phosphate concentrations during a typical 4-hour dialysis procedure. The rate of phosphorus removal is greatest during the initial stages of the procedure and then progressively declines to a low constant level toward the end of the treatment. This decline is due to the decrease in plasma concentration and the slow efflux of phosphorus from the intracellular space and/or mobilization from bone stores.

There are only a few situations in which one might consider adding phosphorus to the dialysate. Hypophosphatemia can be an occasional finding in the chronic dialysis patient who is malnourished and suffering from some chronic disease state. In such patients, adding phosphorus to the dialysate may be an effective means to treat hypophosphatemia without having to use a parenteral route of administration. The phosphate must be added to the bicarbonate component of a dual proportioning system to avoid the precipitation of calcium phosphate that would result from addition to the calcium-containing acid concentrate. Kaye et al. (104) described three hypophosphatemic dialysis patients who were treated by adding phosphorus to the dialysate in a single proportioning system. In these patients, phosphate was added to a bicarbonate concentrate that contained no calcium. To avoid hypocalcemia, calcium was infused into the venous drip chamber as a 10% $CaCl_2$ solution. A final phosphate concentration of 1 to 2 mmol/L was found effective in correcting the hypophosphatemia by the end of a 4-hour session.

Another situation in which addition of phosphate to the dialysate may be useful is in the setting of an overdose. In a patient with normal kidney function and a normal serum phosphate concentration, use of a phosphate-free dialysate will commonly result in hypophosphatemia. In most circumstances, the hypophosphatemia is of short duration and is of little clinical consequence. However, some intoxications may increase the risk for complications of hypophosphatemia such that addition of phosphate to the dialysate may be warranted.

Finally, hypophosphatemia has been noted in patients treated with prolonged daily nocturnal hemodialysis (105). In this setting, adding phosphate to the dialysate may prove useful as a means to normalize the serum phosphate concentration.

DIALYSATE COMPOSITION IN PERITONEAL DIALYSIS

Similar to the strategy in hemodialysis, the composition of the dialysis solution for peritoneal dialysis is designed to create favorable concentration gradients across the peritoneal membrane to achieve maximal removal of endogenous waste products, to maintain acid–base and electrolyte balance near normal, and to maintain the extracellular fluid volume constant. As with hemodialysis, the composition of the dialysate can be individually modified for ultrafiltration and clearance needs.

Osmotic Agents

The addition of a solute to render the dialysate hyperosmolar relative to plasma creates an osmotic gradient that results in the net movement of water into the peritoneal cavity. The degree of hypertonicity, the time that the fluid is allowed to dwell in the abdomen, and the hydraulic permeability of the peritoneal membrane determine the volume of fluid removed. Clinically, the magnitude of ultrafiltrate is determined by subtracting the volume of fluid instilled in the abdomen from the effluent volume.

In commercially available peritoneal dialysates, glucose is the most commonly used osmotic agent used to enhance ultrafiltration. The concentrations available range from 1.36% glucose (1.5% dextrose) to 3.86% glucose (4.25% dextrose). Both the ultrafiltration rate and the time until osmotic equilibrium is reached are directly related to the glucose concentration used. Using 2-L exchanges with cycle times up to 6 hours, solutions containing 1.5% dextrose will generate 100 to 200 mL of net ultrafiltrate. Solutions containing 4.25% under the same conditions will generate up to 800 mL of net ultrafiltrate. By increasing the frequency of exchanges, this ultrafiltrate volume can be increased to as high as 1 L/h using the 4.25% solution. Over time, the osmolality of the dialysate declines as a result of water movement into the peritoneal cavity and absorption of dialysate glucose. By 4 hours of dwell using the 1.5% solution, the tonicity of the dialysate is essentially equal to that of plasma and the glucose concentration of the dialysate decreases to approximately one-half the original value.

The use of glucose as an osmotic agent is well recognized to have several deficiencies. The absorption of glucose contributes substantially to the caloric intake of patients on continuous peritoneal dialysis. This carbohydrate load over time is thought to contribute to progressive obesity, hypertriglyceridemia, and decreased nutrition as a result of loss of appetite and decreased protein intake. In addition, an increasing body of literature suggests that the high glucose concentrations and high osmolality of the currently available solutions adversely affect the function of the peritoneal membrane importantly contributing to technique failure over time.

Ultrafiltration failure resulting from increased permeability of small molecular weight solutes is one of the most frequent reasons patients are transferred from peritoneal to hemodialysis. This increase in permeability can be traced to an increase in the number of blood vessels in the peritoneal membrane effectively enlarging the vascular peritoneal surface area (106). High glucose concentrations have been linked to this process of neoangiogenesis through a variety of mechanisms to include stimulation of vascular endothelial growth factor and toxic effects of advanced glycosylation end products and glucose degradation products (107).

The bioincompatibility of glucose-containing solutions has prompted a search for alternative osmotic agents. Experimental and some clinical studies have been performed using substances such as fructose, sorbitol, xylitol, dextran, and gelatin. For one reason or another, these agents have either been proven unsafe or ineffective as an osmotic agent. Glycerol has received some interest as an osmotic agent particularly in patients with diabetes. This agent is not dependent on insulin for metabolism and may allow for better and easier glucose control in the diabetic population (108).

One of the most promising new peritoneal dialysis solutions uses glucose polymers as the osmotic agent (109). These compounds can be administered as a solution that is iso-osmolar to plasma because they generate an ultrafiltrate through the process of colloid osmosis. This process is based on the principle that water is transported from capillaries in the direction of impermeable large solutes rather than down an osmotic gradient as occurs with glucose-containing solutions. The icodextrin-based dialysis

solution is a polymer of glucose that is now available in several countries. In a 6-hour dwell, the 7.5% icodextrin solution generates an ultrafiltrate volume that is higher than that generated by 1.5% dextrose despite having a lower osmolality (285 vs. 347 mOsm/kg). With prolonged dwell times of 8 to 12 hours, the icodextrin solution provides equivalent or higher ultrafiltrate volumes than that generated by the 4.25% dextrose solution (486 mOsm/kg). The ability to maintain a colloid osmotic pressure for prolonged periods of time makes this solution ideal for overnight dwells in patients on continuous ambulatory peritoneal dialysis (CAPD) as well as daytime dwells for those on automated peritoneal dialysis regimens.

In patients with ultrafiltration failure who would otherwise be transferred to hemodialysis, use of icodextrin has been shown to extend the time that patients remain on peritoneal dialysis by many months (110). In addition, use of icodextrin is associated with less weight gain, improved lipid control, and less hyperinsulinemia as compared with dextrose-containing solutions. It is likely that icodextrin will become the preferred agent for the long dwell in most peritoneal dialysis patients (111,112).

Because patients on peritoneal dialysis have a high incidence of protein-calorie malnutrition, in part, resulting from daily losses of protein and amino acids into the dialysate, studies have also examined the feasibility of using amino acids as a replacement for glucose as an osmotic agent. Use of amino acids should augment the amino acid intake and reduce the net amino acid losses of the patient potentially providing additional nutrition to the patient. The overall absorption of amino acids in various solutions ranges from 60% to 90% depending on the concentration used and the length of the dwell (92). One 2-L bag of 1.0% solution can provide at least 14 g of amino acids. Importantly, these solutions have no major impact on the transport characteristics of the peritoneal membrane and are as effective osmotic agents as glucose.

Initial studies using amino acid–containing solutions were unimpressive with regard to showing an improvement in nutritional parameters. Moreover, use of these solutions was associated with significant increases in the blood urea nitrogen concentration and development of metabolic acidosis. More recent studies have used amino acid–containing dialysates that have been altered to provide the optimal balance between essential and nonessential amino acids required for a chronic kidney disease patient (113,114). Kopple et al. (113) studied the effectiveness of the 1.1% amino acid solution (Nutrineal; Baxter Healthcare) in a group of patients who were clinically malnourished. The patients were fed a constant diet, and the number of amino acid exchanges per day was adjusted so that the total daily dietary protein plus dialysate amino acid intake would be 1.1 to 1.3 g/kg/day. Patients required one to two daily exchanges of the amino acid solution to achieve this goal. The amino acid dialysate was associated with positive nitrogen balance that remained significant throughout the study. In addition, there was net protein anabolism as directly demonstrated from radiolabeled N-glycine studies. Patients tolerated the treatment well; however, some patients developed mild metabolic acidemia.

This same solution has been examined in 15 stable CAPD patients in whom malnutrition was not an entry criterion (114). In this study, one 2-L exchange of the 1.1% solution was performed at lunchtime to ensure the simultaneous uptake of sufficient carbohydrates. Previous experience with parenteral nutrition has shown that optimal utilization of amino acids occurs when there is combined uptake of nonprotein calories and amino acids. Over the 3 months of the study, there was a significant increase in the serum albumin concentration whether baseline malnutrition was present or not. Use of the dialysate in this

manner did not result in acidosis although the blood urea nitrogen increased by 20%. Other studies have also confirmed that this 1.1% amino acid is effective in providing a nutritional benefit particularly in patients who are malnourished (115,116).

In summary, glucose remains the standard osmotic agent used in peritoneal dialysis solutions. In an attempt to develop a more physiologic solution, various new osmotic agents are now under investigation. It is likely that icodextrin will be used with greater frequency in peritoneal dialysis patients particularly as the osmotic agent for long dwell times. In patients with evidence of ultrafiltration failure, use of icodextrin may extend the time certain patients can remain on peritoneal dialysis before having to switch to hemodialysis. Amino acid containing solutions also show promise for patients with evidence of malnutrition. To limit the development of azotemia and acidosis, the use of these solutions will likely be confined to one exchange per day (**TABLE 2.5**).

TABLE 2.5 Advantages and Disadvantages of New Peritoneal Dialysis Solutions

Solution	Advantage	Disadvantage
Icodextrin	Sustained ultrafiltration in overnight dwell in CAPD, long dwell in APD, and during peritonitis, avoids effects of glucose absorption, isoosmotic	Skin reactions (less than 10%), maltose accumulation
Amino acids	Improve malnutrition	Azotemia and metabolic acidosis
Bicarbonate and bicarbonate/lactate buffer	Improved biocompatibility due to neutral pH, ↓ glucose degradation products	Two-chamber bags to separate Ca and Mg from bicarbonate
Glucose sterilized separately at lower pH	Improved biocompatibility, ↓ glucose degradation products	Two-chamber bag required

CAPD, continuous ambulatory peritoneal dialysis; APD, automated peritoneal dialysis; ↓, decrease.

Dialysate Buffer

The buffer present in most commercially available peritoneal dialysate solutions is lactate. In patients with normal hepatic function, lactate is rapidly converted to bicarbonate such that 1 mM of lactate absorbed generates 1 mM of bicarbonate. Even with the most vigorous peritoneal dialysis, there is no appreciable accumulation of circulating lactate. The rapid metabolism of lactate to bicarbonate maintains the high dialysate-to-plasma lactate gradient necessary for continued absorption. This absorption may be somewhat less with use of dialysate that contains higher concentrations of dextrose. Under these conditions, increased ultrafiltrate formation may dilute the concentration of lactate in the peritoneal cavity and therefore decrease the concentration gradient for diffusion. Lactate is normally provided as a racemic mixture of the dextro and levo isomers in approximately equal concentrations. There is some evidence that the natural isomer (l-lactate) is more rapidly absorbed than the D-isomer (D-lactate) (117).

The pH of commercially available peritoneal dialysis solutions is purposely made acidic by adding hydrochloric acid to prevent dextrose caramelization during the sterilization procedure. Once instilled into the abdomen, the pH of the solution rises to values greater than 7.0. The acidic nature and buffer composition of currently available solutions further contributes to the bioincompatibility of peritoneal dialysate (118).

To address this issue, neutral pH solutions buffered with bicarbonate or with a mixture of bicarbonate and lactate have been introduced into clinical practice. Up until recently, bicarbonate was not able to be used as the buffer in peritoneal dialysis solutions because calcium and magnesium would precipitate in the presence of bicarbonate in the setting of an alkaline pH. Omitting magnesium and

calcium from the dialysate was not an option because patients undergoing chronic peritoneal dialysis would develop deficits of these divalent cations. These limitations have largely been overcome by the development of a two-chamber dialysate bag. One chamber contains the glucose and the electrolytes to include magnesium and calcium. The other chamber contains either bicarbonate alone or a bicarbonate-lactate mixture. The advantage of this setup is that glucose can be sterilized at a much lower pH as compared with a single-chamber bag, and as a result, the formation of glucose degradation products is markedly reduced. Mixing of the two components at the time of abdominal installation effectively raises the pH to a neutral value. Thus, the final solution has neutral pH, a low concentration of glucose degradation products, and contains bicarbonate.

In a trial of 106 patients, a pH neutral bicarbonate/lactate-based peritoneal dialysis solution was compared with the conventional acidic lactate buffered solution in which markers of peritoneal membrane integrity and inflammation were examined (119). At the end of 6 months, patients treated with the pH neutral solution had a significantly greater increase in the dialysate cancer antigen 125 (CA125) (a marker of viability and cell mass of the mesothelium). The same group also had a significantly greater decrease in dialysate hyaluronan (a marker of inflammation in the peritoneal cavity). The pH neutral solution is associated with less inflow pain, and no adverse effect has been demonstrated on peritoneal transport. Use of the pH neutral solution has also been shown to result in long-term improvement in peritoneal macrophage function as compared with conventional solutions (120). In addition to improved biocompatibility, the newer pH solutions have been linked to better preservation of residual renal function, less peritonitis, and in nonrandomized trials, there is a suggestion these solutions may provide a survival benefit when compared to conventional solutions (121–125). More rigorous trials are needed to verify the extent these solutions are able to provide improved patient outcomes (126).

In summary, a great deal of progress has been made to improve the biocompatibility of peritoneal dialysis solutions. Both experimental and clinical studies demonstrate that these solutions are much better at preserving peritoneal membrane function. Because no one solution is ideal, it is likely that in the future, each patient will be prescribed a combination of fluids to meet specific individual needs. One can envision a daily regimen in a patient on CAPD consisting of one exchange of amino acids, two exchanges of bicarbonate/glucose, and an overnight exchange of icodextrin (127). Future studies will be required to determine the efficacy of various combinations.

Dialysate Sodium

The Na concentration in the ultrafiltrate during peritoneal dialysis is usually less than the extracellular fluid such that there is a tendency for water loss and the development of hypernatremia. Commercially available peritoneal dialysates have a Na concentration of 132 mEq/L to compensate for this tendency toward dehydration. This effect is most pronounced with increasing frequency of exchanges and with increasing dialysate glucose concentrations. Use of the more hypertonic solutions with frequent cycling can result in significant dehydration and hypernatremia. As a result of stimulated thirst, water intake and weight may increase resulting in a vicious cycle.

The use of a low Na dialysate does lead to net Na removal and can predispose to hypotension in patients with inadequate Na intake. In the occasional patient who is unable to increase dietary Na, the dialysate Na concentration can be raised to decrease the amount of Na removal so that extracellular fluid volume can be maintained.

Dialysate Potassium

Potassium is cleared by peritoneal dialysis at a rate similar to that of urea. With CAPD and 10 L of drainage per day, approximately 35 to 46 mEq of potassium is removed per day. Daily potassium intake is usually greater than this amount, yet significant hyperkalemia is uncommon in these patients. Presumably, potassium balance is maintained by increased colonic secretion of potassium as well as some residual kidney excretion. Given these considerations, potassium is not routinely added to the dialysate.

Maximal removal of potassium with peritoneal dialysis is approximately 10 mEq/h even in the setting of severe hyperkalemia. It should be noted that removal rates with Kayexalate enemas far exceed this value and may approach 30 mEq/hour. In patients undergoing frequent exchanges, hypokalemia may develop. In these instances, potassium can be added to the dialysate to achieve a final concentration of 2 to 3 mEq/L. This is particularly important in patients receiving digoxin because the development of hypokalemia can precipitate arrhythmias.

Dialysate Magnesium

Initially, the standard peritoneal dialysis solution contained 1.5 mEq/L magnesium. The concentration has since been lowered to 0.5 mEq/L to lessen the frequency of hypermagnesemia that was observed with the higher magnesium concentration. As discussed with hemodialysis, a lower dialysate magnesium concentration may allow use of magnesium salts as an additional calcium-free phosphate binder.

Dialysate Calcium

As discussed previously, patients with progressive chronic kidney disease have a tendency to develop hypocalcemia. To avoid negative calcium balance as well as potentially suppressing circulating PTH, commercially available peritoneal dialysis solutions evolved to contain a calcium concentration of 3.5 mEq/L (1.75 mmol/L) (128). This concentration is equal to or slightly greater than the ionized concentration in the serum of most patients. As a result, there is net calcium absorption in most patients when using a conventional dialysis regime. When ultrafiltration volume is high, as occurs with use of 4.25% dextrose concentration at high rates of exchange, net transfer of calcium can be reversed such that calcium balance becomes negative.

As the use of calcium-containing phosphate binders has increased, hypercalcemia has become a common problem when using the 3.5 mEq/L calcium dialysate. This complication has been particularly common in patients treated with peritoneal dialysis because these patients have a much greater incidence of adynamic bone disease as compared with hemodialysis patients (129). In fact, the continual positive calcium balance associated with the 3.5 mEq/L solution has been suggested as a contributing factor in the development of this lesion. The low bone turnover state typical of this disorder impairs the accrual of administered calcium contributing to the development of hypercalcemia. As a result, there has been increased interest in using a similar strategy as has been employed in hemodialysis, namely, lower the calcium content of the dialysate. This strategy can allow for increased usage of calcium-containing phosphate binders as well as more liberal use of 1,25 $(OH)_2$ vitamin D to effect decreases in the circulating level of PTH. In this manner, the development of hypercalcemia can be minimized.

A recent study examined the effects of a low dialysate calcium 1.0 mM as compared to a control calcium solution (1.62 mM) in 51 patients with biopsy proven adynamic bone disease. In this randomized trial lasting 16 months, use of the low calcium-containing solution was associated with both a significant

reduction in episodes of hypercalcemia and increase in PTH levels compared to the control solution. Importantly, bone formation rates in the low calcium group all increased into the normal range, while no significant change was noted in the control group (130).

In summary, peritoneal dialysis solutions are widely available with a calcium concentration of either 1.25 or 1.75 mmol/L. The decision to use one concentration or the other should be made on an individual basis. Most patients can be treated with a dialysis solution that contains 1.75 mmol/L calcium. On the other hand, a low dialysate calcium solution offers a valuable therapeutic option to treat patients with increased doses of calcium-containing phosphate binders and calcitriol with a much lower incidence of hypercalcemia. A low calcium solution may also be of benefit in reversing adynamic bone disease. Close monitoring of patients is required when using a low calcium solution to ensure that secondary hyperparathyroidism is not exacerbated. This is particularly so in patients who are questionably compliant with their calcium-containing phosphate binders. Monitoring of bone mineralization is also indicated with long-term use of low calcium dialysate.

CHAPTER 3

Hemodialysis Vascular Access

Dirk M. Hentschel, Stephen J. Bander, and Steve Schwab

Hemodialysis sustains life in three general circumstances: poisoning, acute kidney injury with kidney failure, and end-stage kidney disease (ESKD). Successful hemodialysis in any of these circumstances requires access to large blood vessels capable of supporting rapid extracorporeal blood flow. Immediate and temporary access to the circulation in acute kidney injury and in poisoning is easily achieved by the percutaneous insertion of dual-lumen dialysis catheters into the femoral, internal jugular, or other large central veins.

The establishment and maintenance of vascular access in ESKD/chronic kidney disease (CKD), however, provides a greater challenge. Adequate dialytic therapy requires reliable, long-term access to the circulation. Vascular access that is beset with complications exacts considerable morbidity and mortality. Reliable, long-term access to the circulation in ESKD is best achieved by the creation of an autogenous arteriovenous (AV) access [arteriovenous fistula (AVF)]. Less desirable but satisfactory is the placement of a non-autogenous prosthetic or biograft access [arteriovenous graft (AVG)].

When reading this chapter, one should not lose sight of the fact that careful preparation for autogenous access creation begins well before the need for hemodialysis and is often the single most important step that the nephrologist can take to ensure long-term, low-maintenance access to the circulation, as tunneled hemodialysis catheters (TCs), while used in the majority of patients for initiation of dialysis, can often lead to severe infections as well as central vein stenosis and occlusion.

Vascular access care in the United States falls into many hands. General, vascular, or transplant surgeons place AVFs, AVGs, and TCs and often perform endovascular procedures to treat access complications. Interventional radiologists are predominantly concerned with placement of TCs and the endovascular treatment of access complications such as stenoses and thromboses. More recently, nephrologists with training in endovascular or surgical procedures have begun to provide access care to dialysis patients. Management of vascular access raises important questions regarding the quality of care that is delivered to patient with ESKD with so many physicians contributing. How good are we at doing what we are doing? Unfortunately, prospective randomized controlled studies in this field are rare, and we often rely on opinion and small retrospective trials. It remains the challenge to the practicing

nephrologists to become knowledgeable conductors of hemodialysis care for their patients.

BRIEF HISTORY OF VASCULAR ACCESS

The history of vascular access for hemodialysis is closely tied to the history of dialysis. In 1924, Georg Haas in Giessen, Germany, performed the first hemodialysis treatments in humans. It lasted for 15 minutes, and he used glass needles to access the radial artery and return blood into the cubital vein (1). In a total of 11 treatments in uremic patients until 1929, Haas used fractionated dialysis to clear approximately 400 mL of blood at a time. The artificial kidney was made up of three glass cylinders with U-shaped collodion tubes. Willem Kolff, a young physician from Kampen, The Netherlands, with the support of H. Berk in 1943 developed a "rotating drum kidney" with larger surface area of the filter made of a cellophane membrane. The first patient he dialyzed was a 29-year-old housemaid with CKD. She underwent 12 dialysis treatments, but the therapy had to be stopped as each cannula placement required a cut down to the artery and she ran out of access sites (2). In 1946, Kolff came to the United States and after a time in New York came to Boston, where he worked with John P. Merril and Carl Walter to construct the "Brigham Artificial Kidney."

The challenge of repetitive vascular access prevented dialysis from becoming a routine method for the treatment of chronic kidney insufficiency. This changed dramatically in the 1960s. Building on the idea of Nils Alwall (Lund, Sweden) to connect artery and vein with rubber tubing and a glass cannula, Quinton et al. (3) developed in Seattle an AV Teflon shunt. Their first patient, Clyde Shields, a Boeing machinist, survived for over 10 years after the insertion of his first Teflon AV shunt in March 1960. The tapered ends of two thin-walled Teflon cannulas were inserted into the radial artery and the adjacent cephalic vein in the distal forearm. While not on dialysis, the external ends were connected by a curved Teflon bypass tube, which was later replaced by a more flexible silicon rubber tubing. As with the availability of cellophane for the earliest artificial kidneys and heparin to maintain anticoagulation, the invention of Teflon and silicon allowed for new medical devices.

In 1966, Brescia et al. (4) (all New York) published their landmark account of 14 side-to-side anastomoses between the radial artery and the cephalic vein at the wrist, the native AVF was born. One year later, Sperling et al. (5) (Würzburg, Germany) presented 15 patients with end-to-end anastomoses, and in 1968, Lars Röhl et al. (6) (Heidelberg, Germany) presented results from 30 patients with radial-artery side-to-vein-end anastomoses. The different anastomosis techniques each fit specific anatomic needs and physiologic considerations. Another example is the Gracz fistula (7) presented in 1977, and modified by Klaus Konner (8), a proximal forearm fistula, that relies on the perforating vein from the superficial to the deep forearm venous system to limit blood flow in the fistula and prevent steal in patients with peripheral artery disease due to age, hypertension, or diabetes.

The Teflon shunt is an early example of an implanted medical device, partly internal, partly external. In 1961, Stanley Shaldon (London, United Kingdom) unable to find a surgeon to place the cannulae necessary for dialysis, inserted catheters into the femoral artery and vein with the Seldinger technique (9,10). Since then, catheters as a dialysis device have evolved to be placed with a cutaneous tunnel in which a Dacron cuff at the catheter's neck ensures secure placement and a relative seal against microorganisms.

Material sciences have continued to evolve the development of grafts for use in hemodialysis. In

1969, George Thomas (11) (Seattle) attached Dacron patches to the common femoral artery and vein, which were then connected with a silastic tube and brought to the surface of the anterior thigh. The Thomas shunt was soon replaced by the arrival of the expanded polytetrafluoroethylene (PTFE) graft, as LD Baker (12) (Phoenix) in 1976 presented first results in 72 hemodialysis patients. The PTFE graft has remained the graft material of choice, although grafts made of biologic material have been available since 1972 (13). More recent strategies are aiming at drug-eluting grafts to enhance the functional life of the access (14) and tissue-engineered blood vessels from autogenous fibroblasts and endothelial cells (15).

In parallel with the advances in surgical techniques and material science, the diagnostic armamentarium of physicians concerned with vascular access care has expanded dramatically. Most of this technology centers on minimally invasive imaging and endovascular procedures. Seldinger's idea of an endovascular guidewire over which diagnostic and therapeutic devices can be positioned is the basis for much of this development (9). In 1972 and 1973, Thelen et al. (16) and Staple (17) independently from each other described the angiographic retrograde imaging of AVFs in hemodialysis patients. David Ergun in 1979 first described a computerized fluoroscopy technique that revolutionized noninvasive cardiovascular imaging (18) and is now widely used in the diagnostic and therapeutic evaluation of dialysis accesses. Dotter et al. (19) and Grüntzig et al. (20) advanced the use of catheter-guided balloon angioplasty, that in 1982 found its first documented use in hemodialysis AVFs and AVGs by Gordon et al. (21).

Providers of hemodialysis care into the 1990s were predominantly access surgeons with vascular, transplant, or general subspecialization and interventional radiologists. This left many of the growing number of dialysis patients in the United States without dedicated access care, and other types of procedures and patients often trumped their interventions. It was into this void that the nephrologists such as Steve Schwab and Gerald Beathard stepped by acquired expertise in dialysis access procedures, documenting equal or superior outcomes compared to established care (22–28), in turn creating interventional nephrology as a distinct clinical field.

VASCULAR ACCESS FOR ACUTE DIALYSIS

Nontunneled dual-lumen central venous catheters are the most available form of vascular access for acute dialytic therapy. Central venous catheters can be inserted at the bedside using the Seldinger technique with ultrasound guidance and may support extracorporeal blood-flow rates greater than 300 mL/min. Separation of the arterial and venous ports minimizes recirculation of blood. Central venous catheters may be used for conventional intermittent hemodialysis as well as continuous renal replacement therapies.

The National Kidney Foundation Dialysis Access Guidelines recommend nontunneled hemodialysis catheters for hemodialysis duration of less than 1 week in acute kidney injury because of the increased infection risk compared with tunneled hemodialysis catheters. Unlike time-limited and relative predictable episodes for intoxications requiring dialysis, recovery from acute kidney injury with need for dialysis is very difficult to predict. In fact, only a minority of patients recover renal function in less than 1 week (29). For this reason, we primarily place tunneled catheters in patients with acute kidney injury, unless the patient is too unstable for transport to the procedure suite or has other contraindications to insertion of a tunneled catheter.

Catheter Materials

Currently on the market available are polyurethane and silicone catheters. Polyurethane catheters are relatively rigid at room temperature allowing bedside insertion, and their softness at body temperature minimizes the risk of vein perforation during prolonged catheterization (30).

Although silicone is the softest and least thrombogenic material, its softness necessitates the use of a peel-away sheath or internal stylets for percutaneous insertion (31). Insertion of silicone catheters by internal or external jugular venotomy is an alternative approach.

Acute Catheter Insertion Sites

Dual-lumen hemodialysis catheters may be inserted into the femoral or internal jugular vein. Because subclavian vein catheter placement may lead to subclavian vein stenosis, subclavian vein catheters should not be placed in patients who will ultimately require fistula creation for chronic hemodialysis.

Femoral Vein

Cannulation of the femoral vein should be performed under ultrasound guidance; instructional videos for insertion technique have been published online (32). Femoral vein cannulation is an invaluable technique for patients with pulmonary edema because it may be performed with the patient in the semirecumbent position. The femoral vein is cannulated immediately below the inguinal ligament as with increasing distance from the inguinal ligament the femoral artery is found more frequently overlying the femoral vein such that attempts to puncture the femoral vein distally leads to higher complications (33). As in obese patients, the inguinal fold is often more distal than the inguinal ligament; its location has to be carefully determined by feeling for the bony landmarks, medially the pubic tubercle, laterally the anterior superior iliac spine. Usually the abdomen has to be moved cranially and taped in place for safe access to the vein. External rotation of the leg increases total and accessible femoral vein diameter and decreases surfaces depth (34). In patients with bleeding diathesis, the initial puncture can be performed using the 21G needle of a micropuncture kit and then increase the guidewire from 0.018 inches to the usually used 0.035 inches wire in the dialysis catheter kit.

The incidence of life-threatening complications is lower for femoral vein cannulation than for internal jugular vein cannulation. Complications of femoral vein cannulation include ileofemoral vein thrombosis, AVF, retroperitoneal hemorrhage from vein perforation, and hemorrhage from accidental puncture of the femoral artery. Using ultrasound guidance increases success of the procedure (risk of failure reduced by 90%) as well as shortens procedure time, while the risk of arterial puncture and hematoma formation are fourfold reduced (35). Patients with femoral vein catheters must remain at bed rest in the hospital. In intensive care unit (ICU) patients with body mass index <28.5, femoral vein catheter colonization rates are comparable or lower than internal jugular vein catheters, while slightly higher in more obese patients, but overall comparable (**FIGURE 3.1**) (36). This observation has been confirmed for nontunneled catheters used in the ICU in general (37) as well as in subsequent studies of dialysis catheters (38). Catheter infections appear to be a random effect and not related to a threshold time beyond which a catheter has been in place as colonization of removed catheter in the same large randomized prospective study (36) was in fact higher for catheters removed within 5 days than those removed after 5 days.

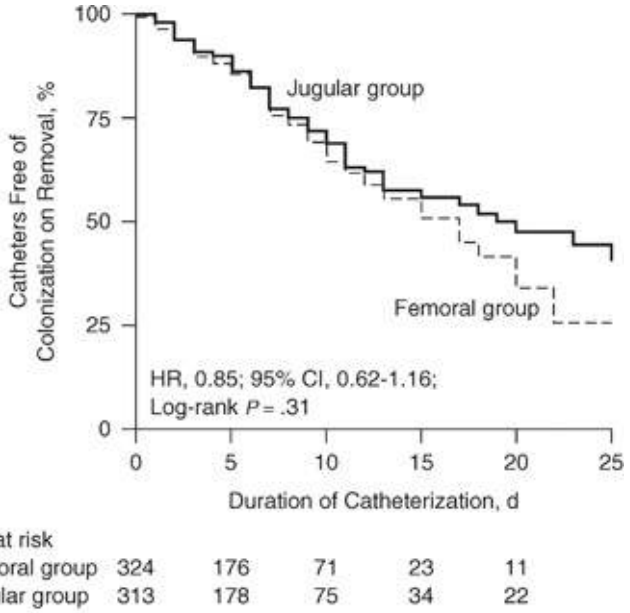

FIGURE 3.1 Colonization of catheter at time of removal in jugular and femoral vein insertion groups. [From Parienti JJ, Thirion M, Mégarbane B, et al. Femoral vs jugular venous catheterization and risk of nosocomial events in adults requiring acute renal replacement therapy: a randomized controlled trial. *JAMA* 2008;299(20):2413–2422.]

The length of the femoral dialysis catheter is important and should be 24 cm or longer to place the catheter tip in the inferior vena cava as otherwise recirculation increases significantly (39).

Subclavian Vein

Subclavian vein catheterization may lead to subclavian vein stenosis, precluding fistula placement in the ipsilateral arm. As mentioned previously, subclavian vein catheters should not be placed in patients for whom chronic hemodialysis is anticipated. Recent guidelines discourage this technique regardless of anticipated duration of use.

Internal Jugular Vein

Ultrasound-guided insertion of internal jugular vein catheters is associated with high success and very low complications rates (35). Traditionally, due to relative stiffness of nontunneled hemodialysis catheters, the recommended target tip position for internal jugular vein catheters has been the superior vena cava to avoid atrial perforations. Typically 13- to 16-cm-long catheters are used for right-sided insertions, and 16 to 20 cm catheters for left-sided insertions. A recent randomized trial of longer, soft silicone nontunneled catheters targeting the right atrium for tip position documented improved dialyzer life span as well as increased dialysis dose for continuous renal replacement therapy in the ICU (40) without increasing atrial arrhythmias. Risk of local hematoma formation as well as vein thrombosis is higher for internal jugular than femoral vein catheters.

Duration of Temporary Catheter Use

Temporary catheters achieve lower blood-flow rates than other types of permanent vascular access. The 2006 update of the National Kidney Foundation/Kidney Disease Outcomes Quality Initiative (NKF/KDOQI) Clinical Practice Guidelines for Vascular Access (41) recommend limiting use of nontunneled internal jugular vein catheters to 1 week because of the high incidence of infection. Other risks include inadvertent removal, hemorrhage, air embolism, and patient discomfort, all of which are

increased with temporary catheters (42). Plans should be made to convert all temporary catheters to a permanent access if use is expected to exceed 1 week (43). For most instances of acute kidney injury requiring renal replacement therapy, insertion of a tunneled hemodialysis catheter is preferred as the primary access modality (29). In some clinical settings where tunneled dialysis catheters are not available or too costly, nontunneled dialysis catheters have been used in conjunction with antibacterial ointments at the exit site for over 30 days with fewer than two infections per 1,000 catheter days (44), and nontunneled catheters may even be used to bridge the time until fistula maturation using antibiotic lock solutions (45). Given the stiffer nature of these temporary catheters, increased central vein stenoses seem likely, but data are lacking, and the use of nontunneled catheters beyond 1 to 2 weeks is strongly discouraged where tunneled catheters are available.

Complications of Central Vein Cannulation

Insertion Complications

Landmark-guided insertion complications become less likely as the operator gains experience (46). The incidence of serious insertion complications is higher for subclavian vein and internal jugular vein cannulation than for femoral vein cannulation (47). **TABLE 3.1** lists the most common insertion complications, which have markedly decreased with the transition from landmark techniques to ultrasound guidance.

TABLE 3.1 Acute Hemodialysis Catheter Insertion Complications

Atrial and ventricular dysrhythmias
Arterial puncture
Hemothorax
Pneumothorax
Air embolism
Perforation of central vein or cardiac chamber
Pericardial tamponade

Atrial arrhythmias may result from endocardial irritation by the guidewire or catheter but are generally of limited clinical significance (48). Ventricular arrhythmias occur in approximately 20% of patients but rarely require therapy (49).

Inadvertent arterial puncture is a common insertion complication. Manual pressure will prevent significant hematoma from femoral artery and carotid artery puncture, even in patients with bleeding diatheses (50). Although serious hemorrhage complicates less than 1% of subclavian vein catheterization attempts (42,51), we do not recommend attempts at subclavian vein catheterization in patients with coagulopathies or severe thrombocytopenia because of the difficulty of applying direct manual pressure to the subclavian artery.

To minimize the chance of fatal pneumothorax, two rules must be followed:

1. The operator should never attempt cannulation of the subclavian vein ipsilateral to the only healthy lung.
2. Even an unsuccessful attempt at subclavian or internal jugular cannulation may still lead to pneumothorax. A chest radiograph should be obtained before cannulation of the contralateral subclavian is attempted.

Perforations of the superior vena cava or cardiac chamber may lead to hemothorax, mediastinal

hemorrhage, pericardial tamponade, and death (51). These complications are rare but are more likely following subclavian vein cannulation than following internal jugular vein cannulation, perhaps because of the curved path that a subclavian catheter must follow. To minimize the chance of perforation during insertion, the operator must never advance the catheter without protection by a J-tipped guidewire. A chest radiograph must be obtained following insertion to confirm that the catheter is within a central vein and exclude pneumothorax. If the catheter tip is in the right atrium, the catheter should be pulled back to prevent right atrial perforation. Prolonged catheterization may lead to erosion and perforation of the superior vena cava; pericardial tamponade should be considered in the hypotensive hemodialysis patient with a central venous dialysis catheter.

Air embolism rarely complicates central vein cannulation (51), but care should be taken to avoid accidental introduction of air through the introducer needle, dilator, or catheter.

Injuries to the brachial plexus (52), trachea (53), and recurrent laryngeal nerve (54) are rare complications of internal jugular vein cannulation.

Use of ultrasonographic guidance during catheter insertion decreases complications and should be used (55,56). Ultrasonographic confirmation of target vein patency before cannulation prevents futile attempts at cannulation of thrombosed veins. In addition, the introducer needle may be inserted under direct ultrasonographic visualization. Fewer needle passes are required for successful cannulation when the ultrasonographic device is used (35). Recent guidelines strongly encourage this technique.

Infection

The mechanism of infection is migration of bacteria from the patient's skin through the catheter insertion site and down the outer surface of the catheter or even more common contamination of the catheter lumen during hemodialysis (57). Rarely, infection is caused by infusion of infected solutions. The use of chlorhexidine-impregnated dressing at the exit site prevents catheter colonization as well as catheter-related bloodstream infections (58). Nontunneled catheter infection rates are higher for femoral than internal jugular and then subclavian vein catheters (59): 1.5, 3.6, and 4.6 infections per 1,000 catheter days in one recent large randomized controlled study (47) with the mean length of catheter use of 5 days.

Bacterial isolates associated with catheter colonization and catheter-related bacteremia (CRB) reflect the location of the catheter. While typical skin flora, such as *Staphylococcus epidermidis*, is most prevalent for any catheter site, gram-negative isolates are more common for femoral vein catheters (36).

Evidence of exit-site infection, even in the absence of systemic symptoms, should prompt catheter removal. Exit-site infection presages bacteremia, presumably because the absence of a cuff permits migration of bacteria along the tunnel and outer surface of the catheter.

Other preventive measures are listed in **TABLE 3.2**. Disinfection with 2% aqueous chlorhexidine at the time of insertion is preferred to disinfection with povidone-iodine or isopropyl alcohol (60,61). Careful attention to use of maximal sterile barrier precautions during catheter insertion or guidewire exchange is recommended (**TABLE 3.3**) (62). Hemodialysis catheters should not be used for infusions or blood sampling, but temporary catheter designs with a third access port for blood sampling and infusions are available. After catheter placement and at the end of each hemodialysis treatment, the skin should be disinfected using chlorhexidine or povidone-iodine solution (63). An antimicrobial ointment, mupirocin or Polysporin, applied to the catheter exit site reduces infections (44,64,65), and antibiotic lock solutions

such as a mixture of cefazolin (10 mg/mL), gentamicin (5 mg/mL), and heparin (10,000 U/mL) can reduce catheter associated infections (45) with catheter infection rate very similar to tunneled catheters over an initial 30- to 60-day period. Lastly, a dry gauze dressing or a semipermeable transparent dressing should be applied at each hemodialysis treatment rather than an occlusive dressing (66,67).

TABLE 3.2 Prevention of Acute Hemodialysis Catheter Infection

Skin disinfection with 2% aqueous chlorhexidine at the time of insertion
Sound sterile insertion technique using barriers, gowns, and masks
Skin disinfection with chlorhexidine or povidone-iodine solution at each hemodialysis treatment
Application of povidone-iodine ointment or mupirocin ointment to the catheter insertion site at each dressing change
Dry gauze dressings
Use of face shield or surgical mask by patients and nurses during connection and disconnection procedures
Limited duration of catheterization

TABLE 3.3 Maximal Sterile Barrier Precautions for Catheter Insertion and Exchange

Large sterile sheet
Sterile gown
Sterile gloves
Hair cover
Face mask
New sterile gloves to handle new catheter for exchange

Adherence to the Centers for Disease Control and Prevention guidelines (68) for hand hygiene is low in both acute and chronic hemodialysis units (69). Aseptic technique during access handling, including use of a surgical mask for staff and patients, and adherence to hand hygiene guidelines decrease the risk for catheter-related infection (62).

A febrile hemodialysis patient with a central venous catheter should be presumed to have CRB unless there is strong evidence to the contrary. Rigors are especially suggestive of bacteremia. Blood cultures should be obtained, the catheter removed, and antibiotics administered. A new catheter may be placed once the patient defervesces. Antibiotic therapy should be continued for 2 to 3 weeks. In the event of metastatic infection (e.g., vertebral osteomyelitis or endocarditis), a longer course of antibiotic therapy will be required.

Catheter Thrombosis

Intracatheter thrombus impedes extracorporeal blood flow. Treatment consists of instilling reconstituted alteplase [recombinant human tissue plasminogen activator (tPA)] (or similar agent) in the affected catheter lumens for 30 to 120 minutes (70). This procedure may be repeated if necessary or tPA left in the catheter overnight. The slow leaking of tPA from the catheter may assist in lysing thrombus that may have formed around the catheter.

If catheter occlusion persists, catheter exchange may be performed using a J-tipped guidewire. We use a method where after careful cleaning of the skin and catheter, the sterile drape is applied such that the catheter ports are outside the sterile field. The catheter is then carefully retracted 2 to 4 cm, clamped just at the skin level, and cut 1 cm from the clamp. The guidewire is passed into the catheter while manually

compressing the catheter. This approach uses a catheter segment that was inside the patient and reduces contamination from passing through and handling of the catheter ports which are difficult to sterilize effectively.

Extracatheter or mural thrombosis is a less frequent but more serious complication (71). Clinically symptomatic vessel thrombosis is most frequent with femoral vein catheters (47); however, the overall incidence is between 0.5% and 1.4%. Treatment of symptomatic central venous thrombosis should include systemic anticoagulation. If the catheter is still needed, it remains in its position but should be removed if not further necessary. In critically ill patients in the ICU, there is often a multitude of catheters, and possible cardiac device leads crowding the central veins, and removal of a catheter at one site and insertion into another may just lead to a second site of thrombosis.

Central Vein Stenosis

Subclavian vein stenosis may occur after placement of subclavian dialysis catheters (72–74), while central vein stenosis occurs less commonly after placement of internal jugular vein catheters (75–77). Arm edema is the presenting complaint of most central vein stenoses. As blood-flow rates in each of the subclavian veins is in the range of 100 to 250 mL/min, and 250 to 500 mL/min in the brachiocephalic veins, it is often only after the creation of an ipsilateral AV access with additional flow rates of 500 to 2,500 mL/min that clinical symptoms develop. This can be an immediate or a delayed occurrence, and in some cases, central vein stenoses develop and become apparent without prior cannulation of the central veins. Formation of venous collaterals can alleviate symptoms over time. While the exact pathogenesis of symptomatic central vein stenoses has not yet been determined conclusively, any form of vein injury and increased blood-flow rates seem to contribute and exacerbate each other.

VASCULAR ACCESS FOR CHRONIC HEMODIALYSIS

According to the most recent United States Renal Data System (USRDS) data collection, at the end of 2013, there were 466,607 prevalent dialysis patients in the United States, a 63.2% increase since 2000. The incidence of new dialysis patient in 2013 was 113,944, 24% larger than in 2000 (78); 90.8% of incident ESKD patient received hemodialysis, necessitating an autogenous AV access (AVF), a non-autogenous (prosthetic or biograft) AV access (AVG), or TC to provide access to high-volume blood flow. Successful hemodialysis procedures require adequate performance of any of these access options.

The ESKD population remains at less than 1% of the Medicare population but accounts for about 5.6% of Medicare spending in 2013. Costs for Medicare patient with an AVF are lower than for patients with a tunneled catheter or graft, and per person per year access event costs are also highest for graft, and higher for catheters than AVFs (USRDS 2010) (79). Creating and maintaining functional access for the large and growing number of dialysis patients poses economic challenges. One may speculate that these costs will rise out of proportion as diabetes and hypertension both affect the peripheral vasculature with potential detriment to long-term access options and increased vascular access complications. Vascular access remains the Achilles heel of chronic hemodialysis. Vascular access that is beset with complications is costly to both the patient and society; vascular access failure has been the most frequent cause of hospitalization for patients with ESKD/CKD; however, the availability of outpatient access centers has markedly reduced the need for admission. The primary AVF is the form of vascular access

most likely to provide long-term complication-free vascular access. The importance of careful preparation for primary AVF placement months before the need for hemodialysis cannot be overemphasized.

Types of Permanent Vascular Access

There are three general types of long-term vascular access: tunneled hemodialysis catheters, autogenous AV accesses (AVF), and non-autogenous (prosthetic or biograft) AV accesses (AVG). The nomenclature for dialysis accesses follows the Society of Vascular Surgery (SVS) definitions. A tunneled catheter is named after the vessel it enters; for example, internal jugular vein tunneled hemodialysis catheter. For AVF site of use (forearm, upper arm, thigh, etc.), the originating artery and the connecting vein are used as well as an indication that this is an autogenous, transposed, or translocated access; for example, upper arm brachial-cephalic autogenous access for an AVF that connects the upper arm cephalic vein with the brachial artery (80).

Tunneled Cuffed Catheters

In 2013, more than 80% of patients initiating dialysis in the United States were using a tunneled hemodialysis catheter (78). The proportion of TC users decreased to 68.3% at 90 days and 20% at 1 year. Overall mortality of patients using a tunneled catheter is higher than for those using an AVF or AVG for dialysis (81,82).

Subcutaneous ports connected to catheters were used for several years in the United States as part of the LifeSite Hemodialysis Access System (83–86). However, this device was removed from the market after several cases of skin breakdown and infection around the device access site.

Catheters for acute dialysis are made of the relatively rigid polyethylene, while TCs are made of silicone, polyurethane, or Carbothane (polyurethane/polycarbonate copolymers). Silicone catheters are very soft, require a larger wall thickness to prevent collapse, and are greatly weakened by iodine, and for these reasons are rarely used. Polyurethane has high material strength, which allows for thinner catheter walls and therefore thinner catheters with equal flow characteristics, and is also less thrombogenic than silicone (30). However, polyurethane is weakened by alcohol, which today is the preferred catheter cleansing solution. Carbothane combines the exceptional material advantages of polyurethane with even greater strength and tolerance of alcohol, iodine, and peroxide cleaning solutions (87).

For two decades, subclavian placement of dialysis catheters was the preferred route (88); however, this has now been abandoned, as venograms revealed the frequent presence of severe stenosis or venous occlusion at the site of subclavian cannulation. Internal and external jugular vein insertion is preferred over femoral, inferior vena cava, and transhepatic catheters. Subclavian vein insertion is only a last resort. More recently, inside-out placement of tunneled catheters, similar to cardiac lead placement, from the right atrial appendix through the anterior mediastinum (89) or the junction of brachiocephalic-subclavian vein (90) with percutaneous exit in the subclavian region has been demonstrated for patients with total occlusion of the chest central veins.

TC insertion can be achieved either be conversion of an existing nontunneled catheter (43) or by *de novo* insertion. Right-sided TC insertion is preferred as the catheter has a more direct passage into the right atrium with fewer wall contacts and better function (91). With each heartbeat, the catheter moves, and a left-sided TC will have two to three wall contact points, eliciting endothelial injury and potentially

initiating a process of progressive central vein stenosis and occlusion. Tunneled catheters should be inserted using ultrasound and fluoroscopic guidance. Methods have been published for insertion of tunneled catheters without fluoroscopy (92), but success rates are lower, and the risk for major injury to large vascular structures as well as the pericardium through dilators and valved sheath is higher. We do not recommend insertion of tunneled catheters without real-time fluoroscopic guidance.

Technical details of the tunneled catheter insertion procedure are beyond the scope of this chapter. However, there are several procedural circumstances, knowledge of which aids the general nephrologist diagnosis and care of the patient with a TC.

The catheter should be sutured to skin at the wings of the catheter. Sutures that attach to the skin at the exit site irritate the skin and may facilitate exit site infections and protrusion of the catheter cuff. The cuff of the catheter should be positioned within 1 to 1.5 cm of the exit site to allow easy removal and exchange of the catheter while at the same time minimizing the length of the catheter segment that is colonized by skin flora between cuff and skin. Sutures that are tied circumferentially around the catheter body have the potential to constrict the catheter leading to dysfunction and facilitate cuff extrusion (**FIGURE 3.2**). This may present as an immediate catheter dysfunction on the day of insertion. The catheter cuff should be fully attached after 3 to 4 weeks, and the wing sutures can be removed if they irritate the patient's skin.

FIGURE 3.2 Catheter tunnel and exit sites: exit-site suture with skin irritation and exposed cuff.

The catheter tip should be positioned in the right atrium when the patient is recumbent during catheter insertion for a particular reason: TCs are encased in a fibrinous sheath in their course through the skin ("tunneled segment") as well as in the intravascular lumen. The only fix point for the catheter is the Dacron cuff which is fixed to the skin by invading skin cells and firmly connected to the fibrinous sheath of the tunneled segment. When sitting or standing, the tissue fixed to the cuff usually follows gravity to a more dependent location pulling up the catheter tip as much as the cuff moves downward. This effect is more pronounced in patients with voluminous breast tissue. The exit site should be in the lateral segment of clavicle and not more than 3 to 5 cm below its lower margin as elastic stretch of skin adds to catheter tip movement. Tunneled catheters support bidirectional 400 to 450 mL/min blood-flow rates (800 to 900 mL/min total volume moved). Recirculation is increased if these flow volumes are exchanged in the superior vena cava or the brachiocephalic veins rather than the right atrium. In addition, prolonged exposure of the relatively narrow brachiocephalic vein and superior vena cava to large blood-flow

volumes leads to stenosis at the site of the catheter tips. This may be an effect of the mechanical injury by catheter tips, jet-like fluid propulsion or suction of the vessel wall, as well as presence of catheter-tethered thrombus. For all these reasons, catheter tip position in the right atrium is preferred.

Several catheter tip designs have been developed to reduce recirculation and allow high flow into the catheter tips: split tips, step tip, symmetric tip, and centrally angled tips. During episodes of catheter dysfunction (see the following texts for more in depth discussion), catheters are often used in reversed configuration, which increases recirculation in all but symmetric tip catheters. Colored dye video studies revealed that only symmetric tip catheters had negligible changes in recirculation when used in a reversed configuration (93). In patients with central vein stenosis or occlusion who are tunneled catheter–dependent, the available space for the catheter tip is shortened, and symmetric-tip catheters are more suitable to function in 2 to 3 cm shorter spaces.

Catheter diameter and length both influence venous and arterial pump pressure with a given blood flow; there is partial collapse of the arterial lumen and expansion of the venous lumen, such that the fraction of delivered flow in catheters decreases with increasing absolute flow rates (91,93). This effect is less pronounced in larger diameter catheters (#15.5 or #16 French vs. #14.5 French) and more pronounced in longer catheters, such as femoral vein or translumbar catheters.

Catheter Dysfunction

Catheter dysfunction can be categorized as early (within the first 4 weeks) and late (after 4 weeks) and, in addition, as static (the catheter has no or minimal aspiration but may be flushable) and dynamic (arterial or venous pressure alarms when blood-flow rates are increased beyond a threshold too low to deliver sufficient clearance, <200 mL/min).

Early dysfunction is usually related to tip position and other technical issues associated with the insertion of the catheter. Immediately after catheter insertion, circumferential sutures around the catheter and fixed at or around the exit site can—either in the context of procedural tissue edema or gravitational pull—constrict the catheter. This type of dysfunction can be treated by cutting the constricting suture and placing new sutures through the catheter wings. Posteroanterior and lateral chest x-ray images, if possible in recumbent and sitting position, are used to evaluate the catheter tip position and confirm that is in the right atrium and not outside vascular structures or in the azygous or hemiazygous vein. If the catheter tip position is not in a position consistent with the superior vena cava or right atrium, a chest computed tomography or fluoroscopic evaluation with contrast dye are necessary to determine location of the catheter and guide further treatment steps. Catheter tips that are retracted into the central veins usually present with early dynamic dysfunction, while catheter tips outside the vessel do not allow for fluid removal (early static).

Late static dysfunction is usually due to intracatheter formation of thrombus. Any fill solution in the catheter lumen very effectively leaks out of the catheter and blood mixes into the catheter (95) within hours after application due to the large diameter of the catheter and differences in viscosity between blood and typically used fill solutions. This type of endoluminal thrombus is very effectively treated by instilling 2 mg tPA into the catheter lumina (96).

Late dynamic dysfunction is usually seen in the context of a fibrinous sheath and catheter-associated thrombus (97). Guidewire-assisted exchange of the tunneled catheter with balloon disruption of the

fibrinous sheath is very effective in treating this type of catheter dysfunction. An alternate strategy for sheath removal is stripping it with a gooseneck snare that is passed through a common femoral vein sheath into the right atrium. The snare encircles the catheter and strips away the fibrin sheath as it is retracted (**FIGURE 3.3**) (98).

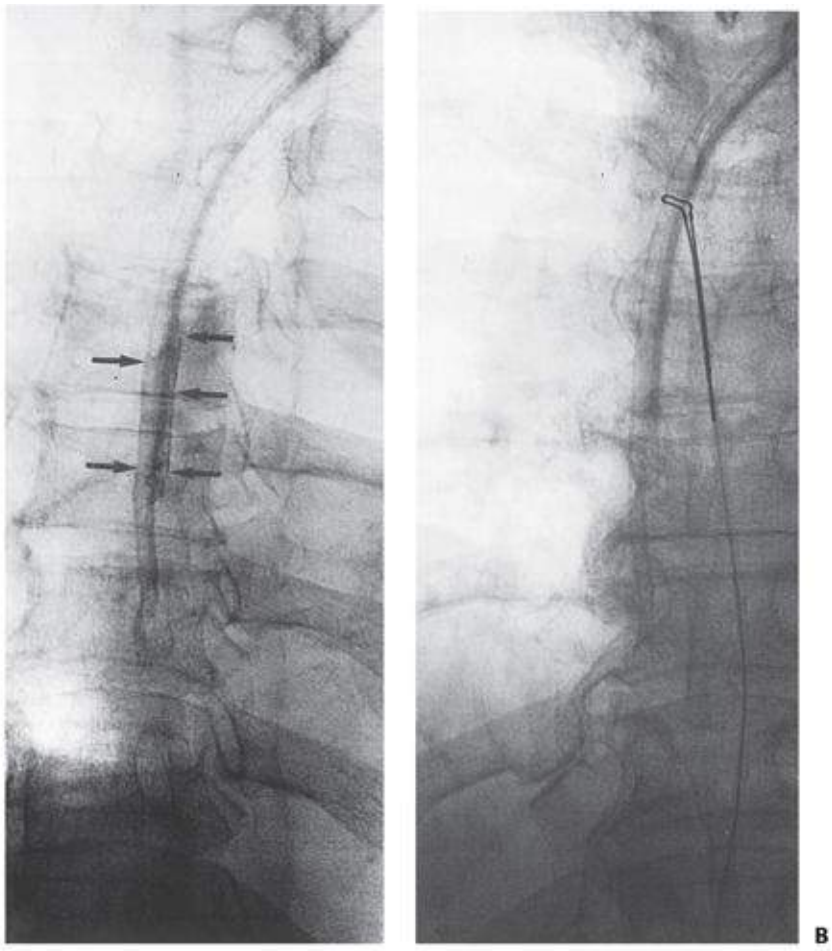

FIGURE 3.3 The catheter fibrinous sheath (arrows) is stripped by advancing a transfemoral snare over a guidewire placed through the catheter port and advanced into the inferior vena cava **(A)**. The snare is repeatedly retracted with mild closing force around the catheter **(B)**.

Cuffed Tunneled Catheter Infection

There are four compartments in a tunneled catheter, each of which may become infected: the exit site, the subcutaneous tunnel, the intravascular segment of the catheter with its associated fibrinous sheath, and intra-atrial organized thrombus attached to the catheter (**FIGURE 3.4**). Indwelling catheters are seen to be colonized within 48 hours when the catheter surface is examined with electron microscopy (99). Infections during the first 10 days after catheter insertions are usually considered to come from the outer surface of the catheter (contamination during insertion procedure or migration along the catheter from the skin), while infections 30 days or more after insertion are considered to originate from the inner surface biofilm. Usually there is colonization of the biofilm prior to bacteremia and clinical symptoms (100).

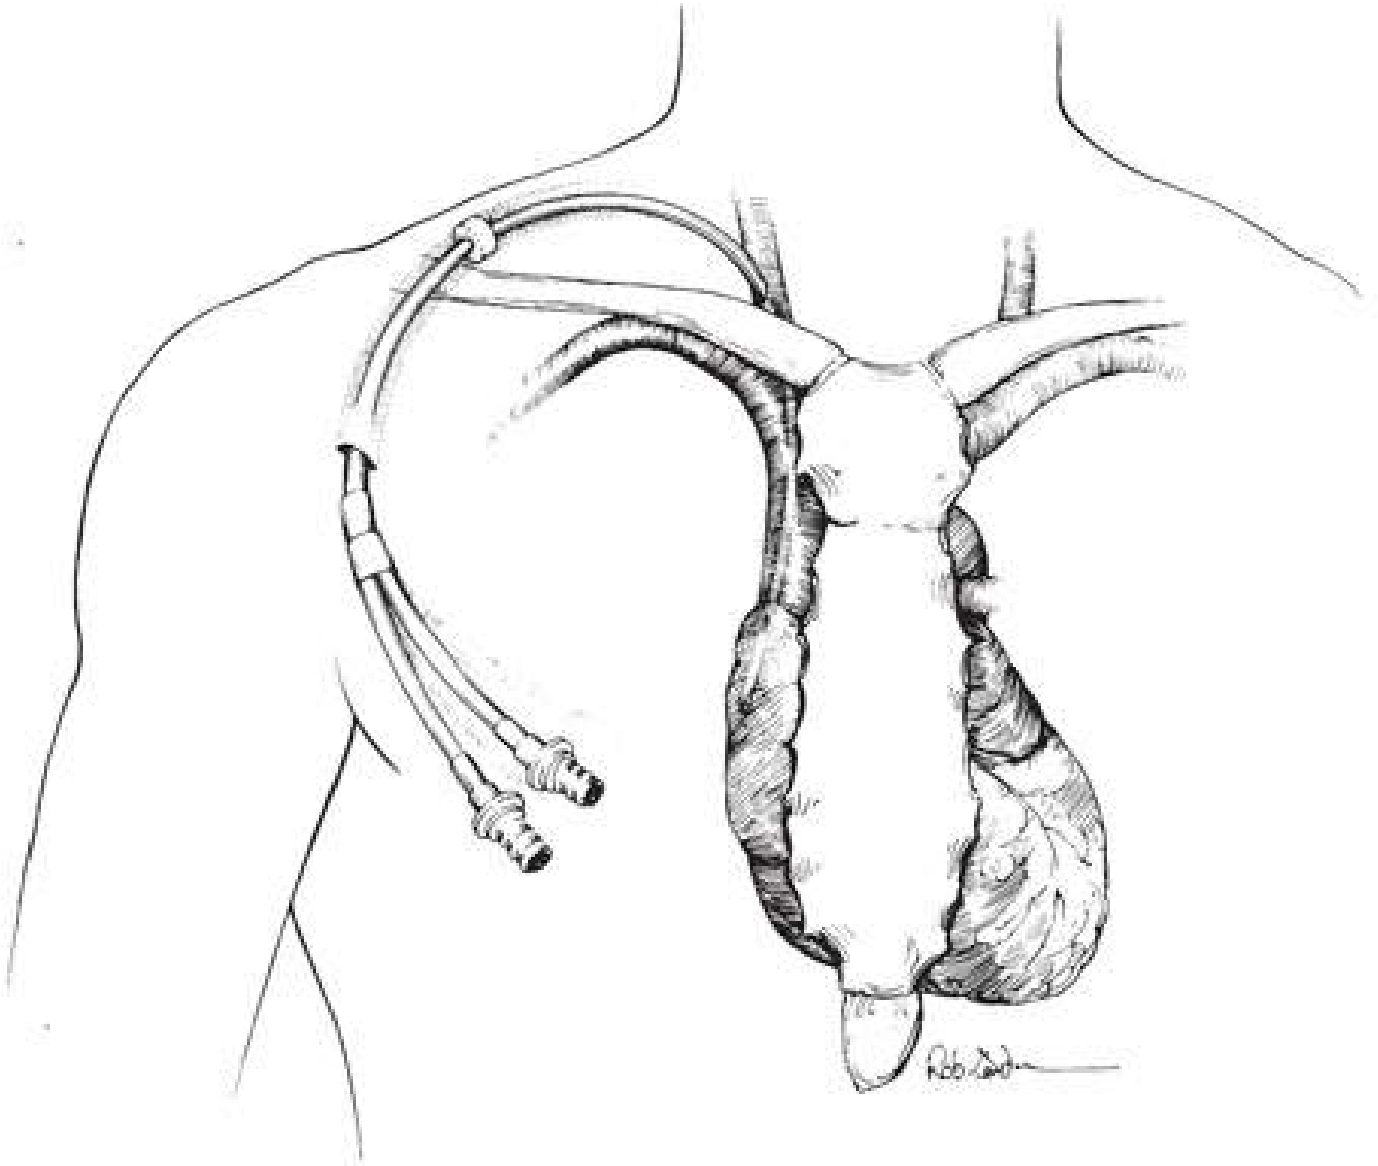

FIGURE 3.4 Cuffed double-lumen silastic catheter inserted through a subcutaneous tunnel into the right internal jugular vein. (From Schwab SJ, Buller GL, McCann RL, et al. Prospective evaluation of a Dacron cuffed hemodialysis catheter for prolonged use. *Am J Kidney Dis* 1988;11:166–169, with permission.)

Exit Site

Exit-site infections (**FIGURE 3.5**) are more common than CRB episodes, by some accounts 50% more, and over 90% are successfully treated with systemic antibiotics as well as local exit site (91). Prophylaxis of exit-site colonization to prevent infections has been evaluated. Johnson et al. (65) demonstrated that application of 2% mupirocin ointment to tunneled catheter exit sites significantly decreased rates of staphylococcal exit-site infections and bacteremias. A potential problem associated with mupirocin prophylaxis is the appearance of resistant staphylococcal strains (101,102). Using Polysporin ointment for tunneled catheter exit-site prophylaxis, Lok et al. (64) demonstrated decreased catheter-related infections and decreased mortality. A preliminary study has shown that application of antibacterial honey (MEDIHONEY) to catheter exit sites is as effective as mupirocin in decreasing catheter-related infections (103). When choosing to apply ointments at the skin exit site, the carrier bases have to be compatible with the catheter material as otherwise focal deterioration may be caused (**FIGURE 3.6**). A dry gauze dressing or a semipermeable transparent dressing should be used to dress the catheter exit site (66,67). Occlusive dressings should be avoided; they trap any drainage and create a moist environment at the exit site. If the

integrity of an exit site appears compromised without infection of the tunnel segment (see **FIGURE 3.5**), then the catheter can be exchanged with retunneling to a new exit site away from the infected area. This procedure requires a cut down on the catheter tunnel near the neck vein insertion site.

FIGURE 3.5 Catheter tunnel and exit sites: exit-site infection.

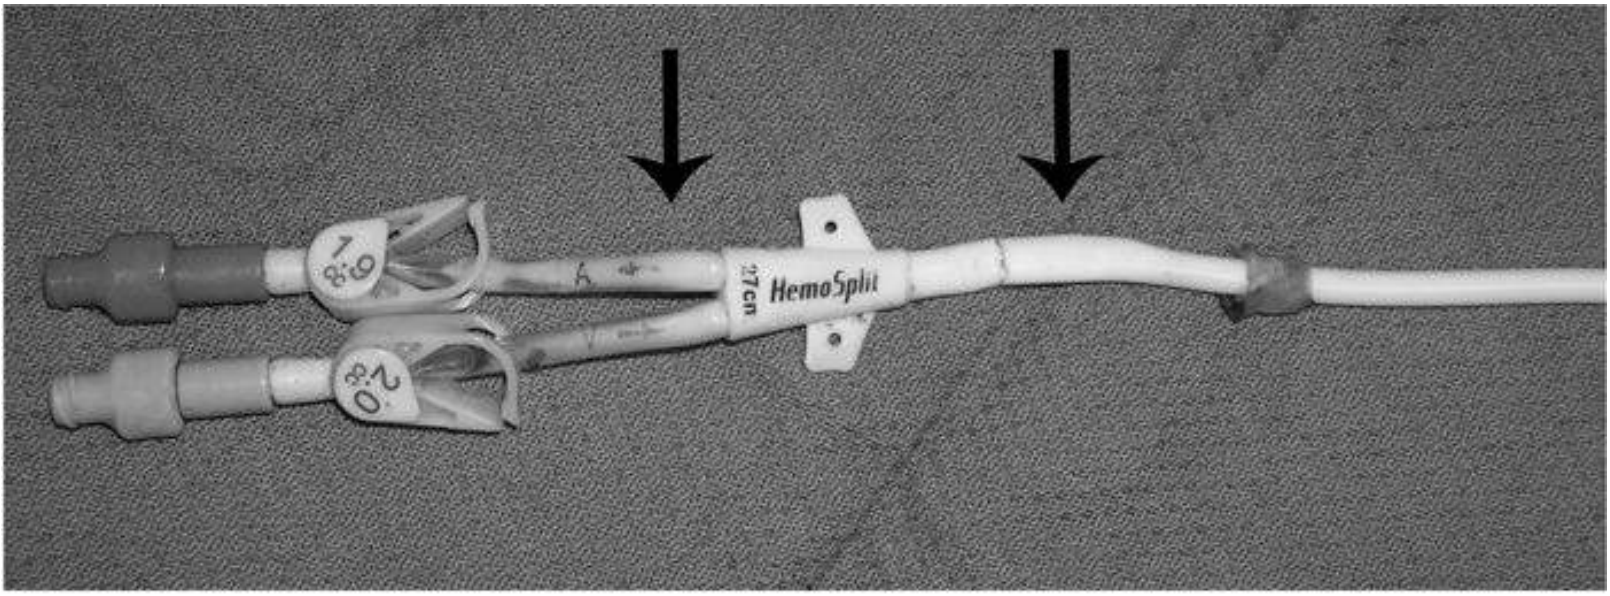

FIGURE 3.6 Catheter segments exposed repeatedly to antimicrobial ointment show dilatation and softening of the tunneled catheters (*arrows*).

Catheter Tunnel

Infections of the tunneled catheter (**FIGURE 3.7**) require removal of the catheter and insertion of a new catheter, usually on the contralateral side as there often is some degree of cellulitis around the inflamed tunnel segment. As there is continuity of the skin tunnel into the endovascular fibrinous sheath, systemic antibiotics should be used for 2 to 3 weeks similar to a CRB. Blood culture and cultures of purulent material expressed during the catheter removal should be sent to narrow antibiotic treatment after initial coverage for gram-positive and gram-negative organisms. The choice of the initial combination depends on local patterns of drug resistance but usually includes vancomycin and a third- or fourth-generation cephalosporin.

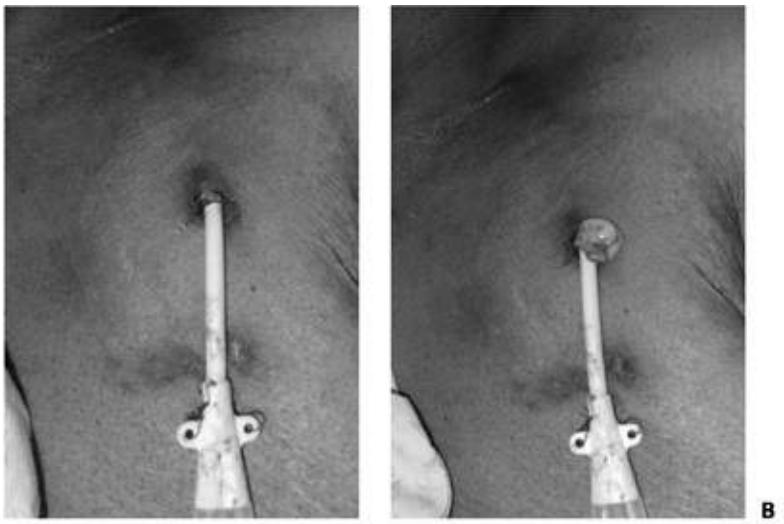

FIGURE 3.7 Catheter tunnel and exit sites: tunnel infection **(A)** revealing pus extrusion from exit site with massage along tunnel tract **(B)**. Note that cuff is not sealing the exit site any more.

Endovascular Segment and Fibrinous Sheath

Infection of the endovascular catheter segment is associated with CRB which is common in patients using a dialysis catheter, and the presence of a catheter is a major risk factor for bacteremia among hemodialysis patients (104,105). The relative risk for infection-related death is increased twofold to threefold among catheter-dependent hemodialysis patients compared to those using fistulas or grafts (106,107). The frequency of CRB reported in several large series ranges from 0.8 to 5.5 cases per 1,000 patient days or 0.9 to 2.0 episodes per patient-year (108,109). This wide range likely reflects differences in practice patterns as rates of bacteremia as low as 1/1,000 days at risk have been achieved with detailed catheter protocols (110). Infection is a common reason for catheter removal and morbidity in dialysis patients (108,110). Bacteremia can result in life-threatening complications, including septic shock, endocarditis, septic arthritis, osteomyelitis, or epidural abscess.

Bacteremia should be suspected when a hemodialysis patient with a catheter develops fever and chills. Paired quantitative blood cultures from the peripheral blood and the catheter are the most accurate for diagnosing CRB (111). This is not routinely performed in outpatient units because of the difficulty in peripheral venous sticks in hemodialysis patients. In the absence of concurrent blood cultures from the catheter and a peripheral vein, a clinical diagnosis of CRB requires exclusion of alternate sources of infection (108). However, bacteremia will often lead to seeding of endovascular devices such that exchange of a tunneled catheter during successful treatment of bacteremia from a different source is reasonable, in particular for *Staphylococcus aureus*. Blood cultures should be obtained from the catheter 1 to 2 weeks after completion of antibiotics for non-CRB to ascertain that the catheter has not been colonized.

Catheter-Related Bacteremia Management

Empiric antibiotic treatment should be initiated immediately if CRB is suspected, without waiting for blood cultures to become positive (108). Gram-positive organisms, including a significant number of methicillin-resistant species, are isolated in the majority of CRBs. However, a substantial portion of bacteremia isolates are gram-negative organisms (108). Therefore, the optimal empiric antibiotic regimen for suspected CRB includes both vancomycin and an antibiotic with broad-spectrum gram-negative bacterial coverage, such as a third-generation cephalosporin. Antibiotic regimens should be adjusted once

culture and sensitivity reports are available. Hospitalization is indicated if the patient is clinically septic or has evidence of metastatic complications such as endocarditis, osteomyelitis, epidural abscess, or septic arthritis. Aminoglycosides are excellent adjuncts for gram-positive infections treated with vancomycin as they are bacteriocidal rather than bacteriostatic. However, there are cumulative effects of aminoglycosides on hearing and balance such that lifetime exposure should be minimized (112). Continued bacteremia with hemodynamic instability despite sufficient treatment with appropriate antibiotics should prompt evaluation for catheter removal.

Treatment strategies for CRB that have been studied in hemodialysis catheter patients with regard to reemergence of the original organism after completion of antibiotics include (a) systemic antibiotics alone for 3 weeks, (b) systemic antibiotics plus a catheter lock solution, (c) systemic antibiotics plus catheter exchange (with or without disruption of a fibrinous sheath), and (d) catheter removal with delayed reinsertion (**TABLES 3.4** to **3.8**).

TABLE 3.4 Success Rate Antibiotics Alone

Source	Number of CRB Rx (number of all catheters)	Type of Study	Follow-up Interval (days)	Number of Cured	Cure Rate

GNR, Gram negative rods

The overall success rate of antibiotics alone is only 50%, and we discourage this approach. Systemic antibiotics with catheter lock overall only succeed in just over 50% of catheter infections, but in some patients with coagulase-negative staphylococci infections, the success rate of approximately 77% may be sufficient if catheter exchange were to represent an undue burden. The utility of antibiotic lock therapy is believed to be treatment directed to the bacterial biofilms that form on the internal and external surfaces of catheters soon after insertion. These biofilms are thought to play a critical role in bacterial antimicrobial resistance and recalcitrant infections (113). Systemic antibiotics do not penetrate the biofilm well, and proteins in the biofilm provide adhesion sites for organisms to bind to, particularly *S. aureus*. Instillation of a concentrated antibiotic–anticoagulant solution into the catheter lumen (the antibiotic "lock") at concentrations significantly higher than those achievable in the blood may permit

successful eradication of the infection while salvaging the catheter (114,115). Systemic antibiotics with exchange over guidewire, and as we perform it, with disruption of the fibrinous sheath during the procedure are as successful as removal and delayed reinsertion. Even for fungal infection, this approach is successful in over 80% of cases. A minority of about 10% of patients in the United States who use tunneled catheters long term is catheter dependent. Moving the catheter to a new site is often not possible, and exchange over a guidewire, frequently with treatment of an associated central vein stenoses or occlusions, preserves the only access option these patients rely on. Instillation of gentamicin (20 to 40 mg) into the catheter tunnel can be used as an adjunct during exchange. Guidewire exchange is the first recommendation for CRB by the Infectious Disease Society of America (116), and nephrologists will have to work within their institutions to create awareness for the special balance that needs to be struck between loss of access sites and catheter removals.

Infection Prophylaxis for Cuffed Tunneled Catheters

Strategies to prevent CRB have been evaluated. Silver-coated tunneled dialysis catheters showed no difference in frequency of bacteremia compared to untreated catheters (117). Routine instillation in catheter lumens of antimicrobial solutions alone and in combination with anticoagulant or lytic solutions has been investigated. A gentamicin–citrate solution and a taurolidine solution have shown efficacy in decreasing incidence of bacteremias when used as interdialytic antibiotic lock solutions (118–120). These practices have not yet gained wide use but may hold promise for decreasing infection rates in the future. Several studies have shown that initiation of best practice techniques and staff education can improve outcomes for CRB, including decreased antibiotic treatment failure and decreased incidence of catheter infections (110,121,122). In a retrospective analysis of 872 patients during more than 476 patient catheter years, Sedlacek et al. (123) found that aspirin therapy, the 325-mg dose, was associated with a decrease in CRB caused by *S. aureus*. This effect was not seen with other antiplatelet agents, at a lower dose of aspirin, or for pathogens other than *S. aureus*. Tunnel dialysis catheters may also be heparin-coated based on studies in central venous catheters that documented a decreased rate of thrombosis and infection (124); however, clinical studies in dialysis populations did not show an effect on dysfunction and mixed effects on CRB rates (125,126).

Emerging Drug Resistance

Since 1996, five vancomycin-indeterminate *Staphylococcus aureus* (VISA) strains, vancomycin minimum inhibitory concentration (MIC) = 8 to 16 mg/L, have been identified worldwide. Vancomycin-resistant *Staphylococcus aureus* (VRSA), vancomycin MIC ≥32 mg/L, have been reported in the United States between 2002 and 2005 (127). Activity against these organisms is reported with new antimicrobials including ceftobiprole, quinupristin/dalfopristin, linezolid, and daptomycin. An older drug, trimethoprim-sulfamethoxazole, appears to be active against some of these organisms as well (128). Cases of resistance to linezolid and daptomycin have already been documented (129). Preventing transmission of antimicrobial-resistant microorganisms is of paramount importance in limiting the occurrence of these infections.

Autogenous and Prosthetic Arteriovenous Accesses

The creation of an AV access, either by direct anastomosis or by insertion of a prosthetic or biologic graft

connecting an inflow artery with an outflow vein, fundamentally changes the existing flow and pressure states of the involved vasculature. Normal brachial artery blood flow is about 30 to 50 mL/min, while radial artery flow is as low as 10 to 15 mL/min. After anastomosis to a suitable graft or vein, flow rates in a 2-mm-diameter radial artery may increase to 800 mL/min. The associated shear stress will lead to arterial remodeling and over time to a larger diameter artery. The larger artery again will allow for higher flow rates at similar blood pressures. Arterial blood-flow wave forms change from triphasic before access creation to biphasic. The access vein experiences very similar changes in blood-flow volume, from less than 10 mL/min in a forearm cephalic vein to 400 to 800 mL/min within several weeks after access creation. Continuous flow changes to pulsatile flow near the anastomosis, which becomes less pulsatile with increasing distance from the anastomosis and addition of collaterals to the outflow network. Veins similarly remodel outward if exposed to the right shear stress and intra-access pressures, remodel little with low flows and pressures, and may form a stenosis with shear stress and intra-access pressures too high. The exact relationship between the different components of the vessel wall and the physiologic stimuli related to blood flow (shear stress and pressure) is currently not fully understood on the molecular level.

Stenoses at the inflow or outflow side of an access affect flow volume as well as intra-access pressures and thereby the biology of the involved vasculature. Recurrent outflow stenoses cause prolonged exposure to elevated intra-access pressures. Healing of needle insertion sites under elevated pressure leads to apposition of additional cell layers and connective tissue, which clinically manifests as aneurysm at the needle insertions sites. Over time, the skin thins and consists mostly of scar tissue. In this state, the reduced elasticity predisposes for prolonged bleeding after needle removal as well as scabbing and eventually ulceration of the overlying skin which may manifest as a terminal bleeding event.

While access stenoses can be treated with angioplasty, stents, or surgical revision, they are highly stenoses and are highly recurrent (outflow more so than inflow), such that this is properly referred to as *chronic access disease.*

Maturation of an autogenous access is defined by its usability for repeated needle insertion and removal. This requires a certain thickening of the vessel wall that is a result of shear stress and pressure-induced remodeling. Augmentation of the access vessel is necessary to avoid penetrating needle insertions and may be weak if there is an inflow stenosis or collaterals in or right after the needle insertion segment. Increased intra-access pressures (pulsatility) may lead to early infiltration and prolonged bleeding and can be found with high inflow (mismatch with access outflow) or an outflow stenosis.

Physical Examination of Vascular Access

Dialysis units may call to refer a patient for a variety of specific complaints:

- “Needles are pulling clots.”—There may indeed be thrombus forming in a needle insertion segment, but this is rare. More commonly, needle tip position is such that the tip or the back hole is not fully within the access lumen; thrombus forms in the adjacent tissue from blood leaking from the needle. This is primarily a sign of difficulty with needle insertion. Most commonly, augmentation of the access vessel is impaired, either due to a collateral or an anastomotic or juxta-anastomotic inflow stenosis. An alternative is the presence of a very small vein diameter as the length of a dialysis needle bevel is

about 4 mm such that the tip can easily cause injury of the posterior wall.

- "Vessel collapses," "access spasms"—During the first needle insertions into an access or a new segment of an access, there may be spasm of the vein at the needle insertion site. Typically, this resolves over the course of 20 to 30 minutes. However, intermittent collapse of the inflow vessel during the entire dialysis treatment may be a sign of access flows near or below dialysis pump speed. This can be seen with a true inflow stenosis or when a needle with the tape holding it in place compresses a flow-regulating inflow narrowing in a way that otherwise sufficient blood flows are reduced to or below pump speed. This can be exacerbated by periods of low systemic blood pressures which also affect access flows.
- "Long bleeding," "bleeding on a nondialysis day"—Bleeding from an access in such fashion is due to increased intra-access pressures, skin deterioration, anticoagulation, or a combination of the three. Other signs of a stenosis such as changes in pulsatility and location of a thrill should be determined.

The physical examination is instrumental in guiding imaging evaluation as well as correlating observed angiographic abnormalities with clinical dysfunction to counter the "oculo-manual" reflex for intervention. Each dialysis access presents with unique features as a result of smallest inflow diameter (flow-limiting/regulating segment), blood pressure, outflow capacity, and presence of collaterals. To capture all (patho-)physiologic components of a given access by physical examination, we suggest to evaluate the following five categories: pulsatility, flow murmur/bruit, thrill, augmentation, collapse of access against gravity (**TABLE 3.9**). Repeated examinations and correlation of physical findings with angiographic features as well as flow measurements will lead to useful mastery of this skill. Collapse of access against gravity can usually not be examined in prosthetic accesses, except if there are well-established needle insertion segment where the surface layer of PTFE has rarified over time (needle insertion aneurysm).

TABLE 3.9 Physical Examination of Dysfunctional Accesses

Type of Access	Arteriovenous Graft	Radial-Cephalic	Brachial-Cephalic	Brachial-Basilic/Brachial
Site of typical stenosis	**venous anastomotic**	**anastomotic/juxta-anastomotic**	**cephalic arch**	**basilic swing point**
Pulsatility	Increased	Decreased	Increased	Increased
Thrill	Only systolic or absent	Poststenotic only	Only systolic or absent	Only systolic or absent
Bruit	Discontinuous	Continuous, faint	Discontinuous	Discontinuous
Augmentation	Any (strong without occlusion)	Weak	Any (strong without occlusion)	Any (strong without occlusion)
Collapse with gravity	None	Complete (occasionally without gravity)	None	None

Pulsatility describes the force of access expansion during systole and the degree of softening during diastole. Very high blood pressures will suggest increased pulsatility, but the access softens remarkably during diastole. An outflow stenosis will lead to increased pulsatility and reduced softening during diastole. An inflow stenosis will blunt the systolic component and create the impression of an "empty" access during diastole, unless there is a coexisting outflow stenosis. Pressure measurements in the body of accesses (needle insertion segment) with "normal" pulsatility typically are in the 20 to 25 mm Hg range for forearm accesses and 25 to 30 mm Hg for upper arm accesses.

The audible **flow murmur** can be characterized by pitch and continuity. A change in pitch toward

higher frequency is typical at the site of a stenosis due to accelerated flow velocity at this site. A discontinuous flow murmur indicates that during diastole, flow is so low that no audible shear force is created. This is the sign of a severe inflow or outflow stenosis. Typically, the stenotic inflow murmur is faint (like a whistle), while the stenotic outflow murmur can be coarse and loud (akin to a wood saw).

A **thrill** is palpable through the skin when the vessel is close enough to the surface and the flow high enough in relation to the diameter of the vessel to create vibration of the vessel wall. A thrill can be the sign of a well-developed access, usual in the inflow segment, dissipating as the access vessel branches and takes a deeper course. It is usually continuous with slight pronunciation during systole. In contrast, a discontinuous thrill can be found with severe stenosis. An isolated thrill is also found focally immediately after a stenosis. The differentiation from a "healthy" thrill can be made by documenting a change in pulsatility at the site of the focal thrill, increased retrograde (inflow side), and decreased antegrade (outflow).

Augmentation is the firming up and enlargement of the body of the access (where needles are inserted) with occlusion of the outflow. Without proper augmentation, needle insertion will be complicated by perforating injuries and hematomas. An inflow stenosis will impair augmentation as will side branches and collaterals between the occluding finger/tourniquet and the inflow. The location of side branches can be elucidated by moving the occluding finger closer toward the anastomosis until augmentation is achieved. With several collaterals, this may be a staged phenomenon.

Collapse of the access with arm elevation (against gravity) is a measure of inflow and outflow capacity match or mismatch. A forearm access typically displays complete collapse, while upper arm accesses typically show only partial collapse. Outflow stenoses or very high inflow will decrease the degree of collapse; banding of an upper arm access or a natural flow-limiting stenosis may lead to complete collapse of an upper arm access.

Enlarged needle insertion sites (and any sites of suspected skin thinning) are best examined while occluding the inflow: The completely empty access allows palpation of firm, layered thrombus inside aneurysms as well as better appreciation of the thickness of the overlying skin by rolling it between thumb and index finger.

Diagnostic imaging includes use of ultrasound as well as angiography using iodinated contrast agents or CO_2 gas. Ultrasound can accurately determine the depth of an access, demonstrate intraluminal thrombus, and provide estimates of access flow by measuring flow in the inflow artery. Angiography provides patterns of flow distribution, unmasking relevant side branches and stenoses. During angiography, access flows can be directly measured using special endovascular catheters based on a modified Fick's equation.

Guided by physical examination, angiographic studies and interventions can be performed with minimal contrast volume (5 to 10 mL), which typically does not jeopardize renal function even in patients with advanced CKD. We dilute contrast 1:1 with normal saline for central venous imaging and 1:3 with normal saline for peripheral images and perform pullback angiograms from central to peripheral (the usual access entry site). Diluted contrast allows for better appreciation of vascular details otherwise hidden by dense contrast.

Decisions to intervene on a given access have to be based on a sum of clinical findings, physical examination, and requirements for dialysis. For instance, a pre-ESKD patient with a stable inflow

stenosis and relatively low flows may be best served with observation rather than recurrent interventions. Care systems have to be created to allow treatment of these access issues immediately before or at initiation of dialysis.

Natural History of Access Function and Dysfunction

First described by Brescia et al. (4) in 1961, the autogenous AV access remains the best form of long-term vascular access. AVFs are the preferred type of dialysis access because they are associated with the lowest morbidity and mortality, have excellent long-term patency, and require the fewest number of interventions to maintain patency. This is in particular true for forearm autogenous accesses (130). It is for these reasons that the NKF/KDOQI guidelines have set a goal of 65% of all hemodialysis patients having a functional AVF which we are soon approaching. The Fistula First Breakthrough Initiative also seeks to increase the use of AVFs for access while simultaneously decreasing the use of central venous catheters. In the United States, without dedicated programs to detect access dysfunction early and treat it appropriately, maturation failure is high (131). Even with interventions, some autogenous accesses do worse than others, require more interventions to function adequately, and still have higher failure rates (132), but accesses with low flow or maturing accesses seem to benefit from interventions (133). Once mature, native fistulas have excellent long-term patency rates and rarely become infected. The authors have seen primary AVFs provide adequate vascular access for 20 years.

The three dominant types of fistulas used in dialysis are the forearm radial-cephalic autogenous access, the upper arm brachial-cephalic or proximal radial-cephalic autogenous access, and the upper arm transposed brachial-basilic access.

Radial-cephalic forearm access is the preferred access if there is an appropriate cephalic vein and associated radial artery. The radial artery ideally will be without calcifications; however, even calcified radial arteries with 2-mm diameter may deliver 600 to 800 mL/min blood flow. The cephalic vein usually branches near the elbow with outflow toward the upper arm basilic, brachial, and cephalic veins, ensuring low intra-access pressures. If only one outflow is available in the upper arm, basilic/brachial is preferred over upper arm cephalic vein outflow as the cephalic arch has a tendency to develop stenoses over time. Maturation of the access to usability is most commonly impaired by juxta-anastomotic stenoses in the swing segment of the cephalic vein as well as lack of augmentation in the setting of multiple collateral veins. We prefer side-branch ligation over coil embolization as the veins are typically very superficial and easy to reach, and the foreign body sensation of a coil in the forearm can be limiting.

The upper arm brachial-cephalic, or proximal radial-cephalic, access is created in the antecubital area where the cephalic vein is mobilized for an end-to-side anastomosis to the brachial artery. A similar anastomosis can be fashioned using the proximal radial artery which aids in limiting flow and preventing steal. In some instances, a Gracz or Konner access (134) can be created by connecting the perforans branch to the deep venous system for an anastomosis with the proximal radial artery. Accesses utilizing the upper arm cephalic vein very often develop a chronically recurrent cephalic arch stenosis and less frequently also in the cephalic vein swing segment. Stenoses of the cephalic arch can be effectively treated with cephalic arch stent grafts (135).

An upper arm brachial-basilic superficialized access can be created as a two-stage or a single-stage procedure. A single-stage procedure involves mobilization of the upper arm basilic vein including a

forearm branch after an incision from axillary to elbow, tunneling of the vein in a curve toward the anterior aspect of the arm with anastomotic area to the brachial artery near the elbow. Instead of tunneling, the vein can just be lifted within the skin flap. Ideally, the vein should come to rest away from the scar of the incision to allow easy palpation and needle insertion. In the two-stage procedure, a forearm branch of the basilic vein below the elbow is anastomosed to the proximal segment of a forearm artery or the brachial artery. This allows the vein to remodel and once there is wall thickening as well as increase in diameter, which is usually after 6 to 8 weeks, when the formal transposition can be done. Tunneling the vein to a new site of anastomosis with the brachial artery has often the best anatomic results. The vein can usually be cannulated 4 to 6 weeks after transposition. Typical sites for stenoses in this access are the “swing” point of the basilic vein as well as the inflow segment. Two-stage accesses appear to mature more frequently.

Other autogenous accesses that can be done are a superior femoral–saphenous vein access in the thigh, but the longevity of type of access over time has not been as good as upper (fore-)arm accesses. A superficial femoral-superficial femoral transposition thigh access is very similar to a basilic vein transposition in the arm and may have very high flows due to the larger vessels involved.

Non-autogenous accesses typically use expanded PTFE (ePTFE) (prosthetic) and less frequently bovine carotid artery, cryoveins, or tissue-engineered tubes with human cells (biograft). They are placed in the forearm in either a loop (brachial or proximal radial artery to cubital median, basilic, brachial, or cephalic vein) or straight (distal radial artery to vein) configuration. Within 3 to 4 weeks, fibrous tissue secures the graft in its subdermal tunnel and helps achieve hemostasis at needle puncture sites. Over time, the PTFE graft material wears out at site of repeated needle puncture. More recently, early cannulation ePTFE grafts have become available that allow cannulation within days after placement, thereby reducing the need for tunneled catheters.

Grafts can be placed in many sites—after exhausting autogenous options and typical placement sites in the upper extremities, chest wall (axillary artery to axillary vein and axillary artery to jugular vein), or thigh (femoral artery to femoral vein), grafts are possible. **FIGURE 3.8** depicts a looped forearm graft and an upper arm graft.

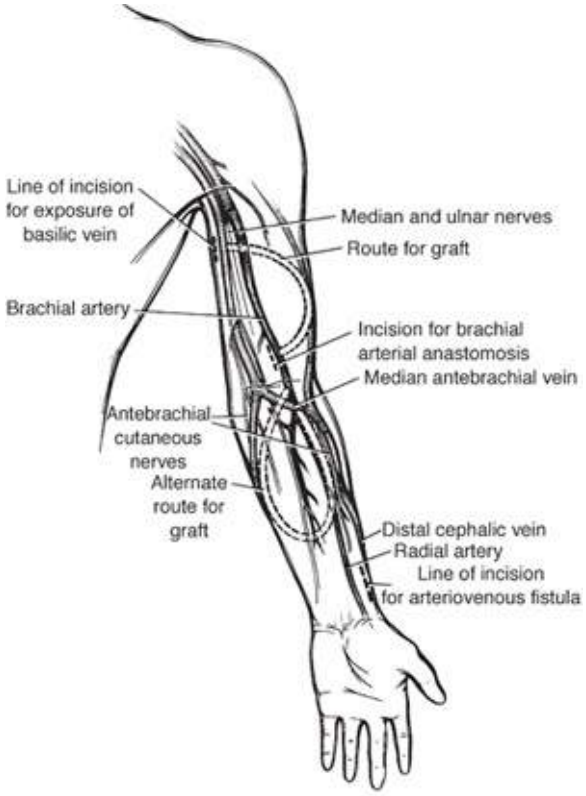

FIGURE 3.8 Looped forearm graft and upper arm graft. (From Stickel DL. Renal dialysis access procedures. In: Sabiston DC Jr, ed. *Atlas of General Surgery*. Philadelphia, PA: WB Saunders, 1994:90–98, with permission.)

Very predictably, grafts develop stenoses at the venous anastomosis or in the immediate outflow vein. Access flows in grafts are related to their length and diameter and tend to be higher early on than an AVF with similar inflow, while the autogenous access has higher flow after many years of use. Although PTFE will withstand numerous thrombectomies and revisions, PTFE grafts are more prone to thrombosis and infection than are primary AVFs. By 3 years, many grafts have been lost to thrombosis or infection.

Preparation of the Patient for Permanent Vascular Access Placement

The role of careful planning for a successful AV access cannot be overemphasized. Studies consistently show that native fistula accesses have the best 4- to 5-year patency rates and require the fewest interventions compared to other access types (82,136). Epidemiologic studies have shown that greater use of fistulas is associated with reduced mortality and morbidity (137–140). Access failure was the most frequent cause of hospitalization for patients with stage 5 CKD, based on data from the USRDS (1995) (141). Increased patient care cost is associated with graft use secondary to the increased number of procedures needed to maintain patency of grafts compared to fistulas (142). The clear superiority of fistula as the permanent vascular access for dialysis has led to national quality improvement projects, such as Fistula First (http://www.fistulafirst.org), with the goal of maximizing the creation of fistulas. The Centers for Medicare and Medicaid Services has set a target of 65% fistula prevalence by 2009 (143,144). Early referral to nephrologists for evaluation and access planning is of primary importance in increasing fistula placement. Careful protection of the central and upper extremity venous and arterial system preserves vessels for fistula creation. Preoperative physical examination by an experienced individual, in combination with upper extremity vascular mapping, increases the number of functional fistulas placed (145–148).

The radial cephalic autogenous access at the wrist of the nondominant arm is the preferred form of

vascular access for the chronic hemodialysis patient, and the primary care physician must be instructed that the patient's morbidity on chronic hemodialysis will largely be determined by the adequacy of his or her vascular access (139). Patients should be taught to protect the vasculature of both arms; they should not permit placement of radial artery catheters and cephalic vein catheters. If possible, venipuncture should be avoided altogether except for the back of the hands. Peritoneal dialysis patients and patients with a kidney transplant should similarly preserve venous real estate in this fashion.

A history of subclavian vein catheter placement or current or previous transvenous pacemaker placement ipsilateral to the planned access site should prompt preoperative imaging to exclude central vein stenosis or occlusion; the presence of an untreatable central vein lesion requires careful access planning with anticipatory access flow reduction (149). Prior use of upper extremity peripherally inserted central venous catheters and central venous catheters (150) is associated with a high incidence (11% to 85%) of upper extremity stenosis and thrombosis (151–154) which leads to loss of potential sites for upper extremity fistulas. A history of severe congestive heart failure, peripheral vascular disease, or prior vascular surgery may limit surgical options.

Examination of the patient's upper extremity arterial and venous systems is important. Assessment of the arterial system includes bilateral blood pressure measurements, characterization of the peripheral pulses coupled with an Allen test of radial and ulnar flow. Insufficient arterial flow will preclude use of an extremity for AV access. Venous system evaluation includes assessment of bilateral arm size compatibility, examination for collateral veins or arm edema, and scrutiny of the patient's arm, neck, and chest wall for evidence of prior central venous cannulation or surgery (41).

Preoperative vascular mapping, the evaluation of arterial and venous vessels in the upper extremity, should be performed on all patients before placement of an AV access. Doppler ultrasound is the preferred method for preoperative vascular mapping (146–148). Vascular mapping of the arterial system includes pulse examination, differential blood pressure measurement, assessment of the palmar arch for patency, arterial diameter assessed by using Doppler ultrasound, and identification of arterial calcification. Venous system mapping comprises venous diameter assessment by Doppler ultrasonography, identification of vein continuity with proximal central veins, and the absence of venous obstruction (145). Venography or magnetic resonance angiography may also be used if central venous stenosis is suspected (155).

Controversy exists about the vessel diameter required to maximize successful maturation of the AV access. In general, studies support a minimum arterial diameter of 2.0 mm and minimum venous diameter of 2.5 mm by Doppler ultrasonography for the successful creation of a fistula. However, smaller vessel diameters have been used successfully to create fistulas. Surgical experience and individual vascular characteristics, such as the ability of the vessels to dilate postoperatively, may influence successful fistula maturation (145,156).

Access creation should begin distally. With enough time predialysis, even small appearing arteries and veins can mature into useable accesses. The increase venous flow of any radial-cephalic autogenous access will increase the success of access creation more proximally, as veins are partially matured.

There is discussion if a forearm loop graft should be inserted prior to an upper arm transposed brachial-basilic autogenous access. The more distal option should be preferred if the graft placement does not make impossible later transposition of the basilic vein.

In those patients in whom neither radial-cephalic nor brachial-cephalic primary fistula creation is possible, a transposed brachial-basilic autogenous access should be placed in the nondominant arm. The transposed brachial-basilic vein fistula is preferred but has several disadvantages compared to other fistulas (157–159). The transposition procedure may create significant arm swelling and patient pain, it is associated with a greater incidence of steal, and it is a technically more challenging surgery, especially in obese individuals. In some instances, a failing forearm graft can be converted to a more proximal fistula (41).

Vascular Access Patency

The chief marker of vascular access adequacy and patency is access blood flow. Low blood flow limits hemodialysis delivery resulting in underdialysis that is associated with increased morbidity and mortality (160). Of equal import, low access blood-flow rates can be associated with stenosis predisposing to access thrombosis and access loss.

Vascular access blood flow depends on the type, the location, and the age of the access. Initial blood-flow rates in primary AVFs are only 200 to 300 mL/min (161,162) but increase to greater than 600 mL/min as the venous drainage system dilates within 4 to 6 weeks (163). Blood-flow rates in non-autogenous accesses are high initially (164,165) but may fall with time because of progressive intimal and fibromuscular hyperplasia in the venous outflow system. Investigators have demonstrated that grafts with blood-flow rates less than 600 mL/min are more likely to clot than grafts with blood-flow rates greater than 600 mL/min (166,167). Grafts constructed using more proximal arteries have higher blood-flow rates (161,164) and may have higher patency rates.

The cumulative patency rate is defined as the percentage of accesses that remain patent at a given time regardless of the need for revision and thrombectomy. Cumulative patency rates for primary AVFs have been reported to be 60% to 70% at 1 year and 50% to 65% at 2 to 4 years (168,169). Cumulative patency rates for PTFE grafts have been reported to be 62% to 83% at 1 year and 50% to 77% at 2 years (166,169,170). Fifty percent or fewer of synthetic grafts are patent beyond 3 years. The lower cumulative patency rates for primary AVFs are due to early fistula failure; approximately one-fourth of these fistulas fail to mature. After correction for early failure, cumulative patency rates are at least as high as patency rates for PTFE grafts. In addition, native fistulas require fewer interventions to maintain patency than do synthetic fistulas.

Access Stenosis and Thrombosis

Stenosis usually precedes access thrombosis. There are three scenarios for stenosis, each with typical clinical signs and symptoms.

An inflow stenosis is usually characterized by decreasing augmentation to a point where staff may have difficulty with needle insertion. As the needle tip may not be perfectly inside the access conduit, “pulling clots” is a frequent comment, although the access has a palpable thrill and audible bruit. Blood flow may be reduced in absolute terms such that clearance is decreased and measurable recirculation can occur. While a prosthetic access may thrombose due to inflow stenosis, this is less common for an autogenous access. However, the last palpable segment of a low-flow AVF with inflow stenosis is between arterial anastomosis and the stenosis. Needle insertion into this space will often cause shutdown of the access by needle occlusion followed by access thrombosis when very tight tape has to be applied

to stop the vigorously bleeding from the pressurized needle insertion site.

An outflow stenosis is characterized by much increase pulsatility of the access, prolonged bleeding from needle insertions sites, and enlargement of needle sites over time. Often, there is layered thrombus in the enlarged needle sites which can be dislodged inadvertently during needle insertion, embolizing into the stenosis to occlude the access. Access flows may be relatively high such that clearance is not yet affected. Particularly in graft, tight tape to control bleeding after needle removal can lead to complete luminal occlusion and then access thrombosis when the patient leaves the tape in place for 24 to 48 hours to avoid rebleeding.

More difficult to detect by clinical signs is the combination of balanced inflow and outflow stenoses: As the outflow stenosis progresses so does the inflow stenosis, with very little increase in pulsatility and postneedle removal bleeding. Only a full examination of the access evaluating continuity of the flow murmur/bruit and location of a thrill will identify this combination that frequently progresses to thrombosis before detection by dialysis unit staff.

Thrombosis is the leading cause of access loss. Thrombosis within 1 month of access creation is likely due to technical errors or to premature cannulation. After the first month, the thrombosis rate is 0.5 to 0.8 episodes per patient-year. Prosthetic accesses thrombose much more frequently than do autogenous accesses.

Approximately 90% of graft thromboses are associated with stenoses of the venous outflow tract (22,169,171,172). These lesions are characterized by intimal and fibromuscular hyperplasia (169,173). Most venous stenoses develop at or within 2 to 3 cm of the vein graft anastomosis (174). The remainder develops in more proximal veins, in central veins, or in the graft itself. Most accesses have more than one stenotic lesion at any one time (175). Arterial disease is now known to be more common than previously thought. Asif et al. (176) found in a multicenter trial that one-third of patients referred to interventional facilities for clinical evidence of venous stenosis or thrombosis had documented inflow arterial stenosis. Subclavian vein stenoses are associated with previous subclavian vein catheterization and with transvenous pacemaker placement (22,73,77). Intragraft stenoses are reported to result from pseudointimal hyperplasia (173) and fibroblastic ingrowth through needle puncture sites.

A minority of graft thromboses occurs in the absence of an identifiable anatomic lesion. Hypotension, intravascular volume depletion, and graft compression during sleep may decrease graft flow and lead to graft thrombosis. Excessive graft compression by patients or dialysis staff attempting to achieve hemostasis following dialysis may lead to graft thrombosis; complete and accurate treatment records may allow the identification and retraining of those individuals who apply excessive pressure.

Prospective Strategies for Maintaining Arteriovenous Access Patency

Prospective Identification of Access Stenoses

As venous outflow stenoses evolve, intra-access pressure increases and access blood flow decreases. Conversely, inflow stenoses lead to decreased intra-access pressures and decreased access flows. Eventually, the access may fail; approximately 90% of access thromboses are associated with venous stenoses (169,171). Prospective monitoring and surveillance of hemodialysis accesses for hemodynamically significant stenoses is advocated by the NKF/KDOQI Clinical Practice Guidelines for Vascular Access update in 2006 (41). A variety of techniques can be utilized to prospectively monitor for

access stenosis (**TABLE 3.10**). It has not been conclusively proven that monitoring and surveillance programs prolong access survival, but a substantial body of evidence supports this conclusion. Access stenoses develop in the great majority of accesses over time; if detected and corrected in a planned and coordinated manner, underdialysis will be minimized and thrombotic events decreased (177). Every hemodialysis unit should institute a vascular access management team whose functions include identification of accesses at risk for dysfunction, tracking access complication rates and instituting protocols to maximize access longevity (178). A number of access monitoring and surveillance methods are available including the following: sequential access flow, sequential dynamic or static pressures, recirculation measurements, and physical examination. The most appropriate monitoring techniques differ, in some cases, for grafts and fistulas.

TABLE 3.10 Methods for the Prospective Identification of Venous Stenoses

Physical examination and clinical assessment (difficulty with needle placement, prolonged bleeding following hemodialysis)
Venous dialysis pressure
Dynamic venous dialysis pressure
Static venous dialysis pressure
Access recirculation
Urea recirculation
Direct measurements of access recirculation (blood temperature monitoring method, saline dilution method, ultrasound dilution method)
Access blood flow
Doppler ultrasonography
Magnetic resonance
Ultrasound dilution
Conductance dilution
Thermal dilution

The goal of an access monitoring and surveillance program is detection of asymptomatic but hemodynamically significant access stenoses. Detection of stenoses and referral for appropriate intervention is key to protecting each dose of dialysis and preventing thrombosis. Hemodynamically significant stenosis is defined as a decrease of greater than 50% of normal vessel diameter and a hemodynamic or clinical abnormality such as abnormal recirculation values, elevated venous pressures, decreased blood flow, a swollen extremity, an unexplained reduction in Kt/V, or inability to achieve prescribed blood-flow rate secondary to elevated negative arterial prepump pressures (177).

Clinical Monitoring and Physical Examination

For both fistulas and grafts, systematic monitoring includes a monthly physical examination by a qualified individual (179). Inspection of the access for swelling and palpation for a pulse and a thrill along the entire length of the graft or fistula vein should be performed (180). A fistula that does not at least partially collapse with arm elevation may have an outflow stenosis. In addition, downstream stenosis can produce an overall dilation of the fistula vein. Visual inspection will reveal new occurrences or changes in character of aneurysms. A low-pitched bruit over an access system and its draining veins should be continuous in systole and diastole. An isolated systolic (discontinuous) bruit or intensification of a bruit suggests stenosis (181). Clinical monitoring of access function is also important. Prolonged bleeding after needle removal is a late manifestation of access dysfunction. Arm edema is a common indicator of

subclavian stenosis. Difficulty with needle placement can be an indicator of intragraft stenosis. An unexplained decrease in the amount of hemodialysis delivered is typically a very late signal indicating the presence of venous stenosis. Arterial inflow stenosis should be suspected if prepump arterial pressures more negative than −250 mm Hg are required to achieve the target blood-flow rate.

Access Blood Flow

Sequential measurement of access blood flow is a widely available method for the prospective monitoring of vascular accesses. Doppler ultrasonographic evaluation, magnetic resonance, and ultrasound dilution are the techniques that have been most extensively studied (41). Unfortunately, these techniques require special equipment and are not in widespread use. Each technique used for access flow measurement has specific limitations. The sequential measurement and systematic trend analysis of data is key to detecting stenosis and referring patients in a timely manner for intervention.

Direct measurement of access blood flow is performed by Doppler ultrasonography or magnetic resonance imaging. Doppler flow is predictive of access patency. Shackleton et al. (167) reported that, in synthetic grafts, Doppler flow less than 450 mL/min had a sensitivity of 83% and a specificity of 75% for the development of thrombosis within 2 to 6 weeks. Rittgers et al. (164) reported a mean blood flow of 307 mL/min in synthetic grafts that clotted within 2 weeks and a mean blood flow of 849 mL/min in synthetic grafts that remained patent. The expense and interobserver variability of Doppler blood-flow measurements have precluded its widespread use. In addition, Doppler measurements cannot be performed during the hemodialysis treatment because the needles prevent proper measurement. Magnetic resonance provides accurate measurements of access flow but is expensive (182).

Indirect techniques to measure access blood flow are ultrasound dilution, conductance dilution, or thermal dilution. A detailed description of the ultrasound dilution technique (183,184) is beyond the scope of this chapter. In brief, the hemodialysis blood lines are reversed. The blood pump is set at a rate of 300 mL/min, and ultrafiltration is turned off. A bolus of isotonic saline is then injected into the venous port. Because the velocity of ultrasound in blood is determined primarily by the blood protein concentration, the isotonic saline will dilute blood protein and change the sound velocity in proportion to the concentration of injected saline in the blood. An ultrasonographic flow sensor on the arterial line measures blood flow in the tubing by a transit-time method and simultaneously detects saline dilution of the blood by measuring the velocity of an ultrasonographic beam. These measurements permit calculation of access blood flow. This technique yields accurate measurements and may be performed during the hemodialysis treatment.

A recent study demonstrated the utility of surveillance of access blood flow by the ultrasound dilution technique (185). Access blood-flow measurements were performed monthly. If access blood flow was less than 600 mL/min or if access blood flow fell by 20% and was less than 1,000 mL/min, fistulography was performed. All patients who agreed to fistulography were found to have significant access stenoses. Percutaneous transluminal angioplasty (PTA) increased access flow by 20% in 80% of the patients. The thrombosis rate for patients in this study was lower than that for historical controls. Of the 10 episodes of thrombosis that occurred during the study period, 8 occurred in patients who did not keep appointments for fistulography or who refused surgical revision after unsuccessful PTA.

Several common errors occur when using any indirect measurement of flow. The dialysis machine blood pump must be accurately calibrated before flow measurement, and this is frequently not done by

busy staff. Access recirculation must be able to be separately calculated from cardiopulmonary recirculation, and this is unavailable with high-efficiency dialysis. Access flow is a function of the ratio of systemic to access resistance. Systemic resistance typically drops as a dialysis session progresses as a function of decreases in cardiac output or blood pressure related to ultrafiltration/hypotension (186). To minimize these errors, protocols should be instituted for monthly flow measurements which include calibration of blood pumps, measurement of flow within the first 90 minutes of a hemodialysis session, and use of the mean value of two separate determinations performed at a single treatment. All measurements of flow, except the ionic dialysance technique, require some disruption or modification of the hemodialysis treatment to obtain data (41). Flow data should be generated monthly for assessment. Systematic analysis of the trend of values in individual accesses is more valuable in detecting dysfunction than an individual reading.

Intra-access Dialysis Pressure

Measurement of dynamic venous dialysis pressure is the least expensive method for the prospective detection of venous stenoses. However, dynamic venous dialysis pressure is affected by factors other than venous stenosis, rendering it the least reliable method for detecting venous stenoses. Because needle gauge and extracorporeal blood-flow rate affect dynamic venous dialysis pressure, these factors must be held constant. It is recommended that dynamic venous dialysis pressure be measured through 15G needles at the beginning of a dialysis session and at blood flows of 50 to 225 mL/min because at higher blood flows, much of the resistance to flow is from the needle, and not the vascular access. In addition, different hemodialysis machines have different pressure monitors and different types and lengths of tubing. Each hemodialysis unit, then, must establish its own threshold pressure. Threshold dynamic venous dialysis pressures range from 125 to 150 mm Hg (41). These variables have led to wide differences among hemodialysis units in their ability to use this technique. The measurement of dynamic venous dialysis pressure is less sensitive and specific than measurement of access blood flow and is very prone to operator error. Indeed, some hemodialysis units have been unable to use this technique.

Elevated static venous dialysis pressures are highly predictive of the presence of venous stenoses. Besarab et al. (187) measured static venous dialysis pressure by inserting a stopcock-transducer system between the venous needle and the venous blood line. Static venous dialysis pressure was measured every 3 to 4 months. Fistulography was performed if static venous dialysis pressure/systolic blood pressure was equal to 0.4, and angioplasty was performed if stenoses resulted in a luminal diameter reduction greater than 50%. As this protocol evolved, the angioplasty rate at their institution increased 13-fold, the thrombosis rate decreased 70%, and the access replacement rate decreased 79%. The measurement of static venous dialysis pressure in this manner requires special equipment. Simplified techniques may allow widespread application of this approach. A static intra-access pressure surveillance protocol is detailed in the most recent NKF/KDOQI Clinical Practice Guidelines for Vascular Access (41). An inexpensive device to measure intra-access pressure has recently been demonstrated and allows in particular home hemodialysis patients to self-monitor their access (188).

Access stenoses do not all occur at the venous outflow tract, and frequently, multiple stenoses exist in a single access. Access pressures are affected by the type of access and location of stenoses. For instance, the intra-access pressure can remain in the normal range if stenosis is present between the needles, or it may actually decrease if inflow stenosis is present. Venous outflow from a native AVF can

occur from multiple collateral veins making intra-access pressure ratios lower than those in synthetic grafts. All of these factors make a single measurement of intra-access pressure or intra-access pressure to systemic pressure ratio less valuable than serial measurements. Tracking sustained pressure changes over time is the most effective way to monitor access dysfunction when using intra-access pressures (189). The NKF/KDOQI 2006 Clinical Practice Guidelines characterize intra-access pressure to systemic pressure ratios which can be used to guide practitioners for referral for intervention. Pressures should be monitored at least twice a month.

A computerized algorithm has been developed that uses an empirical formula to calculate an equivalent intra-access pressure based on the dynamic venous pressure values stored in the machine during a hemodialysis session (190). During a single treatment, the dialysis machine records numerous measurements of dynamic venous pressure simultaneously with a mean arterial pressure. An average equivalent ratio of the intra-access pressure (calculated from the dynamic venous pressure readings) to the systemic pressure is calculated. The average values can be trended with each treatment. When the ratios consistently trend upward and exceed 0.55, the access is at risk for clotting. This technique has been commercialized and can provide monthly reports and trend analysis. These measurements are made during each dialysis treatment.

Urea Recirculation

Hemodialysis access recirculation occurs when dialyzed blood returning through the venous needle reenters the extracorporeal circuit through the arterial needle. Reentry of dialyzed blood into the extracorporeal circuit reduces solute concentration gradients across the dialysis membrane and thereby reduces the efficiency of dialysis. A high degree of access recirculation indicates low-access blood flow and heralds access thrombosis. Access recirculation will not be present until flow falls to the range of 350 to 500 mL/min. In this blood-flow range, fistulas can maintain patency, but grafts are at imminent risk for thrombosis. For this reason, recirculation is not recommended as a routine surveillance system to detect stenosis in grafts (41).

Recirculation is usually caused by a venous stenosis that decreases access blood flow or by reversed needles. When the access blood-flow rate is lower than that demanded by the blood pump, reentry of dialyzed blood into the extracorporeal circuit is necessary to meet the demand of the blood pump (**FIGURE 3.9**). Less commonly, recirculation results from arterial stenosis.

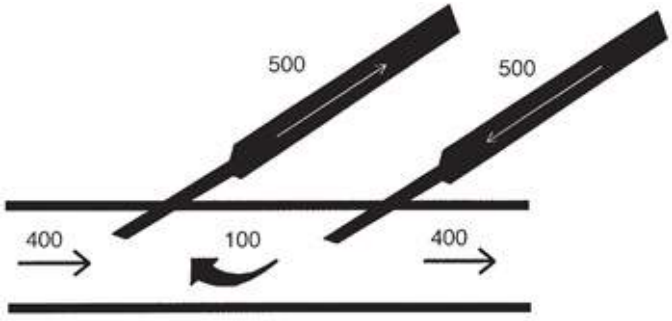

FIGURE 3.9 Access recirculation is 20% because extracorporeal blood flow exceeds access blood flow. (From Depner TA. Techniques for prospective identification of venous stenosis. *Adv Ren Replace Ther* 1994;1:119–130, with permission.)

Access recirculation is calculated from the following formula (**EQUATION 3.1**):

$$\text{Percentage recirculation} = [\text{Systemic (BUN)} - \text{Arterial blood line (BUN)}] / [\text{Systemic (BUN)} - \text{Venous blood line (BUN)}] \times 100 \quad (3.1)$$

Where, ideally, the systemic blood urea nitrogen (BUN) concentration is equal to the BUN concentration in the blood entering the fistula. One can see that access recirculation exists whenever the concentration of urea in arterial line blood is lower than the concentration of urea in systemic blood, indicating reentry of dialyzed blood into the arterial line.

The chief source of error in the determination of access recirculation lies with the determination of the systemic urea concentration. The systemic urea concentration is assumed to be equal to the urea concentration in blood entering the access. Traditionally, systemic blood has been sampled from a peripheral vein in the contralateral arm ("three-needle method"). This method has been found to be inadequate because of two phenomena: AV disequilibrium and venovenous disequilibrium.

The first phenomenon that renders the three-needle sampling method inadequate is AV disequilibrium (or cardiopulmonary recirculation) (191–194). Dialyzed blood (with a low urea concentration) returns to the central veins, dilutes blood returning from the systemic circulation (with a high urea concentration), and reduces the urea concentration in central venous blood (**FIGURE 3.10**). The urea concentration in blood leaving the left heart and entering the hemodialysis access will be lower than the urea concentration in peripheral venous blood. Use of the peripheral vein BUN in the recirculation formula, then, will result in overestimation of access recirculation. The degree of AV disequilibrium increases with increasing extraction of urea by the dialyzer, with increasing extracorporeal blood-flow rate, and with decreasing cardiac output. With increasing extracorporeal blood-flow rate or with decreasing cardiac output, a greater proportion of the cardiac output courses through the dialyzer, increasing the dilution of peripheral venous blood by dialyzed blood.

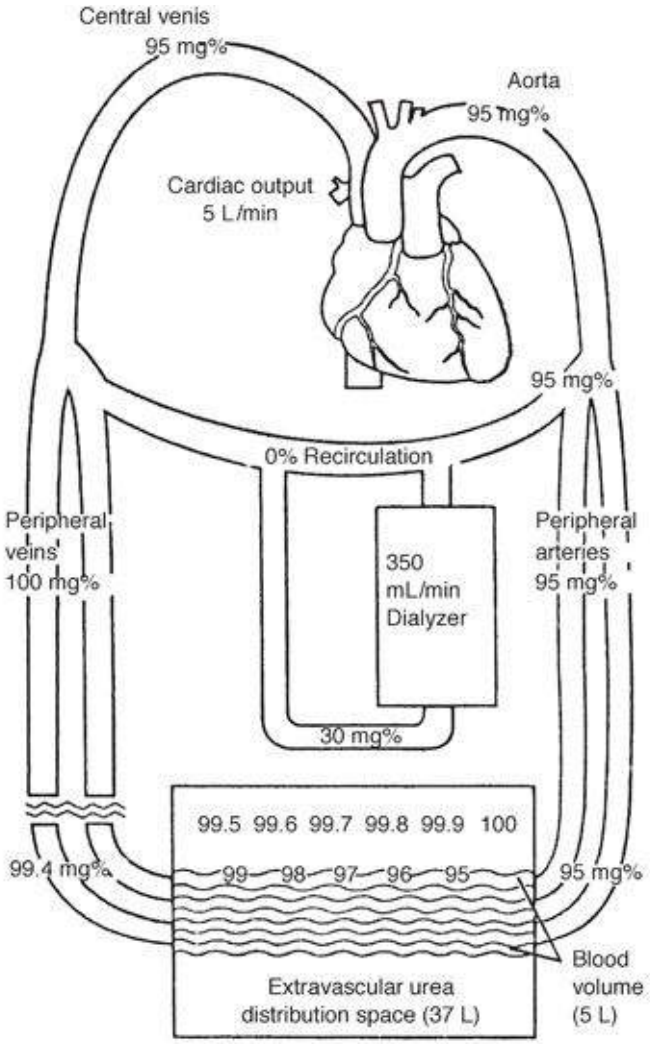

FIGURE 3.10 Arteriovenous recirculation. Dialyzed blood bypasses the systemic circulation, dilutes blood returning from the body, and decreases the concentration of urea in central venous blood. Because the concentration of urea in blood leaving the left heart and entering the access will be lower than the concentration of urea in peripheral venous blood, use of the peripheral vein blood urea nitrogen (BUN) in the recirculation formula will lead to overestimation of access recirculation. In this case, access recirculation is absent, but the percentage of urea recirculation using the peripheral vein method is (100 − 95) / (100 − 30) × 100 or 7%. (From Sherman RA. Recirculation revisited. *Semin Dial* 1991;4:221–223, with permission.)

The second phenomenon that accounts for the different urea concentrations in peripheral venous blood and in blood entering the access is venovenous disequilibrium (191–194). Perfusion of the arm contralateral to the hemodialysis access is low during hemodialysis; urea removal in that limb is diminished in comparison to well-perfused compartments. As a result, the urea concentration is higher in the veins of the contralateral arm than in central venous blood and in blood entering the access. This difference increases with time. Again, use of the peripheral vein BUN concentration in the recirculation formula will result in overestimation of access recirculation.

Fortunately, there is an alternative to the three-needle method. Sherman and Levy (191) have devised the method described in **TABLE 3.11**. In this two-needle method, the extracorporeal blood-flow rate is decreased to 120 mL/min for 10 seconds to clear the arterial line of recirculated blood. Systemic blood is then sampled from the arterial line after the blood pump is shut off. This technique reduces but does not eliminate the effect of AV disequilibrium; systemic blood obtained in this manner will more closely approximate blood entering the hemodialysis access.

TABLE 3.11 Protocol for the Measurement of Urea Recirculation

Turn off ultrafiltration 30 min after the initiation of hemodialysis.
Draw arterial (A) blood line and venous (V) blood line samples.
Immediately decrease extracorporeal blood-flow rate to 120 mL/min.
Turn blood pump off exactly 10 s after decreasing blood-flow rate.
Clamp arterial line immediately above port.
Draw systemic (S) sample from arterial line port.
Measure blood urea nitrogen (BUN) in the three samples.
Percentage recirculation = (S − A) / (S − V) × 100

Adapted from National Kidney Foundation. *NKF-K/DOQI Clinical practice guidelines for vascular access*. New York, NY: National Kidney Foundation, 2001:48, with permission.

The threshold urea recirculation value that should prompt one to request fistulography is not known. Because access recirculation should not occur unless the access blood-flow rate is less than the extracorporeal blood-flow rate demanded by the blood pump (195), any degree of access recirculation is abnormal. Indeed, the blood temperature monitoring method and the saline dilution method have demonstrated that recirculation is absent in well-functioning fistulas (196,197). These techniques directly measure access recirculation and do not require urea measurements; the effects of AV and venovenous disequilibrium are completely eliminated.

Unfortunately, threshold values of urea recirculation have been determined using the three-needle (peripheral vein) method, which overestimates access recirculation (198,199). When the recommended two-needle method is used, urea recirculation values greater than 10% should prompt further investigation. When values exceed 20%, the possibility of reversed needle placement should be considered before fistulography is requested. The blood temperature monitoring method and the saline dilution method provide more accurate measurements of recirculation and are preferred to urea-based methods for measuring recirculation. If recirculation exceeds 5% when measured by these techniques, fistulography should be requested (41).

Treatment of Access Stenoses and Thrombosis

PTA is effective for the treatment of venous stenoses of both autogenous and non-autogenous accesses. The importance of prospective detection of venous stenosis cannot be overemphasized; patency rates are far higher for stenotic accesses angioplastied before thrombosis than for accesses angioplastied at the time of thrombolysis (172,200).

Angioplasty is well tolerated by patients; hospitalization is not required, and hemodialysis may be performed immediately after the procedure. Venous stenoses may also be corrected by surgical revision. This approach, however, usually requires hospitalization and, by use of jump grafts, sacrifices a segment of vein and eliminates a potential vascular access site. Studies comparing PTA with surgical revision have yielded conflicting results (201,202), and one approach cannot be recommended over the other.

PTA is effective for the treatment of venous anastomotic stenoses (**FIGURE 3.11**), inflow stenosis, central vein stenoses (**FIGURE 3.12**), and intragraft stenoses. In addition, PTA may correct multiple venous stenoses, long (6 to 40 cm) venous stenoses, and complete venous occlusions. Initial technical success is achieved in 82% to 94% of cases. In a large and carefully studied series, a successful treatment was defined as one that maintained graft patency and did not need to be repeated; success rates (unassisted

patency rates) were 61% at 6 months and 38% at 1 year. Success rates for repeat treatments were no different than success rates for initial treatments. Other investigators have achieved similar results (174,201,203–208). Conversely, several small randomized trials have questioned the durability of PTA as a therapeutic method (209,210).

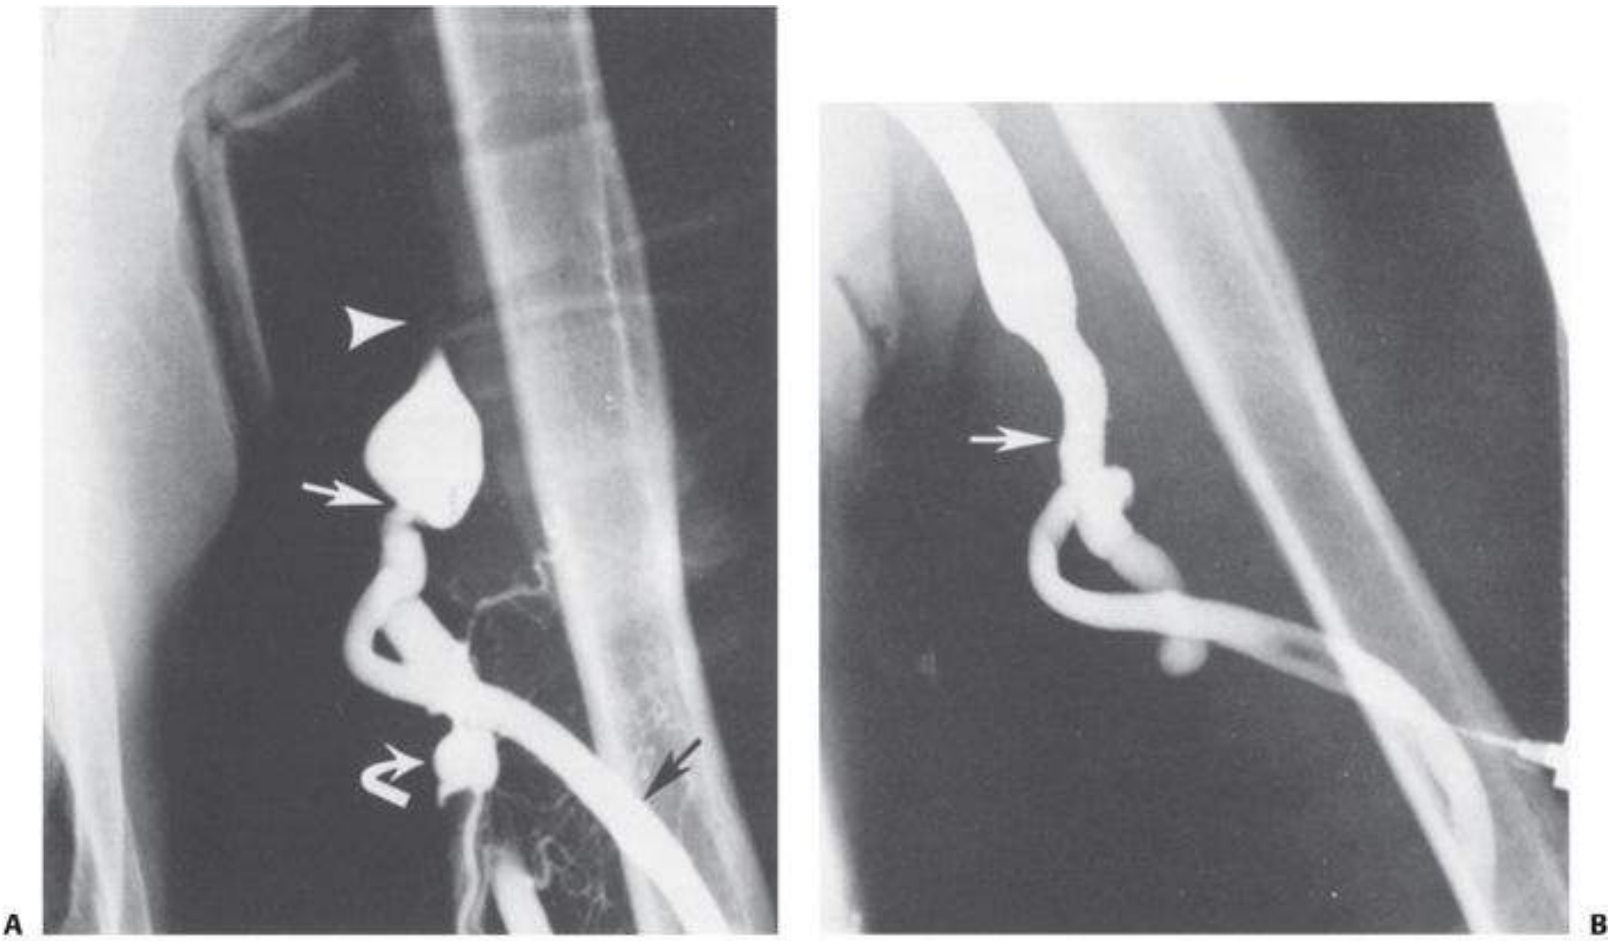

FIGURE 3.11 Stenosis at vein-graft anastomosis **(A)** before and **(B)** after percutaneous transluminal angioplasty. (From Schwab SJ, Saeed M, Sussman SK, et al. Transluminal angioplasty of venous stenoses in polytetrafluoroethylene vascular access grafts. *Kidney Int* 1987;32:395–398, with permission.)

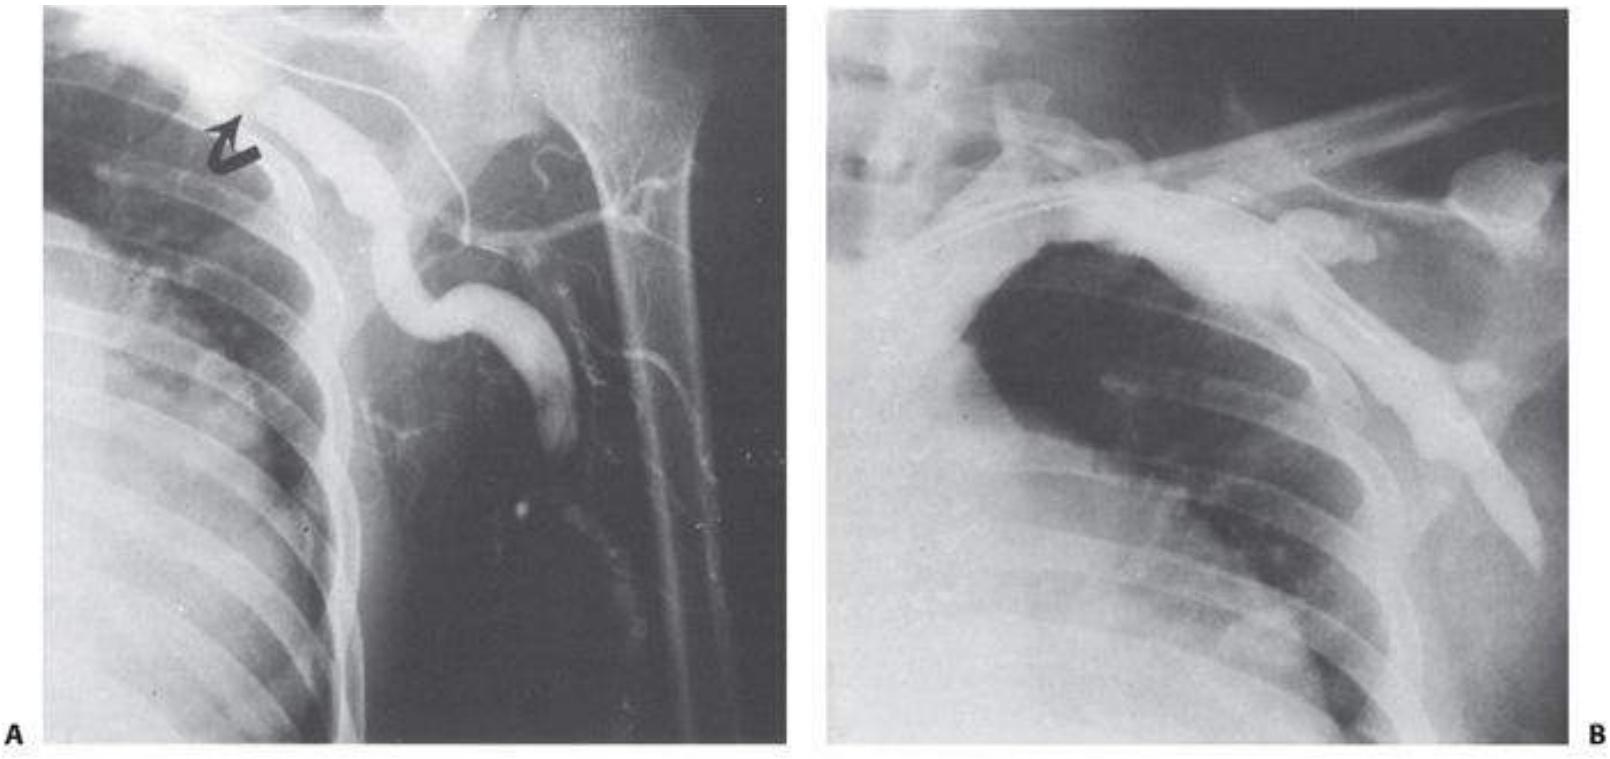

FIGURE 3.12 Subclavian vein stenosis **(A)** before and **(B)** after percutaneous transluminal angioplasty. (From Schwab SJ, Quarles LD, Middleton JP, et al. Hemodialysis-associated subclavian vein stenosis. *Kidney Int* 1988;33:1156–1159, with permission.)

Self-expandable endovascular stents and more recently stent grafts, placed percutaneously, have been used in conjunction with PTA for the treatment of graft venous anastomotic stenoses (211) and appear superior to just angioplasty alone (211). Drug-eluting balloons have first been used (212) with promising results, albeit at a very high cost.

Once thrombosis occurs, surgical thrombectomy, pharmacomechanical thrombolysis, or mechanical thrombectomy may be employed. No matter which technique is performed, correction of the venous stenosis should be performed to maintain access patency. All thrombectomies are associated with micropulmonary emboli. Autogenous accesses with higher thrombus burden are more likely to cause clinically apparent pulmonary emboli. Palder et al. (169) demonstrated that surgical thrombectomy combined with bypass of the venous stenosis (**FIGURE 3.13**) produced significantly longer patency than did simple thrombectomy or patch angioplasty. It has been reported that surgical thrombectomy coupled with PTA is as effective as surgical thrombectomy coupled with surgical revision (213). Success rates for thrombectomy of prosthetic access are usually >90%, while those for autogenous accesses are >70% to 80%. Large aneurysms with very large thrombus burden limit the feasibility and safety of the endovascular approach; however, mini-incision and sheath-hole thrombectomies have expanded the range of accesses that can be approached with a modified endovascular technique. One approach cannot be recommended over the others; instead, the decision as to whether an individual patient should be treated by surgical thrombectomy or by a nonsurgical technique should be guided by the expertise of the treating institution's vascular surgeons and interventional radiologist or nephrologist.

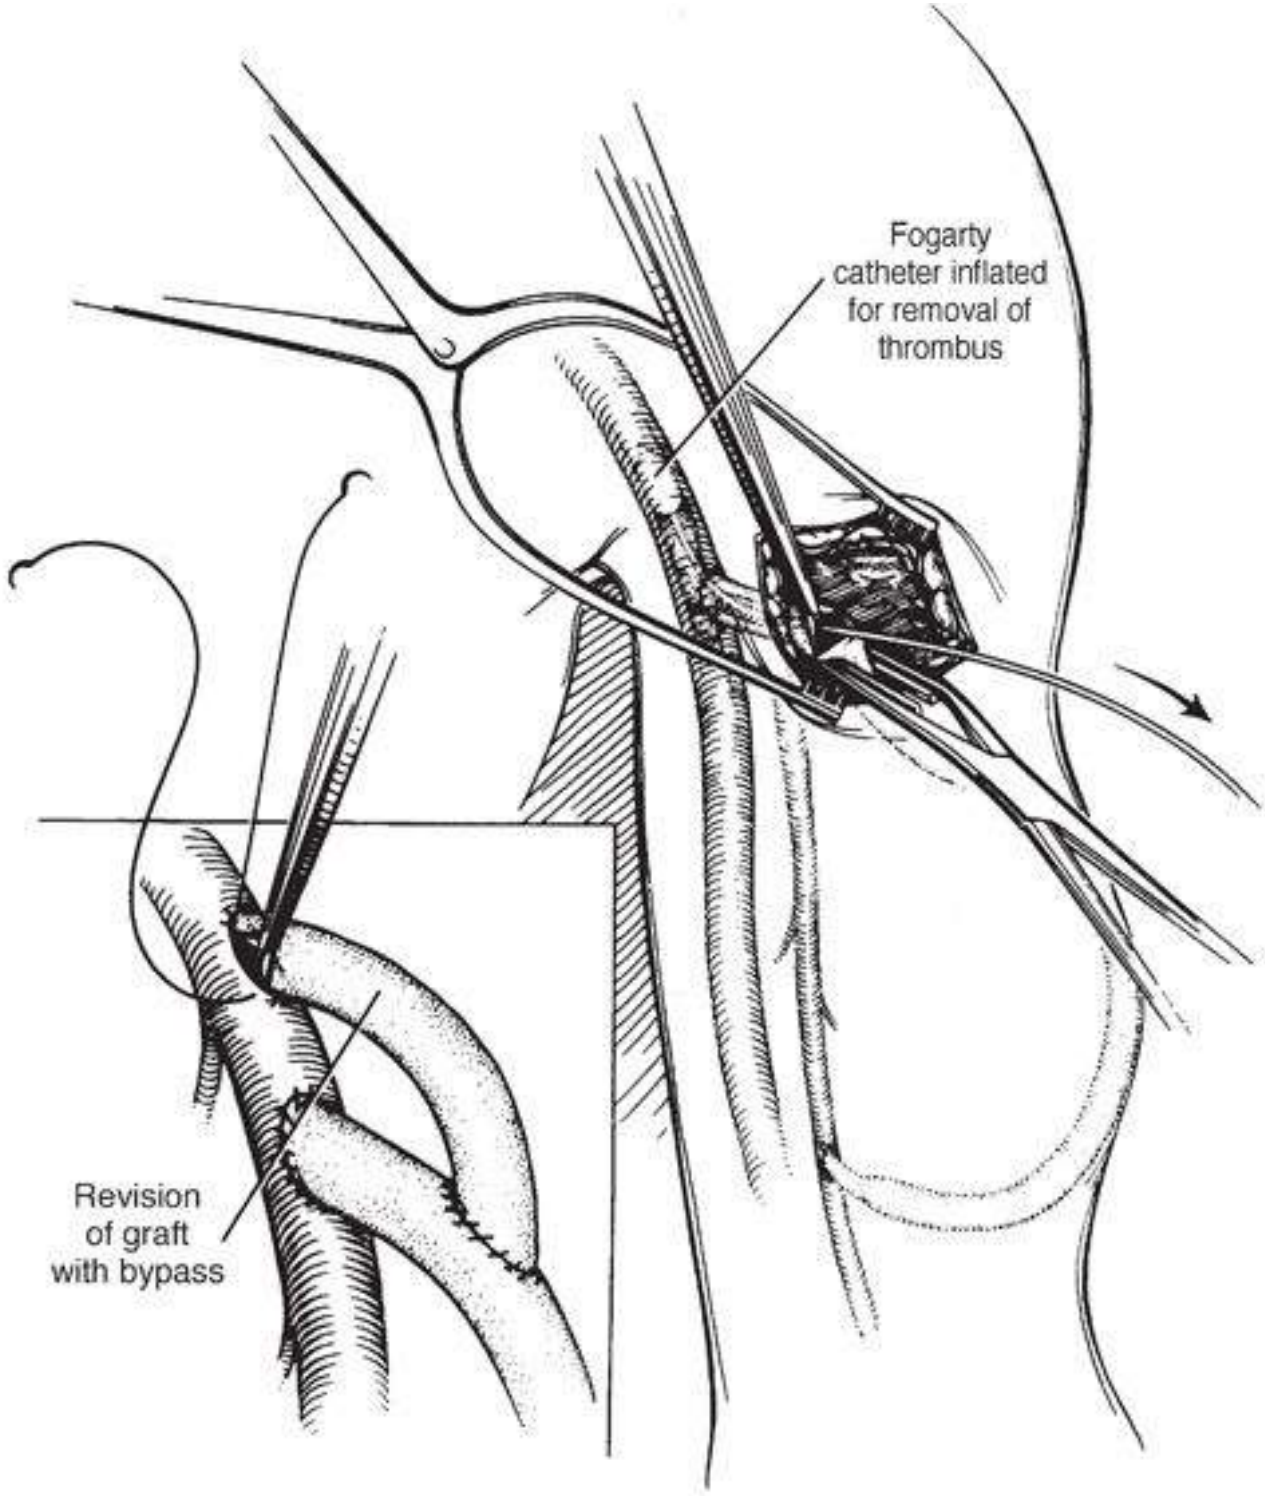

FIGURE 3.13 Thrombectomy of polytetrafluoroethylene graft and bypass of venous stenosis. (From Stickel DL. Renal dialysis access procedures. In: Sabiston DC Jr, ed. *Atlas of General Surgery*. Philadelphia, PA: WB Saunders, 1994:90–98, with permission.)

In pharmacomechanical thrombolysis (pulse-spray thrombolysis) (172,214), angiography is performed to determine the extent of the clot and to visualize the graft and draining veins. Two catheters with closely spaced side holes are inserted into the midportion of the graft in a crossed manner (**FIGURE 3.14**). A thrombolytic agent is "sprayed" into the clot under high pressure, and thrombolysis is achieved by both pharmacologic and mechanical means. An angioplasty balloon is then used to macerate residual clots and to dilate the venous stenosis. This technique is now rarely used.

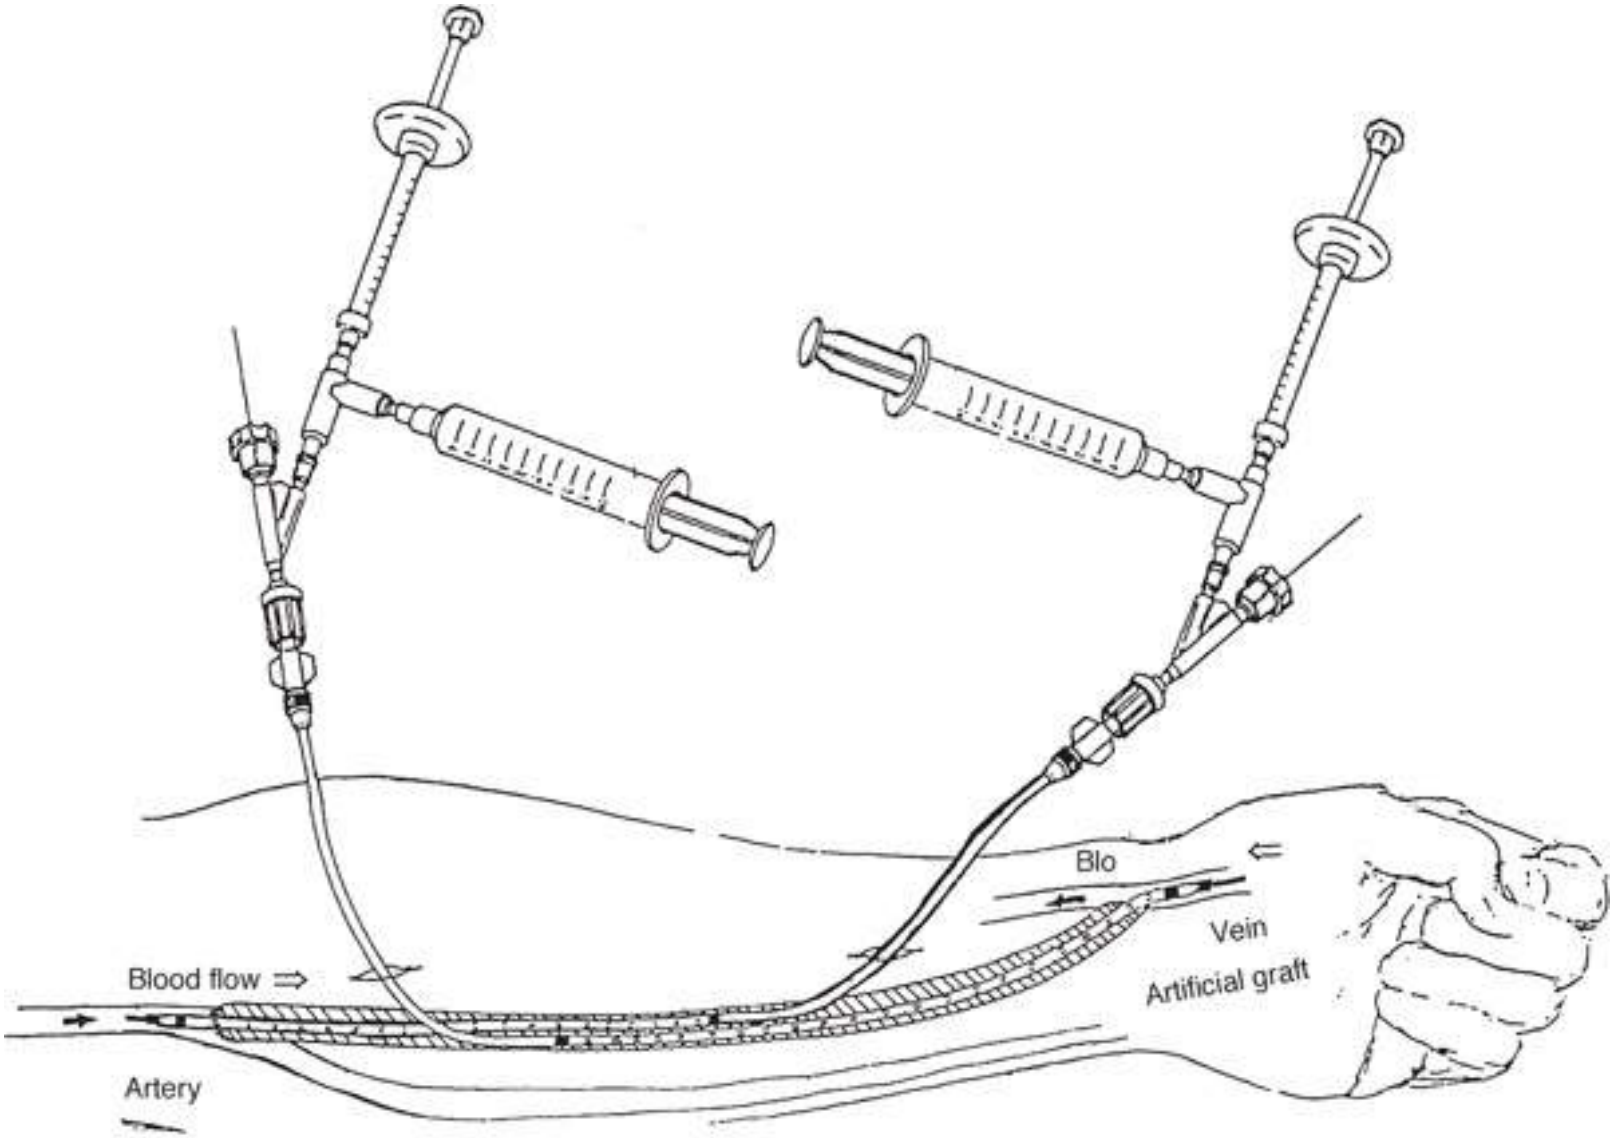

FIGURE 3.14 Pulse-spray thrombolysis. (From AngioDynamics Inc., Glens Falls, New York, with permission.)

The technique of mechanical thrombolysis uses a variety of devices to macerate thrombus and then aspirate or remove otherwise organized thrombus from the vascular lumen (24,214–216). These techniques may be performed in 1 to 2 hours, and the access may be used immediately for dialysis. Angioscopic observation has demonstrated that endovascular techniques utilizing wall-contact devices during thrombectomy leave less detectable material than other techniques (217). Surgical thrombectomy and revision may yield a similar patency rate (218,219), but surgical treatment generally entails delays, hospitalization, and extension of the access up the extremity.

A recent analysis of graft thrombus obtained during thrombectomy revealed colonization in one-third of cases (220).

Other Arteriovenous Access Complications

Infection of Arteriovenous Accesses

Vascular access infection is a serious and, in some cases, life- threatening problem.

Autogenous access infections are uncommon; they are usually localized and can usually be treated successfully with antibiotic therapy (169). However, because these are endovascular infections, it has been recommended that they should be treated as subacute bacterial endocarditis—with 6 weeks of antibiotic therapy.

Synthetic fistula infections are not uncommon; they are the second most common cause of fistula loss (169,221,222). Gram-positive cocci—*S. aureus* and, less commonly, *S. epidermidis* and streptococcal species—are the culprits in most cases. Gram-negative bacteria account for approximately 15% of episodes of bacteremia in hemodialysis patients (223–226).

Some risk factors for graft infection are beyond the nephrologist's control. Intravenous drug use (169), dermatitis overlying the graft, and poor personal hygiene (223,227) predispose patients to graft infection. Femoral grafts have a high infection rate (228) most likely because of the proximity of the graft to the perineum. Nevertheless, preventive measures should be undertaken. We strongly believe that patients should wash the skin overlying their grafts with soap and water before each hemodialysis treatment. This practice may decrease the likelihood of inadvertent introduction of bacteria into the bloodstream during graft cannulation. Monitoring of graft cannulation and infection records may allow one to identify hemodialysis staff who employ poor needle insertion technique.

Fever, chills, and rigors are the typical presenting complaints of the bacteremic hemodialysis patient. Physical evidence of graft infection is often absent. The febrile hemodialysis patient with a synthetic fistula should be presumed to have graft-associated bacteremia unless the history, physical examination, and initial investigations provide strong evidence to the contrary. Blood cultures should be obtained. Initial antibiotic therapy should be effective against gram-positive organisms (including *Enterococcus*) and gram-negative organisms. At our institution, we administer loading doses of vancomycin and an aminoglycoside. Appropriate gram-negative coverage can also be provided by a third-generation cephalosporin, such as ceftazidime, dosed immediately upon the completion of dialysis. Because methicillin-resistant *S. aureus* (MRSA) and coagulase-negative staphylococci are common culprits, a β-lactam antibiotic should not be used as an empiric agent. The antibiotic regimen can be simplified if blood cultures yield a culprit. If staphylococci are isolated that are susceptible to β-lactam antibiotics, a β-lactam should be substituted for vancomycin unless the patient has a β-lactam allergy.

Patients with gram-positive bacteremia who defervesce promptly in response to antibiotic therapy and whose grafts have no associated pustule or abscess can often be successfully treated with intravenous antibiotics alone. However, extensive graft infection may be present even when the physical examination is unremarkable. If fever or bacteremia persists, strong consideration should be given to graft excision. Staphylococcal bacteremia has a propensity to lead to metastatic infection; endocarditis, osteomyelitis, septic pulmonary emboli, empyema, septic arthritis, and meningitis have been reported. Persistent fever or bacteremia should also prompt one to search for evidence of metastatic infection. In hemodialysis patients with *S. aureus* bacteremia, this search should include transesophageal echocardiography to exclude infective endocarditis. If fever and bacteremia promptly remit and if there is no evidence of metastatic infection, a 3-week course of antibiotic should suffice. Otherwise, a 6-week or longer course of antibiotic therapy is required. Regardless of the length of therapy, blood cultures should be obtained after completion of therapy to ensure that the infection has been eradicated. Gram-negative infections less commonly lead to metastatic infection, and a 2- to 3-week course of antibiotic therapy should suffice.

Evaluation by the vascular surgeon is mandatory if a pustule or abscess overlies the graft. Localized infection of the graft may be treated by simple incision and drainage or by partial graft excision and bypass grafting. Extensive infection necessitates total graft excision. Grafts placed within the past month must be completely excised even if the infection is thought to be localized; because these grafts are

incompletely incorporated into surrounding tissue, the infection is unlikely to be localized (41). Finally, it should be noted that bleeding through an area of eroded skin overlying a synthetic graft may be the initial manifestation of graft infection. “Herald bleeding” mandates evaluation by the vascular surgeon.

Vascular Access–Related Heart Failure

If fistula blood flow exceeds 20% of cardiac output, high-output congestive heart failure may develop in patients with ventricular dysfunction (229). Reduction of fistula blood flow by banding or interposition of a tapered synthetic segment may reduce symptoms (230–232). Reduction of access flows may be of particular importance in kidney transplant patients. While overt progressive heart failure is uncommon, other consequences of prolonged high cardiac output such as pulmonary hypertension and cardiac hypertrophy are more frequent. For these reasons and enlarging dialysis, access should prompt evaluation of access flows. Access flows greater than 1,500 mL/min with signs of increase intra-access pressures (pulsatility) should prompt dedicated observation if cardiac function or skin integrity are compromised.

Fistula takedown should be performed in refractory cases. In the authors’ experience, although possible, this occurs rarely.

Hand Ischemia

Hand ischemia following fistula placement may be due to arterial insufficiency or venous hypertension. Arterial insufficiency results from direct shunting of arterial blood through the low-resistance fistula and from vascular steal, in which blood flows retrograde from the palmar arch through the radial artery into the fistula. Symptoms of hand ischemia usually decrease in the weeks following fistula construction, but close observation is warranted. If symptoms are severe (coldness or loss of motor function), fistula blood flow may be reduced by banding or by interposition of a tapered synthetic graft (230–232). If symptoms persist, or if hand viability is ever threatened, the radial artery distal to the anastomosis may be ligated. For brachial-cephalic autogenous accesses, a distal revascularization and interval ligation (DRIL) procedure may be performed in addition to banding. Proximalization of the inflow is another alternative if access flows are already low.

Venous hypertension may occur after side-to-side anastomosis of the radial artery and cephalic vein. In the presence of a proximal venous stenosis or occlusion, there may be retrograde blood flow through the fistula and arterialization of the distal venous system; the pressure in the venous system of the hand will approach arterial pressure. Treatment consists of ligation of the distal vein and correction of the venous stenosis.

Aneurysms and Pseudoaneurysms

True aneurysms occur very commonly in native fistulas and generally cause no problems. Surgical intervention is required only if the aneurysm compromises the arterial anastomosis or shows rapid expansion raising a danger of dissection or rupture.

Pseudoaneurysms of synthetic grafts appear as progressive damage to the graft material leads to inability to seal needle puncture sites. Pseudoaneurysms may rapidly expand or may threaten the viability of the overlying skin. Surgical intervention should be considered in these circumstances to prevent hemorrhage. Surgical treatment consists of excision of the involved graft segment and placement of an interposition graft.

Central Vein Stenosis

Even remote history of a tunneled catheter may over time lead to symptomatic central venous stenosis. Asymptomatic (no arm swelling) central venous stenosis should not be treated as recurrence is more severe after angioplasty. We know little about different types of central venous stenosis. However, some respond to angioplasty, while others recur rapidly. Some of these then respond well to placement of a noncovered stent, while others quickly require placement of stent graft.

A special situation is the external compression of the subclavian vein between the clavicle and the first rib that can be treated with resection of the first rib or the medial clavicle.

In some patients, there is compression of the left brachiocephalic vein between sternum and an enlarged aortic arch. This condition can respond to stent placement but as this is not a stenosis of the vessel, it should be left alone unless symptomatic.

Buttonholes

Buttonholes may be established to allow use of an access with limited length of the needle insertion segment. However, buttonholes are associated with an increased risk of local and systemic infection (233). Clinically, buttonholes mask the presence of outflow stenosis as bleeding is minimized. In this setting (impending), blowout of a buttonhole may occur (**FIGURE 3.15**), which requires surgical resection and repair of the underlying vessel. Often, there is infection of the buttonhole tract and resection is complicated.

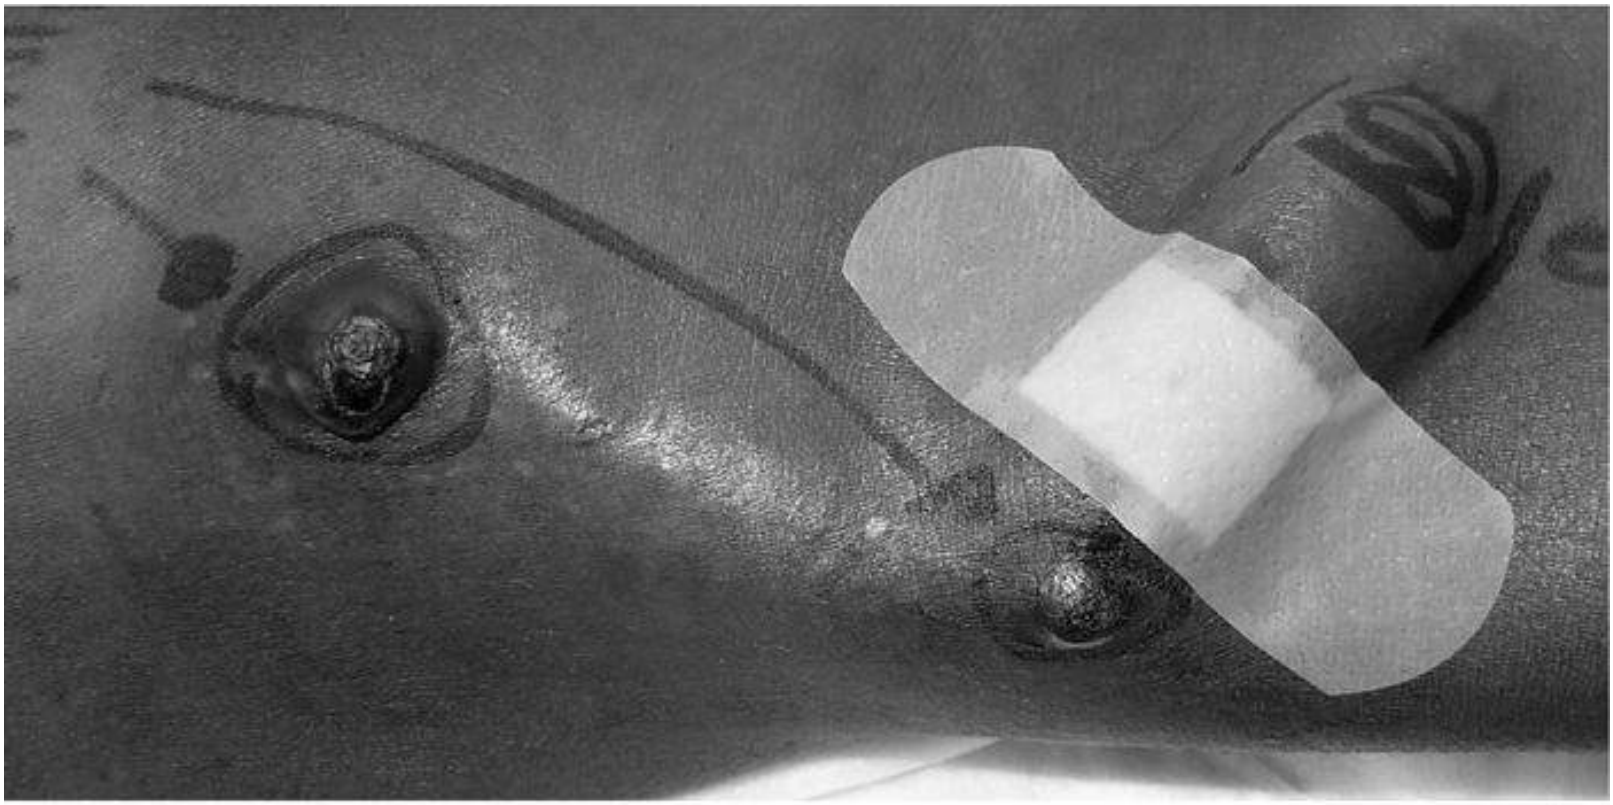

FIGURE 3.15 Buttonholes in pressurized access, presented with bleeding from buttonhole.

Instead of creating buttonholes, an implantable needle guide may be used to assist in creating a tract (234).

More frequent needle insertion with daily dialysis adds strain to the needle insertion sites (235). We therefore recommend use of two sets of buttonholes in patients who dialyze more frequent than every other day.

Other Methods for the Prevention of Access Thrombosis

Prophylactic use of anticoagulation to extend access survival has been evaluated. Two randomized controlled trials, one with low-dose warfarin and the other with clopidogrel in combination with aspirin, have not demonstrated a decrease in thrombotic events or prolonged graft survival. Both studies were associated with statistically significant bleeding complications in the treated populations (236,237). A prospective, randomized trial suggested that dipyridamole decreases the thrombosis rate in patients with new PTFE grafts but that aspirin does not (238). Dipyridamole was not found to be beneficial in patients with previously thrombosed grafts. Fish oil, by inhibiting cyclooxygenase or preventing intimal hyperplasia, may prove to be useful. In a small randomized study, fish oil at a dose of 4,000 mg daily was found to increase the patency rate for newly constructed synthetic grafts (239). Angiotensin-converting enzyme (ACE) inhibitors also hold promise. In animal models, angiotensin II induces smooth muscle proliferation, and ACE inhibitors prevent myointimal proliferation. In a retrospective analysis of synthetic graft survival, it was found that ACE inhibitor therapy was associated with a higher access survival rate (240).

Summary

Double-lumen central venous catheters are the preferred form of vascular access for acute hemodialysis. Insertion complications become less likely when ultrasonographic guidance is used and as the operator gains experience. Several measures may be undertaken that will reduce the likelihood of catheter-related infection. Catheter thrombosis remains a major problem but may be managed by instillation of lytic agents into the catheter lumens or by replacement of the catheter over a guidewire. Because of the association of subclavian vein catheterization with subsequent development of subclavian vein stenosis, subclavian vein catheters should be avoided.

Because autogenous arterial venous accesses are most likely to provide long-term complication-free access, they remain the preferred form of chronic vascular access. Careful planning months before the anticipated need for hemodialysis will maximize the chance for successful access creation and minimize catheter dialysis time. If an autogenous access cannot be created, a PTFE graft should be placed. The use of cuffed catheters as permanent vascular access is discouraged. Once permanent vascular access is established, maintenance of its patency presents a continual challenge to the nephrologist, dialysis staff, vascular surgeon, and interventional nephrologist/radiologist.

Thrombosis is the leading cause of vascular access loss, and venous stenoses are the leading cause of vascular access thrombosis. Prospective detection and correction of venous stenoses appears important to prolong access patency. Institution of a vascular access team whose role is the regular evaluation of access flow in combination with the physical examination is needed to preserve access function.

CHAPTER 4

Anticoagulation Strategies during Hemodialysis Procedures

William J. Dahms, Jr.

Since the inception of the chronic hemodialysis procedure in the 1960s, anticoagulation has remained an important component of adequate treatment management. Traditionally, the challenging task of preventing clotting of the extracorporeal circuit without placing the patient at increased risk for bleeding complications has been managed using unfractionated heparin. However, the recently increased applications of continuous renal replacement therapies (CRRTs) to treat kidney disease have expanded the eligible dialysis patient population. These patients are often critically ill, and many of them have contraindications to heparin use. This chapter reviews some of the approaches to anticoagulation for dialysis procedures. The use of unfractionated heparin as well as low molecular weight heparin (LMWH) will be discussed, as will some of the newer alternative anticoagulant strategies available to nephrologists.

COAGULATION IN DIALYSIS PATIENTS

There remains no universally accepted algorithm for anticoagulation in dialysis patients. This may be due in part to individual patient factors that influence abnormal hemostasis in end-stage kidney disease (ESKD). Although the uremic state tends to cause a bleeding diathesis, dialysis patients have been shown to exhibit hypercoagulable tendencies as well. Some evidence of a thrombotic susceptibility in patients with ESKD includes increased plasma concentrations of fibrinogen (1–3), increased factor VII activity (2,4), and increased fibrinolytic activity (1,3,5). Pulmonary emboli are more common in dialysis patients versus age-matched controls (6), and the anticoagulant proteins C and S have been shown to be deficient in this population (3,7,8).

In addition to patient factors, dialysis procedures themselves invariably induce nonphysiologic levels of turbulent blood flows with high shear stress, which can activate platelets. The exposure of blood to the artificial surfaces of dialysis tubing has also been shown to be thrombogenic, especially in the arterial

and venous bubble traps where blood flow can be slower or even static at times (9).

The type of membrane selected for the dialysis procedure may impact thrombogenicity. Several studies have shown that membranes composed of regenerated cellulose (cuprophane) lead to more activation of coagulation compared with membranes composed of newer materials such as polyacrylonitrile or polysulfone (10–13). The results of two studies suggest that polysulfone membranes have minimal effects on coagulation activation as measured by thrombin–antithrombin complex levels and platelet activation (10,14). The process of dialysis membrane sterilization may affect anticoagulation. This was suggested after significant thrombocytopenia was noted following the introduction of dialyzers that has been sterilized using electron beam technology (15).

The presence of an arteriovenous (AV) access is yet another predisposing factor toward turbulent blood flow, platelet activation, and thrombosis (7). The risk for access thrombosis is greater in polytetrafluoroethylene (PTFE) grafts compared to native AV fistulae (16), and conditions such as systemic lupus erythematosus (SLE) may exacerbate the tendency to thrombose the access (17).

With the interplay of all of the aforementioned clinical entities, adequate anticoagulation should be viewed as essential to the hemodialysis procedure.

UNFRACTIONATED HEPARIN

The anionic glycosaminoglycans present in unfractionated heparin prevent clotting of blood by the inhibition of serine proteases (18). Because heparin used for hemodialysis is a mixture of components, heparin formulations are standardized in terms of international units (IU), using a United States Pharmacopeia (USP) standard heparin as a reference. The therapeutic window for adequate anticoagulation without excessive bleeding using heparin is narrow. As such, measurement of the anticoagulant effects of heparin would be optimal. Unfortunately, the measurement of blood heparin levels is not practical. Historically, assays such as the activated clotting time (ACT) and the whole blood partial thromboplastin time (WBPTT) have been used to measure the anticoagulability of heparin. Both these tests use whole blood and can produce results in minutes, making them desirable for clinical use. Following enactment of the Clinical Laboratory Improvement Amendments (CLIA) of 1988, automated clotting time measurement systems replaced the manually performed WBPTT as the means of monitoring anticoagulation during hemodialysis in the United States (19). This law requires that any laboratory testing of human specimens be performed in a certified laboratory that incorporates quality control, proficiency testing, and calibration verification in its testing program.

Such procedures are associated with increased overhead costs and are difficult to incorporate into everyday use in a busy hemodialysis center. Indeed, many dialysis units in the United States have abandoned the testing of blood for clotting parameters and moved toward developing heparin-dosing algorithms. One such strategy has been developed based on a nonlinear mixed effects population kinetic model that was designed to estimate heparin-loading doses and infusion rates (20,21). In this equation, the loading dose of heparin is derived as follows (**EQUATION 4.1**):

$$\text{Loading dose (IU)} = 1{,}600 + 10 \times (\text{Wgt} - 76) - 300 \times \text{Fd} - 100 \times \text{Fs} \qquad (4.1)$$

In this equation, Wgt is the patient's weight (kg), Fd indicates the presence (Fd = 1) or absence (Fd =

0) of diabetes, and Fs indicates that the patient is (Fs = 1) or is not (Fs = 0) a smoker. The proposed infusion rate based on this model was 1,750 IU/h. Using these parameters to predict heparin-loading doses and infusion rates, one study noted a significant improvement in dialyzer reuse rates with no decrease in the delivered dose of dialysis (19).

Data from Ward et al. (22) demonstrate that the sensitivity to heparin in nonuremic hemodialysis patients correlates with body weight. Low et al. (23) suggested an initial heparin-loading dose of 20 to 25 IU/kg was sufficient to maintain adequate anticoagulation during dialysis based on measured WBPTT. In 2002, the European Renal Association (24) published guidelines for anticoagulation in hemodialysis patients. Their recommendations include a loading dose of approximately 50 IU/kg followed by a continuous infusion rate of 800 to 1,500 IU/h. This approach of giving a loading dose followed by a continuous infusion of heparin offers the nephrologist the ability to titrate dosing to the lowest possible amount to prevent clotting of the circuit while avoiding excessive bleeding risk. The heparin infusion is then titrated off over the last 30 minutes of the dialysis session to allow for clotting time to decrease and to avoid bleeding when the access needles are withdrawn.

An alternative anticoagulation strategy uses intermittent heparin dosing. An initial loading dose of heparin is administered, followed by one or more additional bolus doses during dialysis. Intermittent dosing is simple and eliminates the need for an infusion pump and syringe. However, this approach results in periods of over- and under-anticoagulation compared to the loading dose and constant infusion method (25). Furthermore, the use of intermittent dosing is time-consuming and requires the constant attention of dialysis personnel to ensure that timely heparin boluses are given. **FIGURE 4.1** illustrates the anticoagulation profiles obtained with a continuous infusion versus intermittent bolus dosing of heparin after the initial loading dose is given.

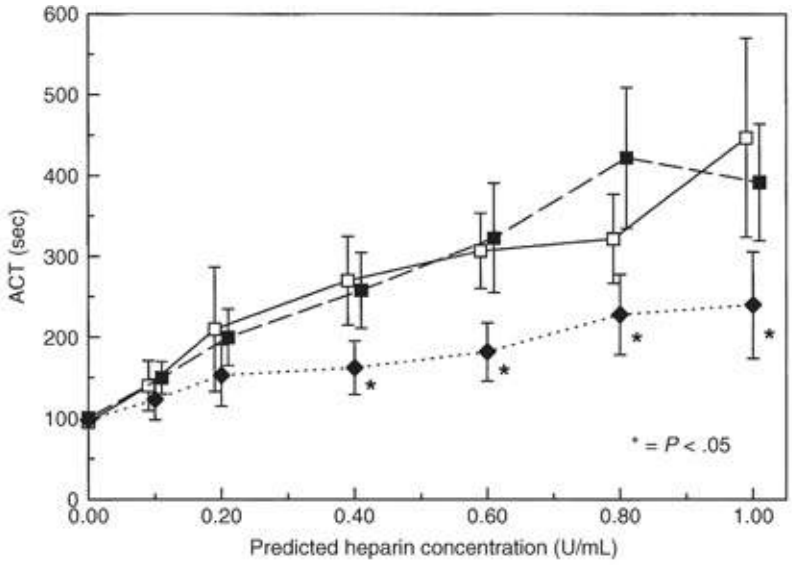

FIGURE 4.1 Idealized anticoagulation profiles during hemodialysis. The solid line shows the clotting time profile obtained with a loading dose and constant infusion of heparin; the broken line shows the profile obtained with a loading dose and midtreatment bolus of heparin. (From Ward RA. Heparinization for routine hemodialysis. *Adv Ren Replace Ther* 1995;2:362–370, with permission.)

Invariably, nephrologists will encounter patients who are at a high risk for bleeding complications. These patients include, but are not limited to, those who have recently had or will be undergoing surgery, those with a history of gastrointestinal bleeding, those with a history of hemorrhagic stroke, and those with severe liver disease. In these cases, low-dose heparin use has been shown to be an effective strategy for anticoagulation (26–28). Low-dose heparinization is achieved using a smaller bolus dose of 10 to 25

IU/kg. Maintenance heparin can then be given either as an infusion at a rate of 11 to 22 IU/kg/h or through small intermittent boluses. However, with low doses of heparin, increases in clotting time have been observed to vary by ±50% from day to day in individual patients who are given the same dose of heparin (29). Taking this into account, low-dose heparin should be reserved for select cases and performed with the understanding that minimizing the bleeding risk may result in increased clotting of the extracorporeal circuit on some occasions.

In addition to the inherent bleeding risks associated with its use, heparin therapy has other associated side effects including worsening of osteoporosis and dyslipidemia, allergic reactions such as pruritus, and thrombocytopenia. Hyperkalemia may be seen due to inhibition of aldosterone synthase (30), although this is seldom an issue for patients with ESKD. The development of heparin-induced thrombocytopenia (HIT), a rare but life-threatening immune-mediated disorder, requires absolute heparin avoidance during dialysis.

LOW MOLECULAR WEIGHT HEPARIN

LMWH preparations are made from depolymerized fractions of heparin. These smaller saccharide chains have a molecular weight of 4 to 8 kDa and inhibit factor Xa up to threefold more when compared to unfractionated heparin, with less affinity for thrombin inhibition (9). For these reasons, monitoring the effect of LMWH requires the measurement of antifactor Xa activity as the activated partial thromboplastin time (aPTT) and ACT are not reliable (31,32). LMWH preparations have been extensively studied during dialysis in patients with ESKD. The longer half-life of LMWH allows these preparations to be given as a single predialysis dose, usually based on body weight (33–36). However, should the dialysis session be scheduled for greater than 4 hours, additional LMWH may need to be given either as a bolus or through continuous infusion (37,38). **TABLE 4.1** illustrates the commonly used dosages of LMWH during hemodialysis.

TABLE 4.1 Common Dosing of Alternative Anticoagulants During Hemodialysis

Medication	Category	Dose	Reference
Enoxaparin	LMWH	100 anti-Xa-IU/kg administered as bolus dose	36
Dalteparin	LMWH	70 anti-Xa-IU/kg administered as bolus dose	35
Tinzaparin	LMWH	2,000–4,500 anti-Xa-IU, adjust dose based on clot visibility and postdialysis bleeding	9,34
Lepirudin	DTI	0.1–0.15 mg/kg bolus before dialysis session 0.005–0.01 mg/kg/h infusion for CRRT	9,39
Argatroban	DTI	250 μg/kg bolus predialysis, followed by either a repeat bolus of 250 μg/kg midsession or continuous infusion of 2 μg/kg/min; dose reduction required with hepatic insufficiency	40
Danaparoid sodium	Heparinoid	35 units/kg bolus predialysis	41,42

LMWH, low molecular weight heparin; DTI, direct thrombin inhibitor; IU, international units; CRRT, continuous renal replacement therapy.

Some authors advocate the use of LMWH as the preferred agent for anticoagulation in patients with ESKD (24). The appeal of single bolus dosing is one potential advantage offered compared to unfractionated heparin. Indeed, in one study, scanning electron microscopy was used to demonstrate that membrane-associated clotting during dialysis was less after treatment with LMWH compared to unfractionated heparin (43). Among the other purported benefits of LMWH include a reduction in the need for blood transfusions (44) and less of a tendency toward hyperkalemia (45).

There has been some debate in the literature about the effect of LMWH on the lipid profiles of dialysis patients. Several studies have demonstrated improvement in the total cholesterol (46–51) and triglyceride levels (46,49–51) in dialysis patients after switching from unfractionated heparin to LMWH. These studies included both diabetic and nondiabetic subjects, and the period of study ranged from 6 months to 4 years. Another study examined the effect of LMWH on lipid profiles in prevalent dialysis patients who had been previously receiving unfractionated heparin. Over 1 year, improvements were noted in total cholesterol, triglyceride, and Apo B concentrations. After the first 12 months, patients were randomly chosen to either continue with LMWH or revert to unfractionated heparin. Although the improvement in lipid profiles continued in the LMWH group, the unfractionated heparin group sustained no further benefit (52).

In contrast, a multicenter trial examining 153 patients on LMWH and 153 patients on unfractionated heparin failed to demonstrate any significant differences in lipid profiles between the two groups except for higher high-density lipoprotein (HDL) cholesterol levels in the heparin group (53). A smaller study by the same authors showed an improvement in lipid profiles after switching 24 incident dialysis patients from LMWH to unfractionated heparin after the first 6 months of treatment (54). These latter two studies suggest that it may be premature to assume that a benefit in lipid profiles is assured when using LMWH.

One factor that has precluded the routine use of LMWH during dialysis procedures is the concern for excess bleeding in patients with kidney disease. A meta-analysis investigating the safety of LWMH in patients with ESKD found no significant difference in bleeding events or extracorporeal circuit clotting when compared to unfractionated heparin (55). Other studies, however, have raised concerns. Brophy et al. (56) used the measurement of thrombin generation time in a prospective *ex vivo* study to demonstrate that the anticoagulant effect of enoxaparin was enhanced in patients with ESKD. These data suggested that even at similar levels of antifactor Xa activity, the effect of enoxaparin in ESKD remains unpredictable and could subject patients with ESKD to bleeding complications. Other clinically significant events such as retroperitoneal hemorrhage, gastrointestinal bleeding, intracranial bleeding, and hemorrhagic pericardial effusion have been described in patients with chronic kidney disease (CKD) stages 4 or 5 who were treated with fixed doses of LMWH (57). Additional concern when using LMWH preparations is that they are only partially reversible using protamine. The package inserts of the three major LMWH preparations commonly used in the United States (enoxaparin, dalteparin, and tinzaparin) state that these agents should be used with caution in patients with a creatinine clearance less than 30 mL/min. These facts, combined with the lack of readily available antifactor Xa level monitoring, suggest that patient safety concerns may outweigh the other purported advantages of using LMWH for chronic dialysis procedures.

ALTERNATIVE ANTICOAGULATION STRATEGIES

Perhaps no other clinical diagnosis has focused more attention on the need for alternative anticoagulant agents than HIT. HIT is a life-threatening disorder resulting from antibodies formed against complexes of platelet factor 4 (PF4) and heparin (39). HIT has been classified into type I and type II, with type II being the most clinically significant entity. In type II HIT, platelet counts usually decline by 40% to 50% from baseline approximately 5 to 10 days after heparin exposure. Clotting of both the venous and arterial circulation can be seen, with 50% of patients developing clot formation of some kind within 30 days on

average (58). Both unfractionated and LMWH have been shown to cause HIT, although the association with LMWH appears to be smaller.

The frequency of HIT in the population with ESKD has been reported to range anywhere from 0% to 12% (39,58). If the diagnosis of HIT is suspected, antibody testing should be used for confirmation, given the potential life-long implications and cost associated with treatment. Treatment of HIT includes absolute heparin avoidance, including all heparin flushes, ointments, and catheter lock solutions. In addition to these precautions, systemic anticoagulation is recommended in patients with HIT to prevent thrombotic complications.

Some alternative anticoagulation strategies that can be used in clinical situations such as HIT as well as in patients who are at high risk for bleeding will now be discussed. **TABLE 4.1** provides the usual dosing schemes for many of these agents during hemodialysis.

Direct Thrombin Inhibitors

Direct thrombin inhibitors prevent thrombin generation by binding to the active site on the thrombin molecule, thereby blocking the conversion of soluble fibrinogen to insoluble fibrin. The three direct thrombin inhibitors approved for use by the U.S. Food and Drug Administration (FDA) are recombinant hirudin, argatroban, and bivalirudin.

A natural derivative from the saliva of the *Hirudo medicinalis* leech species, hirudin, was actually the first anticoagulant used for dialysis procedures in the early 1920s before giving way to heparin (59). The primary route of excretion of hirudin is through kidney elimination. Therefore, its half-life is markedly prolonged in patients with kidney disease. Lepirudin, a form of recombinant hirudin, has been studied in patients with kidney disease including patients undergoing CRRT (60,61). Especially in cases of anuria, the dosing requirements for hirudin are small (60); however, meticulous monitoring of the aPTT levels should be undertaken. In patients on CRRT, lepirudin can be dosed through continuous infusion at 0.005 to 0.01 mg/kg/h, whereas for chronic dialysis, a bolus dose of 0.15 mg/kg can be given before the session (39). Dosing should be carefully adjusted to achieve an aPTT of 1.5 to 2 times normal without exceeding 100 seconds in order to minimize bleeding risk. The reader should also keep in mind that the aPTT does not increase linearly with lepirudin blood levels (62). Therefore, aPTT times that are elevated above the goal range may reflect excessively high levels of blood lepirudin. These situations are all the more dangerous considering that there is no specific antidote to lepirudin. The formation of antihirudin antibodies that can occur in up to 40% of patients who receive lepirudin for more than 5 days and may enhance its anticoagulant effect is another factor to consider when using this agent (63).

Argatroban is a synthetic derivative of L-arginine that was first studied during hemodialysis procedures in the mid-1980s (64). The appeal of this agent for use in patients with kidney disease stems from the fact that it is metabolized and secreted by the liver. A retrospective review of 47 patients with HIT showed that argatroban was a safe and effective anticoagulant for both chronic dialysis and CRRT (40). In a prospective, randomized, three-way crossover study in patients with prevalent ESKD, argatroban was shown to be safe and effective for chronic dialysis (65). Of the three argatroban dosing strategies used in this study, there were no significant differences in achieved urea reduction ratio, thrombotic, or bleeding events. The clearance of argatroban through the dialysis membrane was also found to be insignificant. Using the methods employed in this study, a 250 μg/kg bolus of argatroban with

a repeat 250 μg/kg bolus given midway through the session should achieve adequate anticoagulation. An alternative strategy would be to use an initial bolus of 250 μg/kg of argatroban followed by a continuous infusion of 2 μg/kg/min. Hospitalized patients who are already receiving an argatroban infusion for other reasons can be safely dialyzed without interruption of therapy. Given the hepatic metabolism of argatroban, liver function testing is imperative before using this agent. In cases of hepatic insufficiency, the dosing of argatroban should be reduced to 0.5 μg/kg/min through continuous infusion, and careful monitoring of the aPTT should be performed (39). In general, the aPTT has been found to correlate well with plasma argatroban levels (66), and the goal of therapy should be to achieve an aPTT of 1.5 to 3 times normal. The concern of antibody production against argatroban has not been reported.

Bivalirudin is a semisynthetic 20 amino acid derivative of hirudin. Its primary mode of elimination is through intracellular hydrolysis, with only 20% urinary excretion (67). Similar to lepirudin, the half-life of bivalirudin is prolonged in patients with impaired kidney function. With normal kidney function, the elimination half-life is 25 minutes, and is prolonged to 3.5 hours in dialysis patients (67). Although promising as an alternative anticoagulant to treat HIT, there are little published data regarding the use of bivalirudin in dialysis patients. Currently, the FDA has approved this agent only for use in conjunction with percutaneous coronary intervention.

Danaparoid

Danaparoid sodium is a heparinoid composed primarily of the nonheparin glycosaminoglycan heparan sulfate. Danaparoid exerts its anticoagulant effect by inhibition of factor Xa. Although not currently on the market in the United States, there is considerable experience treating HIT patients with danaparoid in Canada, Europe, and Australia. Danaparoid is considered to be a safe alternative agent to use in patients with HIT despite a 3.2% rate of cross-reactivity with heparin (68). A survey of 81 dialysis units in the United Kingdom revealed that 36% of patients with ESKD who tested positive for HIT were treated using danaparoid (69). Danaparoid is reported to allow successful dialysis without clotting or bleeding complications when administered as a single predialysis dose of 35 U/kg (41,42). Given that kidney excretion is the primary route of danaparoid elimination, monitoring of antifactor Xa levels should be performed before each dialysis session with a goal level of 0.5 to 0.8 IU/mL. Even with dose adjustment, these patients must be considered at risk for bleeding complications.

Regional Citrate Anticoagulation

Regional anticoagulation with citrate has been demonstrated to be an effective alternative for use of heparin. Trisodium citrate infusion into the blood entering the dialyzer chelates calcium and prevents coagulation. Anticoagulation is reversed, and ionized calcium levels restored, through a combination of citrate loss into the dialysate and infusion of calcium into the venous blood line or calcium influx from the dialysate. Multiple protocols have been described for citrate anticoagulation (70–73). The simplest method involves infusion of concentrated trisodium citrate solution into the arterial blood line, coupled with the use of dialysate containing normal levels of calcium and magnesium (71,73). The citrate infusion rate is adjusted to provide a 25% to 75% increase in ACT at the entry to the dialyzer (71–73). Other methods use calcium- and magnesium-free dialysate and reinfuse calcium into the venous blood line (70,74). A prospective study in dialysis patients who required heparin free treatment after recent surgery demonstrated that regional citrate anticoagulation was superior to the use of a heparin-coated

polyacrylonitrile membrane in terms of clotting phenomena that necessitated termination of the dialysis session (75). Citrate anticoagulation may be useful in patients with heparin allergy, but problems with hypocalcemia, hypernatremia, and metabolic alkalosis render this technique more cumbersome than routine heparin anticoagulation (76,77). The dialysate bicarbonate concentration should be reduced to 25 to 30 mM to guard against metabolic alkalosis, which may develop if the bicarbonate generated from citrate metabolism is added to the normal influx of bicarbonate from the dialysate (78). In extreme cases, failure to adequately correct ionized calcium levels has been reported to result in electrolyte imbalance and cardiac arrest (79), and an ability to monitor ionized calcium concentrations during hemodialysis is considered essential for patient safety. One large but uncontrolled trial reported a 99.6% success rate using a regional citrate anticoagulation protocol in 1,009 high-flux dialysis procedures in 59 outpatients with ESKD (80). However, for the abovementioned safety concerns, regional anticoagulation using a citrate protocol is typically reserved for hospitalized patients who are at high risk for bleeding complications. Regional citrate anticoagulation by itself is insufficient to treat patients with HIT given the need for systemic anticoagulation.

Oral Anticoagulation

In general, oral anticoagulation is a poor choice for treating patients with ESKD. There are ample data that suggest warfarin may enhance the process of vascular calcification (81). Furthermore, no studies have conclusively demonstrated a benefit of warfarin on clotting profiles during hemodialysis. In studies looking at both tunneled, cuffed dialysis catheters (82) and PTFE grafts (83), minidose warfarin was no better than placebo at maintaining access patency. As expected, the rates of adverse bleeding events were higher in patients treated with warfarin. Another smaller study used a randomized, crossover design to investigate the efficacy of LMWH versus no anticoagulation in 10 patients with ESKD treated with warfarin [international normalized ratio (INR) 2.0–3.0]. The patients who received no additional anticoagulation had significantly greater clotting of the dialyzer when compared to the LMWH group (84). Taken as a whole, these data suggest that oral warfarin should be reserved for those patients with ESKD who have a defined hypercoagulable state or for those with other compelling indications for continuous anticoagulation such as a mechanical heart valve. A recent retrospective cohort study of incident hemodialysis patients with atrial fibrillation actually suggested an increased risk for new stroke in patients taking warfarin (85). These data seem to be in accordance with some of the more recent studies recognizing advanced chronic kidney disease and ESKD as risk factors for increased bleeding when using oral anticoagulation. In particular, the Hypertension, Abnormal renal/liver function, Stroke, Bleeding history or predisposition, Labile international normalized ration, Eldery (>65 years), Drugs/alcohol concomitantly (HAS-BLED) scoring system defines an increased risk of 1 year major bleeding events in anyone with a history of kidney transplant, ESKD, or a serum creatinine value of greater than 2.6 mg/dL receiving oral anticoagulation for atrial fibrillation (86).

Antiplatelet Agents

The Dialysis Access Consortium Study Group has investigated the use of antiplatelet agents specifically to enhance the patency and reduce the failure rate of the arteriovenous access in hemodialysis patients. One study found that clopidogrel had a modest, but statistically significant, effect in reducing the rate of fistula thrombosis at 6 weeks after access creation (87). Unfortunately, clopidogrel therapy did not result

in a significant increase in the proportion of fistulas that were suitable for dialysis compared to placebo (defined as the ability to sustain a blood pump speed of 300 mL/min or greater in 8 out of 12 dialysis treatments). Another randomized controlled trial examined the effect of dipyridamole plus aspirin given twice daily on the ability to maintain patency in newly created arteriovenous grafts (88). In this study, the treatment group exhibited a modest but significant increase in the incidence of primary unassisted graft patency at 1 year. In both studies, treatment with antiplatelet therapy did not result in significant adverse events, including major bleeding, compared to placebo.

Hemodialysis without Anticoagulation

Dialysis procedures can be successfully performed without the use of anticoagulation. This may be necessary in patients with an active bleeding diathesis (e.g., intracranial hemorrhage). In such cases, membranes with the lowest thrombogenicity (e.g., polysulfone) should be used. To minimize the chances for clotting, treatment times should be ideally limited to 2 to 3 hours and blood flows should be attempted at least as fast as 250 mL/min. Rinsing of the extracorporeal circuit with 25 to 150 mL of saline through the arterial port is another technique, which can aid in the prevention of circuit clotting (89,90).

FACTORS PREVENTING ADEQUATE ANTICOAGULATION

Both dialyzer clotting and excessive bleeding can occur in patients with ESKD who have apparently stable heparin prescriptions. These situations can usually be traced to either patient-related issues or technical problems in therapy delivery.

Patient-Related Issues

Comorbid conditions such as infections, intercurrent illnesses, or underlying disease exacerbations [systemic lupus erythematosus (SLE), chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF)] may change a patient's coagulation status. Intercurrent illnesses have been shown to affect the elimination rate of heparin (91). In cases of infection or disease exacerbations, vigilance should be maintained to ensure proper anticoagulation is maintained. These conditions often require a temporary increase in the heparin dosage to prevent extracorporeal circuit clotting.

Heparin can physically interact with a number of drugs (92); however, with the possible exception of nitroglycerin (93,94), there is little evidence that drugs alter the anticoagulant effect of heparin. Smoking increases the elimination rate of heparin (95), and a history of smoking was found to be a significant covariate in population pharmacodynamic models of heparin dosing in hemodialysis patients (21).

Patients treated with erythropoietin require more heparin to prevent dialyzer clotting (96,97). Whether this fact is a reflection of the induction of higher hematocrit concentrations or a result of some reversal of the uremic bleeding tendency is a matter of speculation. In either case, patients receiving erythropoietin-stimulating agents may require higher doses of anticoagulants to achieve successful dialysis.

Technical Problems in Therapy Delivery

As summarized in **TABLE 4.2**, there are many factors that can potentially go wrong during any given hemodialysis session, thereby leading to either dialyzer clotting or excessive bleeding. These situations

should be investigated before attributing the problem to a faulty anticoagulation prescription.

TABLE 4.2 Problems in Therapy Delivery that May Result in Inadequate Anticoagulation or Failure to Prevent Clotting or Bleeding

Errors in administration of the heparin dose
Heparin doses drawn up incorrectly
Insufficient time allowed for loading dose to distribute
Failure to deliver the prescribed constant infusion of heparin
Problems associated with the blood circuit
Failure to adequately prime the dialyzer
Excessive turbulence in the arterial drip chamber
Excessive recirculation
Failure to rotate needle sites

From Ward RA. Heparinization for routine hemodialysis. *Adv Renal Replace Ther* 1995;2:362–370, with permission.

Errors in the administration of heparin are a common problem. After administration of the heparin-loading dose into the access needle, sufficient saline must be used to ensure that the complete heparin dose enters the circulation. Three to 5 minutes are required for the heparin to distribute in the plasma before extracorporeal circulation is commenced. Failure to follow these steps results in clotting as unheparinized blood enters the dialyzer during the first minutes of dialysis. Once administered, the loading dose begins to be eliminated. If the constant infusion of heparin is not started immediately, this elimination will result in a steadily decreasing clotting time.

A number of factors may prevent the timely administration of the infused heparin. The line from the heparin syringe to the blood line must be primed with heparin during the setup for dialysis to avoid infusing either saline or air during the first 30 minutes of dialysis. In addition, clamps should not be left on the line. Some heparin pumps have a maximum operating pressure. Beyond this pressure, they will not infuse accurately. Post–blood-pump pressures greater than 400 mm Hg should be avoided, particularly when high blood-flow rates are used in conjunction with high hematocrits and small-bore access needles.

Care must be taken to eliminate all air bubbles from the dialyzer during the priming process and to avoid excessive turbulence in the drip chambers during dialysis. Blood–air interfaces predispose to clotting, particularly if they are associated with turbulence and foam formation (12,98–100).

Recirculation in the vascular access may cause clotted dialyzers in the presence of apparently adequate clotting times. As blood passes through the dialyzer, ultrafiltration causes hemoconcentration. Blood of increased hematocrit then returns to the access. Recirculation results in some of this blood being returned to the dialyzer where it is concentrated further. In this manner, the hematocrit of the blood in the dialyzer progressively increases above systemic levels. In extreme circumstances, such as when the arterial access needle is inadvertently placed downstream of the venous needle and ultrafiltration rates are high, the hematocrit in the dialyzer will reach very high levels (greater than 60%), and the dialyzer will clot.

Prolonged bleeding from the access needle sites after dialysis is often blamed on excessive anticoagulation. Although the level of anticoagulation may play a role in this bleeding, mechanical problems related to venipuncture are also frequently a factor. In particular, failure to rotate needle sites with a synthetic graft will lead to destruction of the graft material and make it very difficult to stop bleeding, regardless of the level of heparin. Continued episodes of bleeding after needle withdrawal should also prompt the clinician to search for possible outflow stenosis of the AV access.

SUMMARY

Anticoagulation remains an invaluable ingredient in producing a successful hemodialysis prescription. This goal can best be achieved by a loading dose and constant infusion of heparin using one of the available weight-based nomograms when pharmacodynamic modeling is not readily available. The nephrologist's goal should be to maintain the lowest possible dose of heparin in order to prevent extracorporeal circuit clotting and minimize the risk of bleeding complications. Given the wide patient-to-patient variability, individualization of heparin dosing is required and periodic adjustments will often have to be made. In cases where heparin is contraindicated, the nephrologist now has several different treatment options including the direct thrombin inhibitors and regional citrate anticoagulation, although further studies will be needed before instituting these agents on a wider scale. Finally, both patient-related factors and technical problems with anticoagulant delivery should be investigated when problems arise with dialysis anticoagulation.

CHAPTER 5

Measuring Hemodialysis Using Solute Kinetic Models

Andrew I. Chin and Thomas A. Depner

HISTORICAL PERSPECTIVE

Hemodialysis was first successfully applied during the 1940s to support life in patients with acute kidney injury (1). Soon after, it was clear that life could be prolonged where previously death from uremia was certain. This seemingly miraculous therapy, touted by some as the most effective medical therapy introduced during the last century, was first deliberately used to manage end-stage chronic kidney disease (CKD5) in 1960 (2). It soon became clear that periodic dialysis treatments could sustain life indefinitely, but for the early pioneering patients, the frequency and intensity of treatments were limited by equipment availability and by adverse reactions. In addition, during these early development years, limited membrane permeability and patient intolerance of high blood flows necessitated prolonged treatments often for 8 to 10 hours. As maintenance dialysis was applied to larger numbers of patients, three treatments per week appeared to restore health, whereas two treatments per week regardless of treatment duration were inadequate in anephric patients.

Important developments in the next few decades led to further changes in long-term hemodialysis administration. In the late 1970s, the National Cooperative Dialysis Study (NCDS), sponsored by the National Institutes of Health (NIH), showed that a minimum small solute clearance per dialysis was required for thrice-weekly dialysis (3–5). This heralded a shift in emphasis of hemodialysis adequacy determination from blood solute levels to solute clearance (6). Tolerance of hemodialysis improved as more permeable and biocompatible synthetic membranes became available, as bicarbonate was substituted for acetate in the dialysate, as fluid removal was stabilized by using balance chambers and redundant conductivity monitors, and as severe anemia was reversed by treatment with recombinant erythropoietin (7–9). Notably, improvements in membrane biocompatibility and solute flux allowed shorter dialysis treatments to become feasible, a goal sought by many, especially the patients (10,11). The next major NIH-funded study of hemodialysis patients, the Hemodialysis (HEMO) study, showed that the previously accepted minimum dose standard is also the optimum dose for patients dialyzed three times

weekly (12). One can conclude from this study that a minimum dose, based on small solute kinetics, is still required, but increasing the dose further would not provide any significant benefit to the patient whose life is already compromised by the demands of hemodialysis. More recently, the Frequent Hemodialysis Network trial examined the benefits of more frequent in-center hemodialysis as well as nocturnal hemodialysis compared to conventional thrice-weekly treatments (13,14). Analysis of data from those studies has given us improved methods to estimate small solute clearance at higher dialysis frequencies.

Today, the lives of more than 2 million patients across the globe are supported by long-term hemodialysis (15), which is a tribute to technique refinements that have improved patient tolerance of the treatments. In the United States, where the incident and prevalence rates remain high, concerns have been raised by clinical providers as well as governmental regulatory agencies about the unacceptably high mortality rate of hemodialysis patients compared to the general population and to hemodialysis patients in other countries where hemodialysis is also the predominant form of renal replacement therapy (16,17). Under such scrutiny, the dose and adequacy of dialysis continue to be a focus and benchmark of dialysis excellence (18–21). As a result, the practice of quantifying dialysis by measuring solute clearance has long since moved from the realm of scientific curiosity to acceptance by the dialysis community and a mandated requirement by dialysis sponsors. At present, a variety of options for long-term hemodialysis exists, including frequent home hemodialysis, short frequent in-center dialysis, and long nocturnal dialysis. With such an array of modalities, measuring the “dose” of dialysis is more important than ever to ensure optimal patient care.

This chapter reviews what is known about mathematical models of solute kinetics currently used to measure hemodialysis, including how to implement them and how to interpret the patient-specific parameters generated by the models. Definitions of the symbols used throughout this chapter and their common units of measurement are displayed in **TABLE 5.1**.

TABLE 5.1 **Symbols Used in This Chapter**

Symbol	Unit of Measurement	Definition
avC_0	mg/mL	Average predialysis concentration
B	mL/min	Fluid gain (loss) between (during) dialyses
BUN	mg/mL, mg/dL	Blood urea nitrogen concentration
BW	Any units	Body weight
C	mg/mL	Concentration (e.g., of urea or urea N)
CAPD		Continuous ambulatory peritoneal dialysis
C_{Av}	mg/mL	Average concentration
C_0	mg/mL	Initial (predialysis) concentration
C_1	mg/mL	Concentration in the proximal compartment
C_2	mg/mL	Concentration in the remote compartment
C_D	mg/mL	Concentration in the dialysate
C_E	mg/mL	Postdialysis concentration after equilibration
C_I	mg/mL	Concentration (or conductivity) in blood entering the dialyzer
C_O	mg/mL	Concentration (or conductivity) in blood exiting the dialyzer
C_S	mg/mL	Concentration in systemic blood
C_T	mg/mL	Concentration at time T
D	mL/min	Dialysance
e		Natural logarithm base (2.718)
EKR	mL/min	Continuous equivalent of intermittent clearance
F_{CPR}	Fraction	Fractional cardiopulmonary recirculation
G	mg/min	Urea generation rate
K	mL/min	Total urea clearance
k	min^{-1}	Solute elimination (rate) constant
κ	min	Coefficient to allow addition of K_R to Kt/V
K_0A	mL/min	Dialyzer mass transfer area coefficient
Kt/V	Fraction per dialysis	Fractional clearance index for urea
spKt/V, eKt/V, stdKt/V, nKt/V		Variants of Kt/V (see text)
K_C	mL/min	Intercompartment mass transfer area coefficient
K_D	mL/min	Dialyzer urea clearance
K_R	mL/min	Residual (native kidney) urea clearance
nPCR	g/kg/d	Protein catabolic rate normalized to V
N		Number of treatments per week
Q_{AC}	mL/min	Access device blood flow
Q_B	mL/min	Dialyzer blood flow
Q_D	mL/min	Dialysate flow
Q_F	mL/min	Ultrafiltration rate during dialysis
Q_S	mL/min	Systemic blood flow (C_O minus access flow)
R	Fraction per dialysis	Postdialysis BUN/predialysis BUN
RG	mg	Correction factor for K_R and urea generation
t	min or hours	Time
t_d	min or hours	Dialysis treatment time
t_i	min or hours	Time interval between two dialyses
TAC	mg/mL, mg/dL	Time-averaged concentration of BUN
U_F	L per dialysis	Ultrafiltrate volume
URR	Fraction per dialysis	Urea reduction ratio $(C_1C_2)/C_1$
V_0	mL, L	Predialysis volume of urea distribution
V, V_D, V_T	mL, L	Postdialysis volume of urea distribution
ΔV	mL, L	Change in V during and between dialyses
V_1	mL, L	Volume of the proximal (dialyzed) compartment
V_2	mL, L	Volume of the remote compartment
W	kg	Patient weight
ΔWt	Fraction per dialysis	Fractional weight loss during dialysis

UREA, A MARKER FOR CLEARANCE AND PROTEIN CATABOLISM

The properties that qualify urea as an indicator of dialysis efficiency and adequacy are listed in **TABLE 5.2**. Perhaps because of its low toxic potency, urea accumulates in the blood and tissues of patients with kidney disease to levels higher than any other organic solute. Its rate of production, dictated by net protein catabolism, is constant (zero order kinetics), independent of urea levels in the patient. Its ease of diffusion, most likely because of its small size and relative electrical neutrality, promotes swift movement across extracorporeal dialysis membranes. It also moves easily across most *in vivo* membranes, including erythrocyte membranes, along highly conserved pathways for facilitated transport (22–28). Because of these properties, measurement of urea transport across dialysis membranes is a sensitive index of small solute clearance, a fundamental goal of dialysis.

TABLE 5.2 Properties of Urea Relevant to Kinetic Modeling

Most abundant of organic solutes that accumulate in patients with kidney disease
Distribution volume is total body water
Easily dialyzed
Molecular weight = 60 Da
Chemical formula $CO(NH_2)_2$
Polar, water soluble
Uncharged
Not bound to serum or tissue proteins
Source
Produced by the liver
End product of protein amino acid catabolism
Transport
Passive diffusion *in vitro* and *in vivo*
Facilitated diffusion *in vivo*
Relatively nontoxic

Urea generation correlates closely with protein catabolism, which, in steady-state, stable patients, reflects protein intake, a measure that can provide assistance with dietary management. A relatively precise relationship between urea generation and protein catabolism was found several years ago in two separate metabolic studies, each in a small number of CKD5 and CKD3 to CKD4 patients (29,30). Both studies showed essentially the same result (**EQUATION 5.1**):

$$nPCR = 5{,}420 \times G / V + 0.17 \qquad (5.1)$$

where nPCR is the net normalized protein catabolic rate (g/kg/d) (29), G is the urea nitrogen generation rate (mg/min), and V is the urea distribution volume (mL). Protein catabolism is expressed per kilogram of lean or normalized body weight. The latter is derived from V, assuming that V is 58% of body weight.

Total protein catabolism exceeds net nPCR, often by several fold (31). Protein breakdown releases free amino acids that are mostly reincorporated into new protein. This anabolic resynthesis of protein is a large fraction of the total catabolic rate, the difference representing a smaller net rate of nitrogen loss from irreversible breakdown of amino acids to urea (32). Therefore, nPCR, determined from urea modeling, is a measure of *net protein catabolism*. Net protein catabolism is equal to protein intake in

patients who are in stable nitrogen balance.

Single blood urea levels are difficult to interpret. In a patient not on dialysis, elevated urea levels may well correspond to the syndrome of kidney disease with all of its manifestations. Paradoxically, dialysis patients with low urea levels as a result of low urea generation rates have poorer outcomes (33). Reduced protein-derived urea generation results from poor nutritional intake that is usually due to suppression of the appetite. Appetite suppression is associated with either inadequate dialysis or with comorbid diseases such as infection or cardiovascular disease, the leading cause of death in dialysis patients (3,4,34–36). Low urea levels achieved by adequate dialysis are beneficial, while low levels due to poor nutrition and decreased protein intake are associated with higher morbidity and mortality. The studies of pregnancy in women on hemodialysis support this notion—pregnancy outcomes are improved in women with lower blood urea levels as achieved by hemodialysis (37–39).

Attempts to demonstrate a direct toxic effect of urea have led to the conclusion that urea is at best a mild toxin (40–42), levels of which serve only to mirror other easily dialyzed solutes that are more toxic and responsible for the uremic syndrome (43). Alternatively, an indirect effect of urea such as carbamylation of protein may mediate its toxicity (44–47). However, posttranslational carbamylation of proteins requires time to develop in the presence of high urea concentrations and, conversely, to reverse after lowering the urea concentration. Therefore, the immediate benefits of dialysis that are observed clinically are difficult to explain on this basis. Evidence that carbamylated albumin levels associate with adverse outcomes in a cohort of diabetic hemodialysis patients suggests that long-term effects of protein modification by urea may warrant further investigation (48).

An inescapable conclusion from these observations, and one that guides the clinical application of urea modeling today, is that urea is a poor marker of uremia but its clearance is a good marker of dialysis. Measurements of urea concentration before and following dialysis, when combined with an appropriate model of urea kinetics, provide vital clinical information about both the adequacy of dialysis and the nutritional status of the patient.

FACTORS THAT DETERMINE THE REQUIREMENT FOR DIALYSIS

Several of the patient-specific factors listed in **TABLE 5.3** determine how much dialysis is needed. These include the patient’s size, residual native kidney urea clearance, fluid gain between dialyses, and perhaps in the rare case of pregnancy (37,38,49,50). If adequate dialysis is provided, moderate increases in urea generation do not affect the need for dialysis but instead reflect improved protein nutrition (see section “Protein Catabolism”). Although solute compartmentalization (see section “Multi-Compartment Kinetic Model”) affects the delivery of dialysis, the effect is predictable as explained in the subsequent text, and relatively constant from patient to patient and from time to time, so periodic adjustments are not necessary.

TABLE 5.3 Variables that Impact the Hemodialysis Prescription

Patient variables
Urea distribution volume, equated to total body water (V)
Urea generation rate from net protein catabolism (G and PCR)
Residual (native kidney) urea clearance (K_R)
Fluid accumulation (ΔV)
Solute compartmentalization (K_C)
Dialysis variables
Dialyzer clearance components
Model of dialyzer and its urea mass transfer area coefficient (K_oA)
Blood flow (Q_B)
Dialysate flow (Q_D)
Ultrafiltration rate (Q_F)
Treatment time (t_d)
Schedule or frequency of dialysis (N)

PCR, protein catabolism rate.

Protein Catabolism

Adjusting the dose to the urea generation rate has been considered less important in recent years because patients on average receive higher doses of dialysis (19). Higher doses cause mean urea concentrations to fall below the ceiling that was originally suggested by the NCDS, so an additional adjustment for urea generation is less critical and is usually unnecessary. In addition, increasing evidence suggests that nutrition has a strong influence on patient outcome, so the emphasis has shifted from restricting protein to encouraging more protein and caloric intake (51–53). The United States multicentered Modification of Diet in Renal Disease (MDRD) study also raised concerns about protein restriction adversely influencing survival of patients in stages 3 and 4 of CKD (54,55).

Several investigators have reported a correlation between nPCR and the dose of dialysis expressed as Kt/V, suggesting that increasing the dose of dialysis will improve the appetite (56–59). This conclusion is subject to error for several reasons. First, if the dose of dialysis is not strictly controlled by urea modeling, physicians may simply give more dialysis to patients with high protein intake, creating a correlation that reflects a physician response to appetite rather than *vice versa*. Second, both nPCR and Kt/V are determined from the same set of blood urea nitrogen (BUN) values (see subsequent text); therefore, an artifactual mathematical correlation due to coupling is expected, the magnitude of which depends on the BUN measurement error (60,61). Third, observational studies of the curvilinear relationship between Kt/V and protein catabolism rate (PCR) are confounded by inclusion of very low doses. This causes a false exaggeration of the effect of increasing Kt/V above the range where the relationship reaches a plateau (58,62).

The above errors are important to avoid when interpreting nPCR. However, since appetite suppression is a well-known consequence of uremia and dialysis reverses uremia, we can expect that dialysis will improve the appetite in patients with overt uremia (63). The HEMO study showed no improvement in nutrition after increasing the dose above the current optimal target in patients dialyzed three times weekly (64,65). While some uncontrolled studies have suggested that increasing the frequency of hemodialysis to four to six per week may improve the appetite in some patients (66), the analysis of the Frequent Hemodialysis Network data did not show significant improvements in lean body mass or

nutritional parameters in patients receiving six times a week in-center treatment or those on nocturnal dialysis (67).

Residual Native Kidney Clearance

Seemingly insignificant levels of residual native kidney urea clearance (e.g., 1 or 2 mL/min) can markedly decrease the need for dialysis, but most nephrologists do not compensate for residual function (K_R) by prescribing a lower dialysis dose. Reasons for omitting this practice include the patient inconvenience and provider cost associated with collecting, measuring, analyzing urine, and calculating K_R.Those opposed to the regular evaluation of residual urea clearance have also pointed to the potential negative psychological effect on the patient from stepwise increases in the dialysis treatment time as K_R inevitably declines. It should also be noted that at the present time, regulatory agencies ignore the inclusion of K_R in total clearance and require submission of delivered Kt/V (or urea reduction ratio) as the only accepted clearance measure when dialysis clinic adequacy is monitored. Therefore, a nephrologist who does incorporate K_R in his or her dialysis prescriptions may place the dialysis clinic at risk for financial penalties. However, K_R has a strong influence on patient mortality, both for peritoneal dialysis and for hemodialysis (68–70), so K_R not only affects the required dialysis dose but it also has prognostic significance. In addition to an equivalent clearance of small solutes, residual renal function has other benefits that include removal of poorly dialyzable toxins (71,72). Since dialysis compromises a patient's quality of life, and the primary goal of kidney replacement is improving the quality of life, adjusting the dose in patients with significant K_R is worth considering. Acknowledging this benefit, the most recent Kidney Disease Outcomes Quality Initiative (KDOQI) 2015 guidelines have reemphasized the recommendation to adjust the dialysis prescription in patients who have substantial residual renal function, assuming K_R is periodically updated. Methods for incorporating K_R to create an expression of total depurative function are published in the KDOQI guidelines (73) and are briefly described later in the chapter (see section "How to Add K_R to Kt/V").

Body Size

Body size is an obvious modulator of dialysis need, but the precise denominator to use as an index of size is debated (74–76). Numerous isotope studies in animals and normal humans have shown that the urea distribution volume (V) is equivalent to total body water, which is proportionate to lean body mass (77–79). As discussed in the subsequent text, V is a mathematically convenient denominator, but it may not be appropriate, especially because body surface area (SA) has been used for several decades to normalize native creatinine or inulin clearances (80,81). Because outcome patterns in women and smaller patients differ from that of larger patients (82–84), and most metabolic functions vary with SA, not lean body mass, several investigators have attempted to convert V to SA by adjusting for body height using time-tested formulas for SA (85–87).

The concentrations of uremic toxins in body fluids are thought to modulate toxicity and therefore the need for dialysis (88), but for first-order processes, the concentration is a function of generation and removal and does not depend on the space of distribution. For a patient whose clearance (K) is constant, and whose toxin generation rate (G) is equal to the removal rate, changes in the volume of distribution (V) have no effect on concentration in the steady state (C = G/K). For example, an increase in V from edema

formation or a decline in V from muscle loss would not affect steady-state concentrations if all else remain constant. It is unlikely that edema fluid is a source of uremic toxins, and analysis of outcomes suggests that muscle is also an unlikely source (89,90). Instead, individual solute generation rates modulate toxin concentrations and are therefore the most logical size variables to which the dose should be normalized. Unfortunately, the critical toxic compounds have not been identified, so the precise relationship between their generation rates and body size remains speculative (43).

Use of V as a normalizing denominator for the dialysis dose has also been questioned because observational studies have shown that V independently predicts and correlates positively with survival (91–94). Patients with lower body mass tend to have both a higher Kt/V and a higher mortality risk. African Americans with CKD5 tend to have a higher body mass and both a lower Kt/V and a lower mortality risk (95,96). These opposing effects of V confound the relationship between the V-normalized dose of dialysis and patient outcomes. Adjustment for the independent beneficial effect of V on survival creates an even steeper relationship between the survival benefit of increased dialysis dose (74). Larger patients likely have higher solute generation rates and require more clearance than smaller patients to achieve the same blood concentration. One possible explanation for the higher risk of mortality in smaller dialysis patients is use of V instead of SA, as noted earlier, which may overcorrect for body size, leading to inappropriately lower doses in smaller patients. *Post hoc* analysis of the HEMO study data suggested that women, who are generally smaller in body size, may benefit from the higher targeted Kt/V (97), lending some credence to the idea of underdosed dialysis in this subgroup. The higher risk of mortality may also result from the higher prevalence of malnutrition in smaller dialysis patients. While malnutrition alone portends a poor prognosis in the dialysis patient, it can also result from comorbid conditions including inflammatory states that may independently affect survival (98).

TABLE 5.3 also lists fluid accumulation between dialyses as a component of the dialysis prescription. Although it increases the requirement for fluid removal during each treatment, fluid accumulation actually decreases the need for dialysis both because of a dilution effect and because removing fluid during hemodialysis increases the efficiency of solute removal (99). See section “Effect of Fluid Gain” later in the chapter.

Hematocrit

Solutes other than urea do not always distribute in erythrocytes and transport out of the erythrocyte can be delayed as blood traverses the dialyzer within 10 to 30 seconds. As the red cell mass usually makes up 30% to 40% of a patient’s blood volume, distribution and transport of solutes in erythrocytes can have a significant effect on clearance. Red cell urea transporters are very robust, causing near instantaneous equilibration, so the presence of erythrocytes has little effect on urea clearance (22–28). However, creatinine equilibrates slowly and phosphorus apparently does not move at all across erythrocyte membranes during transit through the dialyzer (100,101). This in part explains the difference between *in vitro* and *in vivo* clearances, an effect that should be kept in mind when developing and applying kinetic models for solutes other than urea.

TARGETING THE AMOUNT OF DIALYSIS

How to Measure Dialysis; How Much Is Enough?

The NCDS showed not only that higher urea levels are not tolerated but also that morbidity and mortality are inversely correlated with protein catabolism (4,102). Because the urea level is directly correlated with urea generation from net protein catabolism, factoring one for the other is the essence of a clearance (see subsequent text). A later mechanistic analysis of the data showed that providing a size-adjusted minimum clearance of urea per dialysis (Kt/V) would assure the best outcome (3). The subsequent HEMO trial showed that further increases in this dose parameter were met with no further improvement in morbidity or mortality, so the minimum dose for three dialyses per week also turned out to be the optimum dose (12). Some observational studies have shown that markedly prolonging the treatment time (e.g., doubling or tripling t_d) on a thrice-weekly schedule may improve survival and intermediary cardiac outcomes (103–105). Analysis of the Dialysis Outcomes and Practice Patterns Study (DOPPS) observational data also suggested that in patients dialyzed three times weekly, incremental increases in treatment time are associated with a lower relative risk of death (106,107). However, no randomized clinical trials have been conducted to test this hypothesis.

The relationships among time-averaged BUN, Kt/V, and nPCR are shown in **FIGURE 5.1**. The "safe zone" is shown below the heavy line representing the isopleth for a single pool Kt/V of 1.2 per dialysis. The curvilinear surface represents the mathematical relationship among the three variables time-averaged concentration of BUN (TAC), nPCR, and Kt/V, for patients dialyzed three times weekly. Note that only two of the three variables are required to find a point on the surface plot, which means that the three variables are mathematically interdependent and that arguments favoring one as more accurate than another are trivial. Note also that the depicted Kt/V values are specific for dialysis given three times weekly. For twice-weekly dialysis or another schedule, the Kt/V axis must be changed.

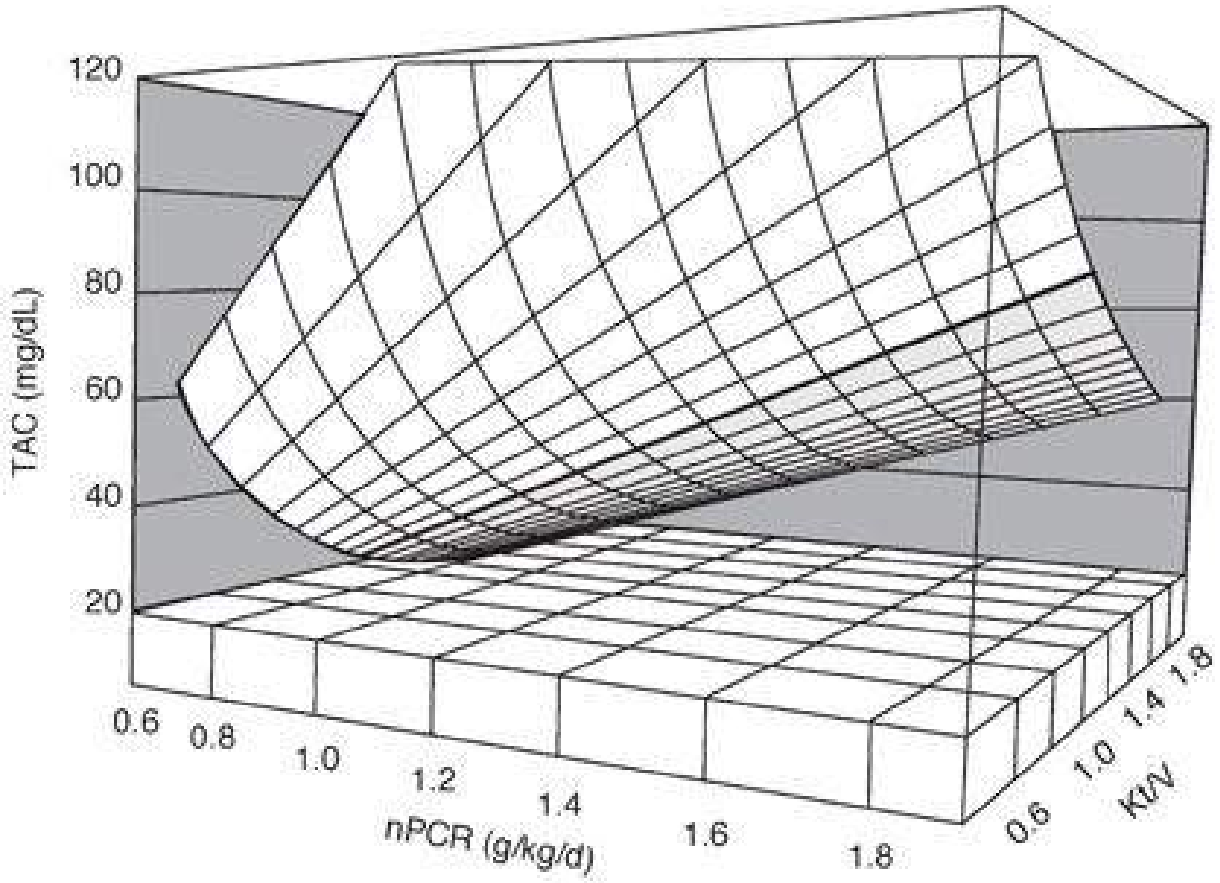

FIGURE 5.1 The mathematical relationships among normalized protein catabolic rate (nPCR), time-averaged concentration (TAC), and Kt/V form a curvilinear plane in three dimensions. Lines running diagonally across the plane are Kt/V isopleths; the line at Kt/V = 1.2 represents the currently accepted minimum standard, and the region of the plane below this is the "safe" domain. Data were derived from the single compartment model; all scales are linear.

The NCDS showed that to achieve optimal patient outcome, one must guarantee that the dose of dialysis (delivered Kt/V) is constant and relatively independent of the BUN (3,6). These findings reflect the failure of the serum urea concentration as an indicator of both dialysis adequacy and uremia (63). This should not be surprising to nephrologists, who have long held a double-standard interpretation of the BUN in patients who do not yet require dialysis. The BUN has been considered important to measure, but when the patient is symptomatic and the BUN is low, it is ignored (102). Some patients have died a uremic death with a BUN as low as 50 mg/dL. Clearly, dialyzable toxins other than urea account for a major part if not all of the uremic syndrome, so control of the BUN is not enough to guarantee adequate dialysis (40–42,88,108).

A safety net, expressed as Kt/V, guarantees the average patient will receive a minimum amount of dialysis, relatively independent of BUN levels and protein catabolism. However, patients' need for dialysis may differ, so if the patient is not improving or is failing for unknown reasons, it behooves the nephrologist to increase the dose of dialysis unless he or she is confident that the dose is already well above the level currently considered a safe minimum and that the patient's symptoms are not related to uremia. This recommendation acknowledges our current inability to define the uremic state more precisely (63), our ignorance of factors that may mediate individual requirements for dialysis, and our concerns about the contribution of protein catabolism to uremia (109–113).

Interpreting Kt/V: Limitations

The term *Kt/V* describes the *fractional clearance* of urea during a single hemodialysis or the fractional

volume cleared. As such, this is a term without units. The fraction can be greater than 1 because blood flow circulates from patient to dialyzer, which allows the body water compartment to be dialyzed more than once during a single treatment. Modeled Kt/V is a measure of the amount or dose of dialysis received by the patient. It correlates with outcome, but the correlation is nonlinear, as demonstrated by the NCDS and other outcome studies (3,4,114). Part of the reason for this nonlinearity is the curvilinear relationship between solute removal and Kt/V as shown in **FIGURE 5.2**. Because dialysis is a self-limiting process driven by diffusion, the amount of solute removed diminishes exponentially as the amount of dialysis is increased linearly. In other words, doubling Kt/V does not double the amount of solute removed and may accomplish very little if the critical solutes have already fallen to low levels or disequilibrium prevents further solute removal. This self-limiting or self-defeating aspect of intermittent hemodialysis is important to recognize when expressing the dose as Kt/V. Once the dose reaches the minimum standard for adequacy, increasing per dialysis Kt/V further does not necessarily improve outcome (12). Kt/V is not a direct measure of outcome or the effectiveness of the dose but is simply a method of assuring dialysis adequacy in the absence of knowledge about the critical toxins removed. As will be emphasized later, Kt/V should not be viewed as a parameter of the dialysis machine but rather as the patient response to a particular dialysis prescription.

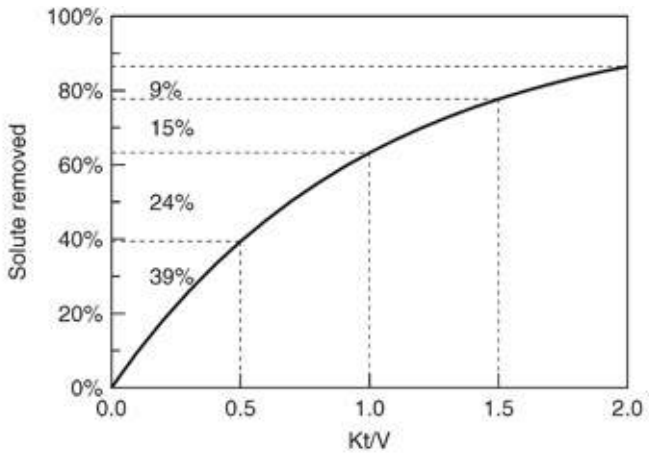

FIGURE 5.2 For each increment in Kt/V, the removal rate falls and will ultimately extinguish. Further increases in Kt/V beyond the plateau for this particular solute afford no benefit to the patient.

SINGLE-COMPARTMENT KINETIC MODEL

Clearance, a Better Measure of Dialysis

The clearance concept is intuitive, but its precise definition, origin, and application often escape nephrologists and even physiologists. It is probably best understood as a measure of the elimination process unencumbered by other variables, including the solute concentration. The solute removal rate is itself a measure of elimination, but for both filtration and dialysis, the rate is a linear function of (proportional to) the concentration. Expressing the elimination process as a clearance takes the effects of both the elimination rate and the concentration out of the rate term:

Clearance (removal rate) / concentration

For dialysis, if the index solute is present on both sides of the membrane, diffusion is proportional to the solute gradient, so we define “dialysance”:

Dialysance = (removal rate) / concentration gradient

When the removal rate is a linear function of concentration, the process is called *first order*, meaning that the removal rate is proportional to the first power of the concentration. In comparison, for zero order processes, the removal rate is constant, independent of the concentration, for example, urea generation by the liver. For both the native kidney, which uses convective clearance, and hemodialysis with diffusion-centered clearance, a generalized equation for a first-order process is (**EQUATION 5.2**):

$$dC / dt = -kC \qquad (5.2)$$

where C is the solute concentration at any time (t) and k is the elimination constant expressed as a fraction per unit of time. Rearranging **EQUATION 5.2**, and multiplying by the volume of solute distribution (V), clearance is defined as (**EQUATION 5.3**):

$$(dCV / dt) / C = -kV \qquad (5.3)$$

where dCV/dt is the solute removal rate and kV is the clearance. Because the removal rate divided by concentration is a flow, clearance is often described as the flow equivalent to complete removal of the solute. This definition is intuitive, but it bypasses the previous steps in the derivation of the clearance concept. Clearance is a useful expression only for first-order processes like diffusion and convection. We do not calculate the urinary clearance of sodium, for example, a non–first-order process.

Because removal of urea by the dialyzer is a first-order process, the rate of removal can be expressed mathematically using **EQUATION 5.2**. Integration over a period of time yields a familiar expression that describes the removal of drugs by a single exponential process (**EQUATION 5.4**) (115):

$$C = C_0 e^{-kt} \qquad (5.4)$$

where C_0 is the initial urea concentration and e is the base for natural logarithms (2.718). The rate of elimination falls with time because the concentration falls with time; that is, the process eventually extinguishes itself. However, the fractional rate of change in concentration, (dC/C)/dt, is constant (−k) and can be determined simply by measuring two timed concentrations, C_0 and C (**EQUATION 5.5**):

$$k = [\ln(C_0 / C)] / t \qquad (5.5)$$

where t is the time interval between measurements of C_0 and C and ln is the natural logarithm. When the fractional removal rate (k) is multiplied by the urea volume of distribution (V), the result is a clearance (K) (**EQUATION 5.6**):

$$K = kV \text{ or } k = K / V \qquad (5.6)$$

By substituting **EQUATION 5.6** into **EQUATION 5.5** and rearranging, another familiar expression appears (**EQUATION 5.7**):

$$Kt/V = \ln(C_0 / C) \qquad (5.7)$$

This equation shows that the log ratio of the starting urea concentration (C_0) to the ending concentration (C) can be used as an index of the amount of dialysis delivered during a single dialysis treatment, circumventing the necessity for measuring each of the three components of the expression Kt/V.

FIGURE 5.3 shows the relationship between time and C expressed as BUN on a linear scale to the left and on a logarithmic scale to the right (116). The slope of the logarithmic line is −k or −K/V. Note that this simplified graphic analysis of urea kinetics gives the *ratio* of clearance to urea volume (K/V). To resolve K, V must be determined independently and *vice versa*. Note also that the absolute values for C_0 and C are not important; their relative values determine Kt/V. For example, if the BUN falls from 150 to 75 mg/dL or from 50 to 25 mg/dL during dialysis, Kt/V is the same. Because Kt/V is determined from BUN measurements in the patient, it is a patient-specific parameter, not a machine parameter; Kt/V is a measure of response to dialysis rather than a measure of the amount of dialysis prescribed (117).

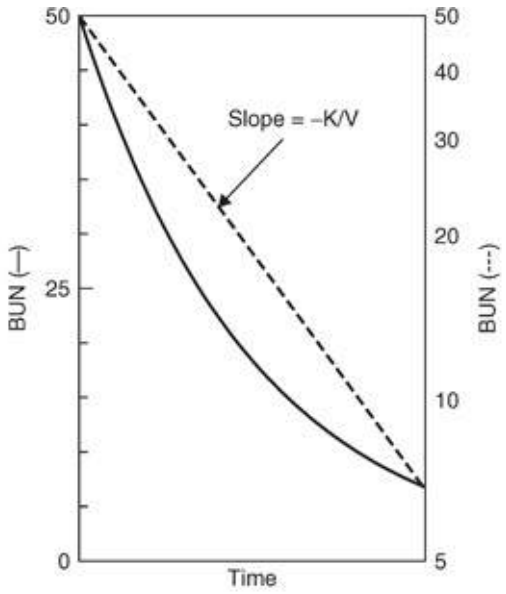

FIGURE 5.3 Blood urea nitrogen (BUN) concentrations fall logarithmically during hemodialysis treatments (**left axis**). The slope of the log decline (**right axis**) is −K/V. (Adapted from Depner TA. Quantification of dialysis. Urea modeling: the basics. *Semin Dial* 1991;4:179–184, with permission.)

Urea generation in milligrams per minute is derived from the change in urea concentration between dialyses in milligrams per milliliter multiplied by the urea volume in milliliters and divided by the time interval in minutes. Because the normalized protein catabolic rate is factored for patient volume (**EQUATION 5.1**), net protein catabolism can be determined from the changes in BUN between dialyses, provided there is no residual renal function or change in volume (**EQUATION 5.8**) (117,118):

$$nPCR = 5{,}420\ [(C'_0 - CT) / t_i] + 0.17 \qquad (5.8)$$

where nPCR is the normalized protein catabolic rate (gram per kilogram body weight per day), C'_0 is the second predialysis BUN (mg/mL), C_T is the postdialysis BUN (mg/mL), and t_i is the time interval between dialyses (min). It is important to note that the simplifications included in **EQUATIONS 5.4** through **5.8** help illustrate fundamental relationships but preclude their use in the clinical setting. These equations should not be used to model urea kinetics in patients because they fail to include several important patient variables already mentioned, the most important of which are native kidney urea clearance and the change in body fluid content during and between dialyses. Both factors lower the predialysis BUN and reduce the required change in BUN during dialysis, complicating the computation of nPCR. A third parameter that has a slight but significant effect on Kt/V and V is the amount of urea generated during dialysis. A more precise mathematical expression of urea concentrations during dialysis includes these additional three parameters (**EQUATIONS 5.9**):

$$d(VC) / dt = G - (K_D + K_R)C \qquad (5.9)$$

where V is the volume of urea distribution, G is the urea generation rate (presumed constant), K_D is the dialyzer urea clearance, and K_R is the patient's native kidney (residual) urea clearance. Integration of **EQUATION 5.9** gives a better, although more complex, expression of urea concentration during and between dialyses (**EQUATION 5.10**) (99,119):

$$C = C_0\left(\frac{V_0 + Bt}{V_0}\right)^{-\frac{K+B}{B}} + \left(\frac{G}{K+B}\right)\left(1 - \frac{V_0 + Bt}{V_0}\right)^{-\frac{K+B}{B}} \qquad (5.10)$$

where V_0 is the volume of urea distribution before dialysis, K during dialysis is the sum of $K_D + K_R$, K between dialyses is K_R, and B is the rate of fluid gain between or during dialyses (a negative value during dialysis). **EQUATION 5.10** can be used to predict a urea concentration profile during and between dialyses such as that shown in **FIGURE 5.4**. It is the fundamental equation used for single pool urea kinetic modeling, but in this case, it is used in reverse, that is, values for K/V and G are fit to measured values of C and C_0 using an iterative computer-generated process. Kt/V is derived primarily from the fall in BUN during a single dialysis, and nPCR is determined primarily from the rise in BUN between dialyses, as indicated in **FIGURE 5.4**. The typical dialysis schedule, three treatments every 7 days, is asymmetric, with 2- and 3-day intervals between treatments. Most models can adjust for this or for any schedule.

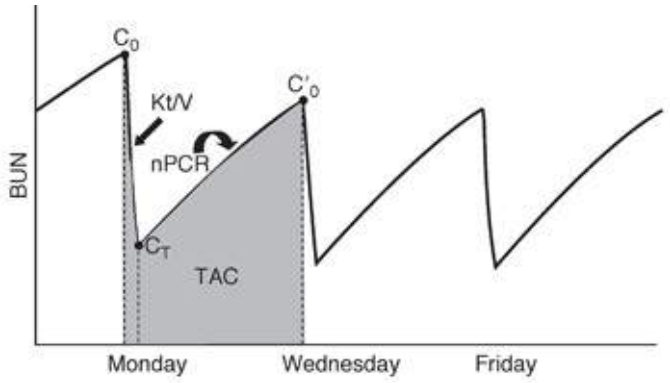

FIGURE 5.4 Weekly blood urea nitrogen (BUN) profile generated by the single-pool model. Kt/V is derived from the fall in BUN during dialysis, normalized protein catabolic rate (nPCR) from the rise between dialyses, and time-averaged BUN (TAC) from the shaded area under the curve. The rise from C_T to C'_0 is nonlinear when fluid is gained and/or when significant residual function exists.

Two–Blood Urea Nitrogen Method

When nPCR is determined from a postdialysis BUN and a subsequent predialysis BUN, only the difference between these two values enters into the calculation (**EQUATION 5.8**); their absolute values are ignored (116). Absolute values are also ignored for the calculation of Kt/V, which is derived mainly from the ratio of predialysis to postdialysis BUN (**EQUATION 5.7**). If the absolute values of the predialysis and postdialysis BUN are also included in the calculations, the third BUN measurement can be eliminated as shown in the subsequent text (99,102,120). This simplifies the urea modeling process without detracting from its accuracy.

The technique for resolving G from only two-BUN measurements is shown in **FIGURE 5.5**. The method requires a weekly steady state of nitrogen balance—that is, a constant dialysis prescription and a constant dietary nitrogen intake from day to day for at least a week. We assume these parameters to be

true, realizing the likelihood of wide protein intake variation from day to day in most people. Paradoxically, the two-BUN technique for measuring nPCR is less influenced by a dietary binge than is the three-BUN method, because the absolute value of the predialysis BUN (the major determinant of nPCR) is determined by more than a single interdialysis interval (120). The two-BUN method also offers the patient less opportunity to influence the result by altering his or her diet during the interval between the second and third blood samplings. However, even when nPCR is carefully measured, the variance is at least twice that of Kt/V.

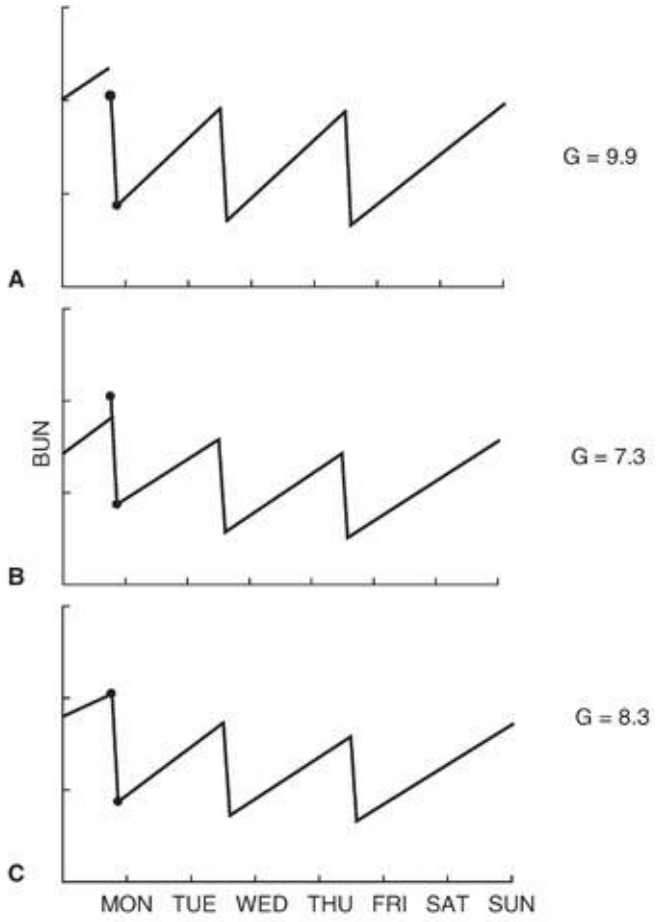

FIGURE 5.5 The two–blood urea nitrogen (BUN) method approximates G using a trial-and-error approach. **A:** G is set too high, predicting an inordinately high predialysis BUN 1 week later. **B:** G is set too low. The computer reproduces the BUN/time profile using different values for G until the calculated predialysis BUN 1 week later matches the measured BUN (as in **C**). (From Depner TA, Cheer AY. Modeling urea kinetics with two versus three BUN measurements. A critical comparison. *ASAIO J* 1989;35:499–502, with permission.)

How to Implement Modeling with Two–Blood Urea Nitrogens

The single-compartment, variable-volume model is the most commonly applied clinical tool for quantifying hemodialysis. Two of the modeling assumptions, single-pool distribution during dialysis and absence of rebound, cause errors that are offsetting (see section "Comparison with the Single-Compartment Model" later in the chapter), so the final calculations of V and Kt/V closely match those of more complex models (121).

The only two unknown variables in **EQUATION 5.10** are G and V; K is measurable and is required to start the modeling process. As shown in the subsequent text, the value chosen for K need not be precisely accurate to determine Kt/V. To start the modeling process, arbitrary values for G and V are chosen and the predialysis BUN is substituted for C_0 in **EQUATION 5.10**. V is then adjusted until the calculated value for

C matches the measured postdialysis BUN using a repetitive (iterative) approach. Then K_D is set to zero, the postdialysis BUN is substituted for C_0 in **EQUATION 5.10**, and G is adjusted until C matches the predialysis BUN, using the technique described in **FIGURE 5.5** for two-BUN modeling. The iterations are then repeated with the new values for G and V. The accuracy of V and G will depend on the accuracy of the chosen value for K, but K/V and G/V will be affected little by inaccuracies in K or V. nPCR can be calculated from G/V using **EQUATION 5.1**, and Kt/V is the product of K and t for the modeled dialysis divided by V. K between dialyses consists of K_R only. Care should be taken to adjust B for asymmetric interdialysis intervals. Any schedule of dialysis treatments can be used, and the entire process takes less than a second of computer time.

The Prescribed Dose

Determinants of dialyzer clearance include the flow rates of blood and dialysate and properties of the membrane, primarily its SA, permeability, and geometry. Similar to the clearance concept, these encumbering variables can be removed from the expression of dialyzer function by defining the dialyzer mass transfer coefficient (**EQUATION 5.11**) (122):

$$K_0A = \frac{Q_B \cdot Q_D}{Q_B - Q_D} \ln\left[\frac{Q_D (Q_B - K_D)}{Q_B (Q_D - K_D)}\right] \qquad (5.11)$$

where K_0A is the mass transfer area coefficient, Q_B is the blood flow rate, Q_D is the dialysate flow rate, K_D is the dialyzer clearance, and "ln" is the natural logarithm. The mass transfer area coefficient, sometimes called the dialyzer intrinsic clearance, is also expressed as a flow and is considered the maximum clearance possible at infinite flow rates for the particular dialyzer model and solute. A rearrangement of **EQUATION 5.11** has practical value for determining the prescribed dialyzer clearance from the machine settings of blood and dialysate flow and is a vital input parameter during the kinetic modeling process described in the subsequent text:

The dialysis center controls the dose by manipulating the dialysis variables listed in **TABLE 5.3** and then calculating the dialyzer clearance using **EQUATION 5.12**. Although it is helpful to be able to measure each of these parameters precisely, standard urea kinetic modeling allows a retrospective estimate of the amount of dialysis delivered to the patient without the need for measuring the prescribed dialyzer clearance, flow rates, or even treatment time. This closes the loop of quality control by allowing a comparison between the amount of dialysis prescribed and that actually delivered (123). Discrepancies between the two can help to detect equipment failures including poorly calibrated or nonoccluding blood pumps, failure of dialysate pumps, problems with reuse devices, and vascular access recirculation.

$$K_D = Q_B \left[\frac{e^{K_0A\left(\frac{Q_D - Q_B}{Q_D Q_B}\right)} - 1}{e^{K_0A\left(\frac{Q_D - Q_B}{Q_D Q_B}\right)} - \frac{Q_B}{Q_D}}\right] \qquad (5.12)$$

Effect of Fluid Gain between and Consequent Ultrafiltration during Hemodialysis

Ultrafiltration during standard hemodialysis, as currently practiced, adds a small increment to urea

clearance or Kt/V. However, the fluid gains between treatments serve to dilute solute levels (**FIGURE 5.6**), potentially mitigating their toxicity. This effect and the additional clearance due to the ultrafiltration itself are incorporated in the formal modeling equation ("B" in **EQUATION 5.10**) and are most clearly seen when comparing urea reduction ratio values with Kt/V at differing levels of ultrafiltration (see section "The Urea Reduction Ratio" later in the chapter).

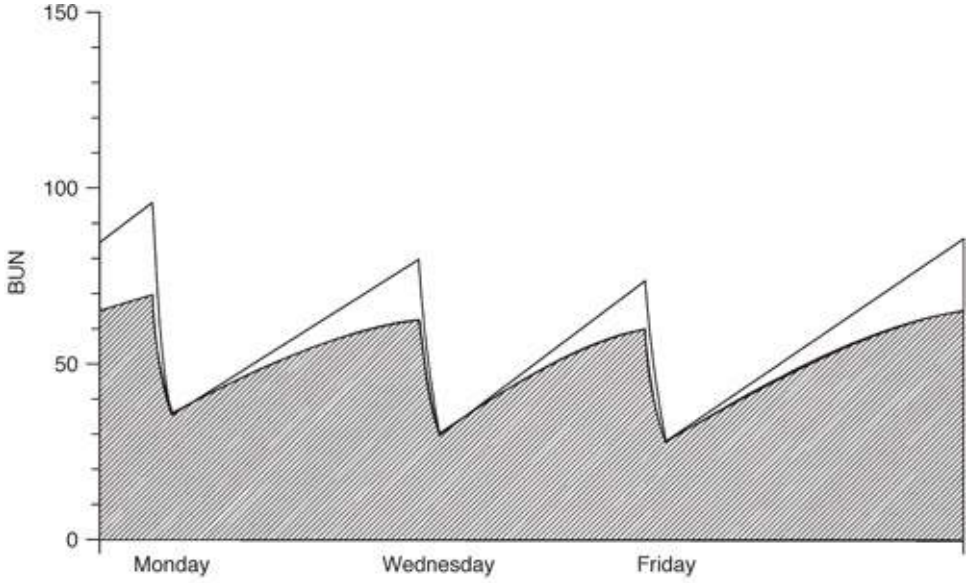

FIGURE 5.6 Effect of weight gain between dialyses. The upper profile of weekly steady-state urea concentrations represents a patient who gains no weight and requires no ultrafiltration during dialysis. The lower profile shows the effect of net fluid accumulation at 3 mL/min in the same patient. BUN, blood urea nitrogen.

To add the small effect of ultrafiltration to the *prescribed* clearance during hemodialysis, an addition term must be added to K_D (**EQUATION 5.13**):

$$\text{Total Prescribed } K = K_D + Q_F\,(1 - K_D / Q_B) \qquad (5.13)$$

where K_D is the dialyzer clearance in the absence of ultrafiltration, Q_B is the dialyzer blood inflow rate, and Q_F is the ultrafiltration rate (mL/min). As the extraction ratio approaches 1, meaning that the clearance approaches the blood flow rate, the effect of Q_F diminishes and eventually extinguishes, because removal of solute across the dialyzer cannot exceed 100%.

Primary Hemofiltration Therapy

The same hollow fiber device used for hemodialysis can be used to filter the blood, eliminating the need for dialysate and providing clearance by convection akin to native kidney function. However, filtered electrolytes and fluid must be replaced, necessitating simultaneous infusion of a sterile physiologic salt solution in large volumes. To achieve adequate solute removal, primary hemofiltration and hemodiafiltration therapy require filtration rates that are much higher than required for standard hemodialysis. Filtration also follows the laws of first-order kinetics, so we can use the same mathematical model developed for hemodialysis to predict blood levels and measure the patient response to the dialysis treatment as Kt/V. The model makes no assumptions about how the urea was removed, only that the process was first order. The patient's blood circulates between the filter and the patient just as it does for dialysis, and concurrent replacement of filtrate causes a rapid decline in solute concentration during treatment that diminishes the effect over time, similar to hemodialysis. The major determinants of the modeled clearance are the predialysis and postdialysis BUN. Some authorities see hemofiltration as a

trend for the future because it mimics the native kidney and has potential for removing larger molecular weight (MW) solutes more efficiently (124). However, outcomes data have not fully supported an advantage to hemofiltration versus hemodialysis (125–129). Of interest, delayed diffusion within the patient, one of the limitations to effective hemodialysis, also appears to limit the effectiveness of hemofiltration (127). Therefore, diffusion plays a significant physiologic role, whether the extracorporeal removal process is diffusive or convective.

How to Add K_R to Kt/V

Considering that the dialyzer urea clearance is usually an order of magnitude higher than the urea clearance achieved by two normal kidneys, the much-reduced clearance (K_R) contributed by the patient's impaired kidneys adds little to total urea clearance during dialysis; its major effect is seen between treatments where it serves to attenuate the rise in BUN as shown in **FIGURE 5.7**. In addition, the continuous nature of K_R makes it more efficient than intermittent hemodialyzer clearance, so simple addition of the two clearances is not possible. Two methods, both of which require formal urea kinetic modeling, have been used to generate a total clearance or total Kt/V that incorporates the effects of both clearances.

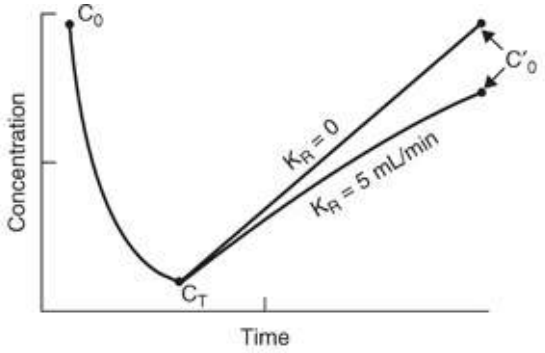

FIGURE 5.7 Effect of residual native kidney clearance (K_R). Dialyzable solute concentrations rise less steeply (*lower curve*) in a patient with significant K_R compared to the rise between dialyses in a patient with zero K_R (*upper line*).

The first and oldest technique is based on and assumption of equivalent values for either the time-averaged concentration of BUN concentration (TAC) or the average predialysis BUN (avC_0) (102). Any of the previously described models can be used to generate TAC or avC_0 from the predialysis and postdialysis BUN while K_R is included in the model. K_R is then removed from the model to calculate the delivered K_D that is required to produce the same TAC or avC_0 in the patient with identical G and V_D. In the absence of K_R, K_D must be increased to maintain the same TAC or avC_0. The new value for Kt/V represents the total effect of both clearances. This approach is equivalent to inflating K_R to a level that mimics the relatively inefficient effect of intermittent dialysis before adding the two clearances. A simplified method that does not require the second set of iterations has been published (99,102) and is discussed in a later section (with details in **EQUATION 5.33** and **TABLE 5.5**). Also, see section "A Simplified Method for Incorporating K_R".

TABLE 5.4 Urea Clearances Defined

Residual clearance
Clearance by the patient's native kidneys, often negligible or absent
Contributes little to total clearance during dialysis
Major effect on urea kinetics occurs between dialyses
Dialyzer clearance
Instantaneous: measured across the dialyzer from simultaneous inlet and outlet BUN
Modeled: integrated from predialysis and immediate postdialysis blood samples
Average dialyzer clearance for an entire dialysis
Not affected by urea disequilibrium
Patient clearance
Also called *whole body clearance*
Derived from the predialysis and equilibrated postdialysis BUN
Always lower than *dialyzer clearance*: difference due to urea disequilibrium
Includes the contribution from *residual clearance*
Continuous equivalent of intermittent clearance
Derived from G/TAC[a] or G/avC_0
Always lower than *dialyzer clearance* or *patient clearance*
Allows comparison of different schedules including continuous treatment

BUN, blood urea nitrogen.
[a]G/TAC is the (urea generation rate) / (time-average concentration).

TABLE 5.5 Values for κ Depend on the Frequency of Dialysis and the Targeted Blood Urea Nitrogen

		BUN Target	
Frequency	t_i Unadjusted	Time-Averaged[a]	Average Predialysis[a]
2	5040	6500	9500
3	3360	4000	5500
4	2520	2850	3700
5	2016	2200	2700
6	1680	1780	2100
7	1440	1500	1700

[a]The underlined numbers have been published. The remaining numbers were derived from urea kinetic modeling.
Depner TA. *Prescribing Hemodialysis: A Guide to Urea Modeling*. Boston, MA: Kluwer Academic Publishers, 1991; Gotch FA. Kinetic modeling in hemodialysis. In: Nissenson AR, Fine RN, Gentile DE, eds. *Clinical Dialysis*. Norwalk, CT: Appleton and Lange, 1995:156–188.

The second method takes the opposite approach by deflating the dialyzer clearance to a continuous equivalent clearance before adding the two. This method is described later in the section "A Continuous Equivalent Dose."

A major barrier that discourages addition of K_R to Kt/V is the inconvenience and expense of a timed urine collection. Non–urea-based methods of estimating K_R may eliminate these barriers. The nuclear medicine isotope determination of kidney function used in patients with relatively preserved glomerular filtration has proven to be inaccurate in more advanced CKD (130). Determining K_R in dialysis patients, using serum cystatin C levels when weekly or standard Kt/V is also known, has shown some promise (131,132). Recent KDOQI guidelines (73) have placed more emphasis on adjusting the dialysis prescription to patient K_R, and we may see more research in this area.

MULTIPLE-COMPARTMENT KINETIC MODEL

As the intensity of hemodialysis is increased and time is shortened, the potential for development of solute concentration gradients, called *solute disequilibrium*, increases. Evidence that disequilibrium develops during hemodialysis derives mainly from the rebound in solute concentration following dialysis (121,133). Even urea, which is a highly diffusible solute, has an easily detected rebound, indicating that the simple, single-compartment model has shortcomings. **FIGURE 5.8** shows a series of BUN measurements in a patient undergoing high-flux hemodialysis. The dashed line, representing the best fit of a single-compartment model, misses the data points by a significant margin, especially early into and immediately following the treatment. Two kinds of solute disequilibrium have been described: diffusion-dependent disequilibrium and flow-dependent disequilibrium; both reduce the effectiveness of hemodialysis.

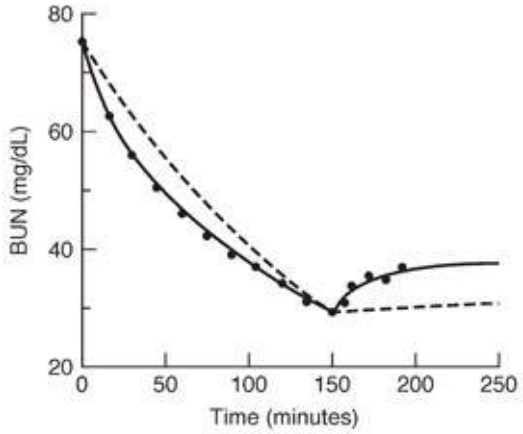

FIGURE 5.8 A two-compartment model (*solid line*) accurately predicts the measured blood urea nitrogen (BUN) values (*solid dots*) in a patient during and following high-intensity hemodialysis. A single-compartment variable-volume model (*dashed line*) overestimates the BUN during dialysis and fails to predict the rebound postdialysis. (From Depner TA. Refining the model of urea kinetics: compartment effects. *Semin Dial* 1992;5:147–154, with permission.)

Diffusion-Dependent Disequilibrium and the Two-Compartment Model

To improve the agreement of modeled predictions with the actual data, an additional compartment can be added as shown in **FIGURE 5.9** (121,134). Cell membrane resistance to diffusion is the physiologic correlate to this mathematical model of hemodialysis urea kinetics, which is patterned after the extracellular/intracellular separation of body water compartments (134). The dialyzed compartment, V_1, is separated from a remote compartment, V_2, by a resistance to diffusion, represented as K_C, the intercompartment mass transfer area coefficient. K_C is a solute-specific permeability factor that correlates positively with SA (e.g., cell membrane area) and inversely with resistance to diffusion between compartments. Addition of the second compartment requires modification of **EQUATION 5.9**:

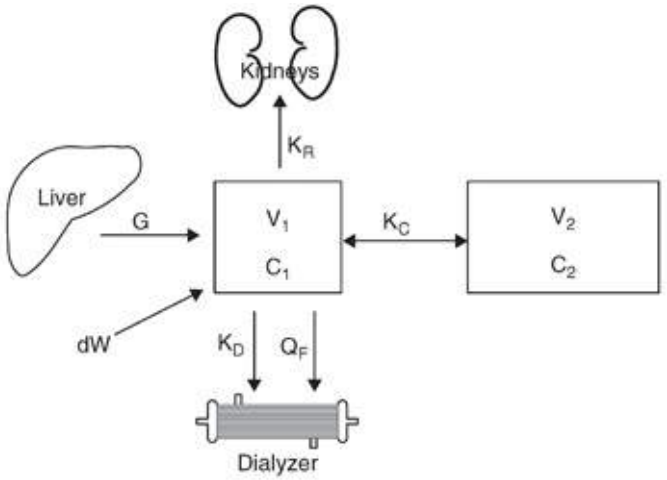

FIGURE 5.9 The two-compartment variable volume model of mass balance shows solute distributed in two compartments, V_1 and V_2. Solute moves by diffusion between compartments, driven by dialyzer removal. The rate of intercompartment diffusion is expressed as K_C, a mass transfer area coefficient. K_R is residual native kidney clearance of urea; K_D is dialyzer clearance; Q_F is ultrafiltration during dialysis; and dW is fluid gain between dialyses. (Adapted from Depner TA. *Prescribing Hemodialysis: A Guide to Urea Modeling*. Boston, MA: Kluwer Academic, 1991, with permission.)

where V_1 is the proximal (dialyzed) compartment volume, V_2 is the remote compartment volume, C_1 is the urea nitrogen concentration in V_1, and C_2 is the urea nitrogen concentration in V_2. Several assumptions are usually made to reduce the complexity of this model. Because urea is generated by the liver and then diffuses into the blood, G is applied only to the dialyzed compartment. Salt and water intake in the interval between treatments causes V_1 to expand and then to shrink during dialysis, but the size of V_2 is assumed to be constant at all times, like the intracellular space.

In contrast to **EQUATION 5.9**, **EQUATIONS 5.14** and **5.15** are not easily solved when V_1 is allowed to vary during and between dialyses. Several solutions have been reported, most of which involve numerical approximations that require a high-speed computer to resolve the four unknown variables, V_1, V_2, G, and K_C (135–139). When this model is applied to clinical data, a better fit between measured and predicted values is observed, as shown in **FIGURE 5.8**. For urea, the ratio V_2:V_1 is usually close to 2 when fitted by this two-compartment modeling technique, which adds support to the intracellular/extracellular basis of the model, with the primary resistance to diffusion at the cell membrane.

$$d(V_1C_1) / dt = G - C_1(K_D + K_R) - K_C(C_1 - C_2) \quad (5.14)$$

$$d(V_2C_2) / dt = K_C(C_1 - C_2) \quad (5.15)$$

Flow-Dependent Disequilibrium

In 1990, another type of disequilibrium was found within the blood compartment during high-flux treatments that could not be explained by the classic model (140). Urea concentration differences averaging 10 mg/dL and as high as 20 mg/dL were found in blood drawn simultaneously from both arms in a series of patients undergoing hemodialysis. The concentration gradient slowly dissipated over a 20- to 30-minute period after dialysis was stopped (140).

To explain the observed dialysis-induced intravascular concentration gradients, another model of hemodialysis urea kinetics was proposed, as shown in **FIGURE 5.10** (117). When the transit of blood through a particular circuit is delayed (e.g., by cutaneous vasoconstriction in a cold environment or during

episodes of hypotension), urea removal from the affected organ is delayed. This causes urea concentrations to fall more rapidly in the central well-perfused compartment (reducing dialyzer efficiency), while higher urea concentrations persist in more peripheral, less well-perfused compartments. Viewed from the most peripheral compartment, flow through the remainder of the body consists of a series of parallel circuits as shown in **FIGURE 5.10**, each of which could be considered a path for recirculation of dialyzed blood. Later studies of the early response to dialysis, the response to exercise and ultrafiltration during dialysis, and measurements of cardiopulmonary recirculation using thermal and ultrasound dilution techniques confirmed the existence of blood flow–related solute disequilibrium (141–145). This convective type of resistance to dialysis has been quantified and is much better understood today. Diffusion-dependent disequilibrium is highly dependent on the nature of the solute as well as the membrane, but in contrast, flow-related disequilibrium, as described by the model, should not be affected by the molecular size of the solute.

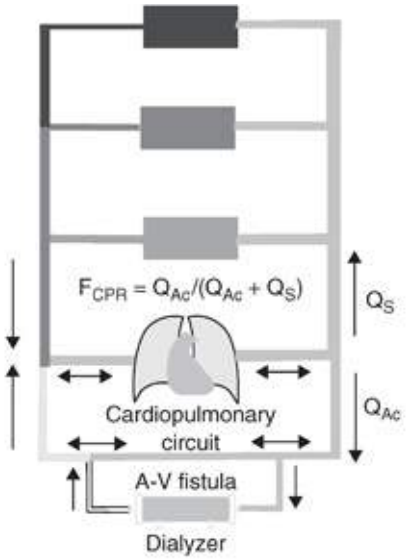

FIGURE 5.10 Flow-related disequilibrium. Solute disequilibrium within the blood compartment is explained by this model of multiple parallel circuits, each with a different blood flow/tissue volume. Blood leaving the heart is distributed to all tissue compartments at the same solute concentration, whereas solute concentrations in the blood leaving each compartment are different. The fraction of dialyzer venous blood that reenters the dialyzer by passing through the heart and lungs (F_{CPR}) is called *cardiopulmonary recirculation*. Q_{Ac}, access blood flow; Q_S, systemic blood flow.

Cardiopulmonary Recirculation

A specific subtype of flow-dependent disequilibrium, probably accounting quantitatively for more than half of hemodialysis-induced convective disequilibrium, has been called *cardiopulmonary recirculation* (143). Cardiopulmonary recirculation represents the fraction of blood returning from the dialyzer that is rapidly returned to the dialyzer through the heart and lungs. It is found only during dialysis conducted through peripheral arteriovenous (AV) shunts (**FIGURE 5.10**) and, accordingly, is absent during dialysis through central venous catheters in patients lacking a peripheral AV access. The recirculation fraction is simply the ratio of access flow to cardiac output (**EQUATION 5.16**):

$$F_{CPR} = \frac{Q_{AC}}{Q_{AC} + Q_S} \qquad (5.16)$$

where F_{CPR} is the recirculation fraction (fraction of blood entering the dialyzer that has recirculated

through the heart and lungs), Q_{Ac} is access blood flow, and Q_S is systemic blood flow (cardiac output minus Q_{Ac}). Part of the deviation from single-pool kinetics shown in **FIGURE 5.8** can be attributed to cardiopulmonary recirculation, which reduces urea concentrations entering the dialyzer to levels below that returning from the systemic circuit (**EQUATION 5.17**) (143):

$$\frac{C_i}{C_s} = \frac{Q_s}{Q_s + K_d} \qquad (5.17)$$

where C_i is the urea concentration in blood entering the dialyzer and C_S is the urea concentration in blood returning from the systemic circuit. The reduced concentration C_i can be substituted for C_0 in **EQUATION 5.10** or for C_1 in **EQUATION 5.14**. Because the magnitude of this effect is predictable, based on estimates of cardiac output and dialyzer clearance, even simpler single-compartment models can incorporate a correction for cardiopulmonary recirculation.

How to Implement Multiple-Compartment Modeling

More than two BUN measurements are required for formal two-compartment modeling. The best time points for obtaining these are midway during dialysis and midway during and at the end of the rebound phase. Numerical solutions to **EQUATIONS 5.14** and **5.15** are used in place of **EQUATION 5.10**. Urea concentrations in each compartment are computed at small time intervals, and then adjustments are made in V_1, V_2, G, and K_C, similar to the single-pool technique, until the computed profile fits the measured data points. C_1 in **EQUATION 5.14** can be adjusted for cardiopulmonary recirculation using **EQUATION 5.17** as shown earlier. A high-speed computer is required for this type of modeling.

Schneditz presented an analogous model (with an analytical solution) from flow considerations alone, a pure convectional model based on differences in regional organ perfusion during hemodialysis (146). Although the pattern of fall in BUN is slightly different, the rebound is indistinguishable from predictions of the classic diffusional model. The effect of flow disequilibrium on the concentration pattern and removal of other solutes has not been measured so it is not yet possible to determine the relative roles of these two radically different models.

Comparison with the Single-Compartment Model

Although the single-compartment variable-volume model fails to estimate intradialysis and postdialysis urea concentrations (**FIGURE 5.8**), it predicts V and, therefore, Kt/V with reasonable accuracy (121,136). The reason for this unexpected performance is the offsetting direction of errors in the numerator and the denominator of the equation for V. If G and ultrafiltration are ignored, V can be calculated during dialysis as the amount of urea removed divided by the change in urea concentration (**EQUATION 5.18**):

$$V = \frac{K_D \int_{t=0}^{t=T} C dt}{C_0 - C_E} \qquad (5.18)$$

where C_0 is the predialysis BUN and C_E is the equilibrated postdialysis BUN.

The amount of urea removed during a single dialysis is the product of K_D and the area under the time versus BUN curve (numerator of **EQUATION 5.18**). **FIGURE 5.11** shows the error in that calculation as the

shaded area between the two-compartment prediction and the single-compartment prediction of urea nitrogen concentrations. The error in the denominator is the difference between the immediate postdialysis BUN (C_T) and the equilibrated BUN (C_E). For the usual 3- to 4-hour dialysis with Kt/V = 1.2 to 1.3, the errors are of similar magnitude and offset each other (136,147). The result is a fairly accurate prediction of V by the single-compartment model, depending to some extent on the rate of ultrafiltration during dialysis. However, urea generation (G) and net protein catabolism (nPCR) are slightly but consistently overestimated by the single-compartment model because there is no compensating error.

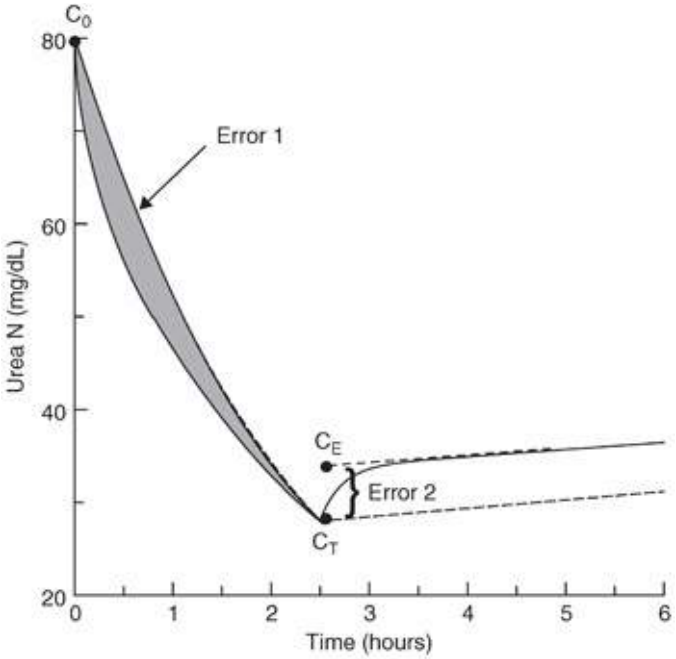

FIGURE 5.11 Balanced errors. The upper boundary of the shaded area shows the single-compartment prediction of blood urea nitrogen (BUN) during hemodialysis. The lower boundary is the two-compartment model line (compare with **FIGURE 5.8**). C_E is the equilibrated BUN extrapolated to the postdialysis time. The single-compartment model overestimates the BUN during dialysis and consequently overestimates the amount of urea removed shown as the shaded area (error 1) and in the numerator of **EQUATION 5.18**. It also underestimates the equilibrated BUN (C_T) causing a false overestimate of the change in concentration (error 2) in the denominator of **EQUATION 5.18**.

Multiple-compartment modeling is not required for routine clinical application but should be used when an accurate profile of BUN during and immediately after dialysis is required, when an accurate measure of G is required, and when modeling the kinetics of solutes other than urea.

eKt/V and the Effect of Treatment Time

Both single-compartment and multiple-compartment models overestimate the amount of dialysis *received* by the patient. The "K" in Kt/V is the effective *dialyzer* clearance of urea (**TABLE 5.4**). More important for the therapeutic effect is the *patient's* clearance, often termed the *whole body* clearance, defined in **TABLE 5.4**. For patients with significant urea disequilibrium, whole body clearance is significantly less than dialyzer clearance because some of the patient's urea is compartmentalized and only slowly released to the dialyzer. Whole body Kt/V, often called *eKt/V*, can be resolved by applying the single-compartment model to the *equilibrated* postdialysis BUN instead of the *immediate* postdialysis BUN (136). Two-compartment models can be used to determine both the effective dialyzer clearance and the patient's whole body clearance because these models predict both the immediate postdialysis BUN and the

equilibrated postdialysis BUN.

Because urea modeling is used to tailor the dialysis dose to the individual patient's needs, concern has been raised about patients who may rebound more than others and may be underdialyzed because the single-compartment model fails to consider rebound. Studies both prior to and during the HEMO study (see subsequent text) found that rebound is highly predictable and that such outliers may not actually exist (148,149). Based on BUN measurements up to 60 minutes postdialysis in several patient cohorts, eKt/V was estimated best by a simple equation, called the *rate equation*, that predicts rebound from the intensity or rate of solute removal during dialysis (**EQUATIONS 5.19** and **5.20**) (149,150):

$$eKt/V = spKt/V - 0.6K/V + 0.03 \qquad (5.19)$$

$$eKt/V = spKt/V(1 - 0.6/t_d) + 0.03 \qquad (5.20)$$

where K/V is the fractional clearance per hour and t_d is measured in hours. **EQUATION 5.20**, which is equivalent to **EQUATION 5.19**, shows that eKt/V relates to spKt/V as a function of treatment time (t_d) or intensity of dialysis (K/V). Although empirically derived, these equations can be predicted from current knowledge about the genesis of rebound from solute gradients in the patient. An alternative, perhaps more accurate rate equation based on retrospective analysis of the HEMO study data from equilibrated blood samples may also be used to estimate eKt/V (**EQUATION 5.21**) (151):

$$eKt/V = spKt/V - 0.40\ (K/V) \qquad (5.21)$$

The magnitude of these gradients is increased by more intense dialysis where intensity is measured as the fractional rate of solute removal (K/V in **EQUATION 5.19** and **5.21**). Assuming that the same dose is given, the intensity of dialysis must increase when treatment time is shortened. Subsequent equations based on treatment time have been developed, all of which predict the effect shown in **FIGURE 5.12** as a reduction in eKt/V with short treatment times despite a constant spKt/V (152,153). The clinical lesson here is that as eKt/V is a better measure of patient clearance than spKt/V, shortening the treatment time also short-changes the patient.

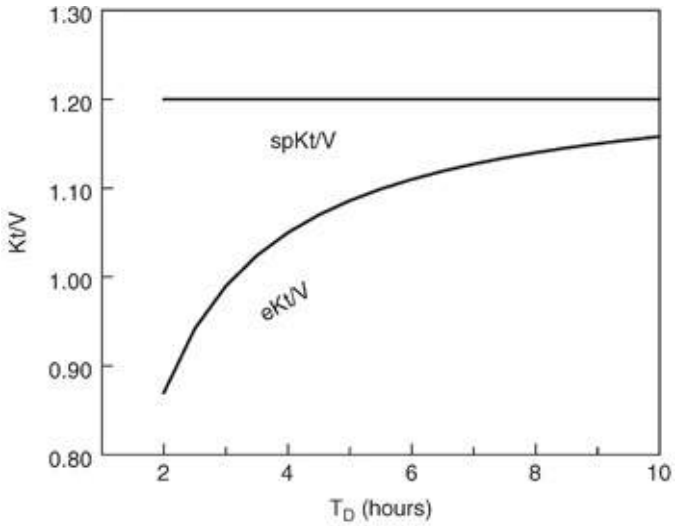

FIGURE 5.12 If spKt/V is set constant (*upper line*), eKt/V falls as treatment time (t_D) is reduced (**EQUATION 5.20**). This shows that dialysis becomes less efficient as t_D is shortened.

Conversely, increasing the treatment time improves the efficiency of solute removal, as shown in **FIGURE 5.12**, and may have other benefits that are not apparent when applying current models of solute

kinetics. Serum concentrations of solutes like phosphate and potassium that deviate significantly from simple first-order kinetics can be predicted by applying more complex mathematical models (154,155). Both predicted and measured removal rates of inorganic phosphate are markedly affected by both treatment time and frequency (155–158). Phosphate is considered an indirect uremic toxin, and observational outcome studies have suggested a benefit from markedly prolonging t_d at a fixed dialysis frequency. In a comparison study to short daily hemodialysis, long nocturnal hemodialysis removed almost twice as much phosphorus per week, and many patients were able to discontinue their phosphate binders (159).

DIALYSATE METHODS

Measuring patient clearance and eKt/V from dialysate collections is analogous to measuring native kidney clearance by collecting urine, except that the blood concentration changes rapidly during the measurement (160–163). Blood sampling can be avoided if equilibrated dialysate samples are taken predialysis, and the previously described models of solute clearance can be used to integrate and predict the intradialysis solute concentrations needed for the clearance measurement. Other advantages of the dialysate method include elimination of the needs for measuring several parameters including ultrafiltration, solute disequilibrium, and blood and plasma water content. Dialysate pumps are less prone to error than blood pumps and can be calibrated volumetrically during treatments. Dialysate is also readily available in large quantities for measurement. The disadvantages of dialysate methods include the cumbersome task of collecting large quantities of dialysate, the requirement for precise analytical methods due to low solute concentrations, and an inherent susceptibility to error when calculating urea clearance due to a requisite subtraction of two large numbers to obtain the desired measurement (164). Bacterial contamination of dialysate can also lead to urea degradation and erroneous dialysate urea concentrations (165). Many of these disadvantages can be circumvented by multiple sampling techniques (160,162), but the method then becomes more cumbersome. As an alternative, applying the rate equation to blood side measurements, as described earlier, gives more precise and reproducible values for eKt/V (164).

To calculate urea eKt/V using the dialysate method, four critical measurements are required: C_0, V, C_D, and Q_D. The predialysis BUN (C_0) can be determined by sampling dialysate after equilibrating the dialysate compartment with the blood compartment by recirculating the dialysate. This has the advantage of giving the true blood water concentration automatically adjusted for the Gibbs-Donnan effect. The patient's urea volume (V) requires measurement of the equilibrated postdialysis BUN (C_E), but it requires only one accurate measurement. Once determined, V will not deviate significantly from month to month unless the patient's weight and/or nutritional status changes (**EQUATION 5.22**):

$$V = \frac{Q_D C_D t - \Delta V C_0 - RG}{C_0 - C_E} \qquad (5.22)$$

where Q_D is total dialysate flow including Q_F, C_D is the dialysate urea nitrogen concentration, ΔV is the fluid lost during dialysis, and RG is a correction for K_R and urea generation. RG is the amount of urea generated during the dialysis minus the amount removed by the patient's native kidneys (**EQUATION 5.23**):

$$RG = t(G - K_R C_{Av}) \qquad (5.23)$$

RG usually contributes very little in conventional three times weekly dialysis and in most patients can be ignored. If included, C_{Av} can be approximated as the log mean $C = (C_0 - C_E) / \ln(C_0 / C_E)$. Total body urea content at the start of dialysis is $C_0(V + \Delta V)$. The amount of urea removed is $Q_D C_D t$.

When solute removal is measured directly, the total effect of a single dialysis can be expressed as the solute removal index (SRI) (166,167). SRI is the fractional solute removal, the amount removed divided by the initial total body content (**EQUATION 5.24**):

$$SRI = \frac{Q_D C_D t}{C_0(V + \Delta V)} \qquad (5.24)$$

Although SRI is a fraction of the initial solute content, the fraction may be greater than 1 because of ongoing solute generation during dialysis. For urea, a direct mathematical relationship between Kt/V and SRI may be demonstrated from **EQUATION 5.7** (**EQUATIONS 5.25** and **5.26**):

$$eKt/V = -\ln(1 - SRI) \qquad (5.25)$$

$$SRI = (1 - e^{-eKt/V}) \qquad (5.26)$$

EQUATION 5.7 can be used here instead of the more complex equations that include G, Q_F, and two compartment adjustments, because the amount of urea removed ($Q_D C_D t$) is measured directly; it includes the contribution of ultrafiltration and requires no correction for G or solute disequilibrium. SRI is easier to conceptualize and has been considered by some to be a better index of small solute removal and a better overall measure of dialysis than Kt/V. Unfortunately, there are no standards of adequacy for SRI. Until such standards are available, SRI can be converted to eKt/V using **EQUATION 5.25** with the understanding that "eK" represents whole body clearance as discussed earlier. Because whole body clearance is always lower than dialyzer clearance, eKt/V determined from **EQUATION 5.25** is lower than Kt/V estimated from one- or two-compartment modeling (168).

Dialysate Conductivity Methods

Measurements of dialysance using simple conductivity probes placed in the dialysate inlet and outlet lines are increasingly used to monitor the delivered dialysis dose (169–171). This inexpensive and noninvasive technique, termed the *ionic dialysance* method, can be automated to provide real-time measurements during each dialysis. Dialysate electrolytes (mostly sodium and its anions) are small molecules with clearances across dialyzer membranes roughly equivalent to that of urea. Therefore, changes in dialysate electrical conductivity can be used to reflect urea diffusion across the membrane. To create a significant electrolyte gradient between blood and dialysate, the dialysate concentration is abruptly increased for a few minutes by altering dialysate/water proportioning. The resulting change in conductivity from dialysate inlet to outlet reflects movement of electrolytes, mostly sodium, into the patient (**EQUATION 5.27**) (172):

$$D = (Q_D + Q_F)\left[1 - \frac{(Co_1 - Co_2)}{(Ci_1 - Ci_2)}\right] \qquad (5.27)$$

where Co and Ci are dialysate outlet and inlet conductivities (mS/cm), D is dialysance (mL/min), Q_D is dialysate flow, Q_F is ultrafiltration flow, and subscripts 1 and 2 indicate measurements before and after

the step-up in conductivity. Several short measurements of conductivity (ionic) dialysance can be averaged over the course of a treatment to improve the measurement precision. If V is estimated and updated periodically, the actual delivered spKt/V can be calculated in real time for each treatment. Ionic dialysance closely correlates with standard blood and dialysate-side measurements of urea clearance but is approximately 5% lower (169,173). **FIGURE 5.13** shows the correlation and slight difference between ionic dialysance and urea clearance by single pool modeling (174). Addition of a step-down in conductivity (decrease in dialysate sodium from baseline) can eliminate this difference (175). Corrections for cardiopulmonary recirculation have also been suggested (175). The conductivity method has several advantages including on-line and more frequent determinations of delivered dose, decreased cost, and elimination of invasive blood sampling. Limitations to use of dialysate conductivity as a substitute for Kt/V derived from urea modeling include the need for an independent measure of V, no accounting for urea generation during the dialysis treatment, and convective clearance from ultrafiltration is not included. The problem with V is difficult to rectify, as the various anthropometric methods for calculating V all appear to substantially overestimate V as compared with V derived from urea modeling, and the difference is unpredictable (82). SA may be a better denominator for clearances measured using conductivity methods.

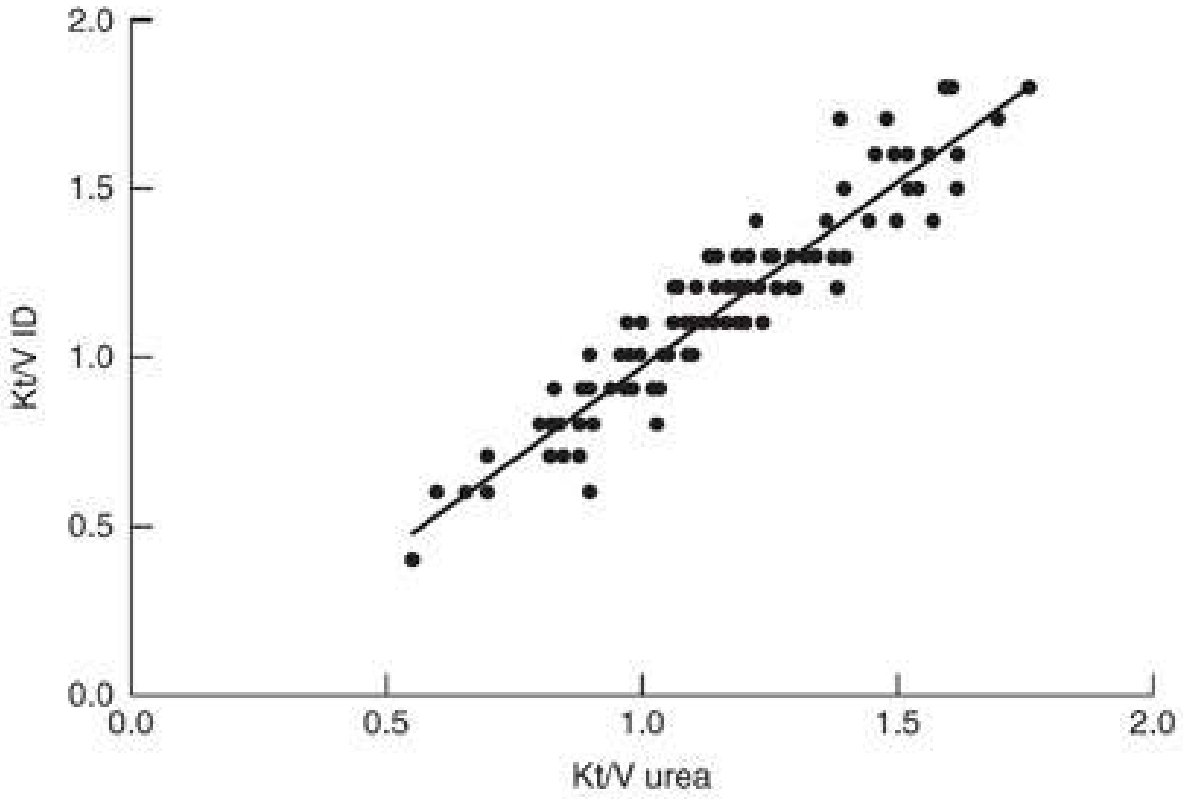

FIGURE 5.13 Modeled Kt versus Kt from on-line ionic dialysance measured during a single hemodialysis treatment in 37 in-center patients. The correlation is good ($R^2 = 0.76$) but the ionic dialysance method consistently underestimated the modeled value. [From McIntyre CW, Lambie SH, Taal MW, et al. Assessment of haemodialysis adequacy by ionic dialysance: intra-patient variability of delivered treatment. *Nephol Dial Transplant*, 2003;18(3):559–562.]

THE DIALYSIS SCHEDULE: MORE FREQUENT IS MORE EFFICIENT

The patient's own tissues present a barrier to intermittent dialysis that is greater than had been anticipated

in the past. Even for urea, one of the most diffusible solutes, resistance to removal can be easily demonstrated as multiple concentration gradients that develop within the patient during both standard and high-efficiency dialysis. Increasing the frequency tends to diminish this effect and allows more efficient removal of solute. This phenomenon is illustrated in **FIGURE 5.14** as a reduced requirement for weekly Kt/V to maintain the same TAC. Increasing the frequency improves the efficiency of dialysis by reducing the amplitude of oscillations in solute concentration and by diminishing patient-dependent disequilibrium (176–178). Advances in dialysis technology have improved the dialyzer and dialyzer membranes but not the resistance to diffusion in patients.

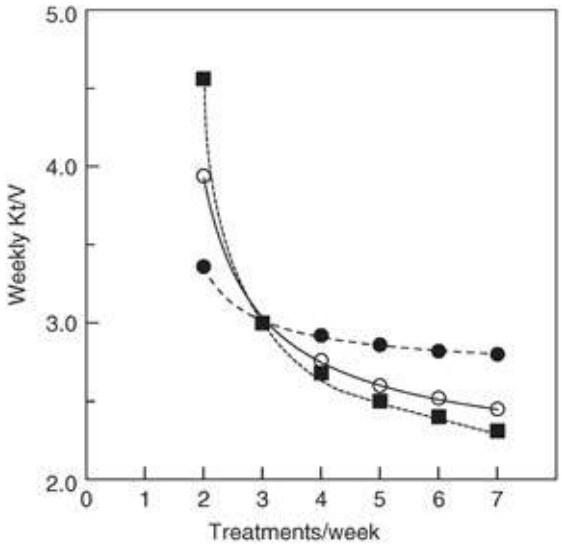

FIGURE 5.14 Kt/V required to achieve the same time-averaged concentration (TAC). As the frequency of hemodialysis treatments increases, the efficiency of each treatment increases. The vertical axis shows the total weekly dose (Kt/V) required to maintain the average blood urea nitrogen (TAC) constant. ● = prediction of the single-compartment model. ○ = two-compartment model predictions for urea (K_c = 500 mL/min). ■ = a theoretical molecule with K_c = 200 mL/min. (Adapted from Depner TA. Quantifying hemodialysis and peritoneal dialysis: examination of the peak concentration hypothesis. *Semin Dial* 1994;7:315–317, with permission.)

Frequent dialysis schedules include short daily treatments with standard blood and dialysate flow rates and long nocturnal treatments using lower flow regimens. Both techniques are reported to improve extracellular volume control, blood pressure, and left ventricular mass (13,14,179). Nocturnal hemodialysis, when performed six to seven nights per week, may better reduce the concentrations of protein-bound, sequestered, and larger MW solutes, including phosphorus and β_2-microglobulin (159,177,180). The NIH-sponsored Frequent Hemodialysis Network trial showed better outcomes with more frequent hemodialysis treatments but not to the extent shown in previous observational studies where confounding by selection bias was difficult to eliminate (13,14).

Application of urea modeling to quantify the dose becomes problematic because dialyzer spKt/V does not reflect patient clearance and a summation of daily Kt/V values to give a weekly Kt/V does not account for the improved efficiency of daily dialysis. Several methods have been proposed to measure the dose when dialysis is performed at different frequencies and intensities.

A Continuous Equivalent Dose

Adhering to the concept of small solute clearance as the best current measure of dialysis dose and adequacy, a continuous equivalent clearance for patients dialyzed intermittently can be defined as the

weekly removal rate divided by the average solute concentration (TAC). For patients in a weekly steady state of nitrogen balance, the urea removal rate should equal the urea generation rate (G). Both G and TAC are readily measured from standard kinetic modeling, so an equivalent kidney clearance (EKR) is easily calculated (**EQUATION 5.28**) (99,181):

$$EKR = G / TAC \qquad (5.28)$$

Mathematically, it can be shown that the EKR for the KDOQI guideline specifying a minimum dialysis Kt/V of 1.2 per dialysis thrice weekly is approximately 3.0 volumes per week. This value does not compare favorably with the accepted continuous peritoneal dialysis guideline of 1.7 volumes per week (182). Two explanations have been given for this discrepancy, each of which forms the basis for another continuous equivalent index of intermittent hemodialysis, called "standard Kt/V" and "normalized Kt/V."

Standard Kt/V

Standard Kt/V (stdKt/V) invokes peak serum urea concentrations as the target of therapy with the presumption that peak levels determine toxicity more so than trough or average levels (183). This method also requires calculation of G and utilizes the mean predialysis BUN, as opposed to TAC, as the denominator in the expression of steady-state clearance (**EQUATION 5.28**). Substituting the average peak urea concentration as the denominator of the clearance expression yields the "standard clearance" from which standard Kt/V is derived (**EQUATION 5.29**) (183):

$$\text{Standard } K = G / avC_0 \qquad (5.29)$$

Because spKt/V and its derivative, eKt/V, can be approximated with simplified formulas (**EQUATIONS 5.19**, to **5.21** and section "Explicit Equations" later in the chapter), another simplified formula has been developed, based on a fixed volume model and a symmetric week, to calculate stdKt/V from spKt/V and eKt/V (**EQUATION 5.30**) (152,183):

$$_{std}Kt/V = \frac{10{,}080\,\frac{1 - e^{-eKt/V}}{t}}{\frac{1 - e^{-eKt/V}}{_{sp}Kt/V} + \frac{10{,}080}{Nt} - 1} \qquad (5.30)$$

where N is the number of treatment and 10,080 is the number of minutes in a week. This formula has been extended to include the effects of fluid accumulation/removal and residual native kidney clearance (184).

Estimating spKt/V at Higher Dialysis Frequencies

EQUATION 5.30 is based on eKt/V which is derived from spKt/V. If the simplified Daugirdas formula is used to calculate spKt/V from pre- and post-BUN values in patients dialyzed more frequently, significant errors occur especially at higher frequencies. A recent modification of the Daugirdas formula corrects this error (185).

Normalized Kt/V

The rationale for a *normalized Kt/V* is based on evidence that although urea is a good indicator solute for dialyzer clearance, it is not a good indicator for whole body patient clearance (88,89,186,187). Other

toxins diffuse less readily among body compartments, creating a steeper dependency of effective clearance on dialysis frequency (176,186,188). Substituting another solute with dialyzer clearance similar to urea but lower K_C than urea yields a *normalized clearance* from which *normalized Kt/V* (nKt/V) is derived (**EQUATION 5.31**) (176,189,190):

$$\text{Normalized K} = G / TAC_X \qquad (5.31)$$

where TAC_X is the time-averaged concentration of another compound with lower K_C than urea.

Calculation of normalized Kt/V is based on the observation that disequilibrium for many small dialyzable solutes is greater than urea disequilibrium. The bottom tracing of **FIGURE 5.14** shows that solutes with low K_C (**EQUATION 5.14**) have a steeper decline in the clearance required to maintain a constant TAC when dialysis frequency varies over a range from one to seven treatments per week (176). Solutes exhibiting higher concentration gradients among body compartments are affected more by changes in frequency than urea. When a lower K_C value is entered into the two-compartment model, greater benefit is seen when frequency increases from three per week to six per week (190). The blood concentrations of solutes with low K_C values fall more than urea as frequency increases. This approach requires a formal two-compartment, variable-volume mathematical model that is not practical for current use in the dialysis clinic, but it demonstrates a fundamental principle that may be useful if the technique can be simplified.

Both standard and normalized clearance are lower than EKR, and when applied to the minimum KDOQI guideline of 1.2 per dialysis thrice weekly, both agree well with the recognized minimum value for weekly urea clearance in continuous ambulatory peritoneal dialysis (CAPD) patients (191). Calculated values for stdKt/V and nKt/V are similar, and both require calculation of G, usually from formal urea modeling. For intermittently dialyzed patients, these continuous equivalent clearances are always lower than the measured dialyzer clearance (spKt/V) and lower than the modeled patient clearance (eKt/V). The difference reflects the inefficiency of intermittent compared to continuous dialysis. **FIGURE 5.14** shows that infrequent dialysis requires a higher weekly clearance to achieve the same TAC as daily therapy.

Standards for continuous equivalent clearances do not change with dialysis frequency, so measures of intermittent hemodialysis can be directly compared to measures of CAPD and to functioning native kidneys. For patients maintained with hemodialysis who have residual native kidney function, the urea clearances may simply be added to stdKt/V, as both are considered continuous clearances. This universal applicability to patients before starting dialysis and after starting any mode of dialysis or transplantation is an attractive feature.

Limitations of Blood-Side Modeling as Frequency Increases

It is important to consider that blood-based methods of dose quantification lose some of their power when applied to more frequent prolonged treatments because the difference between the predialysis and postdialysis urea concentration is reduced leading to greater errors in the calculation of their ratio. As the frequency increases approaching continuous dialysis, blood-side modeling is no longer possible. Measuring the dose of more frequent hemodialysis may require measurement of cross-dialyzer clearances or dialysate methods, similar to measurements of continuous peritoneal dialysis.

SIMPLIFIED APPROACHES TO QUANTIFYING DIALYSIS

Because the relationships among time, solute removal, and clearance are logarithmic and influenced by multiple variables, the mathematical expressions of urea kinetics are often complex. Inclusion of all the pertinent variables using formal modeling requires computer software. To circumvent these complexities and to provide tools for quick "bedside" estimates, simplified approaches to urea modeling have been proposed (111,150,152,184,192–197).

Explicit Equations

Explicit solvable equations eliminate the need for stepwise iterative approximations of Kt/V and nPCR by ignoring the lesser variables. **EQUATION 5.7** is a simplified formula that ignores ultrafiltration, urea generation, and disequilibrium during dialysis. A more accurate formula, derived empirically by Daugirdas (198), is shown here in **EQUATION 5.32**:

$$Kt/V = -\ln(R - 0.03) + (4 - 3.5R)U_F / W \qquad (5.32)$$

where R is the ratio of postdialysis/predialysis BUN, U_F is the total ultrafiltrate volume in liters per dialysis, and W is the patient's weight in kilograms. **EQUATION 5.32** approximates the contributions of urea generation and ultrafiltration during dialysis in the first and second terms, respectively. It requires use of a scientific calculator or log table, but no iterative programming is required.

The protein catabolic rate is more difficult to resolve with explicit formulas because the dialysis schedule, residual clearance, and fluid gain play significant roles (195,199). **EQUATION 5.8** is an example of an explicit equation that ignores fluid gain and residual clearance, but it requires a third BUN measurement. To include the latter variables, and reduce the requirement to two BUN measurements, equations have been derived for hemodialysis given three times and two times weekly, with and without residual clearance (200).

The Urea Reduction Ratio

The urea reduction ratio (URR) is the fractional fall in BUN during a single dialysis (111,193,197) and is mathematically related to Kt/V. The denominator is the predialysis BUN, and the numerator is the difference between the predialysis and postdialysis BUN values. Unfortunately, URR does not account for the effects of ultrafiltration or urea generation during dialysis, both of which allow significant amounts of urea removal with little change in urea concentration (**FIGURE 5.15**). As an example, a dialysis treatment where 4 L of ultrafiltration is removed from a patient with a predialysis weight of 100 kg, the volume removal may augment Kt/V by almost 0.1, whereas URR may be unchanged compared to a treatment where no ultrafiltration was performed. Because urea generation matches urea removal in patients with continuous kidney function or in patient undergoing continuous dialysis (e.g., CAPD), URR is zero and cannot be used to measure depurative function. However, because it is simple to calculate, URR is widely used to quantify intermittent therapies like hemodialysis and assess its adequacy. If standards are set conservatively (high) in centers where URR is the only measure of dialysis, patients should be protected from underdialysis and are better managed than patients in whom no yardstick of dialysis is regularly applied. However, most the time and effort required to obtain and analyze blood samples for formal modeling is also required for measurement of URR, so measuring Kt/V should take little additional

resources.

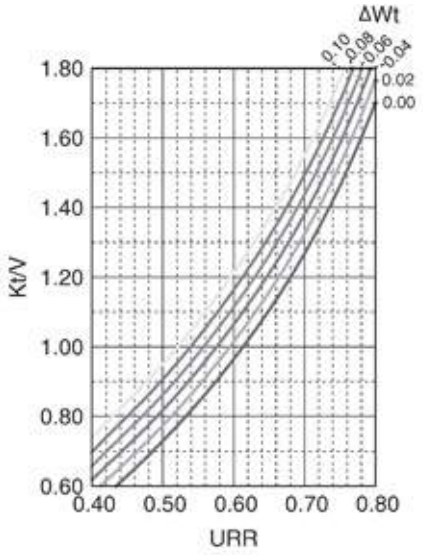

FIGURE 5.15 The logarithmic relationship between the urea reduction ratio (URR) and Kt/V derived from formal urea modeling. This relationship is significantly affected by fluid removal during dialysis. ΔWt is the change in weight during dialysis expressed as a fraction of the postdialysis weight. (From Depner TA. Estimation of Kt/V from URR for varying levels of weight loss: a bedside graphic aid. *Semin Dial* 1993;6:242, with permission.)

A Simplified Method for Incorporating K_R

The first approach described in the previous section, "How to Add K_R to Kt/V," requires multiple additional iterations of the urea kinetic model to achieve an equivalent TAC or $avC_{0,}$ with and without K_R in the model. Because this method has the effect of inflating K_R before adding it to K_D, a simplified equation can be generated to approximate this inflation. The magnitude of the inflation is expressed in the coefficient (κ) (**EQUATION 5.33**):

$$\text{Total Kt/V} = K_D t/V + \kappa K_R/V \qquad (5.33)$$

The coefficient (κ) also represents the time during which K_R is active, including the long interval between treatments. Values for κ can be approximated by applying a formal model of urea kinetics and using average values for G, V_D, and Q_F as the coefficient is insensitive to these parameters. The values for κ shown in **TABLE 5.5** were generated from the single pool model for two to seven dialysis treatments per week (99,102).

A Comparison of Simplified Methods to Formal Modeling

The simplified formulas and graphics mentioned earlier are helpful instructional tools and allow quick estimates when a computer is not immediately available. For routine application in a clinic, however, little is gained by shortcutting formal urea modeling. The most time-consuming and expensive aspects of urea modeling are collecting the blood samples, blood analysis, and entry of data into the computer. Computers allow just about any dialysis clinic to obtain formal kinetic modeling data. In the present era of electronic medical records, the comparison of values to previous analyses, transmission of results to nephrologists, and quality control functions of the dialysis medical director takes but an instant. The terms *quick* and *bedside*, sometimes applied to simplified formulas, are misleading because the time lag between sampling the blood and return of data from the laboratory is ignored. A major goal of urea

modeling is to individualize therapy; ignoring critical variables such as a volume change during dialysis, or assuming a mean value for all patients, defeats this purpose.

PRACTICE GUIDELINES AND STANDARDS

The Hemodialysis Study

The NCDS was the first randomized trial of dialysis dose, but as time passed and both the patients and the practice of dialysis changed, another NIH-sponsored clinical trial, the HEMO study, was instituted to evaluate potential benefits from further increases in the dialysis dose as depicted in **FIGURE 5.16** (201). The method chosen to quantify and control the dose of hemodialysis in this study was formal urea modeling. The equilibrated Kt/V (eKt/V) that accounts for urea disequilibrium and is considered a more accurate reflection of true patient clearance was used to quantify the dialysis dose. The simple rate equation described in the preceding text was used to convert measured spKt/V to eKt/V, eliminating the need for a second postdialysis blood sample. The rate equation was validated before the HEMO study, and in the HEMO pilot study, eKt/V from the rate equation correlated well with eKt/V determined from dialysate collections (148). Patients were randomized to receive either a "standard" dose of dialysis (target eKt/V of 1.05 per treatment) or a "high" dose (target eKt/V of 1.45 per treatment). The two randomized prescriptions were tightly controlled by study investigators so that midway through the study, less than 4% of patients who received the "standard" dose of dialysis fell below the current minimum recommended spKt/V of 1.20.

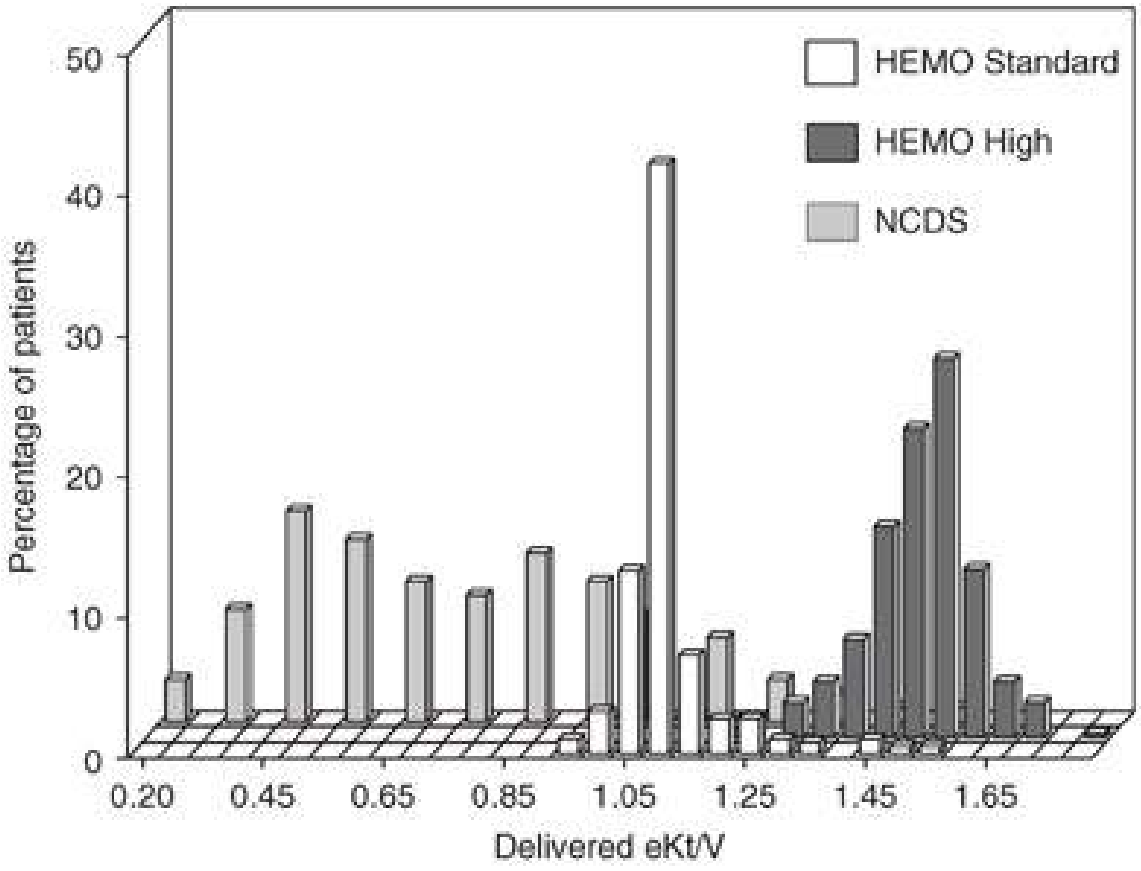

FIGURE 5.16 Distribution of patients in two major clinical trials of dialysis dose, expressed as a function of eKt/V shown on the x-axis. The highest delivered doses in the National Cooperative Dialysis Study (NCDS) were slightly below the lowest doses delivered to patients in the Hemodialysis (HEMO) study.

No significant difference in morbidity or mortality between treatment groups was found at the conclusion of the study. Women who received the higher dialysis dose had a slightly lower risk of death and hospitalization of borderline significance compared to controls, whereas men showed no response to the higher dose. The HEMO study provides strong evidence that the minimum thrice-weekly hemodialysis dose recommended by KDOQI and other standard-setting organizations is also the optimal dose (19,202). Although the study showed no benefit from the higher dose when administered thrice weekly, the results are not inconsistent with reports from uncontrolled studies of improved outcomes after increases in dialysis frequency. Although the delivered high Kt/V averaged 36% higher than the control dose in this study, the separation, when expressed as standard or normalized Kt/V, was only about 17%. On the practical side, it appears that providers have reached a limit to delivering dialysis thrice weekly. Large increases in the weekly effective Kt/V are theoretically possible, as discussed in the preceding text, by increasing the frequency, by applying continuous dialysis, or by markedly prolonging the treatment time. In the Frequent Hemodialysis Network trial, the mean number of treatments per week of the frequent hemodialysis cohort was about 5.2 and the dialysis achieved stdKt/V was 3.54, compared with the conventional group's stdKt/V of 2.49 (203). Increases in dialyzer clearance or short increases in treatment time have less impact when the treatment is given infrequently.

Comparison of the Current Minimum Dialysis Dose with Native Kidney Clearance

The minimum single pool Kt/V of 1.2 volumes per dialysis thrice weekly, established by the latest KDOQI consensus (73), means that more than 100% of total body water is cleared during each treatment. However, this cannot be interpreted to mean that all solute is removed because the blood compartment continuously circulates through the patient and the dialyzer. A better reflection of urea removal is found in the URR, but as shown in **FIGURE 5.15**, URR is confounded by fluid gain between and loss during dialysis, and it loses its meaning for frequent and continuous dialysis. Standard Kt/V, which is a continuous equivalent urea clearance based on comparisons of outcomes in peritoneal dialysis patients versus hemodialyzed patients, is probably a better reflection of the effectiveness of hemodialysis. The tentative minimum dose, expressed as standard Kt/V, is 2.0 volumes per week, which can be converted to milliliters per minute in a patient with an average of 30 L of water (**EQUATION 5.34**):

$$\frac{2.0\ \text{volumes/wk} \times 30{,}000\ \text{mL/volume}}{10{,}080\ \text{min/wk}} = 6.0\ \text{mL/min} \qquad (5.34)$$

Current KDOQI guidelines recommend that dialysis be started, in those who have had a discussion about all options with a nephrologist, when signs or symptoms associated with uremia are noted (73). A particular threshold of glomerular filtration rate at which to start long-term dialysis is no longer advised. During the transition to hemodialysis, native kidney clearance continues to play a role, augmenting solute removal and thereby helping to protect the patient from uremic consequences. However, when the patient loses K_R entirely, the minimum replacement dose may fall below the recommended threshold. Also, when comparing dialyzer with native kidney clearance, other solutes should be considered, many of which are more toxic than urea, do not undergo tubular reabsorption, and have dialyzer clearances that may be significantly lower than that of urea (187). This would explain the high serum creatinine concentration in anephric but well-dialyzed patients, which is often higher than the creatinine concentration in the same patient when hemodialysis treatments were initiated. This paradox is difficult to explain, especially in

view of the HEMO study finding of no benefit from increasing the dose further. Part of the explanation may reside in the nonlinear relationship between the intermittent dialysis dose and the effective continuous clearance as discussed earlier. Another possible explanation is that the marked reduction in toxin levels at the end of dialysis is sufficient to allow recovery from the uremic consequences of high predialysis concentrations, an effect that lasts until the next dialysis.

Protein-Bound Solutes

Solute binding to serum or tissue macromolecules increases the apparent volume of distribution of the unbound molecule, often to levels well in excess of total body weight. Only the free fraction is available for diffusion across either tissue membranes or dialyzer membranes. This seriously limits the effectiveness of hemodialysis, which for highly bound solutes may be totally ineffective as a removal instrument (204). Unfortunately, many protein-bound solutes have been identified in uremic serum, binding mostly to serum albumin. Albumin is a transport protein that should be considered part of the kidney excretory system because the native kidney has the capacity to effectively remove its bound solutes (205–210). Kinetic modeling of serum protein-bound solutes shows a significant effect of dialysate flow and membrane SA, and little additional effect of hemofiltration compared to hemodialysis (211). Additions of sorbent to both hemodialysate and peritoneal dialysate have shown promising augmentation of removal (212). Clinical benefit of targeting the removal of these poorly dialyzed solutes remains to be seen.

PITFALLS OF UREA MODELING

When urea modeling produces unexpected results, a troubleshooting routine should be initiated. The most common sources of error are listed in **TABLE 5.6**. A frequent source of error and probably the greatest source of scatter in the data generated by single-compartment modeling is the postdialysis BUN. Current consensus favors drawing the blood specimen at the immediate end of dialysis (see section “Comparison with the Single-Compartment Model” and **FIGURE 5.11**) while taking precautions against dilution of the blood urea due to access recirculation (213,214). To prevent an error from access recirculation, the specimen should be drawn approximately 10 seconds after slowing the blood pump to approximately 100 mL/min. If the delay is longer than 15 seconds, substantial rebound will occur due to cardiopulmonary recirculation. Special attention should be paid to the distance between the end of the arterial needle and the sampling port in the arterial (inflow) blood line. The volume between these two points should be replaced at least twice during the slow blood flow interval.

TABLE 5.6 Pitfalls of Urea Modeling

1. Errors that affect the delivery or adequacy of dialysis
Predialysis BUN: most reliable of the two measurements
• Avoid any delay (even 30 s) after starting the blood pump.
• Avoid dilution from saline or heparin.
Postdialysis BUN: most subject to error
• Avoid local recirculation.
• Consider urea rebound from cardiopulmonary recirculation and other sources of disequilibrium.
2. Errors that affect the assessment of equipment function
Clearance errors: clearance is almost always overestimated
• Blood flow errors
Low prepump pressure (219)
Poor flow calibration
Poor pump segment occlusion
• Failure to correct for serum and whole blood water content
• Loss of surface area from reuse or clotting
• Inflated manufacturer's *in vitro* clearances
• Recirculation (refer to above)
Timing errors: wall clock syndrome (220)
Volume errors: patients may not conform to the anthropometric formulas
3. Errors that affect the measurement of nPCR
Predialysis and postdialysis BUN errors (see above)
Residual clearance errors

BUN, blood urea nitrogen; nPCR, normalized protein catabolic rate.

Another common source of error is found in deviations of the dialyzer clearance from predictions by **EQUATION 5.12**. These errors usually result from selection of a value for K_0A that was measured *in vitro* (215). Clearances from blood can be significantly lower than clearances measured *in vitro* by the dialyzer manufacturer using saline solutions, due to coating of the membrane by blood products and solute transport in erythrocytes. This error can be avoided by calculating K_0A from cross-dialyzer BUN measurements *in vivo*, using **EQUATION 5.11**, before applying **EQUATION 5.12**. Dialysate flow has been found to influence K_0A *in vitro* but the effect seems to be attenuated *in vivo* (216,217). These errors in K_0A affect only the prescribed dose; they have little or no effect on the delivered dose determined from urea modeling. More detailed discussions of the pitfalls of urea modeling can be found in other references (19,218–220).

Despite the mathematical complexities outlined earlier, the implementation of urea modeling is relatively simple. For instance, the most popular methods for assessing dialysis adequacy require only two BUN measurements. As a consequence, potential errors that might result from measuring more complex functions, such as dialyzer clearance, K_0A, or urea distribution volume, are minimized. Efforts to maintain or improve the reliability of the tests of dialysis adequacy should therefore focus on sampling techniques and accuracy of laboratory measurements. On the other hand, when urea modeling is used to evaluate equipment function, to determine, for example, why the prescribed amount of dialysis does not match that delivered, accurate estimates of dialyzer clearance, urea volume, and dialysis duration are required. **TABLE 5.6** separates the pitfalls of urea modeling into these two major categories, those impacting on adequacy assessment caused by errors in BUN measurement and those affecting assessment of equipment function caused by errors in the prescription or in V.

SUMMARY

It is fortunate and gratifying that an empirically derived treatment such as hemodialysis is so successful in reversing the life-threatening effects of uremia, but since the cause of uremia is inadequate native kidney function, the amount of dialysis substituted should be quantified to assure adequate replacement. What defines adequate versus optimal is less clear as increased frequencies and durations of treatment become more widely available and accepted. Nonetheless, because the major effect of dialysis is small solute removal, it seems reasonable to continue using a readily dialyzable and easily measured solute such as urea as a yardstick. Relative urea removal, expressed as a relative volume cleared, is the essence of the clearance concept.

Carefully controlled studies have shown that the clearance obtained from urea kinetic modeling of the up and down swings in urea concentration found in intermittently treated patients predicts outcome and therefore can be used to judge the adequacy of each treatment. Urea kinetic modeling is a mathematical simulation of urea flux, based on measurements of concentrations before and after intermittent hemodialysis, which allows calculation of urea clearance during dialysis and urea generation between treatments. Established and proven clinical techniques for quantifying dialysis permit tailoring of prescriptions to each patient's need. The goals of urea modeling are first to maintain a uniform quantity of treatment in all patients and second to identify potential problems that impair dialysis efficiency in each patient. The parameters Kt/V (and derivatives eKt/V, stdKt/V) and nPCR obtained from single- or multiple-compartment modeling help dialysis caregivers focus on patients whose prescriptions, including their dialysis schedule, time on dialysis, dialyzer clearance, and dietary protein, need adjustment.

Nephrologists today have accepted the need for measuring dialysis and have dropped the focus on BUN alone because it is a potentially misleading indicator of adequacy. Regulatory agencies have also included quantification of dialysis as a marker of clinical care quality. A consensus has been reached about the minimum dose, expressed as a clearance normalized to body size and treatment time (Kt/V). Several methods have been developed to measure Kt/V and new insights and methods continue to appear that may simplify this measurement in the future. As more patients are treated with frequent in-center hemodialysis, home hemodialysis and long nocturnal dialysis, the utilization of stdKt/V may expand. Inclusion of solute disequilibrium, residual kidney clearance, and recirculation has helped to sharpen the accuracy and usefulness of urea kinetic modeling, and standards are now available and accepted as benchmarks of routine dialysis care.

CHAPTER 6

Hemodialysis Adequacy and the Timing of Dialysis Initiation

Sharmeela Saha and Jay B. Wish

Since the advent of chronic renal replacement therapy in the 1960s, nephrologists have investigated various means of determining the appropriate delivery of dialysis. A review of the relevant literature reveals a considerable evolution during this period, and a discernible trend toward a consensus on what parameters determine adequacy continues to emerge. The concept of adequate dialysis has shifted from the minimum amount of dialysis needed to sustain life into a more complete expression of the amount of dialysis that will be beneficial for optimal patient survival while balancing available resources for maximal efficiency. Hence, adequate dialysis is now closer to “optimal dialysis.”

Despite this increase in the overall size of the end-stage kidney disease (ESKD) population, there has been a markedly slower increase in the number of nephrologists (1). With this imbalance in the number patients to physicians, as well as the financial constraints related to the provision of dialysis therapy, it is necessary to define just what constitutes “adequate” dialysis therapy in order to streamline therapies and establish appropriate clinical guidelines for practice. At the end of 2012, there were 636,905 patients in the United States receiving treatment for ESKD, and over 450,000 of these patients were being treated with dialysis, whereas 186,303 had a functioning kidney transplant; 88,638 ESKD patients died during the year (2,3). Adjusted rates of all-cause mortality are 6.1 to 7.8 times greater for dialysis patients than for individuals in the general age–matched Medicare population. Mortality rates rise with age, reaching 287 per 1,000 patient-years for dialysis patients aged 65 and older, as compared to 62.3 for transplant patients and 47.4 for the general Medicare population of the same age (3).

Costs of dialysis treatments have continued to rise. Health care expenditures on the dialysis population are significant. Among hemodialysis patients prevalent in 2012, 35.2% of discharges from an all-cause hospitalization were followed by a rehospitalization within 30 days, and total Medicare paid claims in 2012 were $28.6 billion (3). Payers, including the Centers for Medicare and Medicaid Services (CMS) and private insurers, are increasingly demanding the demonstration of cost-effective care as a primary criterion in contracting with health care providers such as dialysis facilities. The quality of care

provided continues to be a source of scrutiny and economic strain. A pivotal aspect of the quality of this care is the “adequacy” of dialysis provided.

Beginning in the early 1970s, with the implementation of “Medicare entitlement” relating to payment for dialysis services, CMS has systematically collected facility-specific data regarding the provision of dialysis care. To assist in the collection and monitoring of this patient-specific information, 18 regional ESKD networks were created. One goal of these networks is to establish an oversight system for the provision of dialysis care. Since 1991, the ESKD networks have also been involved in *C*ontinuous *Q*uality *I*mprovement (CQI) projects. Such activities allow individual providers within each network to examine their own practices, define areas for improvement, and develop plans to address the barriers to improvement. One such CQI initiative has been the monitoring and improvement in the adequacy of hemodialysis treatment.

This chapter reviews the key literature in an attempt to define adequate dialysis: how to prescribe it, how to deliver it, how to monitor it, and how to incorporate it into a cycle of CQI to achieve better patient outcomes. This discussion may touch on many aspects of hemodialysis that impact on adequacy, including membrane characteristics, dialysis modality selection, dialysate composition, intradialytic events, vascular assess function, and other important topics that are discussed in better detail elsewhere in this book.

After more than 50 years of providing dialysis therapy, our understanding of hemodialysis adequacy is still evolving. Nephrologists, health care payers, nephrology journals, national collaborative meetings and research funders such as the National Institutes of Health (NIH) continue to devote significant attention and resources to this subject. While the results of clinical trials and observational studies provide a framework for our understanding of the goals of dialytic therapy, ongoing basic and clinical investigations as well as monitoring of dialysis registries will undoubtedly lead to refinement of practice guidelines for prescribing and monitoring hemodialysis adequacy.

HISTORICAL PERSPECTIVE

Until 1974, nephrologists frequently prescribed hemodialysis regimens based on clinical judgment, often paying more attention to fluid balance than to the need to remove metabolic waste products. Amelioration of uremic signs and symptoms was the goal of the latter, but this was invariably subjective. The pathogenesis of the uremic syndrome was not clearly understood, although the paradigm that dialysis clears the blood of a responsible metabolic waste product(s) provided the framework of therapy (4). Multiple toxins have been proposed (**TABLE 6.1**) (5,6), some being linked to specific manifestations of the uremic syndrome; yet, the correlation of uremic symptoms to blood levels of these substances has not been clearly demonstrated. Even today, the true nature of the uremic syndrome remains incompletely understood.

TABLE 6.1 Uremic Solutes with Potential Toxicity

Urea	Middle molecules
Guanidines	Ammonia
Methylguanidine	Alkaloids
Guanidine	Trace metals
β-Guanidinopropionic acid	Uric acid
Guanidinosuccinic acid	Cyclic AMP
γ-Guanidinobutyric acid	Amino acids
Taurocyamine	Myoinositol
Creatinine	Mannitol
Creatine	Oxalate
Arginic acid	Glucuronate
Homoarginine	Glycols
N-α-acetylarginine	Lysozyme
Phenols	Hormones
O-cresol	Parathormone
P-cresol	Natriuretic factor
Benzyl alcohol	Glucagon
Phenol	Growth hormone
Tyrosine	Gastrin
Phenolic acids	Xanthine
P-hydroxyphenylacetic acid	Hypoxanthine
β-(m-hydroxyphenyl)-hydracrilic acid	Furanpropionic acid
Hippurates	Amines
P-(OH) hippuric acid	Putrescine
O-(OH) hippuric acid	Spermine
Hippuric acid	Spermidine
Benzoates	Dimethylamine
Polypeptides	Polyamines
β_2-Microglobulin	Endorphins
Indoles	Pseudouridine
Indol-3-acetic acid	Potassium
Indoxy sulfate	Phosphorus
5-Hydroxyindol acetic acid	Calcium
Indol-3-acrylic acid	Sodium
5-Hydroxytryptophol	Water
N-acetyltryptophan	Cyanides
Tryptophan	

AMP, adenosine monophosphate.
Adapted from Vanholder RC, Ringoir SM. Adequacy of dialysis: a critical analysis. *Kidney Int* 1992;42:540–558.

Although it is inherently not a very toxic molecule (7), urea, a 60-Da solute widely distributed in total body water, has been used as the surrogate for other uremic toxins because of its size, abundance, ease of measurement, and dialyzability. This has often led to confusion by nephrologists and non-nephrologists, believing that the blood urea nitrogen (BUN) level causes uremic signs and symptoms and that dialysis is essential for BUN levels above 100 mg/dL. Historically, the clearance of urea has formed the cornerstone of measuring the efficacy and, by inference, the adequacy of dialysis therapy.

Poor outcomes, despite intensive dialysis treatments and "adequate" urea removal, led researchers familiar with solute kinetics to theorize that larger molecules with molecular weights of 500 to 5,000 Da, "middle molecules," may be responsible for the uremic syndrome (8). The smaller pores of standard cellulosic membranes of the 1960s and 1970s were able to clear urea, but urea clearance often failed to accurately predict patient outcomes. Despite the removal of urea by these membranes, many patients continued to experience symptoms attributable to the lack of removal of some undefined toxic metabolite (9,10). Furthermore, peritoneal dialysis (PD) patients seemed to fare better than hemodialysis patients

despite increased levels of BUN and, by inference, less dialysis. This was ascribed to the larger pore size of the peritoneal membrane as compared to cellulosic hemodialysis membranes and the removal of some larger, ill-defined, middle molecule(s). These observations evolved into what is now known as the *middle molecule hypothesis* (8,11).

In 1974 under the guidance of the NIH, a consensus conference was held to discuss the nature of the uremic syndrome, as well the development of a clinically useful and meaningful marker of dialysis therapy. During this conference, various aspects of dialysis care were examined including the nature and pathogenesis of the uremic syndrome, quantification of dialysis therapy, nutritional status, renal osteodystrophy, as well as several other abnormalities commonly observed in hemodialysis patients.

The stage was set to test whether the clearance of urea or the as-yet-unidentified middle molecule correlated better with outcomes in hemodialysis patients. With the sponsorship of the NIH, a multicenter prospective randomized study was designed and implemented to target BUN levels by varying dialysate and blood flows while affecting the clearance of hypothetical middle molecules by varying the dialysis duration. This landmark study is known as the *National Cooperative Dialysis Study* (NCDS) (12–14).

National Cooperative Dialysis Study

A total of 160 patients were randomized into four groups, with each group targeting either a low or high BUN level (50 mg/dL vs. 100 mg/dL average) measured over a time-averaged period [“time-averaged concentration (TAC) urea”] and a short or long dialysis time (3 ± 0.5 hours vs. 4.5 to 5.0 hours). After a follow-up of 6 months, medical dropouts and hospitalization rates were measured. Subsequently, 12-month mortality rates were measured in follow-up studies (12–14). The results demonstrated that patients dialyzed with high BUNs and short times clearly had poor outcomes, with up to a 70% hospitalization rate (**FIGURE 6.1**) (15). Overall, this initial analysis of the data suggested that BUN was the major factor leading to morbidity. As a result of the findings of this study, for several years after the publication of this study, many nephrologists focused on control of BUN and did not consider the dose of dialysis when prescribing and delivering dialysis therapy (16).

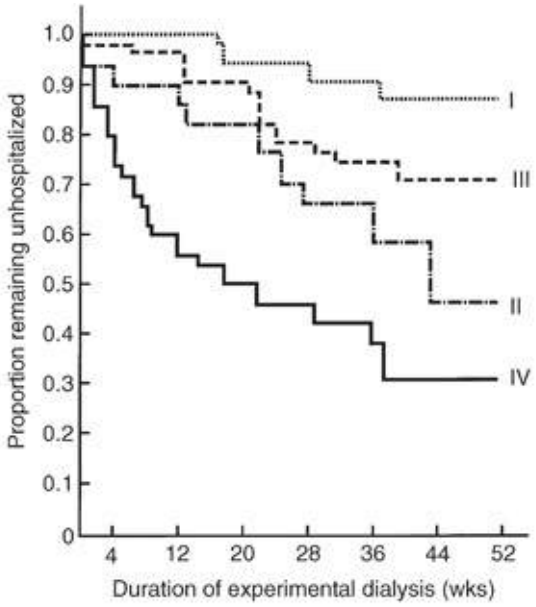

FIGURE 6.1 Proportion of patients in the NCDS remaining unhospitalized, shown as a function of time in the four study groups. The proportion was lower in the high-BUN groups (II and IV) than in the low-BUN groups (I and III). (Reprinted with permission from Lowrie EG, Laird NM, Parker TF, et al. Effect of hemodialysis prescription on patient morbidity: report from the National Cooperative Dialysis Study. *N Engl J Med* 1981;305:1176–1181.)

Despite a number of aspects of the NCDS that persist as controversial, it was the largest multicenter trial for determining dialysis adequacy prior to the Hemodialysis (HEMO) study. Its enduring lesson, which was not learned until subsequent analyses of the NCDS data were published over several years following the study, is that quantifying and providing an adequate delivered dose of dialysis is of utmost importance for a positive impact on outcome. The NCDS also validated the importance of small molecule clearance, which forms the basis of current standards of adequacy (17).

The enormous contribution of the NCDS and its subsequent reanalysis to the current thinking regarding hemodialysis therapy cannot be overstated. Several weaknesses of the NCDS, however, preclude our applying the results universally into clinical practice. These issues point out the need for caution in the interpretation of the NCDS results, and a review of these should help place the study in proper perspective.

Age of the National Cooperative Dialysis Study Cohort

The NCDS study population had an average age range of 18 to 70 years with a mean age of 51 ± 12.9 years (12–14). The dialysis population has since grown older, and the elderly population have different causes of ESKD (18), have varied and more comorbid conditions (19), and have been shown to die sooner regardless of dialysis prescription (20). In fact, after a mean age of 59 years, each year of advancing age has been associated with an approximately 3% increase in the odds ratio for death (20). Elderly patients generally have poorer nutrition, less opportunity for social rehabilitation, and less physical activity. They also have a greater chance of being demented and unable to influence their own treatment, let alone follow prescribed therapy (21,22). All of these factors highlight the changing demographics of the “typical” American dialysis patient and limit the application of the NCDS in determining how to dialyze an aging population.

Comorbid Conditions

Patients who had advanced atherosclerotic cardiovascular disease, pulmonary disease, recurrent infections, cancer, or other significant comorbid conditions were excluded from the NCDS to achieve the expected follow-up period of 1 to 3 years (12–14). However, comorbidity with multiple conditions has increased among patients with ESKD from 1976 to the present (23). Interestingly, a survey of the primary causes of death of dialysis patients highlights cardiovascular disease as the leading cause of death among dialysis patients. Internationally, this pattern of acceptance of older patients with increasing numbers and severity of comorbid illness also holds true (24). Thus, the application of the NCDS data to patients with multiple comorbidities is questionable.

Diabetes Mellitus

Patients with diabetes were excluded from the NCDS. Diabetic nephropathy is the single most common cause of ESKD in the United States (25). The effect of diabetes on survival has been suggested in a report by Collins et al. (19), where higher doses of dialysis may be beneficial in diabetic patients. The application of the NCDS data to a diabetic population is limited.

Duration of Dialysis

The patients entering the NCDS had a mean duration of dialysis of 4.3 hours, while the range studied was 2.5 to 5.5 hours (12–14). There are no data points below 2.5 hours and few data points below 3 hours. As a result of the NCDS findings, duration of dialysis was not considered as important as the BUN. In response to this, manufacturers of dialysis membranes began developing ways to achieve better urea clearance with shorter dialysis duration, as the dialysis facilities preferred to treat more patients for shorter time periods to maximize the efficiency of the facility and personnel (25,26).

It is predictable that as time for diffusion (i.e., dialysis) is shortened, there will be a point at which highly diffusible substances such as urea cease to predict adequate removal of other uremic waste products and an increase in morbidity, if not mortality, may result. Consequently, the role of duration of dialysis as an independent determinant of adequacy is being revisited. Studies have demonstrated a decreased survival in patients with dialysis time shorter than 3.5 hours (26,27). The NCDS data also revealed a trend toward increased morbidity with shorter dialysis times, although it was not as strong a correlation as with high BUN levels (15).

While the NCDS data do not address how to weigh the independent effect of dialysis duration in setting of current high-efficiency and high-flux dialysis membrane technology, observational outcomes have demonstrated the independence of dialysis treatment duration as a predictor of improved mortality rates. In fact, a few dialysis cohort studies have demonstrated that treatment time and dialysis dose are independent predictors of survival. In an Australian and New Zealand cohort, a dialysis time of 4.5 to 5 hours together with a Kt/V (a measure of dialysis dose, see subsequent text) of 1.3 to 1.4 was associated with better overall survival (28). Based on the lack of a statistical interaction between dialysis dose (Kt/V) and session length, the authors further suggest that the optimal “dialysis dose” may be a combination of a Kt/V of more than 1.3 and a treatment time greater than or equal to 4.5 hours, although they do concede that the retrospective nature of their patient cohort limits their ability to imply causation. The association between these “standard” doses of dialysis combined with a longer individual treatment has also been demonstrated by Saran et al. (29) in a large multinational observational cohort of patients. Importantly though, this analysis clearly demonstrated a mathematical interaction between higher Kt/V and

longer session length and further demonstrated that an ultrafiltration rate greater than 10 mL/kg/h was associated with higher risk of both intradialytic hypotension and, more importantly, short-term patient mortality (29). On the other extreme of duration of dialysis treatment, the Centre de Rein Artificiel in Tassin, France, has reported excellent 10-year survival rates, as well as unparalleled anemia and hypertension control in their patient population. The directors of this unit attribute their success primarily to the technique of prolonged daily dialysis treatments (30,31). This form of dialysis therapy, so-called prolonged hemodialysis (PHD), does offer several documented advantages to the prevalent form of in-center, three times per week therapy practiced in the United States. However, the findings of the HEMO study (discussed in further detail in subsequent text) point out that simply increasing the delivered dose of dialysis may not lead to improved outcomes among hemodialysis patients (32). As a modification of daily therapy, the same group from Tassin has proposed thrice-weekly long nocturnal dialysis as a form of therapy that may be more acceptable to a larger number of patients with potentially equivalent outcomes (33). Therefore, in order to achieve patient outcomes similar to those in Tassin, what may be required is a fundamental rethinking of how to deliver dialysis therapy and whether treatment settings other than "in-center" would facilitate improved patient outcomes.

Dialyzer Membrane

The NCDS was performed using purely cellulosic membranes that have been replaced with newer, large-pore, high-flux, and more biocompatible membranes. Applicability of dialysis prescription in the NCDS to current synthetic membranes may be limited.

Quantity of Dialysis

The retrospectively computed dialysis dose (Kt/V, to be discussed later in this chapter) for the NCDS cohort in groups I and III, with target BUN levels of 50 mg/dL on average, was between 0.9 and 1.3 (12). Given that no groups in the NCDS received a greater dialysis dose, it is difficult to determine from the NCDS alone whether this dose is adequate, and impossible to determine whether this dose is optimal.

In another study using urea reduction ratio (URR) to quantify dialysis dose, it was demonstrated that patients receiving a URR of 60% or more had a lower mortality than patients receiving the NCDS URR of 50% or more (20). The HEMO study confirmed that doses of dialysis significantly greater [a single-pool Kt/V (SKt/V) of 1.71] than those currently recommended by the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (NKF-KDOQI) guideline (i.e., a single pool or spKt/V of 1.2) failed to provide additional survival benefit in a representative group of hemodialysis patients on a three times per week treatment regimen. Specifically what was shown in the HEMO study was that with a "standard dose" of dialysis (achieved spKt/V of 1.32), the overall mortality was 17.1%. In the "high-dose" group (achieved spKt/V of 1.71), the mortality was 16.2%, a nonsignificant difference. Reviewing these findings, it is notable that these excellent clearance rates were achieved with mean dialysis times of 190 ± 23 minutes (standard dose) and 219 ± 23 minutes (high-dose group) (34). This finding speaks to the ability of modern dialysis technology to deliver adequate clearance of small molecules with only a modest increase in dialysis time.

Duration of the Study

The patients in the NCDS were studied for approximately 48 weeks, and most of the data were analyzed

at 26 weeks (12). This may not have been enough longitudinal follow-up (19), especially as mortality actually increased approximately 1 year after the study was terminated (27,35). The report by Eknoyan et al. (34) from the HEMO study suggests that in a subgroup of female patients, a higher dose of dialysis may lead to a decrease in the risk of death and hospitalization, but this benefit of increased dose of dialysis did not appear for almost 3 years. Also in a separate subgroup of patients who had been on dialysis greater than 3.5 years at the start of the trial, the use of a high-flux dialysis filter appeared to reduce the risk of death (32,36). Also in the NCDS era, techniques such as ultrafiltration control, bicarbonate dialysate, and variable dialysate sodium programming were not in widespread use. Furthermore, the NCDS outcome measured was morbidity, not mortality (15), as is more commonly used in contemporary studies.

Nutrition

Notwithstanding the previously held misconception that a low BUN is always good, it was shown in the NCDS that the protein catabolic rate (PCR), which is computed to represent dietary protein intake, is a strong and independent predictor of poor outcome (13). This became evident despite the NCDS protocol, which was designed to provide patients with a constant protein intake of 1.1 ± 0.3 g/d/kg body weight. In the final analysis, the actual PCR range was more in the range of 0.6 to 1.5 g/d/kg body weight. Within this range, a strong negative correlation between the PCR and probability of failure (i.e., morbidity such as hospitalization) became evident, as demonstrated graphically in **FIGURE 6.2**. This relationship of increasing probability of failure, with declines in PCR, held true irrespective of randomization to the low BUN (50 mg/dL) or long duration (4.5 hours) dialysis groups. **FIGURE 6.2** shows how patients with very low PCR (0.6 g/d/kg body weight) will have at least a 35% probability of failure despite 4.5-hour dialysis treatment and a low (40 mg/dL) TAC urea. Conversely, a patient with a high PCR (1.2 g/d/kg body weight) will have less than a 15% probability of failure, even with a higher TAC urea of 60 mg/dL and the same dialysis duration.

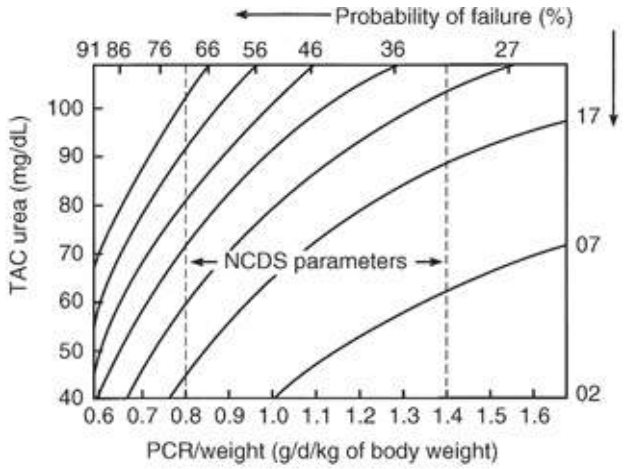

FIGURE 6.2 A comparison of time-averaged concentration (TAC) urea, protein catabolic rate (PCR), and probability of mortality for 4.5-hour dialysis in the NCDS. Subsequent studies have demonstrated how nutrition affects survival in dialysis patients when serum albumin is used as a marker for prognosis. Lowrie (37) reported this with his National Medical Care [now Fresenius Medical Care (FMC)] database in 1990 and again in 1994 (38), which demonstrated a marked increase in mortality as the serum albumin falls. This albumin–mortality relationship has also

been noted by Owen et al. in 1993 (20), as well as several other authors.

Several authors and investigators have given increasing attention to the role that overall nutritional status plays in the survival of dialysis patients, as well as the relationship between adequacy of dialysis, nutritional status, and patient survival. Specifically, in a secondary analysis of the HEMO study, poor nutritional status predicted a high risk for mortality regardless of the targeted (or achieved) dialysis adequacy. In addition to albumin levels, other biochemical indices such as serum creatinine, total cholesterol, anthropometry [i.e., a low body mass index (BMI)] and Karnofsky functional index were each independently associated with higher risk for death. The association of most of these markers with outcome was nonlinear; with the risk of mortality increasing more steeply at lower levels, suggesting that as dialysis patients become progressively malnourished, the risk of short-term mortality escalates. Consistent with these reports, Chertow et al. (39) showed that decreasing serum prealbumin level is associated with all-cause hospitalization and increased mortality independent of dialysis dose. These findings reinforce the need for longitudinally monitoring both nutritional status and adequacy of therapy in all dialysis patients.

Another aspect of this nutrition–mortality relationship that has been explored by Chertow et al. (40) is the complexity of the relationship between dialysis dose, as measured by urea removal, and mortality. One of the most important aspects of the NCDS study came not from the study itself but rather from a reanalysis of the data several years later by Gotch and Sargent (12). In this mechanistic analysis of the data, a method of quantifying dialysis treatment by means of a dynamic rather than the static measure of urea removal was developed and verified as a valid measure of dialysis dose. However, even with the use of this dynamic measure, a complex relationship between dialysis dose and mortality is evident. Subsequently, several authors have independently noted a “reverse J”–shaped relationship between the dose of hemodialysis, as measured by either URR, or Kt/V (both terms are defined in subsequent text). What is meant by “reverse J” is that with both extreme low and high values of urea removal, as measured by URR or Kt/V, there is an unexpected increase in the relative mortality of patients (41,42).

This complexity of the dose–mortality relationship has led some authors to propose that urea distribution volume, V, is a surrogate marker for nutritional fitness. As such, urea distribution volume may possess survival characteristics of its own (40,43–45). Technologic advances have also allowed for the continuous and near instantaneous measurement of ionic or online dialysis clearance and the calculation of a “real-time” Kt/V (46). The advantages of this method include no requirement for blood sampling and that it can be used with each dialysis treatment to predict the delivered Kt/V in real time before the treatment is finished. Among the disadvantages of this technique, however, is that in order to calculate Kt/V, time on dialysis and V must be determined accurately. The latter is a potential problem if anthropometric formulas are used to estimate V because these formulas are estimates that often differ significantly from the true value. Based on these potential shortcomings as well as the lack of outcomes data using this technique, most guidelines for adequacy continue to recommend blood side monitoring of dialysis dose.

The fine balance between trying to delay progression of kidney disease versus inducing malnutrition and the consequent adverse effects on mortality has created substantial confusion and variation in clinical practice, especially with regard to the appropriate timing of initiation of chronic dialysis therapy. Although the Modification of Diet in Renal Disease (MDRD) study (47) had provided some support for

the hypothesis that dietary protein restriction slows the progression of kidney disease, studies have raised concern regarding the effects of pre-ESKD dietary protein restriction on patient mortality after ESKD supervenes. Kopple et al. (48) have concluded that 0.8 g/d/kg body weight of protein is safe for at least 2 to 3 years but recommend that additional indices of nutritional status such as serum transferrin, body weight, urine creatinine, and caloric intake be monitored regularly. The NIH Consensus in 1994 (49) recommended an initial diet of 0.7 to 0.8 g/d/kg body weight in pre-ESKD patients but cautioned to regularly assess for signs of malnutrition. Should such signs become evident, an increase of protein intake to 1 to 1.2 g/d/kg body weight as well as increased caloric intake is recommended. It is notable that decline in protein and energy intake and in indices of nutritional status have been documented in patients with a glomerular filtration rate (GFR) below about 50 mL/min when ingesting uncontrolled diets, suggesting that prescription of this level of protein restriction outside of a clinical trials setting may lead to ingestion of inadequate energy and insufficient protein. Lowrie and Lew (37) have demonstrated a strong correlation between higher serum creatinine levels and improved survival in hemodialysis patients, reflecting better muscle mass, which is likely a marker for nutritional status and may be independent of dialysis dose. All these studies compliment the NCDS and are reflections of the changing emphasis on nutrition in dialysis patients (50–53).

The earlier-noted controversy is further compounded when chronic kidney disease (CKD) patients progress to ESKD and are confronted by a multitude of factors affecting nutrition, such as anorexia due to uremia or underdialysis, the inconvenience of thrice-weekly dialysis schedules, comorbid conditions such as diabetic gastroparesis, hormonal factors, depression, and frequent hospitalizations (54). Indeed, more than one-third of dialysis patients report a poor or very poor appetite, and low self-reported appetite is associated with lower dietary energy and protein intakes, poorer nutritional status, higher comorbidity, and lower quality of life. Secondary analysis of the HEMO study indicated that low self-reported appetite is independently associated with increased hospitalizations, but the association of appetite with death in this study was confounded by comorbidity (55,56). In addition, depression is believed to be the most common psychiatric disorder in patients with ESKD, with previous studies reporting up to 25% of prevalent dialysis patients having a Beck Depression Inventory score in the moderate range of depression (57). Given the prevalence and associations between depression, treatment adherence, malnutrition, and mortality, it is clear that screening for mental health issues is an important part of the care of dialysis patients.

TIMING OF DIALYSIS INITIATION

In 2012, over 90% of new patients (98,954) began ESKD therapy with hemodialysis, 9,175 with PD, and 2,803 received a preemptive kidney transplant (these data exclude patients with missing demographic information). Use of PD and preemptive kidney transplant were relatively more common in younger age groups. Use of home dialysis therapies among incident ESKD patients has increased notably in recent years (3).

The appropriate timing of initiation of chronic dialysis therapy is also closely tied to nutritional markers in dialysis patients. This relationship has been demonstrated in a number of observational studies in which spontaneous dietary protein restriction was observed with declining GFRs (58,59). Concern regarding the long-term consequences of such dietary restriction as well as the long-term effects of long-

standing uremic toxicity has prompted several groups to investigate the appropriate timing of initiation of dialysis therapy. Initially, multiple investigators showed that earlier initiation of dialysis therapy led to prolonged duration of life, increased potential for rehabilitation, and decreases in hospitalization (60–62). The Canada–United States of America (CANUSA) study likewise showed that for patients with weekly creatinine clearances less than 38 L/wk, 12- and 24-month survival was 82% and 74%, respectively. However, in a group of patients with creatinine clearance greater than 38 L/wk, 94.7% of patients survived 12 months and 90.8% of patients survived 24 months (63). While the CANUSA results demonstrate the survival benefit of residual renal function among PD patients, the role of diuretics and residual renal function was investigated among an international cohort of subjects through the Dialysis Outcomes and Practice Patterns Study (DOPPS). In this cohort of subjects, both diuretic use and residual renal function were positively associated with improvements in all-cause as well as cardiac mortality, potentially related to lower interdialytic weight gain and a reduced incidence of intradialytic hypotension. Other authors have postulated, however, that the benefits of residual renal function may be related to improved clearance of uremic toxins with a molecular weight higher than urea and other “small uremic molecules” (64,65). Prompted by these studies, as well as expert opinion, the NKF-KDOQI guidelines advise the initiation of dialysis therapy of some type when the weekly kidney (residual) Kt/V falls below a level of 2.0 (an approximate creatinine clearance of 9 to 14 mL/min/1.73 m^2). Clinical considerations that dialysis may not need to be imminently initiated were (a) stable or increasing edema-free body weight or (b) complete absence of clinical signs or symptoms attributable to uremia (66).

Despite these convincing arguments that earlier initiation of dialysis leads to improvements in patient outcomes, the relationship is still debated. The DOPPS, which compares a large cohort of American dialysis patients to groups of patients from Europe (France, Germany, Great Britain, Italy, Spain) and Japan, has shown that despite earlier initiation of dialysis among the American cohort of patients, the survival of this group of patients was actually worse than those of Europe and Japan. Even after consideration of potential confounding factors such as coexistent comorbidities and nutritional status as measured by serum albumin level, this increase in mortality persisted (67). The Netherlands Cooperative Study on the Adequacy of Dialysis phase-2 (NECOSAD-2) is a large multicenter study in the Netherlands. In this prospective analysis, patient’s health-related quality of life (HRQOL) was measured by means of the Kidney Disease and Quality of Life Short Form repeatedly over the first year of dialysis therapy. Of 237 patients who had measurements of residual renal function measured between 0 and 4 weeks prior to the initiation of dialysis therapy, 38% were classified as late starters based on the NKF-KDOQI guidelines. At baseline, the HRQOL for this group of patients was statistically lower in the realms of physical role functioning, bodily pain, and vitality than those patients who initiated timely dialysis per the NKF-KDOQI guidelines. However, after a follow-up of 12 months, the differences among groups disappeared (68). Another study examined the effects of lead-time bias in perceived increased longevity with an earlier start of dialysis, that is, a perceived prolongation of survival due to longer monitoring of those patients who initiated dialysis at an earlier time in their disease process. In order to overcome the potential effects of lead-time bias, these authors assembled their cohort of patients on the basis of a residual creatinine clearance of 20 mL/min. Early and late start of hemodialysis was defined by a creatinine clearance cutoff of 8.0 mL/min. This analysis clearly showed that lead-time bias is a real phenomenon in dialysis patients and that by monitoring patients from a defined starting point that predates

the initiation of dialysis, there was no difference in 10-year survival among the two groups of patients (69). Together, these studies underscore the need to individualize the timing of initiation of chronic dialysis therapy.

Initiating Dialysis Early and Late Study

Another trial examining the relationship of the timing of dialysis initiation is the Initiating Dialysis Early and Late (IDEAL) study. Published in August 2010, the IDEAL study was a randomized controlled trial of early versus late initiation of dialysis (70). Thirty-two centers in Australia and New Zealand examined whether the timing of maintenance dialysis initiation influenced survival in patients with CKD. Patients at least 18 years old with progressive CKD and an estimated glomerular filtration rate (eGFR) between 10.0 and 15.0 mL/min/1.73 m^2 of body surface area (BSA) (calculated with the use of the Cockcroft–Gault equation) were randomly assigned to planned initiation of dialysis when the eGFR was 10.0 to 14.0 mL/min (early start) or when the eGFR was 5.0 to 7.0 mL/min (late start). Between July 2000 and November 2008, 828 patients underwent randomization, and the mean age was 60.4 years. The primary outcome was death from any cause. Important to note that 75.9% of the patients in the late-start group initiated dialysis when the eGFR was above the target of 7.0 mL/min due to the development of symptoms. The decision to start was at the discretion of the patient's nephrologist. The mean duration of follow-up was 3.64 years in the early-start group as compared to 3.57 years in the late-start group.

The study found that early initiation was not associated with an improvement in survival, the primary outcome, or in several secondary clinical outcomes such as cardiovascular or infectious events. The median time from randomization to initiation of dialysis was 1.8 months in the early-start group and 7.40 months in the late-start group. The mean eGFR, using Cockcroft–Gault equation, was 12.0 mL/min in the early-start group and 9.8 mL/min in the late-start group. In the early-start group, 18.6% started dialysis with eGFR of less than 10.0 mL/min. This population was also unique when compared to the dialysis patients in the United States because PD was the initial method in 195 patients in the early-start group and 171 patients in the late-start group. Baseline characteristics were similar between the early- and late-start groups. The authors conclude that early initiation of dialysis had no significant effect on the rate of death or on the secondary clinical outcomes. Although there was only a 2.2 mL/min difference in actual achieved eGFR in the study, there was a 6-month time difference in time to dialysis initiation between the two groups, and 6 months off hemodialysis is a recognizable opportunity as well as a substantial financial cost savings without a change in survival.

A 6-month delay in initiation of dialysis seems beneficial, but one has to acknowledge that patients need to be very carefully monitored in the interim. The previously cited NECOSAD study clearly shows that HRQOL at the time of initiation of dialysis is significantly lower in those patients who are maintained off of dialysis therapy. Given this and the often subtle symptoms of uremic toxicity, patients with impending dialysis needs will require close monitoring in order to avoid untoward effects of uremia and to make the transition to dialysis therapy as smooth as possible. The decision when to initiate renal replacement therapy should be based on the patient's overall clinical status, not just the GFR, but when the GFR falls below 15 mL/min, the patient should be followed even more closely for signs and symptoms of uremia, and placement of dialysis vascular access for those choosing hemodialysis should certainly be completed at that level of kidney function.

There is not a consensus regarding the modality with which to initiate renal replacement therapy. In

an article by Kalantar-Zadeh et al. (71) published in 2014, the authors propose further investigation to compare twice-weekly hemodialysis versus thrice-weekly hemodialysis in the initiation of renal replacement therapy in patients with ESKD. It is well established that mortality in incident dialysis patients and that the loss of residual renal function is higher in patients on hemodialysis therapy than PD. Erythropoiesis-stimulating agent (ESA) use is higher as well during the first months of dialysis therapy. In the Frequent Hemodialysis Network (FHN) nocturnal trial, there was a more rapid loss of residual renal function in the nocturnal hemodialysis group compared to the standard group (72). In a Taiwanese study, patients on twice-weekly hemodialysis had a slower decline in residual renal function as compared to the thrice-weekly group (73). To date, there are no randomized controlled trials to evaluate if there is a survival advantage with twice-weekly dialysis at initiation. A major confounder in the past in retrospective analyses has been insufficient data regarding baseline and/or subsequent residual renal function. The impetus for twice-weekly dialysis may include theoretical preservation of residual renal function, less frequent cannulations, and possibly complications of arteriovenous access as well as patient quality of life with less time spent on dialysis. However, some concerns include prolonging the interdialytic interval, which may increase the incidence of hyperkalemia, volume overload, and sudden death. In their 2014 publication, Kalantar-Zadeh et al. (71) have proposed 10 criteria including, but not limited to, urine output greater than 500 mL/day, potassium usually less than 5.5 mg/dL, phosphorus commonly below 5.5 mg/dL, and hemoglobin greater than 8 g/dL to ascertain eligible candidates for twice-weekly hemodialysis therapy. They do not specify a particular GFR among the designated 10 criteria. The residual renal function needs to be reassessed monthly along with typical hemodialysis adequacy parameters. The validity of these proposals should be tested in clinical trials. These authors also advocate PD first before hemodialysis, highlighting the benefit of preservation of residual renal function (71).

The choice of an incremental dialysis prescription will require periodic measurement of urine output and endogenous kidney function, which can be an eGFR based on the average of creatinine and urea clearances on an interdialytic urine collection, or a weekly Kt/V for urea based on the predialysis BUN. The dialysis dose will need to be increased as endogenous kidney function inevitably declines. Because hemodialysis is an intermittent therapy compared to the continuous nature of residual renal function, the dialysis Kt/V cannot be simply added to the endogenous Kt/V to obtain the total weekly Kt/V as can be done for PD patients. The use of an “equivalent” Kt/V transformation is required, which is also required to calculate the “equivalent” Kt/V of hemodialysis therapies administered more or less frequently than three times per week. In this context, it is important to recall that the target Kt/V of greater than 1.2 for hemodialysis applies only to thrice-weekly therapy.

O’Hare et al. (74) have reviewed the epidemiologic trends in the timing and the clinical context of dialysis initiation based on reviewing United States Department of Veterans Affairs data in fiscal years 2000 to 2009 (72). In 2000 to 2004, as compared to 2005 to 2009, the mean eGFR at dialysis start increased from 9.8 ± 5.8 to 11.0 ± 5.5 mL/min/1.73 m^2 (p <0.001), and after stratification by illness acuity and a number of symptoms, there was still a significant increase in mean eGFR at initiation over time for all subgroups. The upward trend of eGFR at time of initiation appears to reflect changes in timing of initiation rather than variation in the clinical context or changing indications. The reason for the uptrending eGFR at initiation is unclear, but there are numerous speculations including, but not limited to,

the adaptation of more liberal KDOQI guidelines allowing for dialysis initiation at higher levels of eGFR.

Although there are trends and general guidelines, the approach to dialysis initiation must be individualized. Bargman (75) describes an interesting patient interaction which highlights the many nuances of dialysis initiation and modality selection. Effective predialysis education is essential to allow for a smooth transition, and decisions such as whether to even pursue dialysis versus nondialysis supportive care are paramount. In a prospective observational study published in 2015, authors found that elderly patients with advanced CKD managed *via* a nondialysis pathway that included conservative and at times palliative kidney supportive care survived a median of 16 months with a 53% 1-year survival from the time of referral to a kidney supportive care clinic with mean eGFR of 16 mL/min/1.73 m^2 (76).

When dialysis is selected, the initial question should be in-center versus home therapies. Patients who start dialysis in a nonemergent setting may be candidates for incremental dialysis which could mean fewer sessions of hemodialysis per week or fewer hours per session or both; in the realm of PD, this could translate into just a couple of exchanges per day. Incremental dialysis could potentially ease patients into the transition from a patient with CKD to someone who relies on renal replacement therapy. There is potentially a practical benefit to early-start dialysis in that technical aspects such as malfunctioning PD catheters or needle infiltration of a fistula could be addressed in less dire situations than late-start dialysis. It has also been suggested that the institution of PD is associated with a slowing decline of residual renal function (75). The 2015 KDOQI adequacy update suggests that the decision to initiate maintenance dialysis should rely on a clinical assessment of signs and symptoms rather than a certain level of kidney function (17). The time to initiate dialysis is truly a collaborative process among the patient, medical staff, and any caretakers, and the plan of care should be individualized to allow for the best experience.

DIALYSIS QUANTIFICATION

The most important contribution of the NCDS is the concept that the delivered dose of dialysis can and should be quantified. With urea as the marker for most small molecular weight uremic toxins, the NCDS targeted the dose of dialysis by maintaining a certain TAC urea or midweek predialysis BUN, with the caveat that protein nutrition must be maintained. It is important to note, however, that in this study, which forms the basis for our current measurement and monitoring of hemodialysis therapy, the currently accepted measure of hemodialysis dose, Kt/V, was neither monitored nor was a specific Kt/V “target” measured. Rather, the lasting impact of the NCDS came from a mathematical analysis of the data approximately 5 years after the completion of the study by Gotch and Sargent (12). The conceptual shift that resulted from this analysis moved physicians prescribing dialytic therapies from viewing urea not from a static model (single midweek or averaged blood levels) but from a kinetic model (the change in urea during the course of a hemodialysis procedure). The most familiar kinetic urea model today is Kt/V, which is the paradigm that evolved from analysis of the data consisting of the actual delivered dose of dialysis from the patients in the NCDS (12).

K is the dialyzer urea clearance in milliliters per minute.
t is the time (i.e., duration) of the dialysis therapy in minutes.

V is representative of the volume of distribution of urea (approximately equal to total body water).

This expression attempts to express the dose of dialysis as fractional urea clearance and is analogous to the effects of normal body clearance mechanisms on the blood level of an administered drug.

Measuring the Dose of Hemodialysis

Many methods have been proposed to measure the dose of dialysis a patient receives. The square meter hour hypothesis and dialysis index intended to address this issue (8) but did not take into consideration the volume of distribution of solute (e.g., urea). Teschan in the 1970s proposed a target dialytic clearance of 3,000 mL/wk/L of body water (20). This took into consideration urea distribution volume and, at a regimen of three dialysis treatments per week, a target of 1,000 mL/dialysis/L body water translating to the dialysis index of 1, which was used as the reference point. Certainly, other terms have been devised such as probability of failure in the NCDS (14), URR (20), and, as discussed earlier, the Kt/V (12). The latter two are currently the methods of choice for most institutions. In a large cohort of incident dialysis patients representative of the U.S. hemodialysis population, the overall predictive ability of URR, spKt/V, double pool or equilibrated Kt/V (dpKt/V), and Kt are all essentially the same (77).

Urea Reduction Ratio

The URR is an approximation of the fraction of BUN removed in a single dialysis session. The numerator is the difference between the pre- and postdialysis BUN, and the denominator is the predialysis BUN (**EQUATION 6.1**):

$$\text{URR} = \frac{\text{Predialysis BUN} - \text{Postdialysis BUN}}{\text{Predialysis BUN}} \qquad (6.1)$$

The URR has the advantage of simplicity and has been used extensively to measure hemodialysis adequacy in large patient populations, including the FMC data set reported by Lowrie and Lew, (37) Lowrie (38), and Owen et al. (20) and the ESRD Core Indicators Project reported by the Health Care Financing Administration (now the Centers for Medicare & Medicaid Services or CMS) (78).

However, the URR has several very important shortcomings. Most importantly, like the static TAC urea used in the NCDS, the URR cannot be used to assess the patient's nutritional status, which is an independent predictor of outcome perhaps more powerful than the dose of dialysis (20,54). Although URR correlates well with spKt/V in population studies, significant variability in correlation in individual patients occurs because URR fails to include both the contraction in extracellular volume and the urea generation that typically occurs during routine hemodialysis. Despite these shortcomings, however, when outcomes are correlated with either URR or Kt/V, no difference in "predictability" is detectable. The reason for this lack of a better correlation with Kt/V may result from the narrow range of doses achieved during hemodialysis and the curvilinear relationship between the two parameters. When dose of kidney replacement therapy increases, especially when treatment is given daily, URR approaches zero. URR also is zero in continuously dialyzed patients or patients with normal kidney function. Other disadvantages of URR include the inability to adjust the prescription accurately when the value is off target (by adjusting K or t), inability to add the effect of residual kidney function, and inability to troubleshoot by comparing prescribed with delivered dose.

Kt/V

Kt/V has become the preferred method for measuring delivered dialysis dose because it more accurately reflects urea removal than does URR, it can be used to assess the patient's nutritional status by permitting calculation of the normalized protein catabolic rate (nPCR), and it can be used to modify the dialysis prescription for a patient who has residual renal function. The 2015 KDOQI adequacy guideline highlights how to properly obtain the urea Kt/V and advocates a monthly assessment; however, it also mentions that the URR should not be used routinely as it does not incorporate residual renal function nor does it account for the change in urea volume or urea generation during the course of the hemodialysis treatment (17).

Formal Urea Kinetic Modeling

Formal urea kinetic modeling (UKM) is the most accurate method for determining Kt/V and requires the use of a computer capable of solving differential equations to compute the following variables:

V, the volume of distribution of urea, which is approximately equivalent to total body water
K, by extrapolating a K_oA value for the dialyzer that can be applied within a range of blood and dialysate flows
G, the urea generation rate, from which the nPCR can be computed

Once the K and V are determined, one can arithmetically compute the t (time) required to deliver a target Kt/V. For example, if the target Kt/V is 1.4 and formal UKM has determined that K is 250 mL/min and V is 40 L, then the time required to deliver the target Kt/V of 1.4 would be (40/0.25) × 1.4 = 224 minutes.

The use of the formal iterative UKM model of determining V has been shown to be more accurate that anthropomorphic formulas proposed by Hume and Weyers (79) and Watson et al. (80) because these formulas were derived from analysis of healthy individuals and are probably not applicable to patients with ESKD. Chertow et al. (81,82) has developed an ESKD population–specific equation for calculating total body water based on bioelectrical impedance monitoring. Although determination of V by this method, which utilizes several readily available patient-specific anthropometric parameters, is fairly simple, whether or not it leads to significant differences in the ability to predict patient outcomes is subject to speculation.

Daugirdas II

Although formal UKM is preferred by the Renal Physicians Association (RPA) and NKF-KDOQI clinical practice guidelines for the reasons outlined in the preceding text, its computational complexity has been a barrier to its widespread adoption. Many facilities have chosen instead to employ the more user-friendly second-generation natural logarithm formula for Kt/V proposed by Daugirdas (83), commonly known as Daugirdas II, which takes into account urea removed via ultrafiltration as well as urea generation during the dialysis treatment (**EQUATION 6.2**):

$$Kt/V = -\ln(R - 0.008 \times t) + (4 - 3.5 \times R) \times UF / W \quad (6.2)$$

where:

ln is the natural logarithm.

R is the postdialysis BUN/predialysis BUN.
t is the duration of the dialysis session in hours.
UF is the ultrafiltration volume in liters.
W is the patient's postdialysis weight in kilograms.

The Daugirdas II formula has been shown to approximate the formal UKM-derived result over the full range of single-pool, variable-volume Kt/V values (83–85) and has been endorsed by the NKF-KDOQI clinical practice guideline as the dialysis adequacy measurement of choice for providers unable or unwilling to perform formal UKM.

Surface Area Normalized Kt/V

Daugirdas et al. (86) have noted the inconsistency that eGFR is scaled to BSA in millimeters per minute per 1.73 m^2, but adequacy of dialysis is scaled to urea distribution volume (V). Because the V/BSA ratio is higher in men than in women, scaling the dialysis dose based on BSA instead of V would result in relatively higher Kt for women at the same level of V. Because V scales to weight while BSA scales to 0.425 power of weight, scaling the dialysis dose to BSA would also result in relatively higher Kt for smaller patients of either sex. Kt/BSA has been proposed but would require more accurate estimates of Kt than are readily available in most facilities. An alternative proposed by Daugirdas et al. (86) would be to measure Kt/V but then to rescale it to BSA based on a neutral correction when the V calculated by the Watson formula (Vant) (see section "Formal Urea Kinetic Modeling") equals 35 L in males. The net result is that the "surface area normalized" (SAN) Kt/V = Kt/V multiplied by Vant/(3.271 × $Vant^{2/3}$), and in females, multiplied again by 0.91. For a woman with Vant = 35 L, the target Kt/V would be at least 1.2/0.91 = 1.32. For a man with Vant = 25 L, the target Kt/V would be at least 1.34. The net effect is to increase the minimum required dialysis dose for smaller patients and women of all body sizes and to decrease the minimum required dialysis dose for larger male patients.

Ramirez et al. (87) discuss dialysis dose scaled to BSA and how the surface area–based dialysis dose results in different dose–mortality relationships than the ubiquitous volume-based dosing and that women and smaller patients may be underdialyzed using volume-based dosing. Daugirdas (88) eloquently discusses the scope of Kt/V and dialysis dosing, again highlighting that limiting calculations to total body water, that is, traditional assessments of volume may result in lower doses of dialysis for women and smaller patients. The predictive value of using SAN Kt/V on patient outcomes has yet to be tested in large populations.

Postdialysis Blood Urea Nitrogen Sampling

A number of technical issues involved in measuring dialysis adequacy have raised a great deal of controversy. The foremost is the timing and methodology for drawing the postdialysis BUN sample. This procedure is particularly important because inconsistency will tend to overestimate the dose of dialysis delivered.

Following the conclusion of a hemodialysis treatment, the BUN precipitously rises due to three factors: vascular access recirculation, cardiopulmonary recirculation, and compartmental disequilibrium (**FIGURE 6.3**) (89).

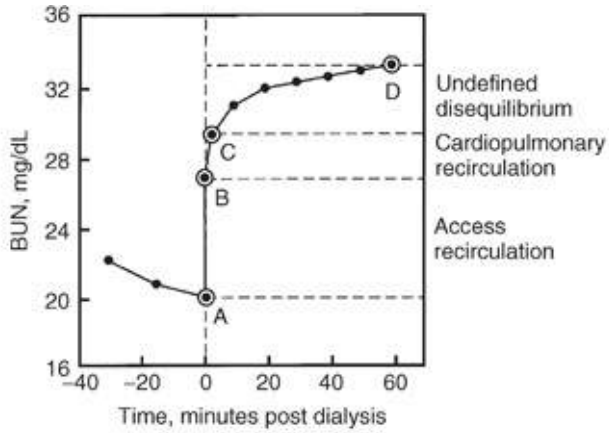

FIGURE 6.3 A typical example of urea rebound, with over half secondary to access recirculation (*A, B*), 15% from cardiopulmonary recirculation (*B, C*), and the remainder due to the resolution of perfusion and/or compartmental disequilibrium. (Reprinted with permission from Depner T. Assessing the adequacy of hemodialysis: urea modeling. *Kidney Int* 1994;45:1522–1535.)

Vascular Access Recirculation

The first BUN rise after a hemodialysis treatment, which occurs within 10 to 20 seconds, is due to vascular access recirculation, if present. Vascular access recirculation occurs when the blood-flow rate through the extracorporeal circuit exceeds the arterial blood flow into the access, making the retrograde flow of blood back through the arterial circuit inevitable. Access recirculation is often the result of downstream venous stenoses at the prosthetic graft venous anastomosis or the subclavian vein.

The effects of access recirculation on the postdialysis BUN disappear within 10 to 20 seconds of the conclusion of the hemodialysis treatment. The importance of access recirculation and improper postdialysis blood drawing technique in the overestimation of dialysis adequacy has been demonstrated in a study of patients with well-functioning peripheral access, in which deliberately failing to follow a "slow flow" sampling technique was associated with an overestimation of dialysis adequacy of up to 40% (90). However, if the blood pump is turned down to 50 to 100 mL/min, it is extremely unlikely that access recirculation will occur, as arterial inflow into the graft or fistula invariably exceeds this rate. Therefore, the NKF-KDOQI clinical practice guideline for hemodialysis adequacy recommends that the blood pump be slowed to 50 to 100 mL/min for at least 15 seconds prior to drawing the postdialysis BUN sample from the arterial port closest to the patient (66).

Cardiopulmonary Recirculation

The second component of the rise in BUN immediately after the conclusion of the hemodialysis treatment is cardiopulmonary recirculation, which is completed in 2 to 3 minutes. Cardiopulmonary recirculation refers to that small portion of blood that returns to the patient through the venous limb of the extracorporeal circuit and then circulates through the heart, lungs, and back to the arterial limb of the extracorporeal circuit without passing through any urea-rich tissues.

Cardiopulmonary recirculation typically accounts for only 15% of urea rebound following the conclusion of the hemodialysis treatment and does not occur when venous catheters are used for angioaccess.

Compartmental Disequilibrium

The third component of urea rebound, due to compartment disequilibrium, is not complete until at least 30 minutes after the conclusion of the hemodialysis treatment.

Originally, this phase was thought to represent the resolution of disequilibrium between intra- and extracellular urea: Extracellular urea is removed effectively during the hemodialysis treatment, and then urea is released from the intracellular to the extracellular compartment at the conclusion of the treatment due to the gradient between the two pools.

It has been suggested that the compartment disequilibrium that occurs during a hemodialysis treatment is not between intracellular and extracellular fluid but between high blood flow vascular beds (such as the kidney, lungs, brain, and other viscera) where relatively little urea is generated, and lower blood flow vascular beds (such as muscle, skin, and bone) where the majority of urea is generated and which are more subject to vasoconstriction during hemodialysis (91). Once the hemodialysis treatment has concluded and blood flow increases to these organs, sequestered urea is "washed out" and the BUN concentration rebounds.

Adherence to the NKF-KDOQI practice guidelines for postdialysis blood draw and the use of formal UKM or the Daugirdas II formula will yield an spKt/V that eliminates the effects of access recirculation but not of cardiopulmonary recirculation or of urea disequilibrium. The NKF-KDOQI hemodialysis workgroup made their recommendations based on the small contribution of cardiopulmonary recirculation to urea rebound and the impracticality of detaining patients for 30 minutes after the conclusion of the hemodialysis treatment to draw the postdialysis BUN.

Equilibrated Kt/V

The magnitude of disequilibrium and urea rebound is proportional to the efficiency of the hemodialysis treatment, which can be described as Kt/V. In other words, the more efficient (shorter t for a given Kt/V) the hemodialysis treatment, the lower the BUN measured immediately after the hemodialysis treatment, and the more the Kt/V based on this BUN will overestimate the equilibrated Kt/V (eKt/V).

Daugirdas and Schneditz (92) have developed a relatively simple formula to estimate the eKt/V, based on the "single-pool" postdialysis BUN sample (drawn as described in preceding text at the conclusion of the hemodialysis treatment) and the treatment time (**EQUATION 6.3**):

$$eKt/V = spKt/V - 0.6 \times spKt/V/h + 0.03 \qquad (6.3)$$

where spKt/V is the single-pool Kt/V calculated from the Daugirdas II formula.

This formula, which obviates the need to draw a 30-minute postdialysis BUN to calculate eKt/V, was able to predict the eKt/V (based on actual 30-minute postdialysis BUN) better than models that use online dialysate urea monitoring (93) or intradialysis BUN measurement according to the Smye et al. (94) technique. The Smye technique is based on the fact that urea rebound disequilibrium (the degree to which the equilibrated postdialysis BUN exceeds the single-pool postdialysis BUN) will equal urea inbound disequilibrium (the degree to which measured BUN during the hemodialysis treatment is less than that predicted by its pharmacokinetics, based on dialyzer clearance and volume of distribution).

HEMODIALYSIS DOSE AND OUTCOME

The survival of patients on hemodialysis tends to be better than that of lung cancer patients but is worse than the statistics for both colon and prostate cancer patients (38). It is significant that the mortality rate of ESKD patients in the United States is greater than that of their counterparts in other countries, notably

those in Europe and in Japan (95). Analysts have tried to explain these data in terms of patient differences, especially with regard to age and comorbidity (19), nutritional status (20,37), incomplete data in the registry (96), and less than adequate dialysis dose delivery (19).

Numerous publications have demonstrated that the delivered dose of hemodialysis is a significant predictor of patient outcome (18). The HEMO trial convincingly demonstrated that above an spKt/V of 1.4, there is no longer a continuous decline in mortality. Moreover, augmentation of middle molecule clearance (as measured by β_2-microglobulin clearance) with the use of "high-flux" membranes failed to confer survival benefits in this large and well-designed study of contemporary hemodialysis practice patterns (32,34).

Renal Physicians Association's Clinical Practice Guideline

The high prevalence of low hemodialysis dose as well as the relatively high mortality among hemodialysis patients in the United States prompted the 1993 publication of the RPA's *Clinical Practice Guideline on Adequacy of Hemodialysis* (97). The RPA guideline was the first clinical practice guideline addressing the care of the patient with ESKD, and its dissemination likely contributed to the decline in patients with URR less than 0.65 between 1993 and 1996 (98).

The RPA guideline recommended a minimum Kt/V of 1.2, based on a probabilistic model to assess how variation in the hemodialysis prescription affected quality-adjusted life expectancy (QALE). The RPA guideline noted that, although QALE increased with raising Kt/V above 1.2, the significant increase in costs required to achieve this higher dose of dialysis must be considered. The RPA guideline's final recommendation reflected a balance of concerns regarding decreasing incremental QALE and marginal cost-effectiveness. For facilities using URR rather than Kt/V, a minimum value of 0.65 was recommended.

National Kidney Foundation's Kidney Disease Outcomes Quality Initiative Clinical Practice Guideline

The first NKF Dialysis Outcomes Quality Initiative (DOQI, subsequently renamed KDOQI) clinical practice guideline on hemodialysis adequacy was published in 1997, revised in 2001, again in 2006 (66), and most recently revisited in 2015 (17). The updated 2015 guideline has maintained the standard of a target spKt/V of 1.4 per hemodialysis session for patients receiving three times per week hemodialysis and a minimum delivered spKt/V of 1.2. The update highlights that residual native kidney function (Kru) may allow for lower doses of dialysis; however, Kru must be measured regularly to ascertain significant residual renal function is present and whether the dialysis dose may need to be adjusted to account for a decrease in residual renal function.

Standard Kt/V (stdKt/V) is the weekly urea generation rate factored by the average predialysis serum urea concentration during the week and allows for the inclusion of more frequent treatments or continuous dialysis treatments, such as PD or residual renal function. For alternative hemodialysis schedules, the recent guideline suggests a target stdKt/V of 2.3 volumes per week with minimum delivered dose of 2.1. Kru of 3 mL/min is equivalent to a stdKt/V of about 1.0 volume per week, and if residual renal function is not accounted for, then PCR will be underestimated. The guideline advocates a quarterly assessment of Kru at a minimum; however, if there has been a change in urine volume, a repeat assessment of Kru should occur earlier. Furthermore, those patients whose dialysis prescription is altered due to significant Kru, it is important to monitor urine volume monthly.

The 2015 update also recommends a minimum of 3 hours per session for patients with low residual renal function and that longer treatment times may be indicated in certain patients such as those having difficulty to achieve their dry weight. With regard to ultrafiltration rate, there is no set recommended value; however, the guideline suggests balancing blood pressure control, solute clearance, intradialytic symptoms, and hemodynamic stability. Finally, the 2015 guideline also recommends using biocompatible membranes for intermittent hemodialysis.

National Institutes of Health HEMO Study

The lower mortality rates reported for hemodialysis patients outside the United States and the extremely low mortality rates reported from Tassin, France, where patients undergo 24 m^2 hours of dialysis weekly (18,31), raise several nagging questions:

1. Is dialysis duration an independent factor in dialysis adequacy (a return to the middle molecule hypothesis)?
2. Are shorter dialysis treatments to achieve a comparable (i.e., more efficient) Kt/V associated with adverse outcomes because they increase urea disequilibrium and therefore underestimate the equilibrated dose of dialysis delivered (which can be corrected for by using a double-pool eKt/V target)? Or is the adverse outcome due to other factors, such as cardiovascular instability or rapid transcellular molecule fluxes?
3. Is there any cost-effective benefit to increasing the dose of dialysis above that recommended by the RPA and NKF-KDOQI guidelines?

In an attempt to answer these types of question, NIH sponsored and completed the HEMO study, a multicenter, prospective, randomized trial designed to assess the effects of hemodialysis dose (i.e., small molecule clearance) and flux (i.e., middle molecule clearance) (34) on morbidity and mortality.

The sweep of this study was comparable to the NCDS but with turn of the millennium technology. Like the NCDS, the HEMO study had four arms in a 2 × 2 matrix:

1. Arm 1: standard urea clearance (URR about 0.67, spKt/V about 1.25, eKt/V about 1.05) and a high-efficiency polysulfone dialysis membrane
2. Arm 2: higher urea clearance (URR about 0.75, spKt/V about 1.65, eKt/V about 1.45) and a high-efficiency membrane
3. Arm 3: Standard urea clearance and a high-flux polysulfone dialysis membrane
4. Arm 4: Higher urea clearance and a high-flux membrane

The main outcome measure of the HEMO trial was again mortality but with several important secondary outcomes were also monitored, specifically cardiac hospitalizations or deaths, infection-related hospitalizations or deaths, declines in albumin, and all-cause hospitalizations. These main and secondary outcomes correspond to the main causes of morbidity and mortality within the U.S. hemodialysis population.

The results of the HEMO trial confirm that the minimum dose of hemodialysis recommended by the aforementioned guidelines is safe. Higher doses of dialysis and the use of high-flux membranes offer no specific morbidity or mortality advantage to the groups receiving these treatments (**FIGURES 6.4** and **6.5**). Therefore, in the context of conventional three times per week hemodialysis, neither the high-flux nor high-dose interventions substantially improved patient outcome compared to low-flux and standard-dose

levels. However, certain secondary results from the trial are consistent with the hypothesis of subtle effects that may be magnified by more intensive therapies that extend beyond the limits of conventional three times per week dialysis. Specifically the use of high-flux dialysis membranes (with improved clearance of β_2-microglobulin) in subgroups composed of women and patients who had been on dialysis more than 3.5 years on entry to the trial showed a trend toward decreased morbidity, hospitalizations, and mortality (34).

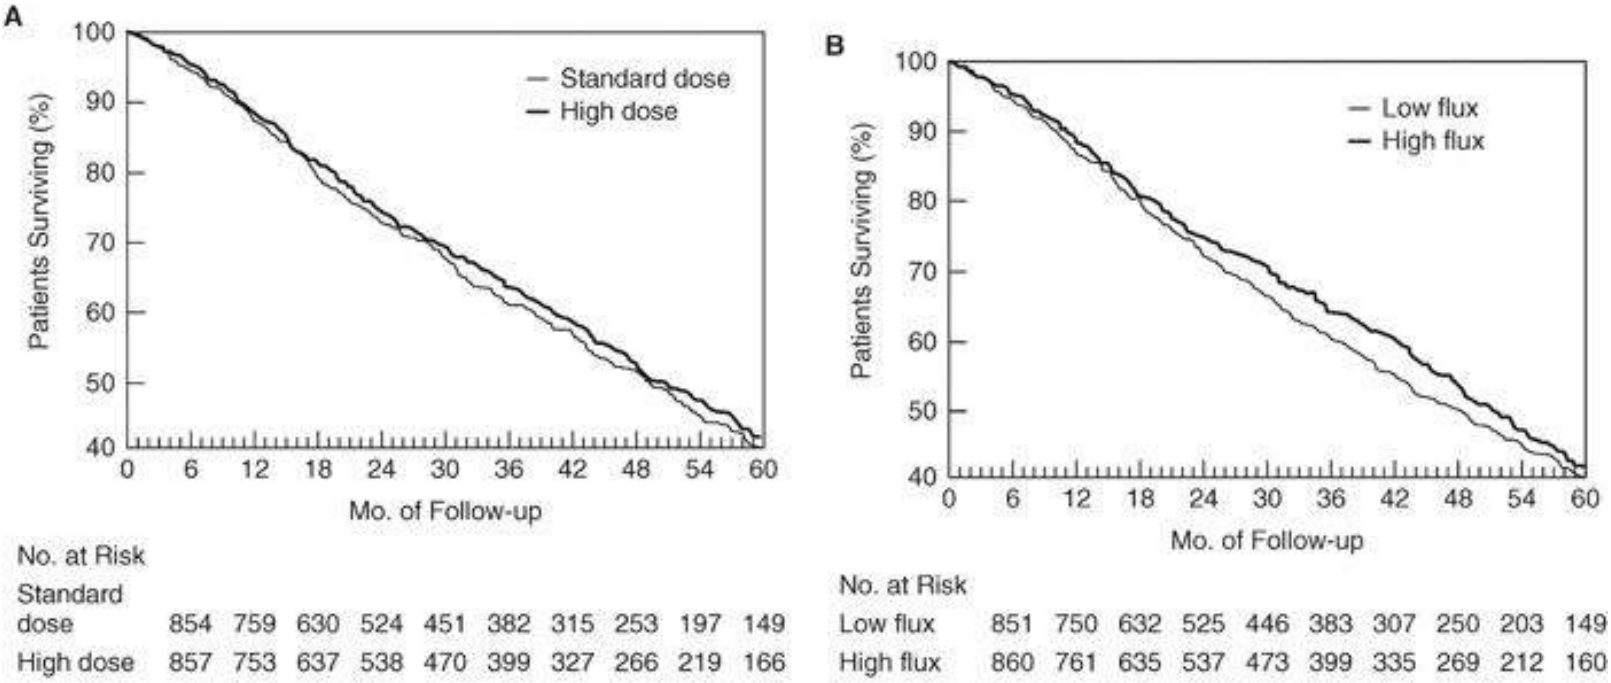

FIGURE 6.4 Survival curves for the treatment groups in the HEMO study. After adjustment for the baseline factors, mortality in the high-dose group was 4% lower (95% confidence interval, −10 to 16; $p = 0.53$) than that in the standard-dose group (Panel A), and mortality in the high-flux group was 8% lower (95% confidence interval, −5 to 19; $p = 0.23$) than that in the low-flux group (Panel B). [Reprinted with permission from Eknoyan G, Beck GJ, Cheung AK, et al. Effect of dialysis dose and membrane flux in maintenance hemodialysis. *N Engl J Med* 2002;347(25):2010–2019.]

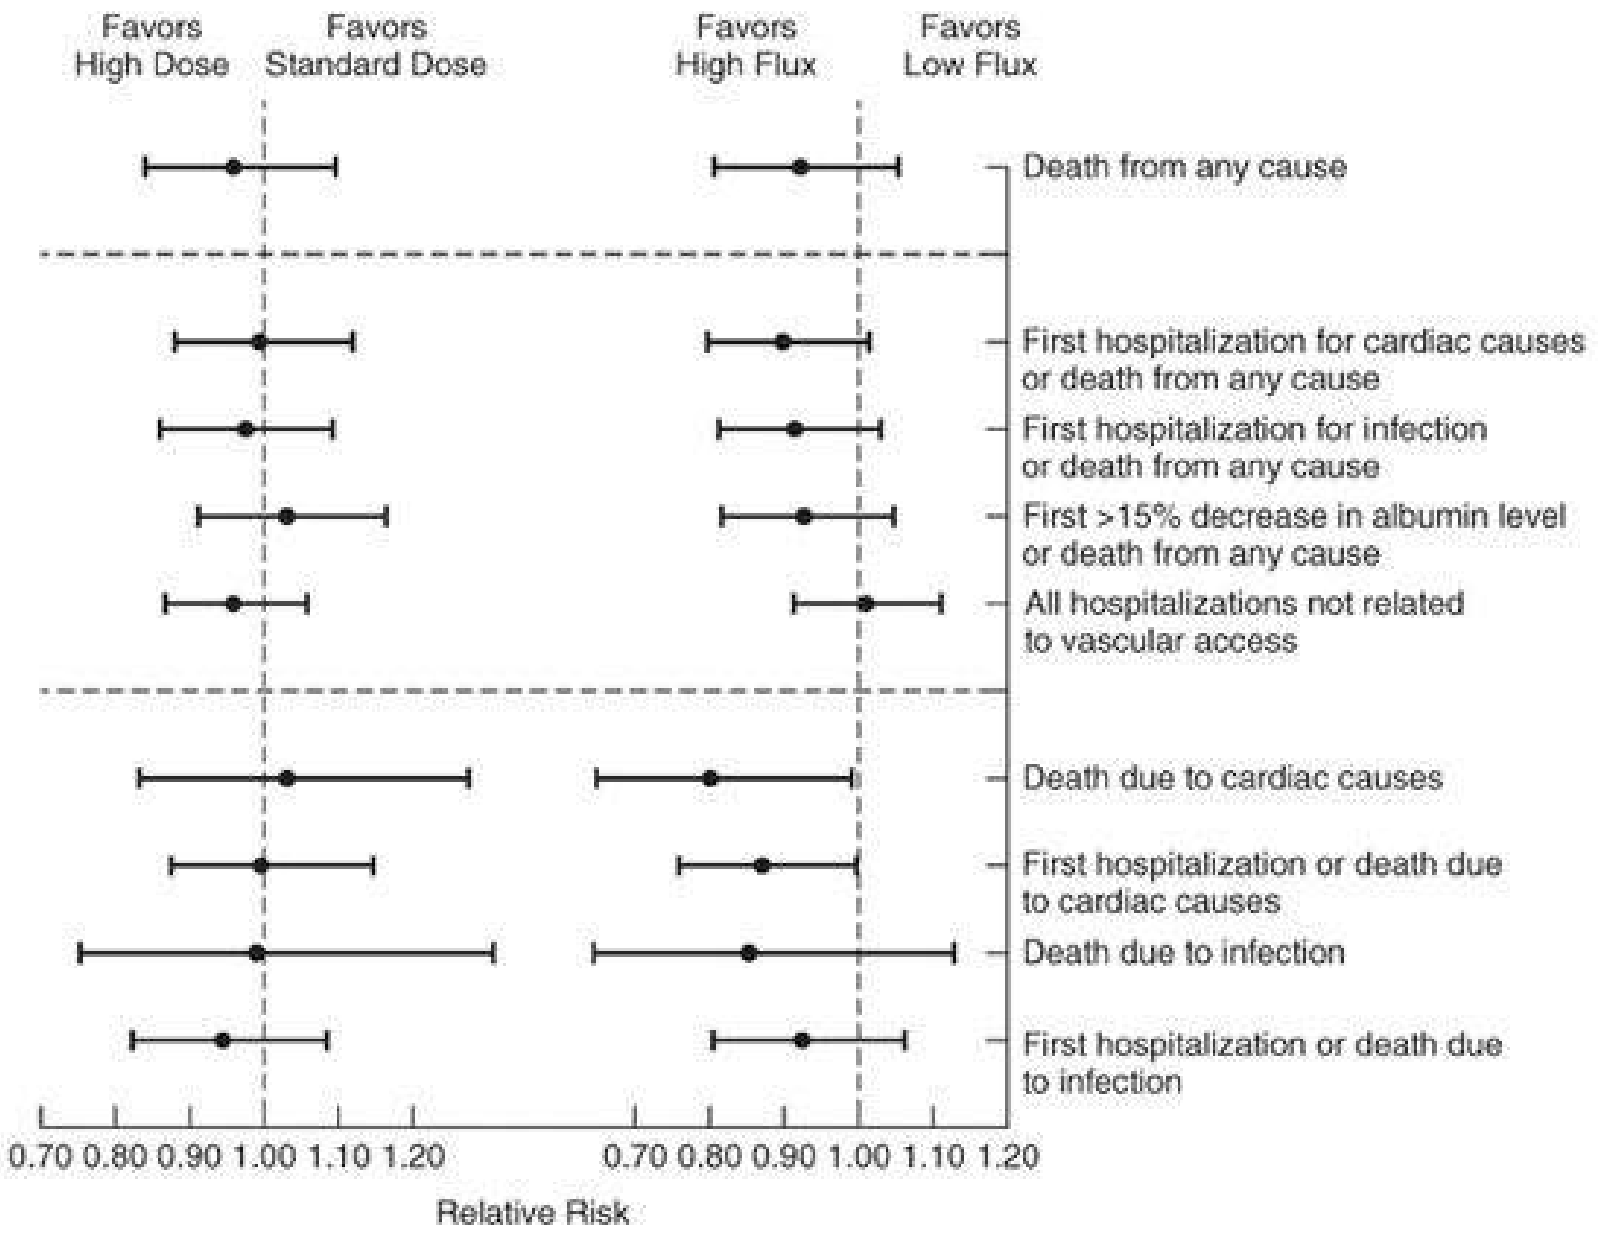

FIGURE 6.5 Effects of the treatment interventions on primary and secondary outcomes in the HEMO study. Values are shown as relative risks and 95% confidence intervals associated with assignment to the high-dose group as compared with assignment to the standard-dose group and assignment to the high-flux group as compared with assignment to the low-flux group. Analyses were stratified according to clinical center and adjusted for baseline age, sex, race, duration of dialysis, presence or absence of diabetes, score for coexisting conditions excluding diabetes, serum albumin level, and the interaction of albumin level with time from randomization. Percentage risk reductions for the high-dose and high-flux groups given in the text are obtained by subtraction of the relative risk from 1 followed by multiplication by 100. [Reprinted with permission from Eknoyan G, Beck GJ, Cheung AK, et al. Effect of dialysis dose and membrane flux in maintenance hemodialysis. *N Engl J Med* 2002;347(25):2010–2019.]

BARRIERS TO ADEQUATE HEMODIALYSIS

The discussion of hemodialysis adequacy must not obscure the fact that other parameters such as nutrition and patient-assessed functional health status have been shown to have an even stronger correlation with patient outcomes. Accordingly, appropriate care of the hemodialysis patient should not be focused on any single indicator such as dialysis dose. However, the clinician has more direct control over dialysis dose than over some of the other factors affecting outcomes, so it may constitute the greatest opportunity for physician behavior to influence patient survival.

Underprescription

Since the 1993 publication of the RPA guideline recommending a minimum URR of 0.65 or Kt/V of 1.2, a discernible trend toward improvements in the delivery of adequate dialysis to U.S. patients with ESKD has been demonstrated in a variety of databases including the ESKD Clinical Performance Measures (CPM) Project, the United States Renal Data System (USRDS), and the DOPPS. According to data from the DOPPS website (which is updated every 4 months), 95% of hemodialysis patients in the DOPPS stratified weighted sample (representative of the United States as a whole) had Kt/V more than 1.2 in 2014 (99). However, despite continued improvements, still some patients do not meet minimum adequacy standards. More disturbing, however, the use of central venous catheters remains unacceptably high, with almost 20% of prevalent U.S. hemodialysis being dialyzed with a chronic venous catheter (99). Underprescription remains a significant problem, accounting for 55% of underdialyzed patients reported by Delmez and Windus (100) and 14% of all patients reported by Sehgal et al. (101).

As might be expected, underprescription of dialysis (Kt/V) is most likely to occur in a patient with a large urea volume of distribution (V), in whom the dialysis variables (Kt) have not been increased in proportion to patient size (102). The relationship between patient size and the likelihood of underprescription of dialysis therapy was also explored by Leon and Sehgal (103) in a group of dialysis patients drawn randomly from 22 chronic dialysis units in northeast Ohio. Using a Kt/V criterion of 1.3 as "adequate" dialysis, they found that 15% of patients were underdialyzed. Prescribed Kt (that portion of dialysis therapy which is modifiable by the prescribing physician) was strongly associated with patient volume, V. However, for every 10 L increment of V, Kt was only increased by a factor of 8.3, rather than 13 L, which would be required to maintain a Kt/V of 1.3. Due to this reduction in prescription, as patient size increased, the proportion of patients with a low prescription also increased from 2% of patients with V less than 35 L to 42% of patients with V 50 L or more (77).

Inadequate Vascular Access

The second most important barrier to achieving the target delivered hemodialysis dose is inadequate vascular access, which decreases the efficiency of dialysis due to both inadequate blood flow and access recirculation. Coyne et al. (104) found that among 146 patients with a decline in Kt/V over a 3-month period, 24% were due to decreased blood-flow rates and 25% were due to recirculation. Sehgal et al. (101) found 11% of his prevalent sample of 722 patients to be using catheters and that catheter use decreases the delivered Kt/V by 0.2. In patients with catheters, shortening of treatment time together with a higher likelihood of access recirculation help explain why minimum adequacy targets are still being missed.

Shortened Treatment Time

Patient noncompliance with treatment time was observed in 3% of the treatments reported by Sehgal et al. (101) in which adequacy was measured and accounted for 18% of the declines in Kt/V reported by Coyne et al. (104). Patient noncompliance reduced Kt/V by a factor of 0.1 in the Sehgal study, which is less significant than underprescription (0.5) or catheter use (0.2). Skipped hemodialysis treatments are obviously an issue in total dialysis dose but would not be reflected by a decreased Kt/V or URR because no blood would be drawn from an absent patient. In a survival analysis of skipped treatments and dialysis prescription noncompliance, Leggat et al. (105) demonstrated an approximate 10% increase in the risk of

death for each hemodialysis session that is missed. In this analysis, the authors also found that approximately 8.5% of patients skipped hemodialysis treatments at least once per month and that 20% shortened treatment times.

Clotting

Clotting during hemodialysis occurred in 1% of the treatments reported by Sehgal et al. (101) in a study that measured adequacy, resulting in a decrease on Kt/V of 0.3. As a general rule, the treatment duration was not extended to compensate for the "down" time of changing the extracorporeal circuit. Also notable is that the overall efficiency of the dialysis procedure decreased due to loss of dialyzer surface area to clotting. Adequate anticoagulation is obviously the most effective method to overcome this barrier to adequacy, but clearly, there are patients whose bleeding risk precludes this approach. Further investigation is needed to determine the best course of action for this small subset of patients.

Other Variables

TABLES 6.2 and **6.3**, adapted from Parker (106), illustrate the plethora of variables that may confound the provision of an adequate dialysis dose. It is clearly not an exact science, and a normal distribution of delivered dialysis from a given prescribed dialysis dose will lead to a significant fraction of patients receiving less than the prescribed dose (107). Therefore, for 90% of patients to receive a delivered Kt/V of 1.2 or more, the NKF-KDOQI guideline recommends a prescribed Kt/V of 1.3 or more (URR 0.70 or more) (66).

TABLE 6.2 Reasons for Compromised Urea Clearance

Patient-related reasons
Decreased effective time on dialysis (breakdown on TABLE 6.3)
Decreased blood-flow rates (BFR)
1. Access clotting
2. Use of catheters
3. Inadequate flow through vascular access
Recirculation
1. Use of catheters
2. Inadequate access for prescribed BFR
3. Stenosis/clotting of access
Staff-related reasons
Decreased effective time (see TABLE 6.3)
Decreased BFR
1. Less than prescribed
2. Difficult cannulation
Decreased dialysate flow rate
1. Less than prescribed
2. Inappropriately set
Dialyzer
1. Inadequate quality of control of "reuse"
Mechanical problems
Dialyzer clotting during reuse
Blood pump calibration error
Dialysate pump calibration error
Inaccurate estimation of dialyzer performance by the manufacturer
Variability in blood tubing

Modified and adapted from Parker TF. Trends and concepts in the prescription and delivery of dialysis in the United States. *Semin Nephrol* 1992;12(3):271.

TABLE 6.3 Reasons for Decreased Effective Time on Dialysis

Patient-related reasons
Late start (patient tardy)
Early signoff
1. With consent (i.e., symptoms)
2. Against advice (i.e., social)
Medical complications (e.g., hypotension)
"No show"
Staff-related reasons
Late start (staff tardy)
Wrong patient taken off
Time calculated incorrectly
Time on/off read incorrectly
Clinical deficiencies (e.g., no time registered)
Premature discontinuation for unit convenience
1. Scheduling conflicts
2. Emergencies
Incorrect assumptions of continuous treatment time (e.g., failure to account for interruptions of treatment like repositioning needles or accidental removal)
Inaccurate assessment of effective time by using variable time pieces
Mechanical reasons
Clotting of dialyzer
Dialyzer leaks
Machine malfunction

Modified and adapted from Parker TF. Trends and concepts in the prescription and delivery of dialysis in the United States. *Semin Nephrol* 1992;12(3):271.

CONTEMPORARY TRIALS OF INCREASED DIALYSIS

Frequent Hemodialysis Network Daily Trial

Another landmark trial in dialysis adequacy research is the large multicenter randomized FHN trial which included two studies. In the first reported study, published in *The New England Journal of Medicine* in 2010, patients were randomly assigned to hemodialysis six times per week (frequent, $n = 125$) or three times per week (conventional, $n = 120$) for a period of 12 months (108). The two coprimary composite outcomes were death or change in left ventricular (LV) mass [from baseline to 12 months, assessed by magnetic resonance imaging (MRI)] and death or change in physical health composite (PHC) score of the RAND 36-Item Health Survey.

Patients in the frequent group averaged 5.2 sessions per week, and their weekly stdKt/V urea was 3.54 versus 2.49 in conventional group. Frequent hemodialysis was associated with benefits in the coprimary composite outcomes, but frequent group patients were also more likely to undergo vascular access interventions. Frequent hemodialysis was associated with beneficial changes for death or increase in LV mass (hazard ratio 0.61) and for death and decrease in physical heath score (hazard ratio 0.70). For time to first access intervention, frequent dialysis was associated with hazard ratio for 1.71 and for multiple interventions hazard ratio was 1.35 for frequent group (**FIGURE 6.6**).

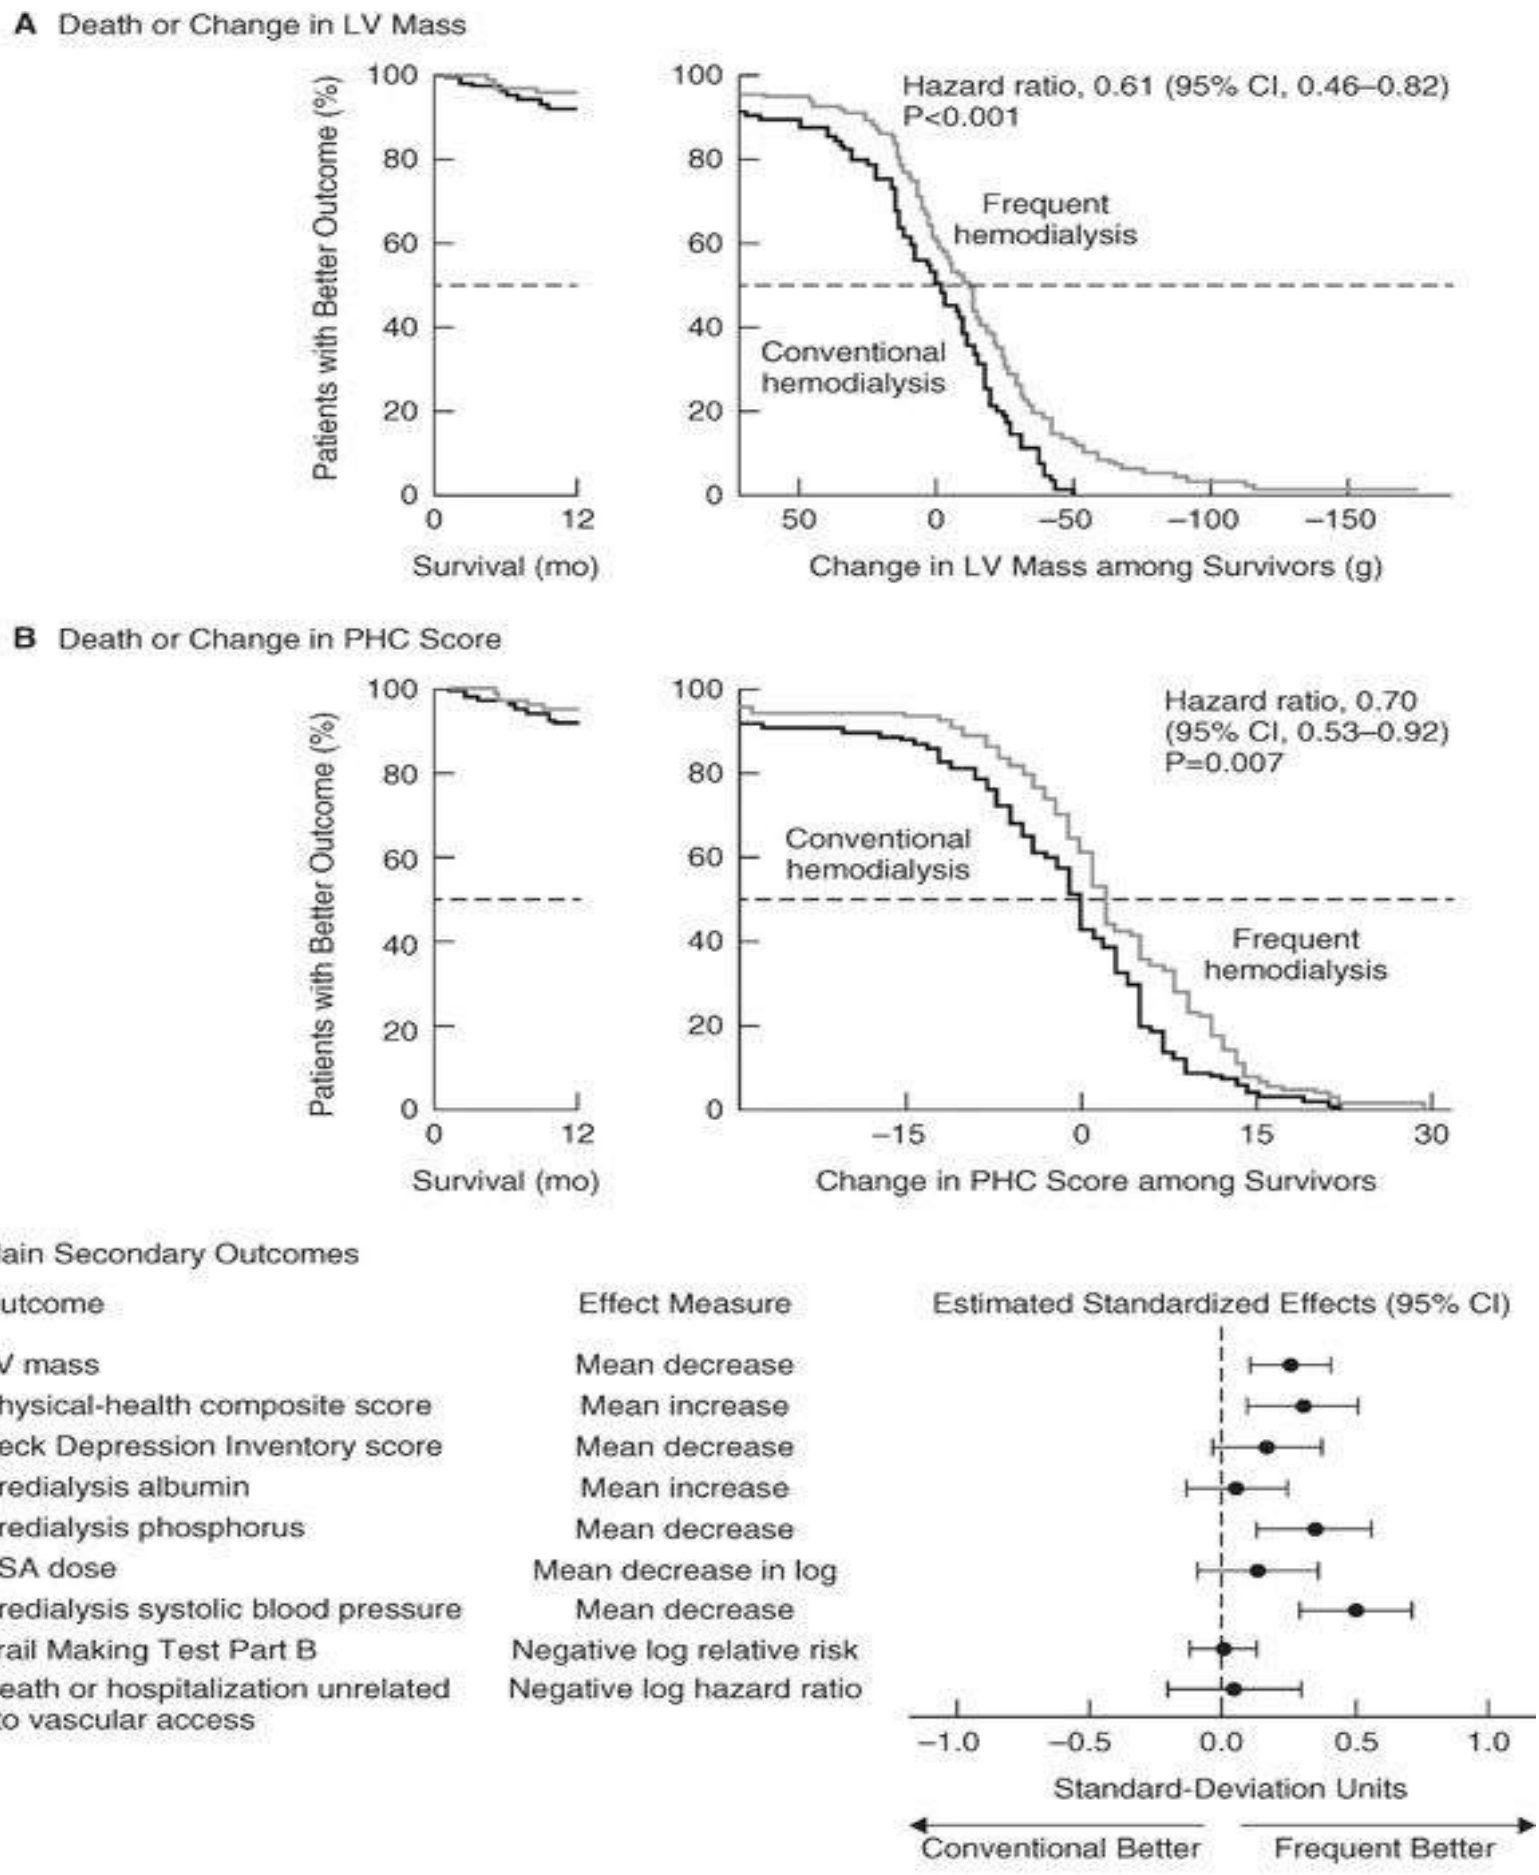

FIGURE 6.6 Coprimary composite outcomes and main secondary outcomes in the Frequent Hemodialysis Network daily trial. Kaplan–Meier curves are shown for the composite outcomes of death or change in left ventricular (LV) mass (Panel A) and death or change in the physical health composite (PHC) score from the RAND 36-Item Health Survey (Panel B). The standardized effect sizes for the main secondary outcomes are shown in Panel C. [Reprinted with permission from Chertow GM, Levin NW, Beck GJ, et al. In-center hemodialysis six times per week versus three times per week. *N Engl J Med* 2010;363(24):2287–2300.]

In this multicenter, prospective randomized parallel-group trial, a total of 78% of the patients who were assigned to frequent arm attended at least 80% of the prescribed sessions. Adherence was high in the daily trial but not in the nocturnal trial discussed later. FHN daily trial has some limitations, including small sample size was not sufficient to determine the effects of frequent in-center hemodialysis on death, cause-specific death, hospitalization, or other events. The rate of death was low in both groups, and therefore, the treatment effect was mostly supported by the intermediate outcomes, 12-month change in LV mass or PHC score. FHN daily trial excluded patients whose expected survival was less than 6 months and patients who residual renal function was more than 3 mL/min/1.73 m^2. Although overall positive for its coprimary outcome, the FHN daily trial was again not powered to definitively assess the effects of frequent dialysis on mortality. The trial has not established frequent dialysis as the standard of care but does continue to raise the ongoing discussion about adequacy and the ever elusive ideal hemodialysis prescription.

Frequent Hemodialysis Network Nocturnal Trial

The nocturnal study of FHN compared daily nocturnal (6 to 8 hours) home hemodialysis to conventional thrice-weekly home hemodialysis (72). Eighty-seven patients were randomized to thrice-weekly conventional hemodialysis or to nocturnal hemodialysis six times per week. The frequent nocturnal arm had a 1.82-fold higher mean weekly stdKt/V urea, 1.74-fold higher average number of treatments per week, 2.45-fold higher average weekly treatment time, and 1.23-fold higher total weekly ultrafiltration. No significant effect of nocturnal hemodialysis for either of the two coprimary outcomes, death or LV mass, or death or RAND PHC (**FIGURE 6.7**). The nocturnal patients had improvement in hyperphosphatemia, but there was a trend for increased vascular access events (**FIGURE 6.8**).

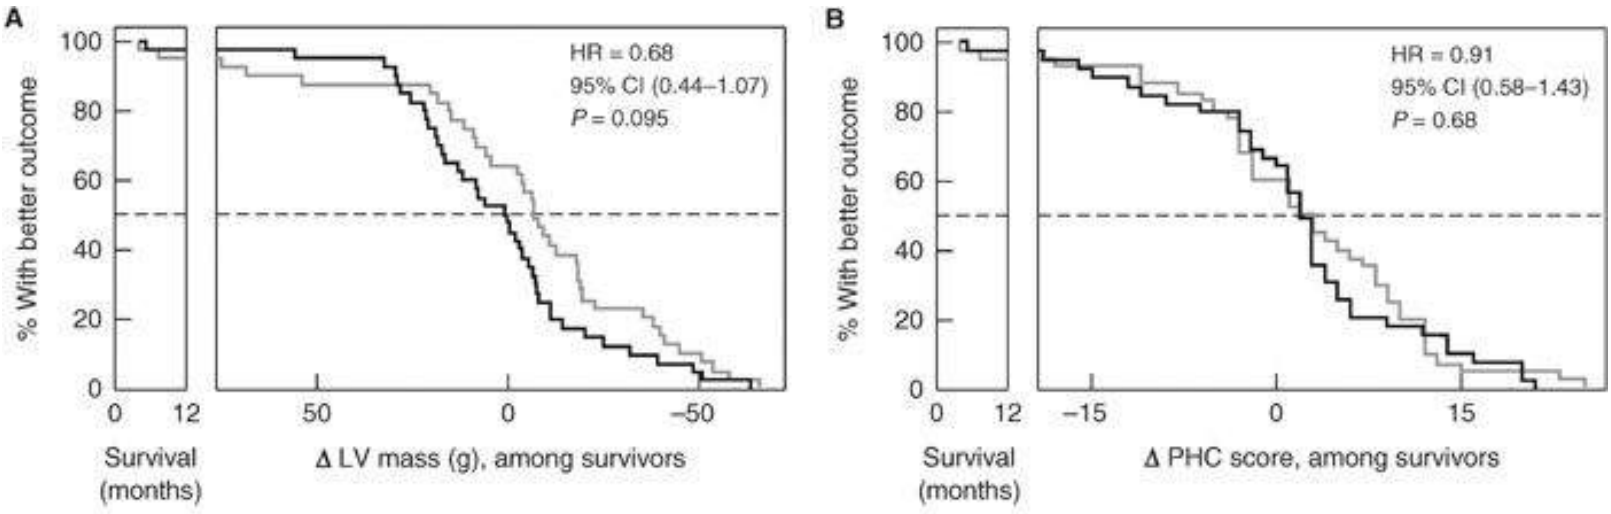

FIGURE 6.7 Mortality/LV mass composite and mortality/PHC composite results in the Frequent Hemodialysis Network nocturnal trial. Kaplan–Meier curves (conventional arm, black; frequent nocturnal arm, red) for the death/LV mass composite **(A)** and the death/PHC composite **(B)**. For any given value of the composite outcome indicated on the horizontal axis (time of death on the left, change in either LV mass or PHC among survivors on the right), the Kaplan–Meier curves indicate the proportion of patients in the respective treatment groups with an equal or more favorable outcome. The horizontal distance between the Kaplan–Meier curves at the 50% value on the vertical axis indicates the median composite outcome results. CI, confidence interval; HR, hazard ratio; LV, left ventricular; PHC, physical health composite. [Reprinted with permission from Rocco MV, Lockridge RS Jr, Beck GJ, et al. The effects of frequent nocturnal home hemodialysis: the Frequent Hemodialysis Network Nocturnal Trial. *Kidney Int* 2011;80(10):1080–1091.]

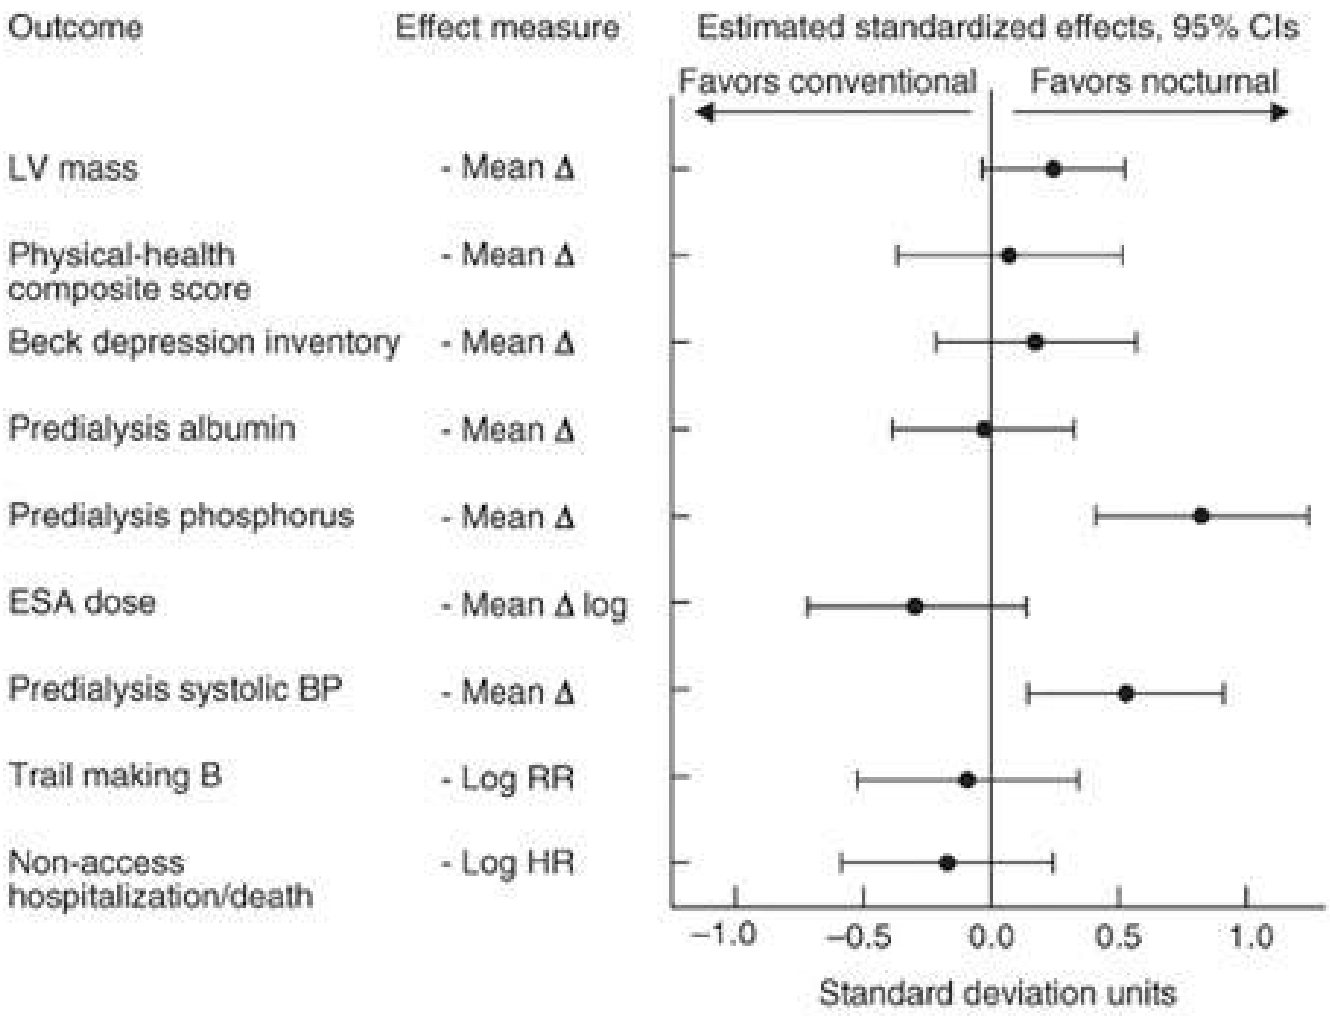

FIGURE 6.8 Main secondary results in the Frequent Hemodialysis Network nocturnal trial. BP, blood pressure; CI, confidence interval; ESA, erythropoiesis-stimulating agent; HR, hazard ratio; LV, left ventricular. [Reprinted with permission from Rocco MV, Lockridge RS Jr, Beck GJ, et al. The effects of frequent nocturnal home hemodialysis: the Frequent Hemodialysis Network Nocturnal Trial. *Kidney Int* 2011;80(10):1080–1091.]

The main limitations of the trial were the small sample size and lower adherence in the frequent arm. Patients in the frequent nocturnal arm had lower adherence (72.7%) than the patients in the conventional arm (97.6%). The study acknowledges that one would need a sample size of 275 patients to obtain 80% power to detect a mean effect on LV mass of 10 g. Another cofounding factor was that only 87.3% of the patients randomized completed the 12 months of follow-up and has actual measurements of both coprimary outcomes. Also, about a quarter of the patients in the frequent arm performed less than five dialysis treatments per week.

Other important differences include that the patients were younger (52.8 years old), had more residual renal function, and were less likely to be African American (26.4%) as compared to the average patients receiving chronic hemodialysis therapy. The residual renal function criterion for the nocturnal trial was greater than 10 mL/min/1.73 m^2 as the average of the urea and creatinine clearances compared to the cutoff of 3 mL/min/1.73 m^2 in the daily trial. Recruitment was challenging as the initial protocol was randomizing to in-center versus home hemodialysis, and eligible patients preferred to be dialyzed at home. Recruitment improved somewhat after the choice was between two types of home dialysis rather than home versus in-center. In conclusion, frequent nocturnal hemodialysis as compared to three times per week hemodialysis did not result in significant benefits in the coprimary outcomes of death/LV mass or death/PHC. PHC improved in both groups most likely secondary to the effect of home hemodialysis.

Time to Reduce Mortality in End-Stage Renal Disease Trial

The TiME Trial is a cluster-randomized, parallel-group pragmatic ongoing clinical trial to determine whether dialysis facility implementation of a minimum session length of 4.25 hours three times per week versus usual care has benefits on mortality, hospitalizations, and HRQOL (109). The primary outcome measure is time to death; a secondary outcome measure is hospitalization rate, and the maximum duration of follow-up is 3 years. The hypothesis is that the risk of death will be lower in the facilities randomized to the intervention group. Another outcome measure is quality of life, assessed with a Health-Related Quality of Life questionnaire. The estimated study completion date is September 2017. The inclusion criteria include ESKD patients over 18 years of age that are on hemodialysis three times per week who have started maintenance dialysis within the prior 120 days. Exclusion criteria are unwillingness to participate or inability to provide consent for dialysis. The nephrology community is anxiously awaiting the results of this pertinent trial with its primary outcome measure, time to death, and the critical variable, dialysis treatment time.

CONCLUSION

Looking forward, it seems that we should, first and foremost, evaluate the patient while evaluating the adequacy of dialysis. Understanding the interaction of the multiple factors that affect overall survival and quality of life will heighten our awareness of specific issues that need to be addressed. We must evaluate nutritional status, physical activity, comorbid conditions, fluid and electrolyte balance, social and home conditions, and find specific barriers to adequate hemodialysis. We must aim for Kt/V of 1.3 or more (URR 70% or more) with a delivered Kt/V of 1.2 or more measured monthly, along with other laboratory values within target ranges. Although one-third of the declines in Kt/V reported by Coyne et al. (104) could not be explained and returned spontaneously to adequate levels, the majority were real and therefore should be investigated and corrected.

Increasing recognition of the underprescription of hemodialysis is still challenging. Facilities constantly reshuffle station allocation and turnover to meet the needs of patients as well as the care team. Increased patient education to improve buy-in of longer treatment times when appropriate needs to occur at the facility level but can and should use the materials and media that have been developed regionally and nationally for this purpose. Peer education by other patients through local, regional, or national patient advocacy groups can also prove to be highly effective in increasing patients' participation in their care. An exploration of the patient's home, family, and socioeconomic situation can provide valuable insights that help to break down barriers to patient partnership.

In the last four decades, we still focus on urea as primarily responsible for the uremic syndrome and as our main marker for dialysis adequacy. Although urea is a good surrogate marker, identifying the responsible toxins and then removing them more efficiently remains a formidable challenge. The continued disparity in mortality rates between the United States and Europe points out the need for continued investigation regarding the most appropriate methods of delivering renal replacement therapy as well as the best indicators for measurement of dialysis adequacy.

The NIH's HEMO study helps to clarify some of these issues and provides guidance in applying hemodialysis technology to achieve the best patient outcomes. We must deal with the fact that 5% of

patients in the DOPPS random sample did not have today's target Kt/V of 1.2 or more and that a larger percentage of incident dialysis patients are classified as overweight or obese, with up to 20% of these patients failing to meet adequacy targets. With contemporary trials such as the FHN studies and TiME, we continue to pursue how to better the care and lives of our patients. We must also consider the kind of dialysis that best suits our patients, including home and incremental therapies. We have the quality improvement tools to identify the barriers to adequate hemodialysis in each of our facilities and the human capital to overcome them.

CHAPTER 7

High-Efficiency and High-Flux Hemodialysis

Thomas A. Golper, Rafia Chaudhry, Iheanyichukwu Ogu, and Gerald Schulman

For a glossary of abbreviations, please see **TABLE 7.1**. In the era of the previous editions of this book, high-efficiency hemodialysis (HEHD) was a prevalent and popular form of in-center hemodialysis (HD), for reasons discussed below. As dialysis sciences progressed in informing us about solute kinetics, ultrafiltration tolerance, and new techniques, it became increasingly more evident that the utilization of HEHD as originally conceived would decrease. However, since it is still being practiced under certain circumstances, we describe the technique and how best to perform it. On the other hand, high-flux hemodialysis (HFHD) is the most prevalent form of HD in the United States currently, and we suspect that this represents >90% of all treatments. When HEHD utilizes a high-flux membrane as described below, that is termed high-efficiency, high-flux hemodialysis (HEHFHD). The year 2001 was the last year that the United States Renal Data System (USRDS) Annual Data Report described HD in a manner where the efficiency and/or flux was reported (1), again emphasizing the overwhelming trend toward HFHD. Furthermore, as the dialysis population aged and was burdened by ever more comorbidities, treatment times (TTs) increased such that the concept of “efficiency” became somewhat less relevant.

TABLE 7.1 Glossary of Abbreviations

HD	hemodialysis
HE	high-efficiency
HF	high-flux
β_2-MG	β_2-microglobulin
DRA	dialysis-related amyloidosis
IDWG	interdialytic weight gain
IDH	intradialytic hypotension
KoA	mass transfer area coefficient
KUF	ultrafiltration coefficient
PR	pyrogenic reaction
Qb	blood-flow rate
Qd	dialysate flow rate
RR	relative risk
TMP	transmembrane pressure
TT	treatment time
UF	ultrafiltration
UFR	ultrafiltration rate
USRDS	United States Renal Data System

DEFINITIONS: HIGH-EFFICIENCY, HIGH-FLUX, AND PERMEABILITY

It is important to conceptualize and understand the basics of high-efficiency (HE) and high-flux (HF) dialyzer devices in order to compare the uses, differences, and technical needs of each. **TABLE 7.2** provides a comparison of the various characteristics of conventional, HE, and HF dialyzers. The definitions of HE and HF procedures were formed primarily from the historical development of HD and the technical needs of each treatment. The primary operating characteristics of HD are blood-flow rate (Qb), dialysate flow rate (Qd), duration and frequency of treatment, and dialyzer characteristics such as membrane surface area and composition, which affects solute dialysance and water permeability. By convention, “small” molecular weight solutes are <500 Da, “middle” molecular weight solutes are 500 to 5,000 Da, and “large” molecular weight solutes are >5,000 Da. Herein, we use urea as the surrogate molecule for “small” solutes and its clearance to define small molecular weight solute clearance. The term *efficiency* has been used with reference to the small solute or urea clearance. *Flux* refers to membrane hydraulic (water) permeability. Solute transfer across the membrane is calculated as the urea mass transfer area coefficient (KoA_{urea}), the theoretical maximum urea clearance at infinite Qb and Qd, and is an intrinsic characteristic of the membrane thickness, composition, and surface area. Obviously Qb and Qd are not infinite, but the greater they are, the greater the clearance. In typical HD, urea clearance is much more highly dependent on Qb than on Qd. However, possibly because of internal filtration/convection, dialyzers with higher flux membranes demonstrate a greater dependence on Qd than dialyzers with low-flux membranes (2). In any case, if 100% of a solute is extracted across the dialyzer, the clearance is equal to the Qb. If the dialysate is 100% saturated with the solute, the clearance is equal to the Qd. So clearance can never exceed either the Qb or the Qd. Thus, for practical purposes, the “efficiency” of a dialyzer is dependent on its surface area, membrane solute permeability, and the operational conditions. Once the KoA_{urea} for a given dialyzer is known, the urea clearance under any given Qb or Qd can be calculated or located on a nomogram (3) and used to compare dialyzers. HEHD is

achieved primarily by increasing surface area, Qb, and Qd. By most conventions, HE dialyzers have a KoA_{urea} >450 mL/min, which translates to *in vivo* urea clearance rates >200 mL/min at Qb 300 mL/min and Qd 500 mL/min. This can then be extrapolated to say that dialyzers can be compared and classified based on urea clearance at a fixed Qb and Qd (**TABLE 7.2**).

TABLE 7.2 Comparison of Conventional, High-Efficiency, and High-Flux Dialyzers

Characteristics	Conventional	High Efficiency	High Flux
KoA_{urea}	<450 mL/min	>450 mL/min	>450 mL/min
Urea clearance	<200 mL/min	>200 mL/min	>200 mL/min
KUF	<15 mL/h/mm Hg	Variable	>15 mL/h/mm Hg
β_2-MG clearance	<10 mL/min	Variable	>20 mL/min

KoA_{urea}, mass transfer area coefficient of urea; KUF, ultrafiltration coefficient; β_2-MG, β_2-microglobulin.

FIGURE 7.1 demonstrates the differences in urea clearances between higher efficiency dialyzers (higher KoA, upper curve) and lower efficiency dialyzers (lower KoA, lower curve) at varying Qb. In lower efficiency dialyzers, urea clearance tends to plateau at lower Qb. By contrast, urea clearance in higher efficiency dialyzers continues to rise with higher Qb and does not plateau until Qb exceeds 400 mL/min. Therefore, an access that can deliver such a Qb is important to take full advantage of HE dialyzers.

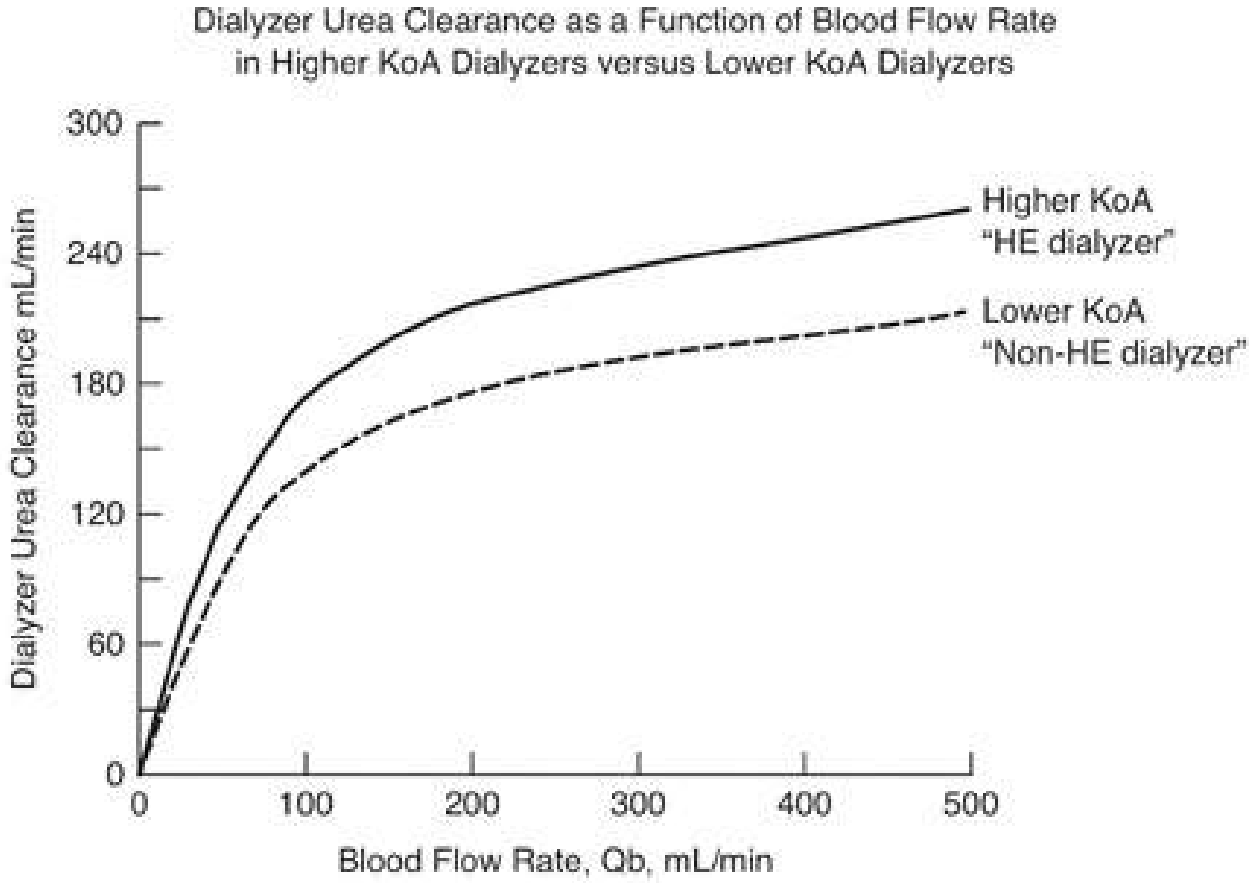

FIGURE 7.1 Dialyzer urea clearance as a function of blood-flow rate comparing a higher efficiency dialyzer with a greater urea mass transfer area coefficient (KoA) to a dialyzer with a lower KoA and lower efficiency.

"Flux" refers to the hydraulic (water) permeability of the dialyzer membrane and can be quantified by the ultrafiltration coefficient (KUF) and sometimes additionally by β_2-microglobulin (β_2-MG) clearance. β_2-MG is an 11.8-kDa molecule implicated in the development of dialysis-related amyloidosis

(DRA) and is used as a surrogate representation for large molecules. KUF is defined as the ultrafiltration rate (UFR) divided by the transmembrane pressure (TMP) and the units are milliliters per hour per millimeter of Hg of applied TMP (mL/h/mm Hg). **TABLE 7.3** lists technical specifications of selected dialyzers commonly in use by the two largest dialysis provider groups in the United States, as examples of how to use the concepts described above.

TABLE 7.3 Specifications of Commonly Utilized Dialyzers in the United States

Manufacturer/Model	KoA (mL/min)	KUF (mL/h/mm Hg)	Surface Area (m^2)	Material Type
Fresenius Optiflux F160NR	1,064	50	1.5	Polysulfone
Fresenius Optiflux F180NR	1,239	60	1.8	Polysulfone
Fresenius Optiflux F200NR	1,317	62	2.0	Polysulfone
Fresenius Optiflux F250NR	1,808	107	2.5	Advanced polysulfone
Gambro Polyflux Revaclear	1,190	50	1.4	Polyarylethersulfone, polyvinylpyrrolidone
Gambro Polyflux Revaclear Max	1,495	60	1.8	Polyarylethersulfone, polyvinylpyrrolidone

KoA, mass transfer area coefficient; KUF, ultrafiltration coefficient.
Gambro Revaclear Polyflux Catalog, http://www.gambro.com/PageFiles/7915/306150161_2_RevaclearSpecs-lo.pdf?epslanguage=en, Fresenius Optiflux Dialyzers Catalog. Accessed July 20, 2015.

As mentioned, another way to define flux relates to membrane permeability defined by the clearance of substances with a molecular weight greater than 10 kDa. This definition owes its origin to the Hemodialysis (HEMO) trial, where HF membranes were defined by KUF >14 mL/h/mm Hg with a mean β_2-MG clearance >20 mL/min (4). The first application of HEHD was characterized by high urea clearance, using cellulosic large surface area membranes, and high KUF in the range of 10 to 20 (5). The high KUF was largely the consequence of the membrane surface area. Cellulosic materials were utilized because of their great tensile strength, which was needed because of the high applied TMP. As membrane synthesis became less costly, the cellulosic membranes were replaced with HF synthetic materials, which had greater KUF, and required less TMP to achieve the same UFR. Hence, dialyzer membranes should ideally be compared under equal operating conditions on the basis of KOA_{urea}, KUF, β_2-MG clearance, and surface area, as well as other factors not discussed here such as extracorporeal blood commitment, biocompatibility, and reuse potential.

TECHNICAL ASPECTS

With the increased popularity of HEHFHD in the United States, standard requirements and features must be met in the current dialysis machines and facilities. Precise ultrafiltration control is a standard feature in most currently available dialysis machines, achieved with varying methods. This section is intended to help clinicians ask specific questions of manufacturers and dialysis providers to investigate which systems are best for a particular facility.

Ultrafiltration Control Systems

Precise ultrafiltration (UF) control is mandatory because of the high KUF of these dialyzers, which actually began as hemofiltration cartridges with KUF of >100 mL/h/mm Hg. Control of fluid balance was best achieved with sophisticated computerized UF controllers to match UF and reinfusion of fluid, thereby

maintaining hemodynamic stability. This historical perspective is important, since the outgrowth of HE and HF treatments came from the clinical comparison of HEHD and hemofiltration during a short TT therapy. The initial UF control systems applied during the era of hemofiltration were the forerunners of the systems applied today. The original microprocessor-based hemofiltration equipment, produced by Gambro Healthcare (Lakewood, Colorado), utilized a sophisticated strain gauge attached to a load cell that measured the rate of weight change from the 35-L containers used to collect ultrafiltrate and provide reinfusion fluid. This was, in fact, the first true volumetric UF control system. But this system was not directly applicable to an on-line, single-pass dialysis system in which approximately 100 to 160 L of fluid had to be accurately measured. Further improvements in the UF control systems for hemofiltration led to a continuous on-line system that used electromagnetic flow sensors to measure dialysate inflow and outflow. This system was microprocessor controlled and had no mechanical flow components. This is classified as the first microprocessor-based electronic UF control system and is still used in some HD machines. A secondary application of these microprocessor-based electronic UF control systems centered on the development of a bearingless rotor placed in a centrifugal flow path, which spun a ring where the optical characteristics were sensed through a fiber-optic network that then determined flow rates. Instead of being electromagnetically based, they are a combination of mechanical and electronic sensing. Typical examples of this type of equipment were produced by Baxter Healthcare Corporation (Deerfield, Illinois) in their 1550 dialysis machines.

The third major type of UF control system, developed in the early 1980s, utilized a mechanical-based system to control the very high KUF of hemofilters (100 to 200 mL/h/mm Hg) and hemodiafilters. These so-called volumetric control systems are based on the creation of a closed inflow and outflow loop by multiple-valve isolation systems, with a secondary UF pump that removed fluid from the relatively closed circuit at a fixed rate. The closed-circuit system matched dialysis inflow and outflow by bellows displacement pumps as the UF control pump generated the appropriate TMP needed to limit UF during the dialysis treatment. Examples of this type of equipment were the Cobe Century III (Cobe Renal Intensive Care Division of Gambro Healthcare, Lakewood, Colorado), the Fresenius series of HD machines (Fresenius Medical Care, Lexington, Massachusetts), the System 1000 by Althin Medical, Inc (Miami, Florida), the Toray UF control system (Houston, Texas), and the Italian Bellco machine (Bellco S.P.A., Saluggia, Vercelli, Italy). The UF control achieved by these mechanical bellows systems was compatible with both HE and HF dialyzers. Some of these systems may still be available on secondary markets. The current mainstream equipment that meets these requirements include the Fresenius 2008K/K^2 machine series.

Bicarbonate Dialysate

Bicarbonate dialysate has become the predominant buffer in the era of HEHFHD. When acetate was the buffering system in the 1980s, the use of more efficient dialyzers with KoA_{urea} >450 mL/min was associated with more frequent intradialytic symptoms and complications. Because of their more rapid diffusion of small solutes, HE dialyzers allowed acetate from the dialysate to accumulate in the patient faster than it could be metabolized (6). High levels of acetate can have a negative inotrope effect and can be vasodilatory peripherally, thus contributing to hypotension (7,8). In addition, acetate dialysate has a low partial pressure of carbon dioxide, which leads to net carbon dioxide removal. By removing the

respiratory drive of carbon dioxide, patients were found to hypoventilate, and hypoxemia was a common problem that may have contributed to acetate intolerance (9). Thus, use of acetate contributed to hypoxemia, decreased cardiac output, and hypotension (10). These complications helped to usher in bicarbonate as the dialysate buffer of choice while using the new HE dialyzers.

Bicarbonate dialysis is not without its own complications and technical difficulties. In contrast to acetate dialysate, which is prepared from a single concentrate that inhibits bacterial growth, bicarbonate dialysate must be prepared from two concentrates to prevent precipitation when stored as concentrate containing calcium and magnesium. One of these concentrates is pH neutral and supports bacterial growth, which can lead to contamination. Solutions are buffered to pH of 5.2 to 5.5 to delay bacterial growth during storage.

SOLUTE CLEARANCE

Defining Uremic Toxins

While many "uremic toxins" remain unidentified and unmeasured, the current measurable solutes have been divided based on molecular weight, as mentioned above. While some small molecular weight substances are easily removed and measurable, there are significant implications of the presence of middle molecules on both morbidity and mortality, including their impact on cardiovascular morbidity. To date, there has been suggestion of approximately 40 groups or categories of middle molecules that may have been identified; these are often thought to be proinflammatory (11).

Diffusive removal capacity of middle molecules is dependent on molecular weight, protein binding, properties of the membrane including porosity and surface area, and molecular kinetic behavior of the middle molecule including compartmental distribution (12). Furthermore, middle molecular removal is directly dependent on increased convective clearance strategies, the latter especially important for protein-bound solutes. HF dialyzers thus may confer additional benefits due to their porosity for middle and large molecular weight toxins, for example, β_2-MG. Several studies have revealed significantly decreased plasma β_2-MG levels in patients undergoing HF therapies (13–16). In a prospective, multicenter study of 380 patients randomized to four different dialysis techniques for 24 months, Locatelli et al. (16) demonstrated substantial reductions in pretreatment β_2-MG levels in patients receiving HD (23% reduction) or hemodiafiltration (16% reduction) using HF polysulfone membranes. In contrast, there were no changes in β_2-MG levels in the patients assigned to cuprophane and low-flux polysulfone HD (13). These results support the hypothesis that removal, as a consequence of membrane flux, may have a greater impact on β_2-MG levels than a lower rate of generation due to biocompatibility. Although a direct relationship between predialysis β_2-MG levels and DRA has not been established, Küchle et al. (17) noted a significantly lower incidence of carpal tunnel syndrome and/or osteoarticular lesions among 20 long-term dialysis patients randomized to HF polysulfone membranes versus low-flux cuprophane membranes after an 8-year follow-up. These findings could have important clinical implications, given the significant morbidity related to DRA in long-term dialysis patients.

Middle molecular removal is thus greatly time-dependent in part due to the rebound effect and mobilization from the multicompartmental distribution (4,12). Hence, clearance may be improved by increasing dialysis frequency or increasing session duration. This is clearly demonstrated by almost

doubling of β_2-MG clearance with increased dialysis time from 4 to 8 hours, despite a similar Kt/V_{urea} (12,18). While the primary analysis of the HEMO study demonstrated no significant effect of membrane flux on mortality, a subanalysis of the HEMO study demonstrates an inverse relationship between mortality and β_2-MG clearance (19). Predialysis β_2-MG concentrations fell over the course of the study in the HF arm patients far more than those in the low-flux arm. Similarly, in the Membrane Permeability Outcome (MPO) study, HF dialysis resulted in statistically significant lower β_2-MG accumulation over a period of 36 months when compared to low-flux group (20). The MPO study further demonstrated a significant survival benefit with the use of HF dialysis membranes in the subgroup of patients with serum albumin ≤4, a relative risk (RR) reduction of 37% after adjusting for confounders.

As dialysis technology evolved, the required “adequacy goals” were achieved in less time. Hence, dialysis session duration was decreased. Incentives for the facility to shorten session duration were the ability to accommodate more patients per day, spreading costs over more patients, and for patients, less time at the facility. Shorter TTs used increased dialysate quantities with increased Qd, but this cost balanced out with the decreased time. And while increased Qb up to 400 mL/min may improve small molecular clearance, it translates into decreased middle molecular clearance due to decreased session time. We fully agree with Vanholder et al. (21) that the small solute definition of “adequacy” of HD, the concept of Kt/V_{urea} is too simple to explain or define the complexities of uremia and modern dialysis techniques.

POTENTIAL BENEFITS

Subgroup analysis of the HEMO study concluded an insignificant trend favoring mortality benefit for large-pore, HFHD membranes in achieving the 1.3 Kt/V goal (4,19). However, these were not necessarily HEHD treatments. Similarly, the MPO study noted superiority for HF dialysis in certain subsets (20). In any case, the emphasis should remain that removal of middle and large molecular weight substances is predominantly time-dependent, and even with the currently available HF dialyzers, clearance of these substances will be greater with longer therapies.

LIMITATIONS

There remains a concern regarding the risk associated with large pore size and the transfer of impurities from the dialysate to the patient. Hence, a very regular control and check for dialysis impurities must be in place and is advocated strongly by European Best Practice Guidelines (22) and Association for the Advancement of Medical Instrumentation (23).

Contaminated dialysate can lead to both short- and long-term complications. Acute pyrogenic reactions (PR) from bacterial contamination or endotoxin exposure may occur in 1 of 10,000 dialysis sessions, and approximately 20% of all dialysis centers report more than one PR per year (24). Less obvious reactions to contaminated dialysate include cytokine release that can contribute to hypotension, sedation, and anorexia. Chronic complications are less well understood or documented. Chronic inflammation due to contaminated dialysate may contribute to the pathogenesis β_2-MG amyloidosis, catabolic loss of muscle proteins, erythropoietin-resistant anemia, and atherosclerotic cardiovascular

disease (25–28).

Historically, it has been thought that HE—and more so, HF—dialyzers are more permeable to endotoxin fragments and therefore lead to more PR. Many investigators have demonstrated that bacterial products can diffuse across dialysis membranes (29,30). It follows that the larger surface areas, permeability, and Qd used in HE–HF dialysis would lead to greater potential diffusion of bacterial products across the membrane. However, *in vitro* studies have demonstrated that cellulosic low-flux membranes are actually more permeable to endotoxin fragments than synthetic HF membranes, which have high pyrogen-adsorbing capacity (31). This perceived benefit may be countered *in vivo* by endotoxin transfer across HF membranes due to backfiltration. They concluded that in contrast to cellulosic membranes, some synthetic membranes do not permit transfer of lipopolysaccharide and attenuate cytokine induction on the blood side of the dialyzer by removal of activated complement factors. Bicarbonate dialysate and HF membranes have been associated with a higher risk of PR (32). Some studies have shown that the practice of reuse, in which water comes into direct contact with the blood compartment, may be of more importance than membrane type (29). Gordon et al. (33) showed no statistical difference in PR rates by treatment modality (conventional, HE, and HF). Despite this controversy, it is accepted that dialysis membranes are permeable to bacterial products, although not uniformly, and important short-term and long-term effects of contaminated dialysate are likely.

ULTRAFILTRATION

UF is performed during dialysis to remove volume accumulated during the interdialytic period which on the average patient on thrice-weekly dialysis ranges between 1 and 4 kg. Actually, the interdialytic weight gain (IDWG) is assumed to be water and treated as such, but this assumption can lead to problems in some circumstances. For this discussion, the IDWG will be assumed to be acquired fluid volume between the dialysis sessions. As discussed earlier, HEHFHD utilizes operating conditions, KoA_{urea}, and KUF and requires ultrafiltration controllers, such that fluid removal at dialysis is quite accurate. Recent observational studies have informed us as to the safety of how much and how rapid the fluid accumulated can be withdrawn at dialysis. Thus, the concept of fast dialysis, which is why HEHD was developed in the first place, starts to become obsolete.

Potential Benefits of High-Flux Hemodialysis

As mentioned earlier, HF can be defined by KUF or by β_2-MG clearance. HF membranes confer additional benefits due to their porosity for middle and large molecular weight toxins. For example, decreased plasma β_2-MG levels are noted in patients undergoing HFHD (16,17,34). Since HEHFHD has some similarities to hemodiafiltration with regard to solute removal of all sizes, a review of that literature is relevant here. In the Dialysis Outcome and Practice Patterns Study (DOPPS), a survival benefit was observed only in hemodiafiltration patients who were treated with high convective volumes (replacements of >15 L per treatment) (35). For optimal efficiency, the use of large convective volumes has been recommended. Other potential benefits of HF membranes include a reduction in erythropoietin resistance, delay in loss of residual renal function, improved lipid profiles, specifically increased high-density lipoprotein (HDL) cholesterol and lowered triglyceride levels, as well as removal of advanced

glycosylation end products, which have been implicated in the pathogenesis of atherosclerosis and DRA (36–45). Furthermore, the use of ultrafiltration with HF dialyzers improved convective clearance of urea (as most of these membranes are also HE) and thus enhanced the shortening of dialysis period, a key motivating force behind its use.

Concerns and Implications

UF which is necessary to maintain volume control can at the same time dangerously promote nonphysiologic fluid shifts and hemodynamic instability. During dialysis, fluid is removed directly from the vascular space. When dialytic removal outpaces redistribution (refilling) from other compartments, circulating volume is reduced and transient myocardial ischemia and intradialytic hypotension (IDH) can result (46). This effect is amplified by limitation in cardiac reserve and autonomic dysfunction, both of which are common among HD patients. Previous research has demonstrated that transient ischemia during dialysis can result in "myocardial stunning" (regional wall motion abnormalities) and associated compromises in cardiac contractility, systolic function, and survival. Ventricular dysfunction in dialysis patients can be particularly hazardous as it has been linked to greater hemodynamic instability during dialysis, which can result in a vicious cycle of further myocardial stunning and cardiac decline (46,47).

In current practice, HD TT is determined by indices of small molecule (i.e., urea) clearance; UFR is adjusted to allow for necessary removal of IDWG within this fixed short TT (47). Excessive IDWG has been shown to be an independent predictor of mortality in a number of observational studies (47,48). Lee et al. (49) showed that increased IDWG percentage is a significant independent predictor of major adverse cardiac and cerebrovascular event in HD patients. Patients with excessive IDWG tend to receive a high UFR within this fixed TT, potentially resulting in increased frequency of IDH. IDH in turn could result in altered sensorium, myocardial ischemia and infarction, blindness, and even stroke (48). Flythe et al. (47) studied three categories of UFR: <10 mL/h/kg, 10 to 13 mL/h/kg, and >13 mL/h/kg, and noted that higher UFR in HD patients are associated with a greater risk of all-cause and cardiovascular death.

The rate-limiting factor for short HD is generally related to patient tolerance of UF, specifically, the ability to correct IDWG while maintaining cardiovascular stability as discussed below. Many factors contributed to this fixed short HD TT, including patient preference for less time on dialysis, economic incentives, availability of HEHF therapies, and results of the National Cooperative Dialysis Study (50). The study utilized short (2.5 to 3.5 hours) and long (4.5 to 5.5 hours) treatment groups for both high blood urea nitrogen (BUN) patient groups and low BUN patient groups. The actual mean TTs achieved were 3.2 and 4.5 hours. Patients in the high BUN and shorter treatment group were hospitalized more frequently than other groups, but this was determined to not be statistically significant (p <0.06), and the final analysis suggested that TT was only marginally important. Although shorter TT did not demonstrate meaningful differences in serum biochemistries other than phosphorous levels, weight gains were typically higher, blood pressure control more difficult, and episodes of IDH more frequent. Although these results were not statistically significant, their potential clinical importance was not emphasized. The rather small sample size (n = 151) and the premature stopping of the National Cooperative Dialysis Study may have contributed to the failure to demonstrate a clinically significant difference between the long and short treatment arms.

There are two options to minimize UFR in current clinical practice: (a) limit fluid intake (i.e., IDWG) and/or (b) allow more time for fluid removal (i.e., extended dialysis time). Experience and

published data demonstrate that interventions aimed at reducing patient's IDWG are often ineffective (47).

There is concern that with short TTs, suboptimal volume removal due to intradialytic symptoms may contribute to the high incidence or persistence of hypertension and ultimately to cardiovascular mortality, which underlies approximately 50% of the deaths in the dialysis population (48). The prevalence of hypertension has been reported in 50% to 80% of chronic HD patients in the United States, and there have been reports of increased antihypertensive medication requirements and a higher prevalence of left ventricular hypertrophy in patients dialyzed for shorter times (51–54). Thus, caution must be exercised when selecting patients for short therapies. A number of investigators describe favorable experiences with short dialysis in patients without excessive IDWG (55,56). For instance, a prospective study by Dumler et al. (55) found no changes in pre- or postdialysis blood pressures in a group of patients dialyzed less than 3 hours compared with conventional TT of between 3 and 4 hours when IDWG <4 kg. Likewise, shorter TTs were not associated with an increase in intradialytic complications, and the frequency of nausea, vomiting, headaches, and back pain was decreased. However, centers incorporating unconventionally long TT observed that most patients were able to discontinue antihypertensive medications (57,58). Extended HD was also associated with near normalization of left ventricular mass and improvement in left ventricular systolic function (48,59). The experience from the centers performing slow nocturnal dialysis and Tassin, France, have repeatedly emphasized the importance of TT, reporting consistently excellent results, especially with respect to blood pressure control, reduced erythropoietin requirements, fluid management, reduced frequency of IDH, and improved quality of life (48,57). The Netherlands Cooperative Study on the Adequacy of Dialysis recently reported the association between excessive UF and mortality, independent of delivered Kt/V (60). Saran et al. (48) examined the relationship between TT and UFR with patient outcome in DOPPS in an international, prospective cohort study of HD patients and facilities. Europe and Japan had significantly longer average TT than the United States. Kt/V increased concomitantly with TT in all three regions with the largest absolute difference observed in Japan. TT >240 minutes was independently associated with significantly lower RR of mortality. Every 30 minutes longer on HD was associated with a 7% lower RR; the reduction with longer TT was greatest in Japan. UFR >10 mL/h/kg was associated with 30% higher odds of IDH and a higher risk of mortality. However, there was no significant trend in mortality with lower categories of UFR. It is uncertain whether, for a given value of Kt/V, short HEHFHD provides the same total therapy as standard or longer TT. Observational data has suggested that any level of Kt/V is associated with a lower RR of mortality when TT is lengthened (61). Furthermore, at higher levels of Kt/V, a longer TT was found to be even more beneficial than the same TT for a lower level of Kt/V. These findings imply a synergistic relationship between TT and Kt/V with respect to mortality risk (48).

The removal of middle and large molecular weight substances is predominantly time-dependent, and even with the currently available HF dialyzers, clearance of these substances will be greater with longer therapies. There are also reports of improved phosphorus control without the use of binders as well as better control of anemia with concomitant decreases in erythropoietin requirements when long TT are employed (58,59,62). Recent data from the Australia and New Zealand Dialysis and Transplant Registry indicate that TT >270 minutes may be associated with a lower RR of mortality and duration of <210 minutes may be associated with a higher mortality risk (61). Short HD is attractive because it offers the potential for reduced labor costs as well as patient and staff convenience. However, the same

requirements for adequacy must apply to these shortened treatments as with conventional HD: to ensure effective solute removal and volume control without compromising patient well-being. At present, most studies evaluating the adverse effects of shortened TT on morbidity and mortality are limited by confounding issues, such as delivery of inadequate small solute clearance, inconsistencies among membrane characteristics with regard to efficiency, flux, and biocompatibility, as well as lack of long-term follow-up. Data in support of extended TT sessions are accumulating and suggest that these modalities may offer significant advantages over conventional therapies. Thus, longer TT may be beneficial in several ways: improved tolerability of the treatment (primarily the result of slower UFR), better removal of larger sized uremic toxins, better control of blood pressure, and better volume management. These mechanisms may in turn reduce cardiovascular morbidity and mortality (48).

There are numerous issues facing nephrologists practicing in today's climate: economic pressures, personnel shortage, patient education, and cultural differences. Because there are no randomized trials evaluating TT and outcome (the TIME trial is underway), we continue to define dialysis adequacy by complicated mathematical equations that are inherently flawed, allowing us to drive time on dialysis toward zero as long as small solute dialyzer clearance continues to increase.

Nevertheless, using an individualized approach to dialysis prescription is generally well tolerated when individual patient characteristics regarding cardiovascular stability, blood pressure, and IDWG are considered. We reiterate our agreement with the argument against the defining of adequate dialysis by the use of Kt/V_{urea} as articulated by Vanholder et al. (21).

High IDWG, volume expansion, the economic barriers to long duration HD, and the inherent unphysiology of thrice-weekly HD all predispose patient to the necessity of higher UFR with increased frequency of IDH and increased risk of death (48). We and many others believe that UFR should factor more prominently into the determination of dialytic TT. Such an approach might involve session-length titration on a nearly session-to-session basis based on observed IDWG with some floor level determined by consideration of urea clearance (47). In particular, John Burkart, as chief medical officer of an intermediate-sized dialysis provider, has implemented a policy that the dialysis duration accomplishes the Kt/V_{urea} goal as well as limiting the UFR to no more than 13 mL/kg/h. If in that duration the IDWG is not removed, the session length is increased, or an extra dialysis session is performed. We strongly endorse this initiative and approach.

CONCLUSION

While we have described the performance of HEHD, we did so predominantly for historical reasons. In general, we do not recommend that approach to chronic maintenance HD. On the other hand, when the treatments are not shortened, HFHD has many advantages. Using small molecule clearance such as Kt/V_{urea} as the definition of dialysis adequacy is an egregious error in our opinion and we have described why. Setting dialysis time by the tolerance of ultrafiltration seems critically important and a limit of 13 mL/kg/h is prudent. We fully agree with Vanholder et al. (21) and strongly urge the dialysis community and regulatory bodies to appreciate the scientific evidence and change the way we define the adequacy of HD.

CHAPTER 8

Long and Daily Hemodialysis

Andreas Pierratos

Despite improvements in the technical aspects of dialysis treatments and some recent clinical improvements, the outcomes of patients with end-stage kidney disease (ESKD) are poor (1). Furthermore, the cost of dialysis continues to increase rapidly due to the increasing number of patients requiring treatment.

In an effort to alter these statistics and their financial impact, several approaches have been considered and studied. These apply to the following:

Dialysis dose: studied initially in the National Cooperative Dialysis Study (NCDS) (2) and then the Hemodialysis (HEMO) and Adequacy of Peritoneal Dialysis in Mexico (ADEMEX) study (3)

Dialysis technology: improved hemodialysis machines, bicarbonate dialysis, better quality membranes, ultrapure dialysate, and so on

Dialysis schedules: Frequent hemodialysis, long hemodialysis, as well as various combinations of the two. The main forms include short daily hemodialysis, long intermittent hemodialysis, and daily nocturnal hemodialysis.

Methods of blood depuration: peritoneal dialysis (PD), the convective techniques (hemofiltration and hemodiafiltration), and the use of sorbents either as complete replacement of dialysis or as adjunct to other methods

Location of the treatment: Locations include hospitals, freestanding units, or home.

Method of delivery: Full care, assisted care, and self-care. Assistance is provided by nurses and technicians, paid helpers, or relatives.

Focus: a shift to address the comorbidities rather than dialysis itself

Finances: Different methods of cost reimbursement such as bundling of ancillary treatment payments with the dialysis fee or use of a capitated system of reimbursement have been employed (4).

In this chapter, the alternative dialysis schedules, specifically long and/or frequent hemodialysis, will be addressed. In addition, aspects of the location of the treatment as well as cost will be also discussed.

HISTORICAL PERSPECTIVE

In the early days of hemodialysis, long (8-hour) dialysis was necessary as the dialysis technique was inefficient (5–7). Improving patient well-being with more than one or two dialysis sessions per week led to the adoption of the current standard of the thrice-weekly dialysis regimen. Improvement in the dialysis efficiency led to shorter hemodialysis sessions.

Perseverance with the original long (8-hour) thrice-weekly regimen in Tassin, France, and some other centers for more than 30 years, was associated with impressive patient outcomes and supported the notion that *long* dialysis was beneficial irrespective of the dialysis dose (8), an idea not clearly supported by the NCDS study (9). Long overnight hemodialysis (nocturnal hemodialysis) three times a week at home is credited to Shaldon (10). Long intermittent hemodialysis is financially attractive in comparison to daily hemodialysis, and therefore, recently, there has been an increased interest in its utilization at home or in the dialysis centers (11,12).

Home hemodialysis was necessary in the early dialysis days as it was less costly. More than 70% of dialyses in Seattle in the late 1960s was performed at home (5). Payment for dialysis with public funds, availability of hemodialysis close to the patients' home, inception of continuous ambulatory peritoneal dialysis (CAPD), and acceptance of dialysis for sicker patients unable to be trained led to the decline of home hemodialysis. Regional or national differences in the dialysis modality distribution are often striking and can be explained by financial, geographic, and cultural factors. For example, despite some decline, home hemodialysis has been more popular in Australia and New Zealand (13). The high incidence of CAPD technique failure and reports of improved outcomes with long and/or frequent hemodialysis rekindled the interest in home hemodialysis, although there is a recent resurgence of PD in the United States (14).

The use of *daily* hemodialysis was reported in the 1960s first by DePalma (15,16) followed by others. Despite better patient satisfaction, blood pressure (BP) control, and anemia improvement, the initial attempts failed due to financial constraints. The published positive outcomes from the use of short daily hemodialysis by a small number of centers in Italy led by Buoncristiani and others (17–19), the advent of quotidian nocturnal hemodialysis (20), as well as interest by industry inspired renewed focus on daily hemodialysis.

Although *nocturnal* hemodialysis thrice weekly at home was used by Shaldon (10), the combination of long and frequent hemodialysis was reported by Uldall in 1994 (21).

Moreover, interest in alternative dialysis schedules was rekindled by the failure of both HEMO (3) and ADEMEX (22) studies to show a decrease in patient mortality rates by increasing the dose in either hemodialysis or PD, respectively.

More detailed historical aspects of home and frequent dialysis regimens are described elsewhere (5). Although most of the studies on daily and long hemodialysis were cohort studies, randomized controlled trials (RCTs) have been recently published. These include the Alberta trial on nocturnal hemodialysis (23) and the Frequent Hemodialysis Network (FHN) trials sponsored by the National Institutes of Health (NIH) (24,25).

Dialysis Prescription/Technical Aspects

Short, *daily* hemodialysis is characterized by dialysis performed for 1.5 to 3.0 hours, 5 to 7 days per

week. There are calls for at least 3-hour short daily hemodialysis as it is characterized by better phosphate control (26). High blood and dialysate flows are used, aiming for the highest dialysis dose possible. Dialysate composition is similar to conventional hemodialysis. It is done either in the dialysis facility or at home.

Daily (*quotidian*) *nocturnal* hemodialysis is performed 5 to 7 days per week (typically 6) during night sleep at home for an average of 8 hours. It is done by the patient or by a helper. Similarly, *intermittent nocturnal* hemodialysis occurs thrice weekly at the facility or at home (usually every other night). Facility-based nocturnal hemodialysis is typically performed by the dialysis staff. Blood flow is low on long hemodialysis (as a rule 200 to 300 mL/min and as low as 100 mL/min in children), whereas a typical dialysate flow is 300 mL/min. Lower dialysate volume is used by the NxStage machine. In the case of the daily nocturnal hemodialysis, the dialysate contains lower bicarbonate [typical: 30 mEq (mmol)/L] and higher calcium concentration [typical: 3.0 to 3.5 mEq (1.5 to 1.75 mmol)/L] than conventional hemodialysis (**TABLE 8.1**). A less significant deviation from the usual concentrate composition of the conventional hemodialysis is followed in the intermittent form. In more than 50% of patients on quotidian and less than 20% on the intermittent form, the dialysate contains a sodium phosphate additive (e.g., Fleet Enema 30 to 135 mL/4.5 L acid or bicarbonate concentrate) which corresponds to a final phosphate concentration of 1 to 3 mg/dL (0.3 to 0.9 mmol/L) (11,27,28). A higher calcium and phosphate concentration than described in the preceding text has been used during the so-called "hungry bone syndrome."

TABLE 8.1 Typical Initial Dialysis Prescriptions for Alternative Dialysis Schedules

	Short Daily	Long Intermittent	Daily Nocturnal
Q_b	350–400	200–300	200–300
Q_d	700–800	300	300
Na	140	140	140[a]
K	1–2	2	2
Bicarbonate	40	35	30
Ca	2.5	3.0	3.5
Phosphate as sodium phosphate—Fleet Enema (mL/4-L jug)	0	0[b]	40[c]
Mg	0.5 mEq (0.25 mmol)/L	1 mEq (0.5 mmol)/L	1.5 mEq (0.75 mmol)/L

[a]Consider lower dialysate Na if a high dose of sodium phosphate (Na_3PO_4) is added (>80 mL Fleet Enema) into the dialysate and significant fluid gains or difficulty to control hypertension are encountered.
[b]Initially, discontinue phosphate binders if serum phosphate is <4.5 mg/dL (1.5 mmol/L) or if on low dose of phosphate binders.
[c]Do not add Fleet Enema initially if the prehemodialysis serum phosphate is high [>6 mg/dL (2 mmol/L)] despite the use of high dose of phosphate binders while on conventional hemodialysis. Stop phosphate binders in all patients.

Although all hemodialysis machines are acceptable for each of the stated regimens, several manufacturers have modified existing machines to be patient-friendly for use at home, and new machines aiming for the short daily or the long hemodialysis market have been produced. Some of the advantages include ease of use, portability, less reliance on water quality, and so on.

Anticoagulation during hemodialysis is similar irrespective of regimen. Danaparoid or argatroban have been used in cases of heparin-induced thrombocytopenia. Low molecular weight heparin has been employed for both as well as for longer dialysis. Tinzaparin has been used during nocturnal hemodialysis (29).

Water treatment at home is accomplished through the use of standard reverse osmosis systems with a carbon tank or the use of deionizer columns. The former provides for less expensive operation, and the latter is less noisy, more relevant to nightly hemodialysis. Occasionally, a water softener prior to water purification system has also been employed. The use of "ultrapure" dialysate is encouraged, although most of the published experience did not include the use of this enhancement.

Although dialyzer reuse has been practiced on home hemodialysis, it has been abandoned with the decrease in the cost of dialyzers (30). Remote monitoring of patients on nocturnal hemodialysis has been practiced by some centers (31–33), but it is considered optional. If BP monitoring without a cuff inflation and decrease in the cost of remote monitoring are achieved, remote monitoring could be attractive (33).

Dialysis Access

All types of accesses including permanent central venous catheters, arteriovenous (AV) fistulas, and grafts can be used with long or frequent hemodialysis either in-center or at home. Although fewer complications were reported in observational studies (34–36), the FHN trial reported increased incidence of vascular complications on daily hemodialysis (37). Lower access survival was also reported on long frequent home hemodialysis compared to long less frequent home dialysis (38). Dialysis catheter survival as well as infection rates were reported to be better on nocturnal hemodialysis when compared to conventional hemodialysis (39,40), but the infection rates were higher than when using AV accesses (41). Safety issues are very important for unattended nocturnal hemodialysis (42). The use of preperforated catheter caps during the dialysis procedure is highly recommended (InterLink, Tego) (**FIGURE 8.1**) (43). They prevent air emboli and bleeding from the "arterial limb" in the case of accidental disconnection.

FIGURE 8.1 The Interlink and Tego venous catheter caps.

The so-called "buttonhole" technique has been used for fistula but not graft cannulation (44). Prospective studies on the outcomes when used at home are missing (44–48). Using this technique, the dialysis needle (usually "blunt," noncutting) is inserted through the same cannulation track. A "buttonhole" is established using regular sharp needles for about 1 week. The use of the buttonhole technique has been associated with significantly higher rate of bacteremias. The putative advantages including less pain,

familiarity with the site, and predictability of cannulation success have not been proved in RCTs. If used, attention should be given to proper technique and antisepsis during the "buttonhole" cannulation. Careful removal of the scab prior to the cannulation and local application of a small amount of antibiotic cream (e.g., mupirocin) after the completion of dialysis on the "buttonhole" has been advocated (47). Caution regarding the use of the buttonhole technique has been expressed by several authors (43,49). Proper secure taping of the dialysis needle is important for nocturnal hemodialysis. A single-needle system is preferable for long hemodialysis as it requires fewer cannulations and is safer in the case of accidental needle disconnection. The lower blood flow provided by the single-needle system is not a limitation for long hemodialysis. A moisture sensor taped on top of the needle insertion site is useful to awaken the patient in the event of blood extravasation during the dialysis procedure (31). An inexpensive nondisposable "enuresis alarm" is used by most centers in the interim until a dedicated product is developed (**FIGURE 8.2**). Commercially available sensors specifically designed for dialysis are available (50). Several inexpensive moisture sensors placed strategically on the floor in the vicinity of the dialysis machine alert the patient in case of either blood or dialysate leak (31).

FIGURE 8.2 The "enuresis" moisture alarm.

THEORY/KINETICS

Small Molecule Removal

The use of Kt/V urea and urea reduction rate (URR) based on the NCDS study became popular as a measure of dialysis dose (51). These parameters are inadequate, however, in explaining the differences in outcomes between various modalities, between different schedules, or related to the presence of residual kidney function. The relatively positive clinical outcomes of patients on CAPD when compared to hemodialysis, despite the lower Kt/V offered by this method (weekly Kt/V 1.7 to 2.0 vs. 3.2, respectively), has been ascribed to the continuous nature of this treatment (52). Continuous (or frequent) dialysis can provide hemodynamic stability and therefore better cardiovascular tolerance and reduced fluctuation of physiologic parameters (53); better removal of larger molecules, which is time-dependent; and decreased exposure to the toxic peak levels of solutes which characterize intermittent dialysis. The most popular measure incorporating this effect of the dialysis frequency is the standard Kt/V (stdKt/V) proposed by Gotch (54,55). Similar weekly stdKt/V values offered by different regimens are expected to lead to similar clinical outcomes. Its calculation is based on the midweek predialysis serum blood urea

nitrogen (BUN) (or the continuous BUN level in the case of native kidney function or CAPD). An stdKt/V of 2.0 corresponds to the Kidney Disease Outcomes Quality Initiative (KDOQI) dose guideline levels.

The usefulness of the stdKt/V in predicting clinical outcomes needs to be established. The use of stdKt/V increases the perceived value of high dialysis frequency, but this dose measure is not affected significantly by the increased dialysis length, as long intermittent dialysis has a smaller effect on the predialysis BUN levels. Therefore, based on this concept, the outcomes of long intermittent dialysis are expected to be inferior to the outcomes of short daily hemodialysis, which has not been established and may not be accurate. A single-pool Kt/V (spKt/V) of only about 0.53 is required daily to maintain the same weekly stdKt/V delivered by thrice-weekly hemodialysis when adhering to the KDOQI guideline dose of a spKt/V of 1.2 per dialysis session. Maintenance of the same length of weekly dialysis after the conversion to the daily regimen provides an stdKt/V of 2.5 to 3 (56). The spKt/V offered by daily nocturnal hemodialysis is much higher at about 1.8 to 2.5 per treatment, whereas the stdKt/V is 4 to 6 for the six times per week regimen (57). This concept of stdKt/V is utilized by the proponents of the NxStage machine. The prescription includes usually lower dialysate volume (about 25 L) with weekly stdKt/V similar to PD to achieve financial feasibility of daily hemodialysis.

Middle Molecule Removal

The evidence that higher larger molecule weight solute removal correlates with better clinical outcomes is supported by some studies (58–60). Patient outcomes correlated well with the length of dialysis, surrogate of middle molecule removal, in two studies from the Australian/New Zealand (61) and Dialysis Outcomes and Practice Pattern Study (DOPPS) registries (62).

As predicted, middle molecule removal is increased mainly by longer dialysis and less significantly by short daily hemodialysis. This was shown by mathematical modeling (63) as well as in clinical studies. Weekly β_2-microglobulin removal increased fourfold from 127 to 585 mg after the conversion from conventional to quotidian nocturnal hemodialysis. Serum predialysis β_2-microglobulin levels decreased from 27.2 to 13.7 mg/dL in 9 months (64). Advanced glycation end-product (AGE) levels decreased on daily hemodialysis (65) as did the levels of protein-bound solutes such as indole-3-acetic and acid indoxyl sulfate (66).

Phosphate Removal

Hyperphosphatemia has been considered a significant risk factor for both kidney osteodystrophy as well as cardiovascular disease and has been correlated to patient mortality (67). Despite the adequate phosphate clearance during dialysis, phosphate removal is limited by the slow intercompartmental movement of phosphate, resulting in low serum phosphate both during and in rebound posthemodialysis (68). The most significant parameter affecting phosphate removal is the length of dialysis. The effect of the dialysis regimens on phosphate control is therefore predictable. Short daily hemodialysis increases phosphate removal because phosphate removal is higher during the early part of dialysis when the blood to dialysate gradient is highest. This has been confirmed by measuring phosphate in spent dialysate (26,69). However, a 2-hour short daily hemodialysis has only a modest effect on serum phosphate as phosphate intake often increases with improving appetite. Significant improvement in phosphate control was found in studies when the dialysis time was extended to 3 hours (26,70). Daily nocturnal hemodialysis is effective in phosphate removal not only leading to elimination of the need for phosphate

binders and unrestricted diet but even necessitating the addition of phosphate into the dialysate in order to avoid hypophosphatemia in 75% of the patients (**TABLE 8.1**) (31,71). The effect of intermittent nocturnal hemodialysis on phosphate removal is also significant, but some patients still needing binders while for others a phosphate additive into the dialysate is necessary (11). In this modality, the predialysis phosphate can be high while the posthemodialysis value can be in the hypophosphatemic range. The effectiveness of long intermittent hemodialysis in phosphate removal is higher than that of short daily hemodialysis (**TABLE 8.2**). The improvement in phosphate control was confirmed in the FHN in both daily and nocturnal trials (70) as well as the Alberta trial (72).

TABLE 8.2 Comparison of the Alternative Schedule Hemodialysis Regimens with Conventional Hemodialysis Based on Preliminary or Confirmed Evidence

	Conventional Hemodialysis	Short Daily (Same Total Weekly Duration)	Intermittent Long (or Nocturnal)	Daily Nocturnal
Small molecule clearance using conventional kinetics (eKt/V)	+	+	++	++++

Patient Selection/Training and Utilization of the Alternative Dialysis Schedules

Patient selection and method utilization are affected by several factors. They include the local availability of the modality, finances, medical indications/contraindications, dialysis team biases, and patient/family choice. In turn, availability of the method depends on local expertise and financial factors.

The type of patients who is treated using the alternative dialysis schedules tend to follow a bimodal distribution. This includes patients who experience "technique failure" in their current modality and for whom an alternative dialysis method is used as a "rescue" treatment (73,74). Alternatively, other patients opt for these dialysis modalities motivated by a desire to improve their quality of life (QOL). The former group of patients tends to be switched either to short daily hemodialysis or intermittent nocturnal hemodialysis in the dialysis facility or daily nocturnal hemodialysis at home. Usual reasons for this

“rescue” treatment include significant hemodynamic instability, cardiovascular disease, refractory hypertension, intra- and interdialytic symptoms, ascites, malnutrition, “failure to thrive,” or large body size. The second group tends to include younger patients who are more likely to dialyze at home. In the absence of comorbidities, it is often difficult to convince prevalent dialysis patients to convert to the alternative dialysis schedules especially in the form of home hemodialysis. Incident compared to prevalent dialysis patients are the more likely to elect to do home hemodialysis irrespective of the regimen. Interestingly, only 56% of the patients on conventional hemodialysis questioned would agree to come to the dialysis facility daily even if the benefits of the method were established (75). Conversely, it has been rare that patients who started on daily hemodialysis revert back to thrice-weekly hemodialysis. The age of patients opting for home hemodialysis is on average 10 years older than in center hemodialysis.

Contraindications for home hemodialysis include patient inability or lack of motivation to be trained in the absence of a suitable helper. Other contraindications include inadequate housing or difficulty with oral communication (including difficulty communicating in the prevalent language) necessary in case of an emergency in the absence of a helper at home. The presence of significant hemodynamic instability is an indication for daily nocturnal hemodialysis. Allergy to heparin is a relative contraindication to home nocturnal hemodialysis. Of course, alternative anticoagulants such as danaparoid or argatroban can be used.

Training for home hemodialysis typically lasts for 4 to 6 weeks and is usually done while on thrice-weekly hemodialysis. Self-care dialysis can be used as an interim phase as it allows for a longer training period. Beyond the basic aspects, the training usually includes blood sampling and spinning for laboratory tests, blood cultures, as well as infusion of intravenous antibiotics and iron preparations. In view of the hemodynamic stability offered by these regimens, the presence of a home helper has not been considered obligatory at least for the long form of dialysis, although it has been required in certain jurisdictions. Monthly laboratory tests and clinic visits every 2 to 3 months are the usual practice.

OUTCOMES

Health Economics and Quality of Life

Health Economics

The cost of dialysis can be viewed from the multiple stakeholders’ perspectives. Stakeholders include the society at large, payers, dialysis facilities, members of the dialysis team affecting the patient’s decision (including health providers), patients themselves, and patients’ families. The cost/benefit ratio to the several stakeholders affects the utilization of the method. Dialysis costs are very high, challenging society’s willingness to pay. (**TABLE 8.3**)

TABLE 8.3 Relative Cost of Hemodialysis (HD) Modalities from Different Stakeholder Perspectives[a]

	Intermittent Thrice-Weekly HD	Long Intermittent HD In-center	Short Daily HD In-center (Half-Time, Double Frequency)	Short Daily HD at Home	Daily Nocturnal HD at Home
Real estate (dialysis unit)	+++	+ (uses existing facilities)	+++	−	−
Capital (excluding real estate)	++	± (uses existing machines)	++	++++	++++
Consumables	++	++	++++	++++	++++
Labor	+++	++(++)[b]	++++	−	−
Transportation cost	++	++	++++	±	±
Payor's perspective in a developed country (including hospitalization/medication cost but not total life cost)	+++++	++(+)	+++	++	++
Payor's perspective in a developing country	++++	++[c]	+++(+)[c]	+++(+)	+++(+)
Provider's perspective (no bundling) (excluding real estate cost)	+++	+++(+)	++++	+++(+)	+++(+)
Provider's perspective (with bundling) (excluding real estate cost)	+++	++(+)	+++(+)	+++	+++
Provider's perspective (capitated) (excluding real estate cost)	++++	++(+)	+++	++	++
Societal perspective	++++(+)	+++	+++	+(+)	+(+)

−, none; ±, negligible; +, very low; ++, low; +++, medium; ++++, high; +(+), variable between + and ++.
[a]Author's assumptions when no data.
[b]Depends on the nurse/technician-to-patient ratio. It needs to decrease by 50% to break even as the length of dialysis is double.
[c]Lower labor cost but usually higher consumable cost than in developed countries.

Some of the important fiscal elements of the alternative dialysis schemes, which contribute to the financial picture, are as follows:

a. Home dialysis is associated with increased capital costs (one machine per patient) but decreased labor costs.
b. Daily dialysis incurs high consumable costs (daily regimen).
c. In-center short hemodialysis may decrease the patient capacity of the dialysis unit due to frequent machine preparation with possible time lost, which consequently affects revenue (76).
d. Long dialysis potentially increases quality with negligible increase in consumable cost ("better bang for the buck").
e. Savings from the putative improved patient outcomes can be derived from both decreased hospitalization rate and length, as well as lower medication utilization.
f. Higher cost to the payer is incurred from possible increased patient survival.
g. Societal, patient, and patient's family benefit can be derived from the improvement of the vocational rehabilitation of the patient with lower utilization of societal services.
h. Possible decreased use of injectables on the alternative dialysis schedule regimens can harm (no bundling) or benefit the dialysis provider's finances (with bundling).
i. Increased cost of dialysis burdens the dialysis provider, whereas decreased hospitalization rates benefit the payer. In a capitated system, it benefits the provider.

j. Increased cost of home utilities (water and electricity) from home hemodialysis is usually incurred by the patient.
k. Transportation cost reduction, by using home hemodialysis, benefit the patient or the publically supported transit system.

The differential cost and benefit allocation among the stakeholders as it is dictated by the structure of the system is *critically* important for the adoption of these regimens. At the international level, the *consumable/labor cost ratio* in different countries also has a major impact on the potential adoption of these methods irrespective of the clinical benefits. In a country with high consumable to labor cost ratio daily hemodialysis is not financially attractive.

Several published studies have addressed the costs of quotidian home hemodialysis (77–79). These studies are either retrospective (80,81) or prospective (78,82–84), and although they are controlled, they are not randomized with the exception of the Alberta study (78). All these studies showed that although the cost of capital and consumables increases on daily (short and nocturnal), the decrease in labor cost offsets the increased expense as long as the treatment is delivered at home. In-center daily hemodialysis is clearly more expensive. Although in a retrospective analysis the decrease in hospitalization offsets the increased cost of the in-center short daily hemodialysis (80), this may apply only to patients with increased morbidity who require frequent hospital admissions (73).

It is reasonable to speculate that home intermittent nocturnal hemodialysis is the least expensive of the alternative schedule modalities. There are no studies published on the cost of in-center intermittent hemodialysis. In this modality, although the cost of consumables is probably similar to conventional hemodialysis, the labor cost has not been quantitated in a published study. Higher labor cost related to the longer dialysis could be offset by the lower staff to patient ratio related to the hemodynamic stability of the patients.

Several studies suggested that daily hemodialysis is associated with fewer hospital admissions and reduced costs for hospitalization, as well as lower cost of medications including erythropoiesis-stimulating agent (ESA), cardiovascular medications, and phosphate binders (on nocturnal hemodialysis) (77,83,85). In all of the studies, the total cost of health care for in-center conventional hemodialysis was higher than for quotidian hemodialysis, with cost savings estimated to be between $5,000 and $10,000 per patient-year (80,82–85). Importantly, home programs were less expensive even when patient-specific savings (such as reductions in hospitalization) were excluded. These results need to be confirmed in more properly designed studies.

Quality of Life

Several approaches to the measurement of the QOL on the alternative dialysis schedules have been adopted. They include dialysis-independent measures, dialysis-dependent measures, and utility scores. Although most studies were not randomized, two RCTs have been published.

Improvements in QOL have been reported on several elements of Kidney Disease Quality of Life (KDQOL) (73,80,86–89). Patient testimonials has been very positive (90). Minutes to recovery after a hemodialysis session were shorter after daily hemodialysis (91).

Utility scores calculating quality-adjusted life years (QALYs) were published in both short daily and nocturnal hemodialysis (89,92). The utility instruments used included the willingness to pay, time trade-

off, standard gamble technique (92), and Health Utility Index tool (83). Daily nocturnal hemodialysis was an economically "dominant" modality as it improved QOL while it decreased cost (92,93). There were no negative effects on QOL measures after the conversion from conventional to in-center intermittent nocturnal hemodialysis (94). The daily hemodialysis arm of the FHN trial demonstrated a significant improvement of the composite end point of death and physical component of the KDQOL (24). The nocturnal arm of the study failed to show improvement in the similar index (25). The Alberta study did not find improvement in the QOL in the patients randomized to nocturnal hemodialysis using the EuroQol five dimensions questionnaire (EQ-5D) index scores ($p = 0.06$) but showed improvement using the visual analog of the same index as well as several kidney disease-specific subscores (95).

Cognitive Function

There is some evidence, in one observational study, of improvement in the cognitive function of patients after their conversion to quotidian nocturnal hemodialysis (96). Improvement in cognitive function, as well as electroencephalogram (EEG) tracing, was also seen on short daily hemodialysis (97). Self-reported general mental health improved on daily hemodialysis in the FHN trial, but the depressive symptoms did not change significantly (98). The FHN trial did not show any improvement in cognition on frequent dialysis (99).

Cardiovascular Effects

Blood pressure, left ventricular geometry, and left ventricular function. Improved BP control has been reported consistently in all forms of alternative dialysis schedules (15,100). This includes short daily hemodialysis (19,73,86,101,102), long intermittent hemodialysis (103,104), and daily nocturnal hemodialysis (105,106). The antihypertensive medication dose was decreased, and medications were often discontinued. This is usually achieved by decreasing the postdialysis weight (dry weight), which is well tolerated on the alternative dialysis regimens. The beneficial effects on BP were confirmed in the Alberta (72) and FHN (24,107) RCTs. Although salt restriction has been advocated for intermittent nocturnal hemodialysis (108), no such restrictions are usually imposed on daily nocturnal hemodialysis patients (27).

Regression of cardiac hypertrophy have been reported on both short daily and quotidian nocturnal hemodialysis (102,105). These effects have been correlated with a decrease in extracellular fluid volume on short daily hemodialysis (102), but this has not been the case on quotidian nocturnal hemodialysis (106) where extracellular volume, as measured by bioelectrical impedance, remained unchanged (105). Regression of left ventricular mass (LVM) was also demonstrated in the Alberta RCT on daily nocturnal hemodialysis. The FHN RCT also confirmed the regression in LVM in the daily arm but showed only a similar trend in the nocturnal arm, likely related to the lower power of this arm of the trial. A more pronounced effect of frequent hemodialysis on LVM was evident among patients with left ventricular hypertrophy (LVH) at baseline. Changes in LVM were associated with changes in BP (109). In the case of intermittent long hemodialysis, although lack of regression of LVH was reported in older studies (110), such a regression was noted in more recent studies (111–113). LV function improved in six patients with LV ejection fraction <40% after conversion to quotidian nocturnal hemodialysis, with the ejection fraction increasing from 28% to 41% (114).

The exercise capacity as measured by the oxygen consumption ($\dot{V}O_2$ max) was found to improve upon

conversion from conventional to nocturnal hemodialysis (115).

Endothelial function, autonomic nervous system. The mechanism of the improvement in BP and regression of LVH has been studied further. There is evidence that quotidian nocturnal hemodialysis is associated with vasodilatation, decrease in sympathetic tone, and improvement in endothelial function.

Using echocardiographic techniques, it was found that the calculated peripheral vascular resistance decreased 1 month after conversion to quotidian nocturnal hemodialysis, as did the serum norepinephrine levels (116). Both the endothelium-dependent (postischemia) as well as independent (response to nitroglycerin) vasodilatation improved (116). The number of the endothelial progenitor cell (EPC) number in the blood increased and function improved (117). Low number and function of the EPC have been associated with increased cardiovascular risk in the non-ESKD populations (118). These abnormalities are highly prevalent in the ESKD population (119). Baroreceptor function as expressed by the heart rate response to changes in BP improved as did arterial compliance (120). Lastly, there was an increase in heart rate variability during sleep, consistent with a decrease in the sympathetic/parasympathetic tone ratio (121). The FHN study also detected beneficial effects of daily hemodialysis in the form of increased vagal modulation and increased beat-to-beat variation (122). Decreased heart rate variability is common in the ESKD population and is associated with poorer cardiovascular outcomes in the general as well as the ESKD population (123,124).

Vascular calcifications. Early evidence suggest that coronary artery calcification score, as measured by helical computed tomographic (CT) scan, did not progress significantly 1 year after conversion from conventional to nocturnal hemodialysis (125). Decrease in vascular calcification was reported on intermittent nocturnal hemodialysis (126). Longer follow-up and controlled studies are needed for confirmation.

Anemia Control/Erythropoiesis-Stimulating Agent Dose

Increase in hemoglobin and decrease in the ESA dose have been described in some of the observational studies on the alternative dialysis schedules (73,86,127). Despite an increase in hemoglobin in the daily hemodialysis group in the FHN daily and nocturnal trials, more frequent hemodialysis did not have a significant or clinically important effect on anemia management (128).

Nutrition

After the conversion to short daily hemodialysis, most patients report increase in appetite and well-being. Patients on nocturnal hemodialysis are on an unrestricted diet, although diet is liberal on both short daily and intermittent nocturnal hemodialysis. Several observational studies have reported increases in serum albumin, prealbumin, cholesterol, and body weight (104,129,130). Serum amino acid pattern improved on daily nocturnal hemodialysis (131). Serum albumin posthemodialysis is usually lower than the predialysis value in the daily nocturnal regimen, likely as a result of increased vascular refilling in the recumbent position (132). The FHN trial, using bioimpedance measures, found that frequent in-center hemodialysis did not increase serum albumin or body cellular mass, whereas frequent nocturnal hemodialysis yielded no net effect on parameters of nutritional status or body composition (133). In the Alberta study, there was a nonstatistically significant increase in serum albumin and dietetic intake of some nutrients (134).

Mineral Metabolism

Calcium balance is of significant importance. Calcium balance is positive on conventional hemodialysis if the patients are on calcium-containing phosphate binders (135). This may contribute to vascular and extraosseous calcifications. In the absence of treatment with calcium-based phosphate binders, calcium balance depends on the calcium absorption from the gastrointestinal (GI) tract and the dialysis-related calcium losses. Negative calcium balance can lead to elevated parathyroid hormone (PTH) and alkaline phosphatase levels as well as decreasing bone density (136). The need for high dialysate calcium levels or oral calcium supplements depends on the length of dialysis (longer dialysis requires lower gradient for the same total flux), dietary calcium, and treatment with vitamin D analogs. Quotidian nocturnal hemodialysis requires higher dialysate calcium compared to the other regimens to maintain calcium balance. A dialysate calcium of at least 3 mEq/L (1.5 mmol) is necessary in the case of nocturnal hemodialysis (137), which may have to be increased to as high as 4.5 mEq (2.25 mmol)/L in cases of bone repair, following surgical or medical parathyroidectomy (as when on calcimimetics), or pregnancy (138). High-dialysate calcium can be either fixed [usually 3.5 mEq (1.75 mmol)/L] or variable following the needs of the patient, as dictated by serum levels of calcium pre- and posthemodialysis, and PTH. This can be achieved by adding calcium chloride powder into the “acid” or bicarbonate concentrate [7 mL of powder increases dialysate calcium concentration by 0.5 mEq (0.125 mmol)/L]. Calcium and phosphate precipitation does not take place in the presence of low pH in the “acid” concentrate. It should be expected that in order for the calcium balance to be maintained, the posthemodialysis calcium could even be in the hypercalcemic range. This should be avoided, if possible, in the presence of vascular calcifications.

PTH has been reported to decrease in both short and nocturnal hemodialysis (26,126,136). This is mainly a function of dialysate calcium. PTH can be changed by adjusting dialysate calcium. The PTH target on short daily or nocturnal hemodialysis has not been established. Until this happens, KDOQI guidelines regarding the target PTH should be followed. Increased levels of serum alkaline phosphatase, in the presence of high PTH levels, warrants an increase in dialysate calcium in the absence of hypercalcemia.

As described in the preceding text, phosphate removal increases and hyperphosphatemia improves on daily and long dialysis schedules, although the improvement on short daily hemodialysis is seen when the length of dialysis is increased to 3 hours (26). This was confirmed during the Alberta (139) and FHN trials (70). The need for phosphate binders decreases with the weekly dialysis duration. About 20% of patients on every other night hemodialysis, and 75% of the patients on quotidian nocturnal hemodialysis need phosphate addition into the dialysate usually in the form of sodium phosphate (see preceding text). The dose of both calcium and phosphate additive is adjusted based on serum values of calcium and phosphate.

The improvement in phosphate control and the improved ability to achieve PTH targets leads to improvement or normalization of the Ca × P product (in all patients in the case of daily nocturnal hemodialysis) (126,140). This led to resolution of extraosseous calcification in one patient (141).

Sleep

Sleep disturbances are highly prevalent in the population with ESKD (142). They present in a multitude of forms including sleep apnea, insomnia, restless leg syndrome, periodic limb movements, and daytime

sleepiness. Sleep apnea mainly in the obstructive form affects patients at all stages of kidney disease including chronic kidney disease (CKD), dialysis, and transplantation (143–146). Conventional hemodialysis and PD do not offer significant benefit.

Nocturnal hemodialysis was found to improve obstructive sleep apnea (OSA) (147) associated with improvement in nocturnal oxygen saturation. Daytime sleepiness and periodic limb movement were not affected (148). The mechanism for the improvement is unclear, but it may be related to enhanced chemoresponsiveness to CO_2 on nocturnal hemodialysis (149). Other possibilities include improvement (decrease) of the pharyngeal collapsibility or decrease in the pharyngeal edema (150,151). Nocturnal rostral fluid shift during the night is associated with the severity of OSA in ESKD (152). This can be ameliorated by nightly dialysis (both PD and hemodialysis) (147,153).

Patient Hospitalization/Survival

The impressive patient survival rates on intermittent long hemodialysis reported by the Tassin group (85% over 5 years) may have been partially related to the patient selection criteria (8,154). Two studies based on the national databases of Australia and New Zealand, and data from the DOPPS, found an association between length of dialysis and patient survival over and above the effect of dialysis dose (61,62). Consistent with these studies, decreased hospitalization and a survival advantage on in-center intermittent nocturnal hemodialysis as compared to conventional hemodialysis has also been reported (155). Although the overall hospitalization rate was not different, cardiovascular disease-related admissions were fewer in the short daily group using the NxStage machine versus thrice-weekly dialysis controls, whereas infection-related admissions were higher. Patient survival rates were slightly better as well (156,157). Patient survival rate using mostly long intermittent dialysis at home (usually every other night) was reported (38). The survival rate of patients on in-center daily hemodialysis was lower than the thrice-weekly dialysis population likely related to the high comorbidity rate in this population, which has likely led to the adoption of this expensive regimen (74). Conversely, the survival of patients on home intensive hemodialysis was higher than the in-center thrice-weekly dialysis population (158). Other observational studies also reported similar results favoring frequent dialysis (19,159). The patient survival rates on daily nocturnal hemodialysis were comparable to the U.S. cadaveric transplantation survival rates (84.5% vs. 86.2% over 5 years) (160), but treatment failure/death was higher in the daily nocturnal hemodialysis group when compared to the Canadian transplantation population (161). In a recent study, 1,116 daily hemodialysis patients from the United States Renal Data System (USRDS) database were matched by propensity scores to 2,784 contemporaneous patients on PD and 3,173 patients on conventional hemodialysis. The composite hospitalization rate was lower on daily hemodialysis than PD [Hazard Ratio (HR) 0.73] or conventional hemodialysis (HR 0.68) (162). The HR for switching to in-center hemodialysis for PD versus Daily Hemo Dialysis (DHD) was 3.4 (<0.001). In a recently published study, the survival of patients on nocturnal hemodialysis was lower than the home hemodialysis control in the nocturnal arm of the FHN trial (163). The deaths took place mainly during the year after the completion of the study. The results were unexpected and contradict the data from the observational studies. It should be noted that the survival rate of the control group was surprisingly low, the sample size was small, and there was a high rate of hemodialysis prescription change after the completion of the study. A similar analysis of patients on the daily arm of the FHN trial followed over a median of 3.6 years revealed that the relative mortality hazard for frequent versus conventional hemodialysis was 0.54 (95%

confidence interval, 0.31 to 0.93), suggesting that daily hemodialysis may benefit patients with ESKD (164).

In summary, there is evidence suggestive of improved hospitalization and patient survival rates on frequent and/or long hemodialysis, but they are based on observational studies. There was an unexpected higher mortality in the nocturnal hemodialysis group than the controls in the FHN trial mainly during the year after the completion of the trial, whereas the mortality of patients on daily hemodialysis was lower than the controls.

Daily Hemo(dia)filtration

Convective techniques have been used for several decades. Their utilization is higher in Europe with little adoption in North America (165,166). The main advantage of convection is the enhanced large molecular solute removal. Clinical outcomes include improved intra- and interdialytic tolerance, improved QOL, better hypertension control, and evidence for improved patient survival (165,167,168).

Despite the enhanced middle molecule removal exemplified by β_2-microglobulin, the thrice-weekly hemodiafiltration does not have a significant effect on predialysis levels of β_2-microglobulin. Daily hemofiltration and hemodiafiltration have been used; the former in the home setting (169) and the latter in the in-center setting (170). The outcomes were similar. The results on short daily hemodialysis had the added advantage of the improved middle molecule removal offered by the convective techniques. They included improved BP and hyperphosphatemia control as well as improvement in several elements of QOL measures. There was a regression of cardiac hypertrophy. Predialysis β_2-microglobulin levels decreased.

Pediatric Daily Hemodialysis

Quotidian nocturnal hemodialysis as well as daily hemodiafiltration have also been used in children. There have been reports of improved well-being, nutrition, and school attendance as well as growth (171–174).

Obstacles for the Alternative Schedules/Modality Choice

Despite the favorable literature on the alternative dialysis regimens, their adoption has been slow. The main reasons for the slow change have roots in several areas:

Reimbursement structure. Although there is evidence that the cost of daily hemodialysis at home, when seen from the payer’s perspective, can be lower than the in-center hemodialysis, the savings in most jurisdictions do not benefit the dialysis providers which incur the added expense of the daily treatments.

Lack of training and experience/inertia. Most of the physicians, nurses, and dialysis centers have limited or no expertise with daily or home hemodialysis. This, in the absence of other incentives, fosters inertia.

Limited adaptation of hemodialysis machines for home dialysis. Despite some remarkable progress toward more patient-friendly hemodialysis machines for use at home, the difficulty in training patients for home hemodialysis is a significant obstacle in the adoption of the alternative regimens. Most experts do not expect more than 20% to 25% of the patients to be able to perform home hemodialysis using current

technology.

Lack of dialysis industry incentives. Under the current reimbursement structure, there is limited incentive for the dialysis industry to pursue the alternative dialysis modalities. This may change as new dialysis machines are produced, the cost of daily hemodialysis decreases to meet the current reimbursement rates, or if there is an adjustment of either the dialysis reimbursement rates or structure. The contribution of the industry to the adoption of the alternative dialysis techniques and wider adoption of home hemodialysis is pivotal. This may be changing. Recently, several new machines have been produced, and others will be available in the next few years.

If daily hemodialysis is not available due to insufficient funding, overnight hemodialysis every other night or three times a week at home or in the dialysis facility should be considered. Assuming there is accessibility to daily hemodialysis and until the methods (short vs. nocturnal) are more formally compared, the choice of modality should be based on patient choice, medical indications, and local expertise. Daily nocturnal hemodialysis is the closest to the normal kidney function, offers better hemodynamic stability, excellent phosphate control, and improves sleep apnea. These advantages are to be weighed against the potential for deficiency syndromes (no evidence yet), long exposure to dialysis membranes, and safety concerns at night. Daily convective therapies are also attractive, but more experience is needed before they are widely adopted especially in the home setting.

Randomized Controlled Trials

Two RCTs on daily hemodialysis have been published. Most of the outcomes have already been incorporated in this chapter but will be summarized below.

The Alberta trial (2007): Fifty-two patients from two centers in Alberta, Canada, were randomized to receive home nocturnal hemodialysis six or three times weekly for 6 months. Primary outcomes were change in LVM and QOL.

Results: Nocturnal hemodialysis significantly decreased LVM, improved selected kidney disease-specific domains, but not the overall QOL. It improved BP control and hyperphosphatemia but not anemia control.

The FHN trial (sponsored by NIH) (2011): The trial included two arms: the daily in-center trial—245 patients from 11 regional centers in the United States and Canada randomized to 12 months of six times per week or three times per week hemodialysis and the nocturnal trial—87 (out of 250 initially planned) patients from eight regional centers randomized to 12 months of six times per week home nocturnal or three times per week home conventional hemodialysis. The primary outcomes of both trials were death/LVM composite score and death/PHC (physical health component of KDQOL) composite score.

Results: The daily trial was associated with significant improvement of the death/LVM outcome, but the nocturnal trial was associated by only a similar trend. The daily trial showed an improvement in the death/primary health composite (PHC) outcome but not the nocturnal trial. Both trials showed improved BP as well as phosphate control; the latter was more pronounced in the nocturnal trial. There was some improvement in the autonomic nervous system parameters. Frequent dialysis did not improve anemia control, cognitive function, albumin, or body cell mass. Frequent dialysis was associated with more vascular access complications and nocturnal hemodialysis with a more rapid

decline in residual kidney function. There were an increased number of deaths during the year after the completion of the study on nocturnal hemodialysis. It is unclear if the negative results of the nocturnal trial were related to method itself or the low patient enrolment rate, the looser enrolment criteria [higher glomerular filtration rate (GFR) up to 11 mL/min], or the high percentage of enrolled incident rather than prevalent patients, when compared to the daily trial (164). The survival rate of patients on daily hemodialysis was higher than the controls, suggesting that daily hemodialysis should be considered for selected patients (165).

CONCLUSION

There are significant benefits ascribed to long as well as frequent dialysis. Out of these, BP improvement, regression of LVH, phosphate control, and QOL improvements (only partially in nocturnal hemodialysis) were confirmed by RCTs. The rest of the benefits were shown only in observational studies, where usually patient served as their own controls. Although until recently, hospitalization and survival benefits of frequent or long hemodialysis were based on observational studies, the recently published results of the FHN trial showed increased mortality rates after the completion of the study in the nocturnal hemodialysis patient group but decreased mortality rates in the daily hemodialysis patient group compared to controls.

The financial benefits using long intermittent dialysis in-center or at home are firmer, although daily hemodialysis in-center is more expensive. Daily home/nocturnal hemodialysis may be financially beneficial in countries with high labor/consumable price ratio especially for patients who are expected to be on dialysis for longer than 1 year.

CHAPTER 9

Home Hemodialysis

Brent W. Miller

Hemodialysis performed in the patient's home has been a safe and effective form of dialysis therapy for over 40 years (1). The dialysis principles discussed in the previous chapters apply equally to therapy in the patient's home, but the logistics of delivering care in the home and involving the patient in every aspect of his or her therapy necessitate a different approach than conventional center-based hemodialysis.

Similar to peritoneal dialysis, many reports outline benefits of various forms of home hemodialysis; however, the overwhelming majority are uncontrolled, observational and retrospective analyses. For example, a recent attempted review comparing home hemodialysis and center-based hemodialysis found only one short-term randomized controlled trial involving nine patients and concluded no definitive relative statements could be made contrasting the medical risks and benefits of the two modalities (2). Thus, this chapter focuses on the principles and practical points specific to home hemodialysis.

HISTORY

The concept of an outpatient hemodialysis center in the United States was not fully developed until the mid-1970s when legislation granted coverage for hemodialysis to most citizens regardless of age (3). This led to a rapid expansion of center-based dialysis culminating in the 2000s with thrice-weekly, center-based outpatient hemodialysis being the therapy of choice of greater than 90% of end-stage kidney disease (ESKD) patients. Prior to this event and the subsequent development of widespread, successful outpatient peritoneal dialysis in the 1980s, a large proportion of hemodialysis was performed in the patient's home, usually by a family member or close friend (**FIGURE 9.1**). Some staff-assisted home hemodialysis has been done, but the associated labor costs have made this impractical for the majority of patients.

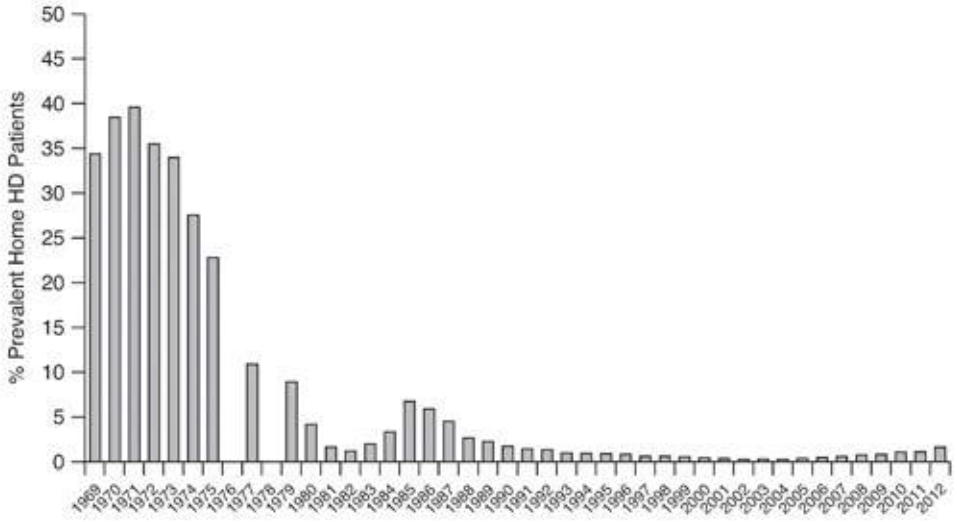

FIGURE 9.1 Prevalence of home hemodialysis in the United States 1969–2012. Data taken from the Final Report of the National Dialysis Registry, 1976, the Bureau of Health Insurance (BHI), and United States Renal Data System (USRDS) 2014. (Adapted with permission from Advanced Renal Education Program, Fresenius Medical Corporation of North America.)

TECHNICAL CONCERNS

Machine

Almost any dialysis machine can and has been utilized in the patient's home. Several dialysis machines have been studied for safety and efficacy in the home and approved for home use by the U.S. Food and Drug Administration (**TABLE 9.1**) (4,5). The NxStage System One utilizes a cartridge-based extracorporeal circuit and dialysate of up to 60 L with lactate as a buffer. Its maximum dialysate flow is 300 mL/min (**FIGURE 9.2**). The Fresenius 2008K@home is based on a traditional hemodialysis machine requiring water treatment similar to traditional hemodialysis and bicarbonate as a buffer (**FIGURE 9.3**). Four other hemodialysis machines designed specifically for home hemodialysis are under development: The Tablo hemodialysis machine from Outset Medical with an integrated patient interface and production of dialysate from tap water, the PAK hemodialysis machine from Fresenius Medical, a sorbent-based hemodialysis system, the Vivia hemodialysis machine from Baxter Healthcare and the Quanta SC+ from Quanta.

TABLE 9.1 Comparison of Common Settings of the Two Current Home Dialysis Systems Approved by the U.S. Food and Drug Administration Specifically for Home Dialysis Use

	NxStage System One	Fresenius 2008K@home
Dialysate delivery	Bagged sterile fluid or batched dialysate production	In-line reverse osmosis machine or de-ionized water tanks
Maximum dialysate flow	200–300 mL/min	800 mL/min
Typical Q_D/Q_B	0.3–0.5	1.5–2.0
Dialysate buffer	Lactate 40 or 45 mEq/L	Bicarbonate (variable)
Dialysate potassium	1 or 2 mEq/L	1–3 mEq/L
Dialysate sodium	140 mEq/L	130–140 mEq/L
Dialysate calcium	3 mEq/L	2–3.5 mEq/L

FIGURE 9.2 Current NxStage home hemodialysis system. **A:** Complete system with dialysis cartridge, machine, and water treatment system together. **B:** NxStage System One with premixed, bagged fluid as dialysate. (Images used with permission of NxStage Medical, Inc.)

FIGURE 9.3 Conventional home hemodialysis system with the Fresenius 2008K@home **(A)** and a reverse osmosis system that can be connected to the patient's home water supply **(B)**. (Photographs used with permission and provided courtesy of Fresenius Medical Care.)

The choice of a machine is important for the home dialysis program. Machines will differ in their cost, maintenance, physical footprint, portability within and outside the home, plumbing and electrical requirements, training time, set-up and breakdown time, and water and dialysate preparation. While it is feasible and sometimes helpful to use multiple hemodialysis machines within a home program, this will introduce more required training, knowledge, and experience of the entire staff.

Water

Successful dialysis starts with the production of water free from microbiological and chemical contaminants that can harm the patient (6,7). While water production in the outpatient unit is similar in each unit, each patient's home installation will be unique. Furthermore, while the cost of providing water and dialysate in the outpatient unit is usually less than 2% of the overall cost of the treatment, it is a major cost in the home hemodialysis treatment and also entails some cost to the patient for additional water usage and plumbing. The Centers for Medicare and Medicaid Services (CMS) has applied water quality and testing standards developed by the Association for the Advancement of Medical Instrumentation (AAMI) since 1987. These standards are updated approximately every 5 years (8). The water quality of both the outpatient unit and the patient's home is ultimately the responsibility of the medical director of the dialysis facility. These general principles of water treatment for hemodialysis are covered in Chapter 8.

In the home environment, the water system will be unique in every installation while adhering to the same AAMI standards. The source water should be tested to see if it meets the minimum standards of the Safe Water Drinking Act (9). If the source water does not meet these standards, then the product water should undergo an AAMI analysis to ensure the contaminants have been removed by the water treatment system. Numerous water supplies in the United States have elevated levels in the source water of elements such as iron, manganese, sulfates, copper, lead, aluminum, and others that will need to be tested in this way. Furthermore, occasional contamination of municipal water supplies such as the Elk River accident with 4-methyl cyclohexane methanol in West Virginia in 2014 can endanger the home hemodialysis patient (10). Most water treatment systems will adequately remove these contaminants; however, the poor source water quality may lead to early exhaustion of components of the treatment system at substantial cost and inconvenience. In this circumstance, installation of a second system between the source water and the water treatment system will often alleviate the problem.

Dialysate

Dialysate can be provided in a patient's home in a number of methods: bagged dialysate delivered to the patient's home similar to peritoneal dialysis, dialysate prepared in the patient's home prior to dialysis, or in-line dialysate from an appropriate water source mixed at the machine. Cost, convenience, storage, installation, and maintenance all factor in the type of dialysate to utilize.

Bagged dialysate similar to peritoneal dialysis has the advantage of providing a sterile, ultrapure dialysate to the patient. However, limitations accompany this advantage. Practical considerations of delivery, storage, cost, and logistics generally limit this method to approximately 30 L of dialysate yielding a single pool urea Kt/V of approximately 0.7 in the typical 80-kg adult; thus, in the absence of significant residual renal function, more than three times a week dialysis will be needed to obtain what is currently considered "adequate" hemodialysis based on small molecule clearance. Second, lactate is typically the base in bagged dialysate fluid for both stability and microbiological concerns. Lactate showed improvement in tolerability over acetate as a hemodialysis buffer before the widespread introduction of bicarbonate-based buffer (11). Yet, in hemodialysis with a lactate buffer, serum lactate levels will be increased slightly, but patients with significant liver dysfunction, higher volumes of dialysate, and/or poorly controlled diabetes may not tolerate lactate as defined by a serum lactate level of >5 mEq/L and transient symptoms of muscle cramping, lower blood pressure, nausea, headache, or weakness. Lastly, the production of bagged dialysate offers a limited number of dialysate baths negating one of the benefits of home hemodialysis—optimizing the dialysis prescription for the individual.

Replicating dialysate production similar to the outpatient unit or the acute care setting in the hospital also has limitations. Typically, either a reverse osmosis (RO) machine or a deionized (DI) water system must be installed in the patient's home. The RO machine adds another machine to install, maintain, and monitor. The DI system usually requires an outside vendor to change the tanks and regenerate the beads in addition to plumbing installation delivering the water to the machine in the home.

Several systems that produce water and dialysate in novel methods in the home are being developed. These include the use of sorbent, distillation, and miniaturization of the dialysate production.

Home dialysis regimens often use lower dialysate flows (<500 mL/min) and total dialysate volumes (<60 L) necessitating a change in standard chemical components of the dialysate bath, particularly small molecules such as potassium (12). Some have termed this *low-volume dialysis*, but no consistent term has been applied (**FIGURE 9.4**). Whereas a conventional hemodialysis treatment may use a blood flow of 400 mL/min and a dialysate flow of 600 mL/min, home dialysis treatments may use a dialysate flow much lower such as 200 mL/min. As dialysate flow is decreased relative to blood flow, the dialysate effluent will be more highly saturated (**FIGURE 9.5**). To remove the same amount of solute over the same time, the starting gradient in the dialyzer must be higher (13,14). For example, a potassium bath of 2 mEq/L for a 3-hour conventional, high-efficiency hemodialysis treatment with a dialysate flow of 600 mL/min (108 total L of dialysate with approximately 20% solute saturation) will need to be changed to 1 mEq/L for the 3-hour home hemodialysis treatment at 200 mL/min (36 total L of dialysate with approximately 80% solute saturation).

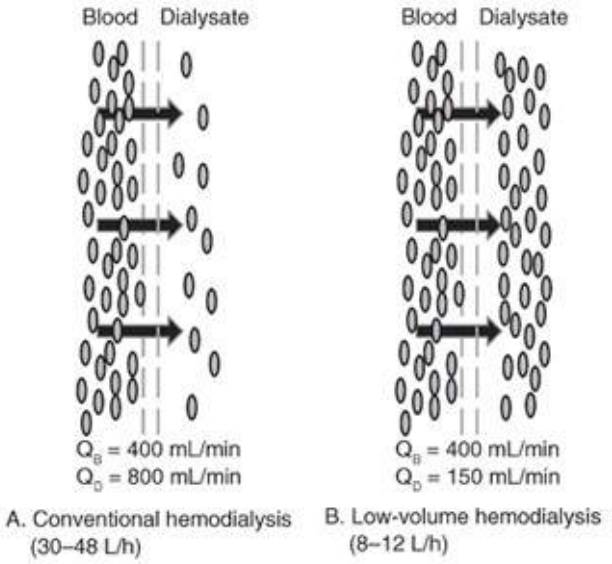

FIGURE 9.4 As Q_D/Q_B is changed from conventional hemodialysis **(A)** to low-volume hemodialysis **(B)**, dialysate saturation increases dramatically. Thus, small molecule clearance for the same period of time is not directly proportional to the decrease in dialysate volume particularly as Q_D exceeds 350 mL/min.

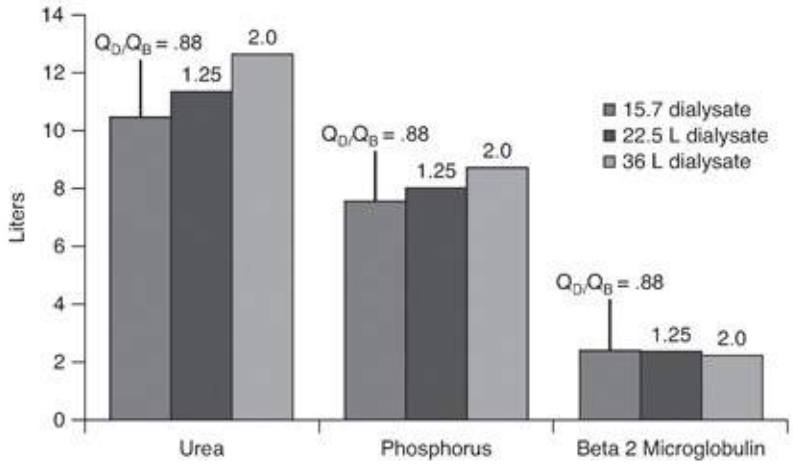

FIGURE 9.5 Removal of solutes over 45 minutes of hemodialysis with a constant blood flow of 400 ml/min with varying dialysate volumes. Note that: 1) dialysate saturation of all solutes decreases as Q_D/Q_B increases and 2) solute removal does not increase for the large molecule as dialysate volume is increased over a constant time. (Adapted from Bhimani JP, Ouseph R, Ward RA. Effect of increasing dialysate flow rate on diffusive mass transfer or urea, phosphate and β2-microglobulin during clinical haemodialysis. *Nephrol Dial Transplant* 2010;25:3990–3995.)

Finally, it is important to note that as dialysate flow is increased relative to blood flow, the incremental amount of small molecule clearance rapidly decreases particularly as dialysate flow moves above approximately 350 mL/min (**FIGURE 9.6**). Because of the incremental cost of additional water and dialysate preparation, several dialysis providers have reduced their conventional dialysate flow to a maximum of 500 mL/min and suggested even 400 mL/min.

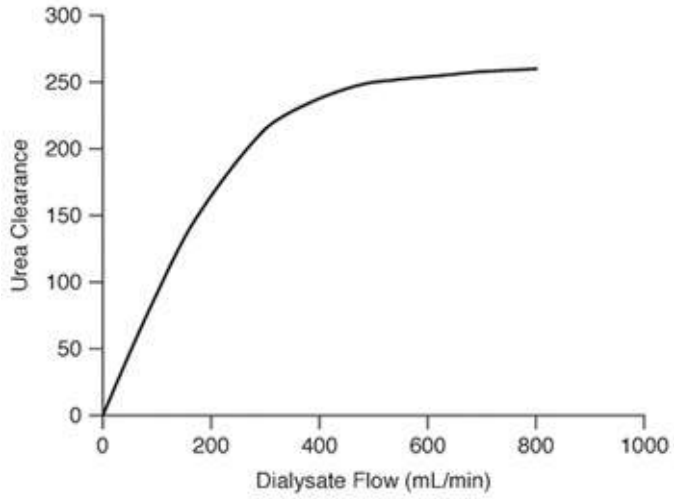

FIGURE 9.6 Estimated urea clearance as a function of dialysate flow with a fixed blood flow of 400 mL/min based on historical observations. Note that the efficiency (amount removed/dialysate utilized) of urea clearance begins to decline significantly after approximately 350 mL/min and precipitously after approximately 500 mL/min. Thus, significant urea clearance can be achieved with dialysate flows of <200 mL/min or approximately 30 L in a 3-hour hemodialysis treatment.

One of the more common home dialysis machines, the NxStage System One, utilizes a fixed dialysate flow to blood flow ratio ("the flow fraction" or Q_D/Q_B), typically less than 0.5, in order to saturate the relatively small amount of dialysate. Adjusting the "flow fraction" down will increase the saturation of the dialysate or the efficiency of the dialysis treatment, while increasing the flow fraction will decrease the efficiency of the treatment. Similarly, the Fresenius 2008K@home machine can utilize a fixed Q_D/Q_B of 1.5 or 2.0 ("autoflow").

CLINICAL CONCERNS

Patient Selection

Not every patient is willing or capable to perform hemodialysis at home. Placing a patient who is unwilling to follow treatment protocols at home raises additional safety concerns. Furthermore, training patients for home hemodialysis is a time-consuming, labor-intensive, and expensive process. If patients fail at home shortly after training, both nursing morale and the financial performance of the home dialysis program suffer.

However, choosing patients whom in some physician's eyes seem to be the perfect candidate for home therapy—less comorbid illnesses, employed, extensive social support networks, younger age, well-educated, and so on—does not necessarily ensure success. First, that "ideal" candidate rarely exists. Second, many of those patients are doing well with their current therapy and may not see a substantial improvement with home therapy. Lastly, the patient whom may benefit the most from home hemodialysis and succeed at home hemodialysis is not well-defined and not always obvious to the physician.

In lieu of studies or trials that evaluate this question, a simplified approach generally works. First, why does the patient want to perform home hemodialysis or, alternatively, why is the physician recommending home hemodialysis? Is the specified expectation or reason a measurable outcome that can be evaluated in a reasonable time frame (**TABLE 9.2**). Second, what type of support at home does the patient have? *Support* should not be confused with *effort* by family members, friends, or care partners in the home. Patients should be encouraged to perform as much of the dialysis treatment as possible and be involved in their care as much as possible. Kidney failure and dialysis is a long and difficult journey, and encouragement and support are critical to the success, particularly at home. Having a spouse, family member, or friend actually *performing the dialysis treatment* is not crucial to success for every patient. In fact, the additional stress on the "care partner" may lead to modality failure despite the improvement of the patient clinically. Lastly, while it seems that the amount of support would correlate with success at home, some data suggests that success is more likely to occur where the patient's expectation of support matches what is actually received rather than the absolute quantity delivered (15).

TABLE 9.2 Patient-Centered Outcomes for Potential Home Hemodialysis Patients

Control over treatment schedule
Removal of frequent travel to dialysis center
Substantial involvement in care
More frequent dialysis
Ability to travel with dialysis equipment
More time with family and friends
Better blood pressure control
Improved appetite
Improved physical activity

To help delineate these issues, it is helpful for the patient to meet with the treatment team (nurse, social worker, nephrologist, financial representative) to discuss these issues before training. Having additional small meetings with the patient and family separated may allow previously unvoiced concerns to be discussed. These concerns may be as simple as "I don't want my home to become a medical facility" or "will this interfere with our intimacy?" or as complex as "I have a demanding 40-hr job and now you are asking me to learn and perform dialysis on my spouse after work . . . ."

Prescription Management

Kinetic modeling and solute clearance are discussed at length in Chapters 6 and 7. Although those concepts remain the same for hemodialysis at home, the change in location of the dialysis treatment unshackles the nephrologist and the patient from the logistics and rigid thrice-weekly schedule of the typical outpatient dialysis center. Thus, multiple options for dialysis including varying schedules, different frequencies, and longer times as discussed in the preceding chapter are obtainable. For the patient, tailoring a dialysis schedule to a particular lifestyle is also possible and likely a major motivation for performing dialysis in the home even if the medical outcomes are equivalent. This motivation should not be discounted when considering the prescription. For example, the patient may want to perform dialysis at night after work during the week and early in the morning on the weekend.

While the relative risks and benefits remain to be studied definitively in controlled trials, optimizing solute clearance at home by increasing the dialysis frequency or length as discussed in preceding chapter is easily obtainable in the patient's home. Certain patients, such as those with a longer life expectancy or transplant sensitization, may desire a prescription that optimizes larger solute clearance, lowers ultrafiltration rates, controls plasma phosphorus, and may lower utilization of erythropoiesis stimulating agents.

Several studies suggest that a dialysis frequency greater than 3 times per week may be preferable for many patients. Several analyses of large databases, most recently in 2011 with United States Renal Data System (USRDS), demonstrated markedly increased all-cause mortality and cardiovascular hospital admission rate related to the long interdialytic interval in thrice-weekly hemodialysis (16). A randomized, 1-year trial of thrice-weekly hemodialysis versus six times weekly hemodialysis in 247 patients demonstrated an improvement in the combined end point of mortality and left ventricular hypertrophy (17). Conversely, a longitudinal follow-up of the 87 patients from the Frequent Hemodialysis Network study of nocturnal hemodialysis suggested a potential lower survival with more frequent, home nocturnal hemodialysis (18). However, this study has several limitations including a conventional arm that provided longer dialysis than is typically performed, a large number of both incident patients and patients with significant residual function, and a large number of patients from one of the study centers. Analysis of loss of residual renal function in the study was higher in the nocturnal arm; thus, one potential conclusion is that intensive dialysis regimens should be reserved for anuric or oliguric patients (19).

The nephrologist should also consider potential changes to the prescription that will enhance the stability and safety of the treatment in the home environment in addition to optimizing the solute removal (**TABLE 9.3**).

TABLE 9.3 Changes in Home Hemodialysis Prescription That May Optimize Stability and/or Safety

Careful adjustment of the estimated "dry weight" during the training period
Limitation of ultrafiltration rate
Avoidance of long interdialytic intervals
Lower blood flow
Lower dialysate temperature
Longer dialysis times
Use of single needle for access
Avoidance of large meals during treatment
Use of bicarbonate-based buffer

Training

The different types of adult learning are usually not topics in medical training; however, knowledge and application of learning principles is key to the success of a home hemodialysis program. While this may be more important for the nurse trainer to utilize, the nephrologist should review training materials and techniques to ensure successful training of all patients. Additionally, training is often thought of as the intense, initial phase. But it is important that ongoing training and retraining are regularly incorporated into the home hemodialysis program.

The dialysis treatment itself is usually incorporated into the patient training time. Most nephrologists have patients train in an outpatient facility, but occasionally, home-based training in a stable patient can be accomplished. Training usually takes 4 to 6 weeks depending upon the intensity, type of machine, and learning ability of the patient. Most nephrologists check urea kinetics and electrolytes after 1 week and make further adjustments to the prescription so that the patient is on a final, stable prescription before being sent home. Patients who increase the frequency of their dialysis schedule will often need a change in the estimated dry weight, decreased antihypertensive medications, and a higher potassium bath.

Patient Burnout

The improvement in dialysis patient survival and the increasing length of kidney transplantation waiting times often means that a patient will experience multiple dialysis modalities. It is important not to view either a temporary or permanent change from home hemodialysis to another dialysis modality as a "failure" and engage the patients and their families in discussions about the impact of performing dialysis has on their life, how they are coping with the impact, and whether a change is needed. Currently, approximately 4% of patients on hemodialysis stop each month. About half is due to kidney transplantation and death, and the remaining transfer to center-based dialysis for a variety of reasons.

Ongoing involvement of the multidisciplinary team with frank, open discussions of the burden of the therapy and its effects, social isolation, and changes in family dynamics may preclude a significant problem.

When a patient or family member expresses negative concerns about the burden of therapy, temporary placement in an outpatient center should be offered. This may entail a few self-care treatments in the home training area or alternatively a longer intermission of conventional hemodialysis in an outpatient setting. Additionally, there may be certain situations that necessitate a respite from the home setting: changes in vascular access, temporary or permanent loss of a care partner, illness, or electrical and water problems in the home. The routine flux of patients in and out of the home program should be expected and planned.

Vascular Access

Vascular access is discussed at length in Chapter 4. For the home hemodialysis patient, several additional concerns need consideration: patient training, technique, ergonomics, safety, management of potential infection, and clinical monitoring of the vascular access. All types of vascular access utilized in center-based dialysis have been successfully utilized in patients at home. The type of access should not be a deterrent to a patient dialyzing at home.

Currently, approximately half of home hemodialysis patients cannulate themselves and half have care partners performing cannulation. Rarely is fear of cannulation an insurmountable obstacle to home hemodialysis training. Since all dialysis patients may be taught self-care in their therapy, it is often helpful

to begin cannulation training before starting home hemodialysis training (unless the patient is new to hemodialysis).

For the patient with the arteriovenous fistula (AVF), either the rotating site ("rope-ladder") or single-site ("buttonhole) method of cannulation can be chosen. The pros and cons of the single-site approach are discussed in Chapter 4. Although many practitioners believe the self-cannulator has less discomfort and easier needle insertion, this has not been adequately studied and the infectious risk appears higher as currently practiced (20–22).

The sites of cannulation should be chosen with careful collaboration between the training nurse and the patient. The patient should give significant input to the ergonomics of cannulation and decannulation, while the nurse should choose the safest sites. For example, the nonmedical person choosing a site to insert a needle may inappropriately see the top of an aneurysmal dilatation as the easiest site to be successful. Removal of the needle also demands careful attention especially for the self-cannulator. The synchrony of safe needle removal, placement in an appropriate waste container, pressure, and hemostasis is often more technically difficult than needle insertion. Another ergonomic factor for the self-cannulator at home is the insertion and subsequent removal of both arterial and venous needles in a proximal or upward direction in both AVF and arteriovenous graft (AVG).

Similar to peritoneal dialysis, aseptic technique cannot be emphasized, monitored, and retrained enough. Aseptic technique is often a foreign concept to the new home hemodialysis patient. Several antibacterial agents are available to utilize in the event of a significant local skin reaction to one (**TABLE 9.4**). Whether or not to utilize an antibiotic cream or ointment after hemostasis, particularly of single-site or "buttonhole" cannulation, remains unresolved (22).

TABLE 9.4 Antibacterial Agents for Home Hemodialysis Vascular Access

Povidone-iodine solution
Chlorhexidine gluconate 2% and isopropyl alcohol 70%
Chlorhexidine gluconate 0.5% and isopropyl alcohol 70%
Sodium hypochlorite 0.114%
Alcohol

Unlike peritoneal dialysis, the signs and symptoms of an access infection in a home hemodialysis patient can be subtle. The threshold for a clinical evaluation, potential blood cultures, and possible preemptive antibiotics should be low. How and where to perform these should be determined prior to the end of patient training for each patient so no delay will occur when a potential problem develops. With a documented access infection, the patient's aseptic technique should be reviewed, observed, and adjusted as needed. Similarly, the home hemodialysis program should monitor the rate of bloodstream infections carefully. Since the 2016 CMS national standard is approximately 0.27 bloodstream infections per 1,000 patient-days, a home hemodialysis program of 10 patients should not see more than one bloodstream infection per year and ideally not more than one bloodstream infection every 3 years (23).

Changes in the vascular access should be noted for possible intervention. An unexplained decline in urea kinetics would be one measure. Reports from patients of changes in blood flow, increased venous pressure during dialysis, or a change in bleeding after pulling needles may indicate a problem with the access. One of the advantages of home dialysis is that a full exam of the access can occur monthly by the physician without needles in place and a complete range of motion of the limb. Assessing the appearance,

thrill, bruit, augmentation, temperature, and location of the cannulation sites is easy to do in the home patient during a clinic visit by both the nurse and physician.

SAFETY CONSIDERATIONS

Home hemodialysis as currently practiced has an excellent safety record (24). In one review of two home hemodialysis programs, only seven serious events were noted over 500 patient-years, and most of those events were operator errors that could be prevented by a combination of technology and education. However, several specific topics merit discussion.

Hypotension

Some have estimated that intradialytic hypotension, defined as the need to stop ultrafiltration and administer saline intravenously, occurs in up to 20% of conventional hemodialysis treatments. Hypotension in the home environment poses a clear safety risk and must be minimized. The most common cause of intradialytic hypotension in the home environment is incorrect calculation or entry of the ultrafiltration volume. Some of the strategies to reduce hypotension in the outpatient center also are available in the home such as limiting the ultrafiltration rate to approximately 10 mL/kg/h, decreasing the dialysate temperature, and avoiding antihypertensive medications prior to the dialysis treatment.

Bleeding

Miscannulation of AVF or AVG should be reported promptly to the home dialysis nurse to determine the cause such as incorrect location, angle, depth, or advancement of the needle. Infiltration of blood into a misplaced venous needle can cause significant blood loss, pain, and impair the future function of the access. Venous dislodgment of a needle with the arterial needle still in place with the blood pump engaged can lead to life-threatening blood loss quickly, particularly if the patient is performing a nocturnal hemodialysis treatment while sleeping. Fortunately, this is a rare event, but moisture detectors placed near the venous needle can help prevent this from occurring.

Air Embolism

Hemodialysis technology has advanced so that air embolism during a hemodialysis treatment is extraordinarily rare. Air embolism now occurs during manipulation of the vascular access either prior to or after the dialysis treatment. Careful training and emphasis is needed in this regard; a patient death from air embolism during manipulation of a central venous catheter following a home dialysis treatment occurred at the University of Iowa in the 87-patient Frequent Hemodialysis Network trial (25; P. W. Eggers, written communication, March 2008).

Leaks

The placement of large quantities of water in close proximity to electrical equipment and a patient requires several safeguards. Prior to installation, the home should be inspected so that ground fault circuit interrupter outlets are utilized and appropriate pans and moisture detectors are installed underneath the equipment.

Outpatient Follow-up

One of the most surprising aspects of home hemodialysis is the effort the provider must provide after successful training. Most nephrologists perform a face-to-face encounter monthly with their home hemodialysis patients. This often works best if a multidisciplinary approach including the dialysis nurse, dialysis social worker, and renal dietitian are included in this visit. Treatment logs for the month are reviewed for problems. Most patients draw their monthly blood work themselves and bring it to the center for analysis. Full medical waste containers can be exchanged for empty containers. While many supplies may be delivered to the patients' homes, it is often more cost-effective to have the patient pick up smaller supplies such as needles, gauze pads, syringes, and so on at this visit.

As with all forms of dialysis, problems will occur that require medical attention. A clear communication strategy should be in place for the patient. Technical problems with the machine should be routed to either the biomedical technician of the dialysis center or the technical support staff of the dialysis machine manufacturer. Medical problems should be routed to the home dialysis nurse or nephrologist on call. Many home dialysis programs will post this contact information physically on the dialysis machine for patient ease.

Future Advances

In the United States, only 2% of ESKD patients utilize home hemodialysis at present. One of the impediments to more patients choosing this therapy is the slow pace of technologic advancements applied to home hemodialysis. One can understand the lack of incentive in developing innovative medical devices for a small proportion of a relatively small number of people in a low-margin, capitated fiscal environment; however, the inflexibility and fixed labor and capital costs of center-based hemodialysis, the lengthening of transplant waiting times, and the continued high failure rate of peritoneal dialysis may eventually add motivation for new approaches to home hemodialysis.

CHAPTER 10

Continuous Dialysis Therapeutic Techniques

Piyush Mathur, Celina Cepeda, and Ravindra L. Mehta

Acute kidney injury (AKI) is a frequent complication in critically ill patients and reflects a broad spectrum of clinical presentations ranging from mild to severe injury that may result in permanent and complete loss of renal function. AKI represents a significant risk factor for adverse outcomes and has been associated with mortality greater than 50% (1). The underlying mechanisms of AKI include a decrease in the kidney's ability to excrete nitrogenous waste, manage electrolytes, regulate intravascular volume, and regulate acid–base status (2,3). Depending on the severity of AKI, dialysis is often required to support renal function. Over the last two decades, significant advances have been made in the availability of different dialysis methods for replacement of renal function. Renal replacement therapy (RRT) can be provided as hemodialysis, hemofiltration, or a combination thereof and as intermittent, or as continuous therapy. Intermittent hemodialysis remains the mainstay of RRT in most part of the world, and modifications in duration and operational characteristics of the therapy have resulted in development of prolonged intermittent renal replacement therapy (PIRRT) also termed slow low-efficiency dialysis (SLED). The most common form of continuous therapies is peritoneal dialysis (PD), which is not as commonly used to manage AKI. Continuous renal replacement therapies (CRRTs) encompass several methods of hemofiltration and hemodialysis and are increasingly utilized for managing patients with AKI in the intensive care unit (ICU) setting (4,5). In this chapter, we provide a description of CRRT techniques, an outline of the key areas of application, and a summary of the results with these therapies.

MODALITIES OF CONTINUOUS RENAL REPLACEMENT THERAPY—TECHNICAL CONSIDERATIONS

Terminology

Continuous therapies encompass a variety of modalities that vary in the terminology. Recently, an international group of experts has developed the Acute Dialysis Quality Initiative (ADQI) (6) and has proposed adopting previously developed standardized terms for these therapies. The basic goal was to link the nomenclature to the operational characteristics of the different techniques (7). Each letter in the

acronym represents a specific characteristic related to the duration, driving force, and operational features. The letter C is used in all the terms to describe the continuous nature. The letters AV or VV in the terminology identify the technique's driving force, that is, the mean arterial pressure (MAP) for arteriovenous (AV) circuits and external pumps for venovenous (VV) circuits. Solute removal in these techniques is achieved by either convection, diffusion, or a combination of both these methods. Therefore, the letters UF, H, HD, and HDF identify the technique's operational characteristics:

Convective techniques, including ultrafiltration (UF) and hemofiltration (H), depend on solute removal by solvent drag (8).
Diffusion-based techniques, similar to intermittent hemodialysis (IHD), are based on the principle of a solute gradient between the blood and the dialysate (9).
Hemodiafiltration (HDF) processes use both diffusion and convection in the same technique. In this instance, both dialysate and a replacement solution are used, and both small and middle molecules can be removed easily (10).

The only exception to this nomenclature system is the acronym SCUF (slow continuous ultrafiltration), which designates UF alone without any fluid replacement.

TYPES OF CONTINUOUS RENAL REPLACEMENT THERAPY MODALITIES

As discussed in section "Terminology", the predominant mechanism of achieving clearance defines the modality of CRRT.

Simple diffusion: continuous venovenous hemodialysis (CVVHD)
Convection: continuous venovenous hemofiltration (CVVH)
Combination of both [continuous venovenous hemodiafiltration (CVVHDF)] (**TABLE 10.1** and **FIGURE 10.1**)

TABLE 10.1 Modalities of Continuous Renal Replacement Therapy

	SCUF	CVVH	CVVHD	CVVHDF
Vascular access	VV	VV	VV	VV
Average blood flow (mL/min)	100	100–200	100–200	100–200
Dialysate flow (mL/min)	0	0	10–30	10–30
Replacement fluid (L/d)	0	21.6	0	16.8
Ultrafiltrate (mL/min)	2–8	10–30	2–4	10–30
Anticoagulation	Yes/no	Yes/no	Yes/no	Yes/no
Clearance mechanism	C	C	D	C + D
Urea clearance (L/d)	1.7	16.7	21.7	30

SCUF, slow continuous ultrafiltration; CVVH, continuous venovenous hemofiltration; CVVHD, continuous venovenous hemodialysis; CVVHDF, continuous venovenous hemodiafiltration; VV, venovenous.

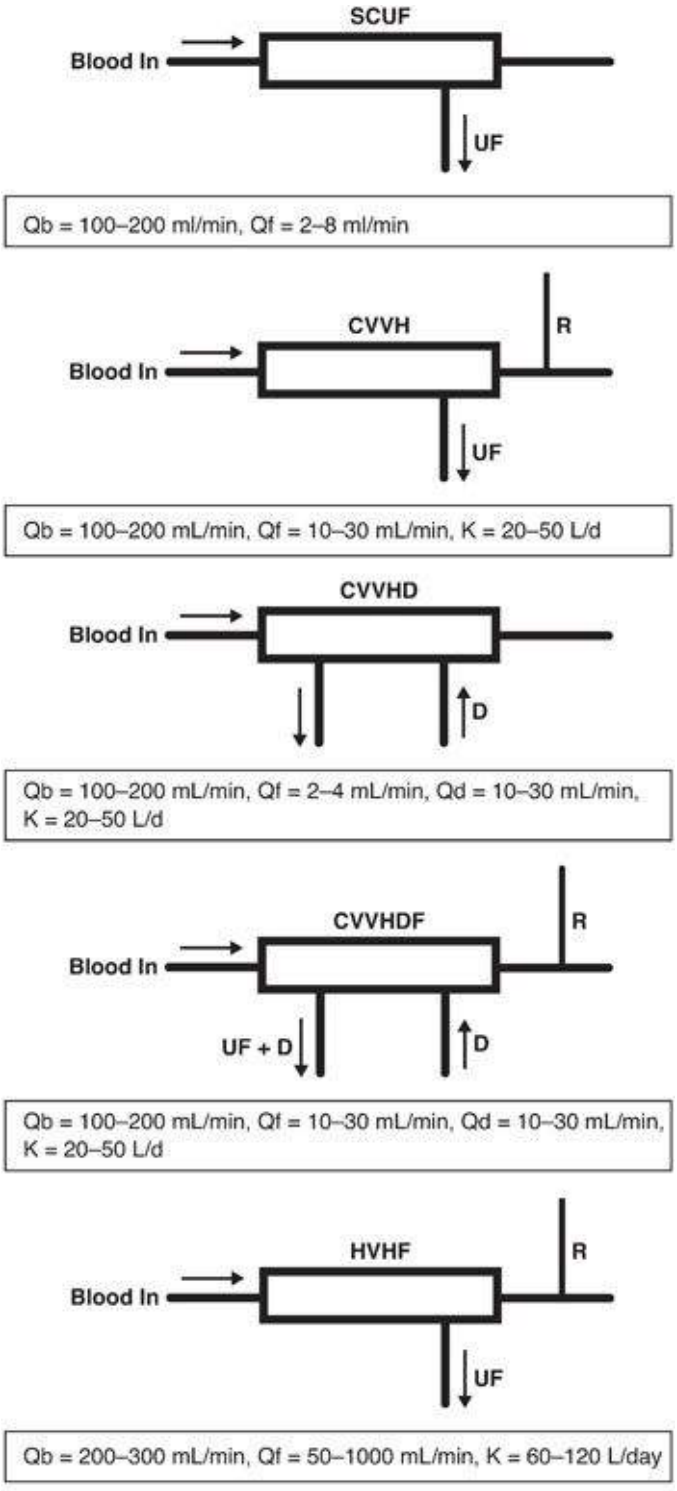

FIGURE 10.1 Modalities of continuous renal replacement therapies (CRRTs). Commonly available modalities in intensive care unit (ICU). SCUF, slow continuous ultrafiltration; Qb, blood flow; Qf, ultrafiltration rate; CVVH, continuous venovenous hemofiltration; R, replacement; UF, ultrafiltration; K, clearance; CVVHD, continuous venovenous hemodialysis; D, dialysate; Qd, dialysate flow; CVVHDF, continuous venovenous hemodiafiltration; HVHF, high-volume hemofiltration. [Adapted from Cerdá J, Ronco C. Modalities of continuous renal replacement therapy: technical and clinical considerations. *Semin Dial* 2009;22(2):114–122.]

MACHINES AND COMPONENTS OF CONTINUOUS RENAL REPLACEMENT THERAPY

Modern CRRT machines are designed specifically for acute dialysis and are equipped with a friendly user interface to perform SCUF, CVVH, CVVHD, and CVVHDF. These new machines utilize preset

disposables, have integrated safety alarms, fluid balancing controls, and connected blood modules that are controlled with sophisticated microprocessors in the machine. The ease of setting wide range of blood, dialysate/replacement flows as well use of highly permeable membranes and pressure sensing systems has improved clearances of large molecules and efficiency of the treatment (11).

VASCULAR ACCESS AND CIRCUIT FOR CONTINUOUS RENAL REPLACEMENT THERAPY

A well-functioning vascular access is a prerequisite for successful CRRT. Several options now exist for access and can be selected based on individual patient requirements, local availability of the various catheters, and unit expertise. AV fistulas and grafts are generally not recommended for CRRT due to the risk for needle displacement and high risk for injury to the access that may make it unusable in the future. If an AV fistula or graft is to be utilized, it should be for a very limited time and preferably cannulated with plastic angiocatheters to minimize risk of complications.

Temporary or tunnelled cuffed hemodialysis (HD) catheters are currently used as vascular access for CRRT. Temporary catheters are generally inserted at bedside ideally under ultrasound guidance (USG) by modified Seldinger technique into internal jugular (IJ), femoral, or subclavian veins using stringent sterile precautions. Although tunneled, cuffed, double-lumen silastic catheters are the preferred access for short- and intermediate-term use in chronic dialysis patients, they are generally not the initial choice for CRRT as they are more difficult to place (12). However, if CRRT continues for longer than a week, ideally a tunnelled catheter should be placed for improving blood flow and reducing the risk of infections.

ADQI recommends use of USG for catheter placement as its use has been reported to reduce the failure and complication rates of central venous catheter insertion in level II and III studies. A single-center study (13) and meta-analysis (14) showed that USG reduces placement failure, complications, and need for multiple attempts.

Optimal site for catheterization in any given patient is determined by the risks of thrombosis and infection, ease of placement, and adequacy of function. The right IJ vein is preferred for temporary catheter, given its more direct route to superior vena cava. The left jugular vein has a more circuitous route to the right atrium, and this can lead to inadequate blood flow in patients with frequent neck movements. Femoral veins should be used as second choice for CRRT, given their ease of accessibility. Subclavian veins cannulation is discouraged, as it may lead to stenosis of the vessel and may interfere with the functioning of an AV fistula or graft that maybe required in the future (15).

Most clinicians do not consider catheter location to be a determinant of risk of infection, as results of various studies are conflicting. A recent meta-analysis has not shown any difference in the rate of catheter-related bloodstream (CRB) infections between the three sites (16). Another prospective study showed that frequency of catheter-related bacteremia was similar in jugular and femoral cannulation. The main risk factors for development of CRB were duration of catheter use and the number of performed dialyses (17). A prospective study by Oliver et al. (18) in 218 patients concluded that IJ catheters may be left in place for up to 3 weeks without a high risk of bacteremia, but femoral catheters in bed-bound patients should be removed after 1 week. Other characteristics, which may influence infection rates, include the catheter material and antimicrobial coating or impregnation. Polyurethane catheters are

preferred for CRRT. A prospective randomized study showed that use of polyurethane HD catheters impregnated with minocycline and rifampin decreases the risk of catheter-related infection (19). Another prospective study proved the efficacy of catheter-restricted filling using an antibiotic lock solution in preventing CRB (20). But toxicity, allergic reaction, and bacterial resistance are the concerns associated with antibiotics limiting their widespread use. Recently, trisodium citrate (TSC) has been advocated as a catheter lock solution because of its antimicrobial properties and local anticoagulation. In a multicenter, double-blind, randomized controlled trial (RCT); TSC 30% was compared with unfractionated heparin 5,000 U/mL for prevention of catheter-related infections, thrombosis, and bleeding complications. The study was stopped prematurely because of a difference in catheter-related bacteremia (p <0.01) (21). After this trial, many studies have shown safety and superiority of TSC over heparin (22,23).

Besides infection, catheter malfunction due to thrombosis, kinking of catheter, fibrin sheath around catheter tip is another complication associated with CRRT. Instillation of heparin into both lumens prevents formation of intraluminal thrombus. However, in a completely occluded catheter by thrombus, recombinant tissue plasminogen activator (rtPA)/alteplase can be instilled to reestablish blood flow. In a study by Daeihagh et al. (24), tissue plasminogen activator (tPA) used in a dose of 2 mg with median dwell time of 24 hours appears to be as effective as urokinase for reestablishing adequate blood-flow rates through HD catheters that are thrombosed or have low blood-flow rates. tPA was effective in establishing adequate blood-flow rates (≥200 mL/min) during the next dialysis session in 87.5% cases. Another study also showed that Reteplase installation in dysfunctional HD catheters with dwell until the next HD session was effective in restoring catheter function in 87% of episodes. A dose of 1 U appears to be as effective as 4 and 6 U (25). Fibrin sheaths that form outside the catheter are resistant to thrombolytics and may require mechanical brushing or stripping (26).

ANTICOAGULATION FOR CONTINUOUS RENAL REPLACEMENT THERAPY

As in other extracorporeal circuits, anticoagulation is essential to prevent the activation of clotting mechanisms within the circuit (27,28) and is necessary for effective delivery of CRRT. The choice of anticoagulant should be based on multiple factors, including (a) the access site; (b) the nature and geometry of the membrane; (c) whether enhancements for UF, such as predilution, are used; and (d) the clinical status of the patient and preexisting coagulation abnormalities. The ideal anticoagulant should provide optimal antithrombotic activity with minimal bleeding complications and negligible systemic side effects. It should be inexpensive, have a short half-life, and be easily reversed (29). Adequate anticoagulation ensures efficacy of the filter in fluid and solute removal, overall filter longevity, and optimum patient management. When the anticoagulation is insufficient, filtration performance deteriorates and the filter may eventually clot (30), contributing to blood loss. Excessive anticoagulation, on the other hand, may result in bleeding complications, which have been reported to occur in 5% to 26% of treatments (31).

Several methods of anticoagulation are now available, and the key features of the most common methods are summarized in **TABLE 10.2**.

TABLE 10.2 **Anticoagulation Methods**

Method	Initial Dose	Maintenance Dose	Advantage	Disadvantage	Monitoring
Heparin	30 U/kg bolus	5–10 U/kg/h	Standard method Easy to use Inexpensive	Bleeding risk Thrombocytopenia	aPTT 1.5–2 times of normal
LMWH Nadroparin/ dalteparin Enoxaparin	15–25 IU/kg 0.15 mg/kg	5–10 IU/kg/h 0.05 mg/kg/h	Decreased risk of bleeding Higher anti-Xa/anti-IIa Lesser HIT	Poor reversibility with protamine Expensive Monitoring not easily available	Factor Xa levels; maintained between 0.1 and 0.41 U/mL
Regional citrate	4% trisodium citrate 150–180 mL/h	100–180 mL/h 3%–7% of BFR, Ca replaced by central line	No bleeding No thrombocytopenia Improved filter efficacy Longevity	Complex; needs Ca monitoring; alkalosis	ACT: 200–250 maintain ionized calcium 0.96–1.2 mmol/L
Heparinoids (Danaparoid)	750–2,500 U	1–2 U/kg/h	Decreased HIT	Bleeding risk Cross-reactivity with heparin/PF4 Prolonged half-life in renal failure No antidote	Anti-Xa level between 0.25 and 0.35 IU/mL
Thrombin antagonist Hirudin Argatroban	250 μg/kg	0.005–0.01 mg/kg/h OR 0.002 g/kg bolus doses 0.5–2 μg/kg/min	Can be used in patients with HIT Hepatic excretion, so no dose modification in renal failure	Renal excretion: prolonged half-life No antidote	Ecarin clotting test (ECT): not easily available Target: 80–100 s aPTT 1–1.5 times normal
Platelet inhibiting agents Prostacyclin		2–8 ng/kg/min infusion prefilter	Better circuit life	Hypotension Expensive Usually needs UFH coadministration	Not required aPTT when UFH used
Nafamostat		0.1 mg/kg/h	No heparin	Anaphylaxis Agranulocytosis hyperkalemia	ACT

aPTT, activated partial thromboplastin time; LMWH, low molecular weight heparin; HIT, heparin-induced thrombocytopenia; BFR, blood-flow rate; ACT, activated clotting time; PF4, platelet factor 4; UFH, unfractionated heparin.

Unfractionated Heparin

Unfractionated heparin (UFH) continues to be the most commonly used anticoagulant. It catalyses the inactivation of thrombin, factor Xa and factor IXa by antithrombin. The main advantage of UFH is the large experience, the short biologic half-life (90 minutes but can increase up to 3 hours in presence of renal insufficiency), the availability of an efficient inhibitor, and the possibility to monitor its effect with routine laboratory tests. Limitations of UFH includes time- and dose-dependent unpredictable pharmacokinetics, resulting in considerable inter- and intrapatient variability (32), resistance to heparin due to reduced level of antithrombin III in renal insufficiency, high incidence of bleeding, and heparin-induced thrombocytopenia (HIT) (33–36). Dosing of heparin and target activated partial thromboplastin time (aPTT) varies in different units with the aim of maintain aPTT 1.5 to 2 times of normal. UFH is usually administered as a bolus of 30 IU/kg (2,000 to 5,000 IU), followed by a continuous infusion of 5 to 10 IU/kg/h into arterial limb of the dialysis circuit. Circuit survival time ranges from 20 to 40 hours. In view of the potential side effects of heparin, alternative methods of anticoagulation have been investigated, including regional heparin/protamine, low molecular weight heparins, heparinoids, thrombin antagonists (hirudin and argatroban), regional citrate, prostanoids, and nafamostat, with regional citrate

anticoagulation (RCA) gaining wider acceptance with the development of simplified and safer protocols.

Low Molecular Weight Heparin

Recently, low molecular weight heparins (LMWHs) have been shown to be safe and effective drugs for anticoagulation of CRRT circuit (37–40). These agents have higher anti-Xa/anti-IIa activity than UFH (32), less protein binding, more predictable pharmacokinetics, and lesser incidence of HIT (41). The LMWHs are potent agents with renal excretion, have an increased half-life compared with UFH, poor reversibility with protamine because of stronger anti-Xa effect, more expensive than UFH, and also require specialist laboratory monitoring. Nadroparin, dalteparin in a dose of 15 to 25 IU/kg as bolus followed by 5 to 10 IU/kg/h (39–40), and enoxaparin as 0.15 mg/kg and a maintenance infusion starting at 0.05 mg/kg/h are the agents used in various studies (38).

Regional Citrate

Citrate ($C_6H_7O_7$) is a small negatively charged molecule with a molecular weight of 191 Da. The use of citrate as anticoagulant in HD was first described by Morita et al. (42) in 1961 and in CRRT circuit by Mehta et al. in 1990 (43). Since then, various studies have shown better filter life and less bleeding with citrate in varied patient population including severe sepsis, liver failure, cardiac surgery, and both adults as well as pediatric patients population (36,44–61). In a prospective randomized multicenter trial by Hetzel et al. (62), citrate was found to have less systemic anticoagulation, a lower risk of bleeding, and a longer hemofilter patency. Some studies have shown evidence of improved biocompatibility by decreasing thrombogenicity and low polymorphonuclear cell degranulation (63–65), while effects of citrate on complement activation are not uniform (66–68). A recent study by Schilder et al. (69) has not shown any difference in mortality and renal outcome between RCA and UFH, but citrate was superior in terms of safety, efficacy, and costs.

Citrate is infused into the blood at the beginning of the extracorporeal circuit which chelates ionized calcium and provides anticoagulation in the circuit. Optimal regional anticoagulation occurs when the ionized calcium in the postfilter circuit is kept below 0.35 mmol/L. Calcium-citrate complex which is formed in the circuit is freely filtered and is lost in effluent, so calcium is infused systemically to replace the lost calcium to keep the ionized calcium within normal limits and infusion is titrated accordingly. Citrate which enters the body is metabolized by tricarboxylic acid pathway in liver, kidney, and skeletal muscles, and each citrate molecule yields three bicarbonate molecules, thereby avoiding systemic anticoagulation. Patients with severe liver failure and lactic acidosis may have difficulty in metabolizing citrate and may develop citrate toxicity, which is characterized by increased total to ionized calcium ratio, metabolic acidosis, and high anion gap (55,70–73). Other complications which may occur during RCA are hypernatremia particularly with hypertonic sodium citrate and metabolic alkalosis when too much citrate enters the circulation (43); therefore, frequent monitoring of electrolytes, acid–base status, and ionized calcium is required.

Various protocols for RCA have been described in literature (36,44–60). The ideal CRRT protocol should provide volume control, metabolic (acid–base and electrolyte) control, and adequate solute clearance, without significant complications related to bleeding or clotting. **TABLE 10.3** shows CRRT prescription and citrate protocol at University of California, San Diego (UCSD). **FIGURE 10.2** shows

CRRT circuit using RCA.

TABLE 10.3 Continuous Renal Replacement Therapy Prescription and Regional Citrate Protocol at University of California, San Diego

Modality	CVVHDF	Allows combination of diffusive and convective clearance Consequently, UF rates can be limited and do not require high blood-flow rates for filtration fraction (FF).
Membrane	M 100	0.9 m^2 AN69 polyacrylonitrile membrane adequate for clearances required
Blood-flow rate	100 mL/min	Not constrained by access, adequate flow for maintaining filtration fraction <25%
Effluent volume	2.2 L/h	Allows small solute clearance of approximately 37 mL/min, adequate clearance to compensate for catabolic state and for reduction due to partial predilution
Dialysate flow rate	1 L/h	Slower than blood-flow rate with complete saturation of dialysate for small solutes; diffusive clearance = 16.7 mL/min
Predilution fluid	0.5 L/h	Administered prefilter, prepump dilutes blood entering the filter with filtration fraction of 25%.
Postfilter replacement fluid	0.7 L/h	Administered postfilter in venous circuit; volume greater than all anticipated intake to allow fixed effluent volume and clearance Volume adjusted hourly to achieve desired fluid balance.
Anticoagulation	4% trisodium citrate	At access exit through three-way stopcock to chelate ionized calcium and prevent clotting; rate 160–200 mL/h adjusted to maintain postfilter ionized calcium 0.25–0.4 mmol/L; provides base from conversion of citrate to bicarbonate
	0.1 mEq/mL calcium chloride	Replaces calcium removed across filter, administered through separate central line at initial flow rate of 40–60 mL/h and adjusted to maintain peripheral ionized calcium of 1.12–1.32 mmol/L
Dialysate fluid composition	0.45% saline + 40 mEq of Na as $NaHCO_3$ or NaCl + Mg 2.0 mEq/L + 2–5 mEq/L KCl + 0.1% dextrose	Low sodium (117 mEq/L) allows removal of sodium load in trisodium citrate (Na = 420 mmol/L, citrate 140 mmol/L), varying amounts of bicarbonate added to provide extra base for correction of acidosis and compensate for bicarbonate loss across filter, no calcium allows removal of citrate-calcium chelate.
Predilution fluid composition	0.9% saline	Isotonic for diluting blood
Postfilter fluid composition	0.9% saline, 0.45% saline + 75 mEq/L of sodium bicarbonate, sterile water + 150 mEq/L of sodium bicarbonate	Normal saline adequate to maintain normal sodium levels. Additional bicarbonate added to solutions depending on acid–base status and bicarbonate requirement
Monitoring	Serum electrolytes and blood gases Postfilter ionized calcium Peripheral ionized calcium UF/plasma urea nitrogen Fluid balance	Initially every 12 hours then every 24 hours: Adjust solutions composition. Postfilter ionized calcium every 12 hours: Adjust citrate flow rates. Peripheral ionized calcium every 12 hours: Adjust $CaCl_2$ drip. UF/plasma urea nitrogen every 12 hours: Assess filter efficacy and allow preemptive change in filter if ratio <0.6. Fluid balance: Set goals every 24 hours and monitor and adjust fluid balance by varying amount of replacement solution hourly to achieve target balance desired.

CVVHDF, continuous venovenous hemodiafiltration; UF, ultrafiltration.

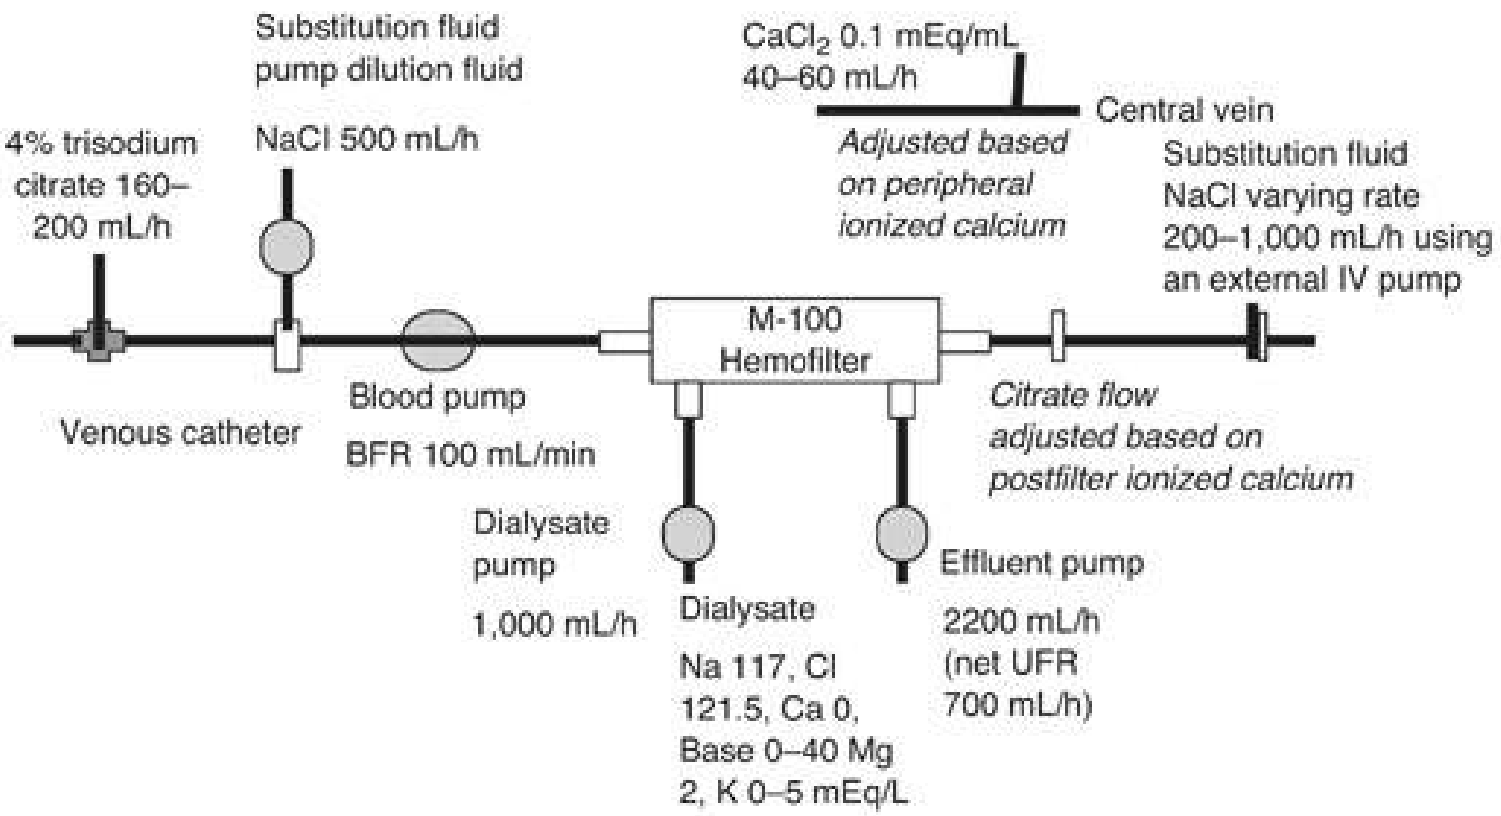

FIGURE 10.2 Continuous renal replacement therapy (CRRT) circuit using regional citrate anticoagulation with the Gambro PRISMA machine and M-100 filter.

Other methods for anticoagulation in CRRT include regional heparin/protamine (37,74), heparinoids (75), thrombin antagonists [hirudin (76–78) and argatroban (79–83)], and platelet-inhibiting agents (prostacyclin and nafamostat) (84–91). Each of these techniques has unique advantages and disadvantages, and anticoagulation for CRRT should be adapted to the patient's characteristics and institution's experience. Doses, advantages, and disadvantages of these agents are summarized in **TABLE 10.2**.

CONTINUOUS RENAL REPLACEMENT THERAPY SOLUTIONS

All CRRT other than SCUF and CVVHD require the use of replacement fluids to compensate for the ultrafiltrate removed. HD and HDF techniques in addition use a dialysate. The composition of these solutions can be varied extensively to achieve specific metabolic goals (92). Commercially prepared sterile fluids are now available as premixed dialysis and replacement solutions for CRRT. Fluid can also be manufactured at the level of pharmacy/hospital, but manufacturing or customization is labor intensive, more expensive, have short shelf life, and is prone for human error (93,94).

TABLE 10.4 shows the composition of the most commonly used solutions for replacement and dialysate.

TABLE 10.4 Continuous Renal Replacement Therapy Solutions

	1.5% Dianeal	Hemosol AG 4D	Hemosol LG 4D	Baxter	UCSD Citrate	PrismaSate BK0/3.5	PrismaSate BK2/0
Na (mEq/L)	132	140	140	140	117	140	140
K (mEq/L)	–	4	4	2	4	0	2
Cl (mEq/L)	96	119	109.5	117	121	109.5	108
Lactate (mEq/L)	35	–	40	30	–	3	3
Acetate (mEq/L)	–	30	–	–	–	–	–
Bicarb (mEq/L)	–	–	–	–	Variable	32	32
Ca (mEq/L)	3.5	3.5	4	3.5	–	3.5	0
Mg (mEq/L)	1.5	1.5	1.5	1.5	1.5	1	1
Dextrose (g/dL)	1.5	0.8	0.11	0.1–2.5	0.1–0.5	0	0.11

UCSD, University of California, San Diego.

A consequence of all CRRT methods is the ongoing loss of bicarbonate and electrolytes across the filter generally equivalent to the plasma concentration of these solutes times the total effluent (UF and dialysate) flow rates (9). Bicarbonate losses can be replaced by addition of sodium bicarbonate or other base (e.g., lactate, acetate, citrate) to replacement solution administered intravenously, addition of base to the dialysate, or by a combination of these techniques (95). One of the major advantages of CRRT is that the composition of replacement fluid and dialysate can be modified to achieve any specific change in plasma composition.

Fluid Composition

Alkali

The choice of alkali depends on the clinical situation and availability. Both lactate and bicarbonate can correct metabolic acidosis as lactate is metabolized to bicarbonate by the liver.

Lactate-Based Solutions

Available lactate concentrations range from 28 to 49 mM. When base solutions other than bicarbonate are used, replacement of buffer stores depends on the metabolic rate for conversion to bicarbonate. In the absence of lactic acidosis, endogenous lactate clearance does not appear to be impaired. However, the filter clearance of lactate accounts for only 2.4% of overall lactate clearance (96). Lactate levels are generally higher with lactate solutions and might confuse the interpretation of blood lactate levels. Whether this hyperlactatemia is associated with morbidity is not clear. Potential concerns are hemodynamic compromise (96) or increased urea generation (97). Additionally, the ability to convert lactate to bicarbonate might be impaired in the setting of hypotension and multiorgan failure and could contribute to the deleterious effects of lactate accumulation (97). Hyperlactatemia can become pronounced during high-volume CRRT. “Lactate intolerance” is arbitrarily defined as a 5 mmol/L or more rise in serum lactate levels during CRRT.

Bicarbonate-Based Solutions

Bicarbonate concentrations are typically 22 to 35 mM and are preferred in patients with lactic acidosis and/or liver failure (98). One practical issue with the use of bicarbonate-based solutions is that it is difficult to store premixed bicarbonate solutions. A study by Kanagasundaram et al. (99) concluded that

sustained bacterial contamination of bicarbonate-based CVVHD is common and could relate to the completeness of dialysate circuit change. Another factor to consider is that premixed solution containing calcium and bicarbonate shows evidence of microprecipitation of calcium carbonate crystals. Although some centers have developed nonsterile bicarbonate solution for CRRT, this practice is not recommended (99,100).

The combination of citrate anticoagulation and bicarbonate-containing solutions has been used effectively to manage complex acid–base disorders (43–59). At our center in UCSD, the hospital pharmacy prepared customized solutions for CRRT. Standard formulation at UCSD uses 1 L of 0.45% saline, to which is added 40 mL of 23% saline (yielding a sodium concentration of 117 mEq/L and a chloride concentration of 121.5 mEq/L), 1.5 mEq/L of magnesium, and 0 to 5 mEq/L of potassium. We use a dialysate dextrose concentration of 0.1% (43). In some circumstances, we add bicarbonate to the dialysate, substituting the 23% NaCl with $NaHCO_3$ so that the final concentration of sodium is 117 mEq/L. More recently, secondary to nationwide drug shortages of bicarbonate, we switched to commercial calcium dialysate and replacement fluids and have not found any difference in filter performance.

ADQI recommends that lactate is an effective buffer in most CRRT patients. Bicarbonate is preferred in patients with lactic acidosis and/or liver failure and in high-volume H. When citrate is used as anticoagulant, no other buffer should be administered, but monitoring of pH is required.

Electrolytes

The replacement fluid and/or dialysate should contain electrolytes in concentrations aiming for physiologic levels and taking into account preexisting deficits or excesses and all inputs and losses. Customized solutions will be required in patients with some electrolyte imbalances, but these fluids should be used with caution, as accidental alteration is infusion rates can lead to significant electrolyte derangements. Therefore, frequent monitoring of serum electrolytes is imperative during CRRT. Most commercially available solutions do not contain phosphate but prolonged use of CRRT is associated with hypophosphatemia. Several methods are used to manage this problem including enteral feed with high phosphorus concentrations, intravenous supplementation with sodium phosphate (101). Recently, the U.S. Food and Drug Administration (FDA) approved Phoxillum Renal Replacement Solutions (BK4/2.5 and B22K4/0) as a replacement solution for CRRT to correct electrolyte and acid–base imbalances. The drug can also be used in the case of drug poisoning when CRRT is used to remove dialyzable substances. This product from Baxter is the only FDA-approved premixed solution including phosphate in a 5-L bag. (See more at http://www.pharmacytimes.com/product-news/fda-approves-new-solution-for-continuous-renal-replacement-therapy)

MODALITIES OF CONTINUOUS RENAL REPLACEMENT THERAPY—CLINICAL CONSIDERATIONS

Principles of Continuous Renal Replacement Therapy

Solute removal in CRRT can be obtained by convection, diffusion, or both. Each component of the therapy can be precisely controlled, and by use of high-flux membrane filters, removal of middle and high

molecules can be maximized.

Diffusion

Diffusion is movement of solutes across concentration gradient through semipermeable membrane and depends upon

- Concentration gradient (Cs)
- Surface area of membrane (A)
- Thickness of membrane (Mt)
- Diffusion coefficient of the solute (D)
- Temperature of solution (T)

The gradient is affected by the dialysate infusion rate (Q_d) and blood-flow rate (Q_b). The dialysate runs countercurrent to the blood, so faster Q_b allows for greater gradient. This is the same technique used in IHD, but Q_d are much slower than Q_b so there is complete saturation of the dialysate. Therefore, the Q_d is the rate-limiting factor for solute removal, but it allows for enhanced clearance. The smaller the size/weight of the solute and the greater the gradient, the more efficiently solute clearance occurs.

Diffusion Flux of a Given Solute $Sd = (Cs / Mt)\ D \cdot T \cdot A$

Convection

Convective techniques (UF and H) rely on what is known as "solvent drag," whereby dissolved molecules are dragged along with ultrafiltrated plasma water across a semipermeable membrane driven by a transmembrane pressure gradient (TMP) in response to a hydrostatic or osmotic force. The process of forcing a liquid against a membrane is called ultrafiltration; the fluid collected after it passes through a membrane is the ultrafiltrate. This can be described by the following equation (**EQUATION 10.1**):

$$Uf = Kf \cdot TMP \qquad (10.1)$$

Kf = coefficient of hydraulic permeability

where Pb is hydrostatic pressure of blood, Puf is the hydrostatic pressure of the ultrafiltrate or dialysate, and π is the oncotic pressure of plasma proteins (**EQUATION 10.2**).

$$TMP = (Pb - Puf) - \pi \qquad (10.2)$$

The convective clearance (Cx) of a solute x will therefore depend on the following (**EQUATION 10.3**):

$$Cx = Jf \cdot Cs \cdot S \qquad (10.3)$$

- Jf = amount of ultrafiltration
- Cs = concentration of solute in plasma water
- S = sieving characteristics of membrane

Sieving coefficient (S) is the ratio of solute concentration in filtrate to solute concentration in plasma and is regulated by the reflection coefficient of the membrane ($S = 1 - \sigma$). A solute with an SC of 1 means that it can pass freely through a filter; if the SC is 0, then a solute cannot pass through the filter at all. Protein-bound solutes or those that exceed the molecular weight cutoff (generally 20,000 Da for

polysulfone and polyacrylonitrile membranes) have sieving coefficients less than 1.

Solute Clearances

In all forms of CRRT, the "effluent" from the filter represents the end product of the filtration process and comprises the ultrafiltrate in CVVH, the spent dialysate in CVVHD, and the combination of the ultrafiltrate and spent dialysate in CVVHDF. Consequently, filter clearance (UF × V/P) for most CRRT circuits is equal to Qef (the effluent flow rate = V) × SC (UF/P) for most small and middle molecules and is directly proportional to the amount of effluent volume. Blood-side clearances often do not match the filter clearances, as membrane adsorption modifies the amount of solute in the ultrafiltrate. Consequently, for some solutes [such as tumor necrosis factor-α (TNF-α)] that are adsorbed by membranes, SC can be low, but overall blood clearance can be greater than filter clearance.

CRRT vary in their ability to remove small and middle molecules. For small-sized solutes (e.g., urea nitrogen, creatinine, phosphates), filter clearances were directly proportional to the effluent volume and did not vary significantly with convective or diffusive removal across a spectrum of effluent volumes (0.5 to 4.5 L/h). In contrast, β_2-microglobulin removal was influenced by the membrane type and the amount of convective clearance (102).

Clearance of molecules in CRRT circuits also depends on the site of replacement solution administration either pre- or postfilter.

In postdilution CVVH (purely convective therapy), primary determinants of solute clearances are ultrafiltration rate (Qef), sieving coefficient of membrane (S). Therefore, clearance in milliliters per minute (K) equals to product of ultrafiltration rate and sieving coefficient (**EQUATION 10.4**).

$$K = Qef \cdot S \qquad (10.4)$$

For small molecules, as S approaches unity, clearance equals the UF rate in postdilution.

Removal of ultrafiltrate across the filter concentrates the cellular elements and proteins in the blood emerging from the filter and is directly proportional to the ratio of ultrafiltrate to plasma flow rate (filtration fraction = FF). Plasma flow rate in turn depends upon blood flow (Qb) and patient hematocrit (Hct). Therefore, in postdilution CVVH (**EQUATION 10.5**):

$$FF = Qef / Qb\,(1 - Hct) \qquad (10.5)$$

Previous studies have demonstrated that FF >20% contributes to reduced filter performance and filter clotting. Consequently, if UF rates are increased, the blood-flow rate should be increased to maintain FF less than 20%. As higher blood flows are usually difficult to reach with the temporary dialysis catheters and poor hemodynamics among these patients, achieving higher doses are difficult to do in postdilution mode.

Predilution fluid replacement reduces the FF and reduces the solute concentration in the blood entering the filter. Thus, it is useful in preventing clotting of the extracorporeal circuit and to extend filter life. The effective small-solute clearance (K) for predilutional H is equal to Qef × (Qb/[Qb + Qr]), where Qb and Qr represent blood and replacement fluid rates. Clearance in predilution H is less than in postdilutional H for the same Qef. However, because of the dilution of blood entering the filter, much higher filtration fractions (larger Qef and Qr) are feasible in predilutional H (103).

In convective removal, the only way to increase solute clearances is to increase the amount of

ultrafiltrate generated and consequently increase the volume of replacement fluid given. A study by Brunet et al. (104) showed that convection is effective than diffusion in removing middle molecular weight solutes during CRRT and that high convective fluxes should be applied if the goal is to remove middle molecules more efficiently.

CONTINUOUS RENAL REPLACEMENT THERAPY—APPLICATIONS

Fluid Management in Continuous Renal Replacement Therapy

Volume management is an integral component of the care of critically ill patients to maintain hemodynamic stability and optimize organ function. The dynamic nature of critical illness often necessitates volume resuscitation and contributes to fluid overload particularly in the presence of altered renal function. Diuretics are commonly used as an initial therapy to increase urine output; however, they have limited effectiveness due to underlying AKI and other factors contributing to diuretic resistance. In this setting, successful volume management with CRRT depends on an accurate assessment of fluid status, an adequate comprehension of the principles of fluid management with UF, and clear treatment goals. In the Beginning and Ending Supportive Therapy (BEST) for the Kidney study (105), fluid overload was present in 36.7%, while oliguria and anuria was present in 70.2% of patients. Fluid overload increases complications associated with acute lung injury, acute respiratory distress syndrome (106–108), tissue healing, gut, and cerebral edema (109). Emerging data overwhelmingly suggest that fluid overload is associated with adverse outcomes (110–112).

CRRT techniques have three inherent characteristics that make them highly effective and versatile methods for fluid control (113) (a) the use of highly permeable membranes, (b) the infusion of various replacement solutions, and (c) the continuous nature of the techniques. Adjustments in the UF and replacement fluid rates allow CRRT techniques to serve as fluid regulatory systems that can maintain fluid balance without compromising the system's ability to maintain metabolic balance. A major distinction for these methods is the ability to dissociate solute removal (e.g., sodium) from fluid balance. As an example, by varying the composition of the replacement fluid or dialysate, solute balance can be altered while overall fluid balance can be kept even, negative, or positive (113). Fluid removal in CRRT is achieved by formation of an ultrafiltrate. The UF rate used depends on two factors: the type of technique and the fluid balance requirements of the patient. In convective techniques (CVVH), the UF rate can vary from 0.5 to 12.0 L/h, although most centers use a range of 1.0 to 3.0 L/h. When dialysate is used (CVVHDF), almost all the current machines limit UF rate to a maximum of 2 L/h.

Bouchard and Mehta (114) describe three techniques for achieving fluid balance with CRRT (**TABLE 10.5**). The level 1 technique is to vary the net ultrafiltration rate (Quf) to meet the anticipated fluid balance needs over 8 to 24 hours; the net ultrafiltrate is the difference between the total ultrafiltrate (the plasma water removed) and the total replacement (the fluid given to the patient). As an example, a patient may have a total anticipated fluid intake of 3 L with a desired 1-L net loss over 24 hours; the Quf would be set at −170 mL/h (3 L + 1 L/24 h). This may not be the best technique to use, as there may be unanticipated changes in clinical status and fluid needs, leading to a different net ultrafiltrate that is different from the desired fluid balance. Also, effluent volume and treatment dose will vary, as net Quf

are not steady with this method.

TABLE 10.5 Continuous Renal Replacement Therapy (CRRT) Fluid Balance Techniques

Variable	Level 1	Level 2	Level 3
Intake	Variable	Variable	Variable
Non-CRRT output	Variable	Variable	Variable
Ultrafiltration rate	Variable to achieve fluid balance	Fixed to achieve target effluent volume	Fixed to achieve target effluent volume
Substitution fluid rate	Fixed ≤ Q_{uf}	Postdilution replacement varies to achieve −, zero, or + fluid balance.	Postdilution replacement varies to achieve −, zero, or + fluid balance.
Fluid balance	Achieved by varying Q_{uf}	Achieved by adjusting amount of substitution fluid	Targets the hourly fluid balance to achieve a predefined hemodynamic parameter
Key difference	Output varies to accommodate changes in intake and fluid balance goals.	Output is fixed to achieve desired solute clearance and allow flexibility in accommodating varying intake.	Output is fixed to achieve desired solute clearance and allow flexibility in accommodating varying intake.
Examples	SCUF, CVVHD	CVVH, CVVHDF	CVVH, CVVHDF
Advantages			
Patient factors	Strategy similar to fluid removal in intermittent dialysis	Solute clearance is constant. Allows variation in intake. Individualizes prescription.	Solute clearance is constant. Allows variation in intake. Individualizes prescription.
CRRT factors	Fluid balance calculations can be deferred to longer intervals (every 8–12 h).	Clearance requirements dissociated from fluid balance. Deceases interactions with CRRT pump to adjust UFR. Regimen simplified for caregiver.	Clearance requirements dissociated from fluid balance. Deceases interactions with CRRT pump to adjust UFR. Regimen simplified for caregiver.
Disadvantages			
Patient factors	Patient assumed to be in static state. Similar to ESKD prescription. Intake may fluctuate. Fluid boluses not accounted for. Commonly over- or undershoot. Fluctuations in solute clearance, especially when dependent on convection.	Requires hourly calculations for amount of fluid replacement to be given. Potential for fluid imbalances if balance sheet not used.	Requires hourly calculations for amount of fluid replacement to be given. Potential for fluid imbalances if balance sheet not used. Requires scale be made for hemodynamic parameter targets.
CRRT factors	Requires frequent interactions with CRRT pump to adjust UFR. Underutilizes CRRT for fluid removal only.	Requires use of external pump to achieve fluid regulation.	Requires use of external pump to achieve fluid regulation.

SCUF, slow continuous ultrafiltration; CVVHD, continuous venovenous hemodialysis; CVVH, continuous venovenous hemofiltration; CVVHDF, continuous venovenous hemodiafiltration; UFR, ultrafiltration rate; ESKD, end-stage kidney disease.
Data from Bouchard J, Mehta RL. Volume management in continuous renal replacement therapy. *Semin Dial* 2009;22(2):146–150.

The level 2 method of maintaining fluid balance is to vary the amount of postdilution replacement fluid administered; the net ultrafiltrate stays the same and exceeds the anticipated hourly intake. With this technique, the postdilution fluid is not given through the CRRT pump but through a separate pump. A patient can be maintained in negative fluid balance by decreasing the amount of postdilution fluid received to be less than the total output, in positive fluid balance by increasing postdilution replacement to be greater than all output, or in even balance by having equal postdilution replacement and total output. This method allows for variation in intake and a predetermined convective clearance, as net ultrafiltrate does not vary as in the first technique.

The level 3 technique is similar to the second, but fluid balance is tailored to achieve a targeted

hemodynamic parameter every hour. Predefined targets are set for parameters, such as central venous pressure (CVP), MAP, or pulmonary arterial wedge pressure, and scales are prescribed to achieve these targets. For example, if the CVP is to be maintained between 8 and 12 mm Hg, when this is achieved, the scale would determine that net fluid balance be set to zero. If the CVP is above target, the scale would call for fluid removal; if CVP is below target, then fluid would be added. This technique allows for greater flexibility and maximally utilizes CRRT as a fluid regulatory device.

DRUG CLEARANCE AND DOSING IN CONTINUOUS RENAL REPLACEMENT THERAPY

Some drugs are removed significantly by CRRTs, and a substitutional dose is required to prevent underdosing of the substance. Doses used in IHD cannot be directly applied to these patients, and drug pharmacokinetics is different than those in patients with normal renal function. Dose amount and frequency can be calculated from knowledge of the basic pharmacokinetic factors relating to distribution and elimination of a drug within the body, along with knowledge of the desired drug concentration in plasma.

A fundamental concept in pharmacokinetics is drug clearance, that is, elimination of drugs from the body, analogous to the concept of creatinine clearance. Clearance can conceptually be considered to be a function of both distribution and elimination. In the simplest pharmacokinetic model,

V is the volume of distribution, and K is the elimination constant (**EQUATION 10.6**). V is the volume of fluid in which the dose is initially diluted, and thus, the higher the V, the lower the initial concentration. K is the elimination constant, which is inversely proportional to the half-life, the period of time that must elapse to reach a 50% decrease in plasma concentration. When the half-life is short, K is high and plasma concentrations decline rapidly. Thus, both a high V and a high K result in relatively low plasma concentrations and a high clearance. It is possible to predict elimination of a given drug by CRRT from the knowledge of the relative contributions of the various mechanisms of clearance to total clearances (**EQUATION 10.7**).

$$\text{Clearance} = V \cdot K \qquad (10.6)$$

$$Cl\,(T) = Cl\,(R) + Cl\,(HB) + Cl\,(EC) \qquad (10.7)$$

where Cl (T) is total clearance, Cl (R) is renal clearance, Cl (HB) is hepatobiliary clearance, and Cl (EC) is extracorporeal clearance via CRRT. If there is high nonrenal clearance via hepatobiliary route, then extracorporeal clearance is usually nonsignificant. The same applies to situations where renal clearances remain important despite need of CRRT. **FIGURE 10.3** shows drug metabolism in its simplest form.

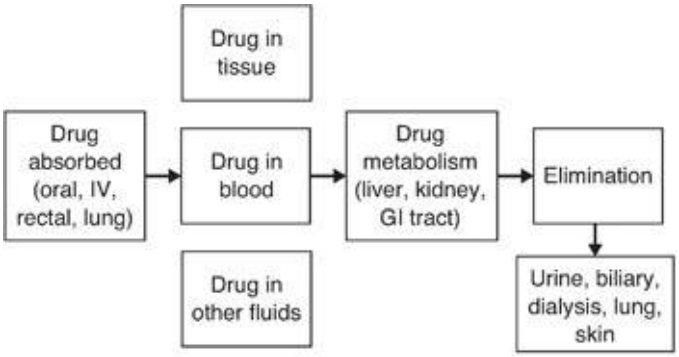

FIGURE 10.3 Drug metabolism in body. For any given drug and dose, the plasma concentration of the drug will rise and fall according to the rates of three processes: absorption, distribution, and elimination.

Depending on the mode of CRRT, the combined dialysate and ultrafiltrate flow rates have been recommended as a rough estimate of creatinine clearance. During CVVH, solute elimination Cl (H) is through convection and depends upon ultrafiltration rate (Qf) and sieving coefficient (S), whereas CVVHD utilizes diffusion gradients through countercurrent dialysate flow, and drug removal depends on dialysate and blood-flow rates. CVVHDF utilizes both diffusive and convective solute transports and can require a large amount of fluid to replace losses during UF.

The pharmacokinetics of drug removal in critically ill patients receiving CRRT is very complex, with multiple variables affecting clearance and both patient- and CRRT technique–related factors should be considered for drug dosing in CRRT. In general, factors which affects drug dosing are bioavailability, volume of distribution, protein binding, lipid solubility, drug metabolism, loading and maintenance dose, and dialysis-related factors like molecular weight of drug, type of dialyzer, mode of CRRT, and various flow rates. These variables make generalized dosing recommendations difficult. Drug–protein complexes have a larger molecular weight; therefore, antibiotics/drugs with low protein binding capacity in serum are removed by CRRT more readily. Similarly, drugs that penetrate and bind to tissues have a larger volume of distribution, reducing the quantity removed during CRRT. Sepsis itself increases the volume of distribution, extends drug half-life, and alters the protein binding capacity of many antimicrobials. CRRT mechanical factors may also affect drug clearance. Increasing the blood or dialysate flow rate can change the transmembrane pressure and increase drug clearance (115). The dialysate concentration may also affect drug removal in H. Lastly, the membrane pore size is directly proportional to the degree of drug removal by CRRT, often expressed as a sieving coefficient. Generally, biosynthetic membranes have larger pores, which result in higher drug clearance rates especially for drugs of middle molecular weight size like vancomycin (MW = 1,450 Da) or daptomycin (MW = 1,620 Da) (116,117). Other CRRT technique-related factors that influence drug clearance are placement of replacement fluid (pre- vs. postfilter) and filter age. Prefilter replacement fluid dilutes the blood that is presented to hemodialyzer and decreases the amount of drug that is cleared. Uchino et al. (118) demonstrated that vancomycin clearance was lowest when all fluids were given prefilter and almost 25% higher when fluids were given postfilter. Similarly, other factor that is less studied is hemodiafilter age (119). The sieving coefficient for a drug is highest at commencement of CRRT and declines with time because of building up of protein layer on membrane and decline in number unclotted hollow fibers. Mode of CRRT also impacts drug clearance, particularly at larger dialysate/ultrafiltrate flow rates, and with higher molecular weight drugs. The drug clearance at any given dialysate/ultrafiltrate flow rate is:

CVVH > CVVHDF > CVVHD

These patient, drug, and mechanical variables significantly diminish the utility of routine pharmacokinetic calculations for determining antimicrobial dosing during CRRT.

TABLE 10.6 summarizes various factors effecting drug clearances; **TABLE 10.7** summarizes antibiotic dosing in CRRT.

TABLE 10.6 Factors Affecting Drug Clearance in Continuous Renal Replacement Therapy

Drug- and Patient-Related	Dialysis-Related
Bioavailability	Molecular weight of drug
Volume of distribution	Type of dialyzer
Protein binding and lipid solubility	Mode of CRRT
Drug metabolism	Flow rates
Elimination route	
Loading and maintenance dose

TABLE 10.7

Antibiotic Dosing on Continuous Renal Replacement Therapy

Drug	CVVH	CVVHD/CVVHDF
Amphotericin B formulation		
Deoxycholate	0.4–1.0 mg/kg q24h	0.4–1.0 mg/kg q24h
Lipid complex	3–5 mg/kg q24h	3–5 mg/kg q24h
Liposomal	3–5 mg/kg q24h	3–5 mg/kg q24h
Acyclovir	5–7.5 mg/kg q24h	5–7.5 mg/kg q24h
Ampicillin-sulbactam	3 g q12h	3 g q8h
Amikacin	10 mg/kg load and then 7.5 mg/kg q24–48 h	
Aztreonam	1–2 g q12h	2 g q12h
Cefazolin	1–2 g q12h	2 g q12h
Cefepime	1–2 g q12h	2 g q12h
Cefotaxime	1–2 g q12h	2 g q12h
Ceftazidime	1–2 g q12h	2 g q12h
Ceftriaxone	2 g q12–24h	2 g q12–24h
Cefuroxime	1.5 g q8–12h	1.5 g q8h
Clindamycin	600–900 mg q8h	600–900 mg q8h
Ciprofloxacin	200 mg q12h	200–400 mg q12h
Colistin	2.5 mg/kg q48h	2.5 mg/kg q48h
Daptomycin	4 or 6 mg/kg q48h	4 or 6 mg/kg q48h
Fluconazole	200–400 mg q24h	400–800 mg q24h
Imipenem-cilastatin	250 mg q6h or 500 mg q8h	250 mg q6h, 500 mg q8h, or 500 mg q6h
Levofloxacin	250 mg q24h	250 mg q24h
Linezolid	600 mg q12h	600 mg q12h
Meropenem	1 g q12h	1 g q12h
Moxifloxacin	400 mg q24h	400 mg q24h
Nafcillin or oxacillin	2 g q4–6h	2 g q4–6h
Piperacillin-tazobactam	2.25 g q6h	2.25–3.375 g q6h
Ticarcillin-clavulanate	2 g q6–8h	3.1 g q6h
TMP/SMX	2.5 mg/kg TMP q8h (consider higher doses with CVVHDF)	
Vancomycin	1 g q48h	1 g q24h
Voriconazole	4 mg/kg PO q12h	4 mg/kg PO q12h

All dosages are administered intravenously, unless otherwise indicated. The recommendations assume an ultrafiltration rate of 1 L/h, a dialysate flow rate of 1 L/h, and no residual renal function. CVVH, continuous venovenous hemofiltration; CVVHD, continuous venovenous hemodialysis; CVVHDF, continuous venovenous hemodiafiltration; TMP/SMX, trimethoprim/sulfamethoxazole.

MOBILIZATION DURING CONTINUOUS RENAL REPLACEMENT THERAPY

Research has shown that early mobilization is a safe and effective practice in the ICU, although there are many barriers making mobilization difficult. Despite studies demonstrating benefit, patients with femoral vascular catheters placed for CRRT are frequently restricted from mobilization. The mobility barriers for patients undergoing CRRT include risk to the HD catheter that is accessed and attached to an extracorporeal circuit at all times, along with the potential to disrupt flow, leading to clotting of the circuit and interruption of therapy. In addition, other barriers to consider include disease severity, cognitive state and ability to follow commands, adequate staff to assist, and equipment that is needed for the mobilization. Wang et al. (120) studied mobilization of 33 patients in ICU undergoing CRRT with different vascular access. In their study, patients underwent one of three levels of mobilization intervention as appropriate: (a) passive bed exercises, (b) sitting on the bed edge, or (c) standing and/or marching. They found that mobilization during RRT via a vascular catheter in patients who are critically ill is safe and no episodes of filter occlusion or failure occurred during any of the interventions. Also, catheter dislodgment, hematoma, bleeding, and nursing workloads between the intervention shift and the following shift were no different from nonintervention group. Brownback et al. (121) also reported successful mobilization of patient on CRRT. However, large multicenter studies are warranted to confirm the benefits of mobilization during CRRT.

COMPLICATIONS DURING CONTINUOUS RENAL REPLACEMENT THERAPY

CRRT is commonly used in critically ill patients with AKI. Clinicians must be aware of the complications associated with CRRT, particularly at higher doses. **TABLE 10.8** summarizes the common complications associated with the use of CRRT.

TABLE 10.8 Complications during Continuous Renal Replacement Therapy

Vascular access	Bleeding
	Thrombosis
	Hemothorax
	Pneumothorax
	Hematoma
	AV fistula
	Aneurysm
	Infection
Extracorporeal	Hypothermia
	Air embolism
	Reduced filter life
	Anaphylaxis and immune activation
Electrolyte and acid–base disturbances	Hypophosphatemia
	Hypomagnesemia
	Hypocalcemia
	Hypokalemia
	Hypo- and hypernatremia
	Metabolic acidosis
	Metabolic alkalosis
Hematologic	HIT
	Hemolysis
Nutritional losses	Loss of amino acids/proteins, vitamins, and trace minerals

AV, arteriovenous; HIT, heparin-induced thrombocytopenia.

Vascular Access

Complications of vascular access, including infection and vascular injury, are a common concern with CRRT. These complications are reported to occur in 5% to 19% of patients, depending on the access site selected. Arterial puncture, hematoma, hemothorax, and pneumothorax are the most common complications reported. AV fistulas, aneurysms, thrombus formation, pericardial tamponade, air embolism due to increased negative pressure, and retroperitoneal hemorrhage have also been described. Another concern is catheter-related infection, and all measures should be taken to reduce it. These include stringent sterile placement technique, catheter care, avoidance of the femoral site, use of antibiotic coated catheters, and use of antimicrobial locking solutions. Lastly, clinician should also keep in mind recirculation of blood through double-lumen catheters, which may affect delivered dose by hemoconcentrating the blood and premature filter clotting.

Extracorporeal Circuit

Hypothermia is common with CRRT. This occurs because replacement fluids and dialysate are not warmed leading to cooling of core temperature secondary to extracorporeal radiant heat exchange which occurs in 5% to 50% of patients. This may result in heat loss of 750 kcal/d, thereby increasing the patient's daily energy requirement. Thermal loss may also mask fever, delaying recognition of infection, thereby delaying administration of antibiotics. The newer CRRT machines have warming devices to prevent heat loss. Extracorporeal circuit/filter membrane may activate inflammatory-immune mediators including various cytokines which may increase protein breakdown and energy expenditure. Rarely, anaphylactoid reactions due to bradykinin activation, particularly with use of angiotensin-converting enzyme (ACE) inhibitors have been described.

Hematologic

CRRT needs either systemic or regional anticoagulation to prevent filter clotting. These critically ill patients have multiple factors which make them prone for increased risk of bleeding, particularly with heparin which is used as systemic anticoagulant. The use of heparin can also lead to HIT. CRRT also reduces number of platelets and impairs platelet aggregation. Some hemolysis also occurs because of shearing forces through the circuit or roller pump. Other causes of hemolysis include electrolyte abnormalities—hypophosphatemia, hyponatremia, and hypokalemia.

Electrolytes and Acid–Base Disturbances

Hypophosphatemia and hypomagnesemia are the commonest electrolyte disturbances associated with CRRT. Phosphate clearance is significantly high due to larger filter pore size and ongoing intercompartmental mass transfer. Hypophosphatemia is associated with higher doses and if severe enough can lead to decreases in cardiac output and blood pressure, rhabdomyolysis, respiratory muscle weakness, and granulocyte dysfunction with increased infection rates. Commercially available replacement fluids do not typically contain phosphate or magnesium, so these electrolytes need to be replaced separately. Sodium and acid–base disturbances can also occur during CRRT and should be monitored 6 to 8 hourly.

Nutritional Losses

Most critically ill patients on CRRT are hypercatabolic and in addition lose nutrients across dialysis membrane. Several factors including insulin resistance, release of inflammatory mediators, infection, metabolic acidosis, and so forth affects protein breakdown. Amino acid loss in patients on CRRT is estimated to be 10 to 20 g/d depending on UF volume, and patients should receive increased daily protein or amino acid intake to about 1.5 to 2.5 g/kg/d; of note, carbohydrates should be given at 5 to 7 g/kg/d and lipids at 1.2 to 1.5 g/kg/d (122–124). Larger molecules like albumin are also lost particularly with increased filter age. Water-soluble vitamins, micronutrients, and trace elements are also lost during CRRT and should be replaced during prolonged therapy.

THERAPEUTIC GOALS, INTENSITY, AND OUTCOMES OF CONTINUOUS RENAL REPLACEMENT THERAPY

The CRRT prescription ideally is targeted to match the therapeutic potential of the technique to specific goals for the patient. The broad goals for treating AKI with dialysis are to (a) maintain fluid and electrolyte, acid–base, and solute homeostasis; (b) prevent further insults to the kidney; (c) promote healing and renal recovery; and (d) permit other support measures (e.g., nutrition) to proceed without limitation. CRRT techniques differ in their operational characteristics and their ability to provide renal support, and these differences should be considered in the dialysis decision. For instance, CRRT techniques can be successfully utilized for fluid regulation, selective replacement of specific electrolytes, for example, bicarbonate, without the addition of sodium or fluid, or to add substances to the blood.

Dosing and intensity of CRRT are generally defined in terms of solute clearance and is traditionally assessed by measuring clearance of urea. For a small uncharged molecule such as urea, clearance during

continuous H is essentially equal to the UF rate because the filter membrane negligibly impedes the passage of urea. Thus, in the simplest way, effluent volume (derived from blood-based kinetics) is thought to represent clearance and is used to prescribe and measure dose in CRRT. This would require that filter permeability stays the same over time; filter permeability is equal to effluent fluid urea nitrogen (FUN)/blood urea nitrogen (BUN), which should equal to one.

Most studies considered the prescribed dose as the effluent rate represented by milliliter per kilogram per hour and reported this volume as a surrogate of solute removal. Because filter fouling can reduce the efficacy of solute clearance, the actual delivered dose may be substantially lower than the observed effluent rate. Claure-Del Granado et al. (125) in their study concluded that effluent volume significantly overestimates delivered dose of small solutes in CRRT. Much of this variation in dose may be accounted for by the use of standard doses of CRRT unadjusted for weight, and it is far from clear whether estimates of ideal body weight, premorbid weight, "dry" weight, or actual body weight should be used (126,127). This greatly confounds the interpretation of observational data on CRRT dose since weight is likely to have a complex causal relationship with outcome.

To assess adequacy of CRRT, solute clearance should be measured rather than estimated by the effluent volume. Prescribed urea nitrogen clearance (K) in milliliter per minute can be calculated by effluent rate from following equation (**EQUATION 10.8**):

$$K = Q_d + Q_{uf} \qquad (10.8)$$

where Q_d = dialysate flow rate in milliliter per minute and Quf = total ultrafiltration volume in milliliter per minute which is equal to replacement fluid rate (Q_r) plus net fluid removal rate (Q_{net}). Therefore, prescribed urea nitrogen clearance (K) is (**EQUATION 10.9**):

$$K_{prescribed} = Q_d + Q_r + Q_{net} \quad \text{(effluent volume rate)} \qquad (10.9)$$

Delivered K is derived from the ratio of mass removal rate to blood concentration. This is based on the principle that the effluent represents the end product of filtration and compromises the sum of the net fluid removal rate (Q_{net}), the spent dialysate (Q_d), and the replacement fluid rate (Q_r) in combined therapies like CVVHDF. Because urea nitrogen is a small molecular solute, the ratio of the concentration of effluent FUN to BUN is generally 1. Clearance is then (**EQUATION 10.10**):

$$K_{delivered} = \frac{FUN\ (mg/dL)}{BUN\ (mg/dL)} \times \text{effluent volume rate} \qquad (10.10)$$

Various trials have assessed relationship between intensity of CRRT and outcomes of AKI. In the first of these, Ronco et al. randomly assigned 425 critically ill patients with AKI treated using continuous venovenous hemofiltration(CVVHF) at a single center to ultrafiltration rates of 20, 35, or 45 mL/kg/h (128). Survival 15 days after discontinuation of CRRT was significantly better in the highest and intermediate dose arms in comparison with the lowest dose arm (58% and 57% vs. 41%, respectively; $p < 0.001$). On the other hand, in contrast to above study and Saudan et al. study (129), two studies (130,131) that included 200 and 106 patients, respectively, failed to demonstrate any beneficial effects of increased CRRT intensity on patient survival or renal recovery. Disparity in these results and consequent

uncertainty about the optimum dosing of CRRT in the ICU led to the initiation of the Acute Renal Failure Trial Network (ATN) and Randomized Evaluation of Normal versus Augmented Level Replacement Therapy (RENAL) studies. The Veterans Affairs/National Institutes of Health Acute Renal Failure Trial Network (ARFTN) (132) performed a large, multicenter study comparing standard-dose CVVHDF of 20 mL/kg/h to high-intensity CVVHDF of 35 mL/kg/h in critically ill AKI patients; it demonstrated no significant difference in 60-day all-cause mortality, rate of recovery of renal function, and duration of RRT. The Randomized Evaluation of Normal versus Augmented Level (RENAL) Renal Replacement Therapy Study (133) was another large, multicenter study comparing CVVHDF effluent flow of 40 mL/kg/h to 25 mL/kg/h to see if there was a difference in 90-day mortality and continued need for RRT in ICU patients with AKI; there was no significant difference in either outcome between the two groups. The ATN and RENAL studies have now established an upper limit of intensity for CRRT, but CRRT dose should be prescribed on the basis of patient body weight to the established effluent flow rate target of 20 to 25 mL/kg of body weight per hour. DOse REsponse Multicentre International collaborative initiative (DO-RE-MI) study (126) was sought to evaluate the relationship between RRT dose and outcome. This was a prospective multicenter observational study in 30 ICUs in eight countries from June 2005 to December 2007. Dose was categorized into more intensive [CRRT ≥35 mL/kg/h, intermittent renal replacement therapy (IRRT) ≥6 sessions per week] or less intensive (CRRT <35 mL/kg/h, IRRT <6 sessions per week). Study concluded that no evidence for a survival benefit afforded by higher dose RRT and actual delivered dose of RRT in AKI patients is frequently smaller than the prescribed dose. Recently, in a single-center, prospective, randomized controlled study (CONVINT), Schefold et al. (134) compared effect of two major RRT strategies (IHD and CVVH) on mortality and renal-related outcome measures. They concluded that intermittent and continuous RRTs may be considered equivalent approaches for critically ill patients with dialysis-dependent AKI.

Patient outcomes after starting CRRT are influenced greatly by underlying disease and comorbidities and indication for initiation, among other clinical criteria. In 2013, Schneider et al. (135) conducted a systematic review and meta-analysis of the literature at the time to analyze data on dialysis dependence among critically ill survivors of an episode of AKI that required acute RRT; patients who initially received IRRT were compared to those who initially received CRRT. Seven RCTs and 16 observational studies were identified. Pooling all studies together demonstrated that IRRT was associated with 17 times increased risk of dialysis dependence compared to CRRT. This increased risk was present even when subgroups were analyzed (RCTs pooled and observational studies pooled separately); however, the increased risk was not statistically significant among RCTs.

Allegretti et al. (136) analyzed a prospective cohort of ICU patients started on CRRT with AKI at a single center to examine renal recovery and in-hospital and postdischarge mortality. They found only 25% of AKI patients were dialysis-free at the end of the follow-up period (4 years of rolling postdischarge data). While in the hospital, mortality was about 61%; after discharge, about 28% of patients died. The total rate of renal recovery was 93% by the end of the study period.

More recently, Wald et al. (137) performed a retrospective cohort study matching 1:1 CRRT and IRRT patients in the ICU with AKI. Only those patients that survived past 90 days after RRT initiation were followed for a median duration of 3 years. It was found that chronic dialysis risk was lower in those patients who received CRRT versus IRRT [hazard ratio 0.75, 95% confidence interval (CI) 0.65 to 0.87].

These results confirmed the findings of Schneider's review and meta-analysis.

Data for children regarding mortality has been gathered from the Prospective Pediatric Continuous Renal Replacement Therapy (ppCRRT). Overall mortality was 42%. Survival was lowest for patients who had fluid overload and electrolyte imbalances at CRRT initiation. Children weighing over 10 kg and those older than 1 year of age had better overall survival.

Other reviews and observational studies have shown worse outcomes seem to be associated with greater burden of illness, multiple organ involvement, and hemodynamic instability. Also, infant survival has been consistent between about 35% and 45%, and infants less than 3 kg have worse survival around 24% compared to infants over 3 kg (41%) as reported by Symons et al. (138) in 2003. **TABLE 10.9** summarizes various factors which can affect dose delivery in CRRT.

TABLE 10.9 Factors Affecting Dose Delivery in Continuous Renal Replacement Therapy

Filter clotting/type of anticoagulation
Decreased sieving coefficient
Secondary membrane formation
Concentration polarization
Changing catabolic rate/urea generation in AKI and critically ill patients
Catheter-related problems (type of catheter, site of placement, hygiene, etc.)
Circuit down-time (routine filter changes)
Time off for diagnostic procedures and therapeutic interventions

AKI, acute kidney injury.

CONTINUOUS RENAL REPLACEMENT THERAPY IN SPECIAL SITUATIONS

Continuous Renal Replacement Therapy in Sepsis and Multisystem Organ Failure

Severe sepsis and septic shock are the primary causes of multiple organ dysfunction syndrome (MODS) and is associated with AKI in 5% to 50% of the patients. The sequence of events leading to septic shock and MODS is initiated by endotoxins or other structural components of microorganisms that cause inappropriate inflammatory response through the cells responsible for immunity and release of inflammatory mediators such as cytokines, active products of complement, arachidonic acid metabolites, nitric oxide, oxygen reactive substances, proteases, and so forth. CRRT is often used with the concept of modulating immune response in sepsis. With the intention of influencing circulating levels of inflammatory mediators, several modifications of CRRT have been developed over the last years. These include high-volume H, high-adsorption H, use of high cut-off (HCO) membranes, and hybrid systems like coupled plasma filtration absorbance.

Small experimental and human clinical studies have suggested that high-volume hemofiltration (HVHF) may improve hemodynamic profile and mortality. High-flux H (Qf = 60 mL/kg/h) performed by Servillo et al. (139) in their study demonstrated interleukin-6 (IL-6) mRNA reduction after 12 hours of treatment and a progressive increase after 24, 48, and 72 hours. In the Impact of High-volume Veno-venous Continuous Hemofiltration in the Early Management of Septic Shock Patients With Acute Renal Failure (IVOIRE) trial (140), there was no evidence that HVHF at 70 mL/kg/h, when compared with

contemporary standard-volume hemofiltration (SVHF) at 35 mL/kg/h, leads to a reduction of 28-day mortality or contributes to early improvements in hemodynamic profile or organ function. HVHF, as applied in this trial, cannot be recommended for treatment of septic shock complicated by AKI. Recently, Clark et al. (141) did systematic review and meta-analysis which included four trials and found that there was no difference in primary outcome of 28-day mortality and secondary end points like recovery of kidney function, lengths of ICU and hospital stays, vasopressor dose reduction, and adverse events. They concluded that presently insufficient evidence exists of a therapeutic benefit for routine use of HVHF for septic AKI.

With respect to immunomodulation, the use of HCO membranes has also been considered. High-permeability hemofilters are characterized by an increased pore size which facilitates the filtration of inflammatory mediators. Pilot trials in septic patients with AKI demonstrated immunomodulation by altering neutrophil phagocytosis as well as mononuclear cell function *ex vivo* (142,143). Atan et al. (144) measured proapoptotic or pronecrotic activity using annexin V-FITC and showed significant drop in proapoptotic activity across the filter for the CVVH-HCO group ($p = 0.043$) but not for the CVVH-Std group.

CONTINUOUS RENAL REPLACEMENT THERAPY IN HEART FAILURE

The cardiorenal interaction is a dynamic, bidirectional interplay wherein acute decompensated heart failure (ADHF) patients often develop AKI and volume overload. Congestive heart failure (CHF) and chronic kidney disease (CKD) share common risk factor like hypertension, atherosclerosis, and diabetes mellitus for the development of each disease. Analysis of Acute Decompensated Heart Failure National Registry (ADHERE) (145) database found that 30% of the patients hospitalized with heart failure have renal insufficiency. Not only is the comorbidity of CKD at hospitalization for heart failure is common but development of AKI with worsening renal function is also common and has significant implications for patient outcomes.

Improved understandings of the pathophysiology of ADHF and renal dysfunction and limitations of conventional therapy have led clinicians to employ different forms of extracorporeal therapy to treat this difficult clinical syndrome. Intermittent isolated UF (IUF), SCUF, and CVVH have been used as modes of extracorporeal therapy to treat ADHF.

Currently, there is minimal data supporting the use of IUF in management of heart failure and is associated with hemodynamic instability (146). In comparison to IUF, studies have demonstrated benefits of SCUF in the treatment of ADHF. UF versus usual care for hospitalized patients with heart failure: The Relief for Acutely Fluid-Overloaded Patients with Decompensated Congestive Heart Failure (RAPID-CHF) trial offered more insight into potential benefits of SCUF over usual care. This trial showed early application of UF for patients with CHF was feasible, well tolerated, and resulted in significant weight loss and fluid removal. Safety and efficacy of SCUF was demonstrated in ultrafiltration versus intravenous diuretics for patients hospitalized for acute decompensated heart failure (UNLOAD) study (147). This study was designed to compare the safety and efficacy of venovenous UF and standard intravenous diuretic therapy for hypervolemic heart failure (HF) patients and concluded that UF safely

produces greater weight and fluid loss than intravenous diuretics, reduces 90-day resource utilization for HF, and is an effective alternative therapy.

IUF and SCUF share a common principle that the extracorporeal blood circuit only changes in the form of fluid removal via a pressure gradient and the fluid removed is isotonic with minimal solute clearance. CVVH, however, not only removes fluid but also provides a means to correct metabolic derangements like acidosis and electrolyte disturbances. Correction of hypocalcemia via CVVH may improve cardiac function in ADHF as cardiac myocytes depends on intracellular calcium for effective function (148). Recent evidence suggests that myocardial depressant factors like IL-8 and anti-monocyte chemoattractant protein-1, which have adverse effect on cardiac function are effectively removed via H (149,150). Despite of above potential benefits, robust clinical data to use CVVH as first-line therapy for ADHF is required.

CONTINUOUS RENAL REPLACEMENT THERAPY IN ACUTE BRAIN INJURY

AKI occurs in 8% to 23% of patients with acute brain injury (ABI) and is an independent predictor of poor outcome in these patients (151,152). The patient with an ABI requiring RRT presents a major problem in that conventional IHD may exacerbate the injury by compromising cerebral perfusion pressure (CPP), either after a reduction in cerebral perfusion or because of increased cerebral edema. To maximize full potential neurologic recovery in patients requiring renal dialytic support, it is important that treatments do not themselves cause further cerebral ischemia. The goal for ABI and increased intracranial pressure (ICP) patients is to maintain CPP >60 mm Hg; this is done by ensuring MAP stays up, as CPP = MAP − ICP. With IHD, intradialytic hypotension is common, leading to decreased MAP and CPP and increased ICP by compensatory cerebral vasodilation. This may result in infarction or secondary injury. Also, dialysis disequilibrium results when solutes are removed quickly causing shifts in intracellular fluid; worsening cerebral edema and further increases in ICP ensue.

CRRT should be the first option in these patients because it is associated with less increase in ICP compared with intermittent therapies (153). Using computed tomography (CT) scans to measure brain density, Ronco et al. (154) showed an increase of brain water content after IHD, whereas no such changes were observed after CRRT. CRRT is also associated with better maintenance of cerebral blood flow autoregulation after traumatic brain injury (155). The disadvantage of CRRT is that anticoagulation may be required, and anticoagulants with systemic effects may provoke intracerebral hemorrhage, either at the site of damage or around the ICP monitoring device. RCA is therefore the preferred mode of anticoagulation in these patients. Also, citrate may provide some neuroprotection by attenuating hypoxic neuronal injury through its effects on astrocytes and oxidative phosphorylation (156). Kidney Disease: Improving Global Outcomes (KDIGO) suggests CRRT, rather than intermittent RRT, for AKI patients with ABI or other causes of increased ICP pressure or generalized brain edema.

SUMMARY

CRRT is now the leading form of RRT for AKI in ICUs worldwide and is widely accepted as the most

appropriate therapy for vasopressor-dependent patients who require RRT for AKI in the ICU. However, practice variation in the application of CRRT remains considerable owing to the absence of clear evidence-based guidelines. Presently, CRRT has many applications and its use can be adapted to fit different situations beyond the classic renal indications. In the near future, technical developments in extracorporeal devices will lead to the creation of multiple organ support therapies, so that comprehensive replacement or at least support can be provided to multiple organs simultaneously. Such machines ideally will be able to automatically detect both "traditional" (urea) and "inflammatory" (cytokines) solutes in plasma of critically ill patients in order to automatically (or semiautomatically) tailor the therapy toward the "perfect blood purification" system (**FIGURE 10.4**).

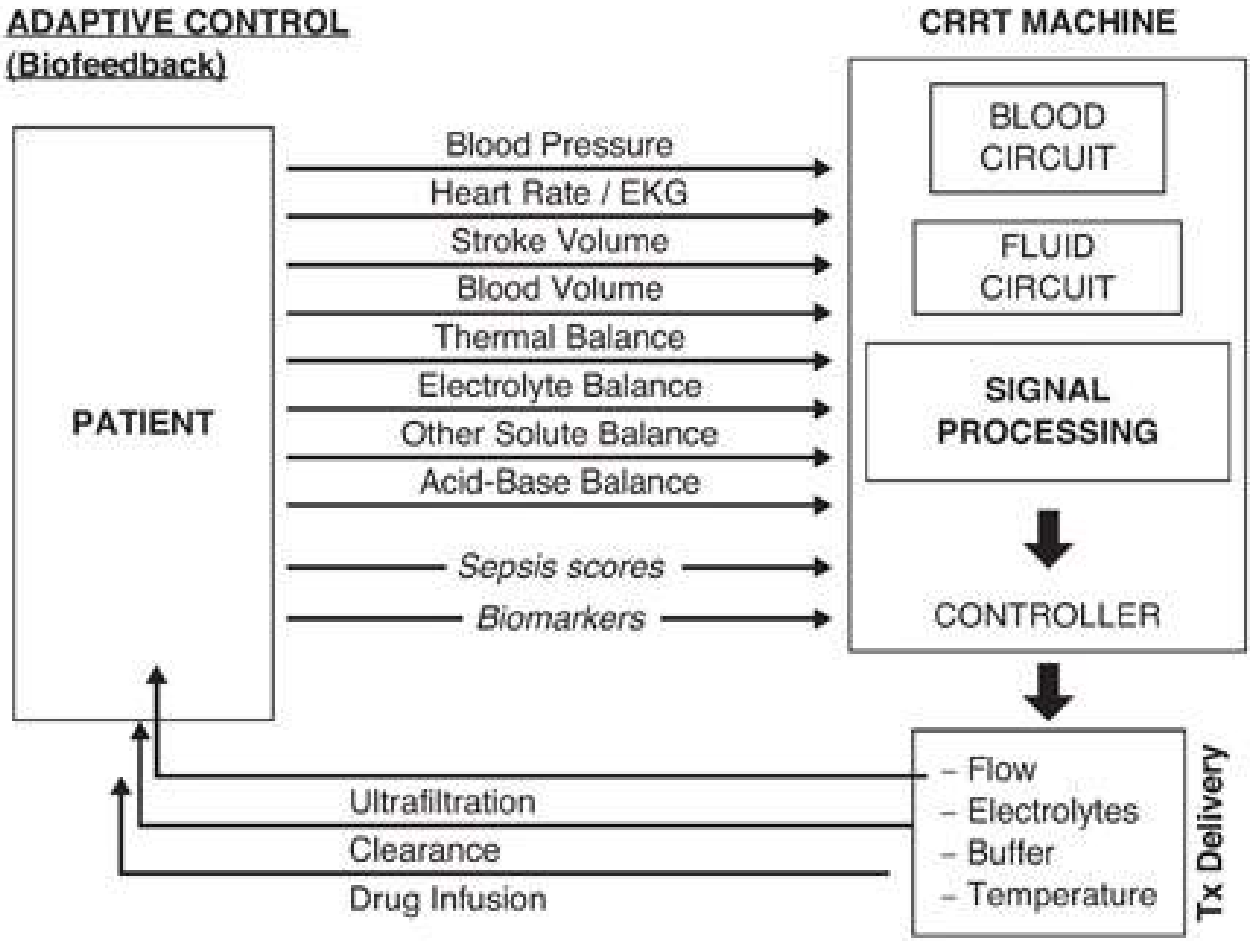

FIGURE 10.4 The "ideal" future renal replacement technology. The "ideal" future renal replacement technology will couple renal replacement therapy intensity (treatment delivery) with different biofeedback systems to tailor dose and ultrafiltration rate to the complex needs of the individual critically ill patient. EKG, electrocardiogram; Tx, treatment. (Adapted from Ronco C, Ricci Z, De Backer D, et al. Renal replacement therapy in acute kidney injury: controversy and consensus. *Crit Care* 2015;19:146.)

CHAPTER 11

Renal Replacement Therapy—Wearable and Implantable Therapies

Edward R. Gould and William H. Fissell

Prior to the advent of dialysis, kidney disease was a death sentence. The introduction and widespread use of the semipermeable membrane for semiselective removal of small solutes changed that. This use of the semipermeable membrane in this fashion was initially described by Thomas Graham in 1861—who also coined the term “dialysis.” He described diffusion of crystalloids through a membrane of vegetable parchment (1). However, it would be another century before dialysis was implemented as a human medical treatment.

After disappointing results in Germany in the early 1920s, the first successful dialysis treatment for acute kidney injury is attributed to Willem Kolff of the Netherlands in 1944–1945. In the subsequent decade, Dr. Nils Alwall (2) modified his dialysis apparatus to include higher pressure rigid dialyzers. This development allowed for volume removal through the application of a pressure across the dialysis membrane.

The final necessary technology was the development of vascular access that was reliable and relatively safe for outpatient use, first by Scribner, Quinton, and Dillard. These technologies allowed the introduction of outpatient chronic hemodialysis. Since their introduction, renal replacement therapies have moved from the intensive care unit, where they temporized the critically ill with kidney disease, to the clinic where nearly 400,000 Americans receive life-sustaining therapy for their end-stage kidney disease (ESKD) at a cost of over $40 billion a year, according to 2009 data (3).

As the first therapy designed to replace a failed organ, dialysis provides a durable treatment option for an otherwise fatal diagnosis. That, however, does not mean that the patients receiving routine outpatient dialysis are the same as their counterparts who are otherwise healthy. Indeed, the burden of dialysis extends well beyond simply the actuarial expense. Dialysis patients are at increased risk of cardiovascular death, they suffer from reproductive irregularities, and they have the socioeconomic consequences of the time spent on dialysis. These burdens have led to renewed interest in modernizing and mobilizing the dialysis technologies to help mitigate these repercussions and, ideally, improving the

clinical outcomes of patients on dialysis.

BASIC PRINCIPLES

Dialysis practices vary around the world, but in the United States, it is generally performed three times weekly in an outpatient unit using an extracorporeal circuit that includes a semipermeable membrane. Given that the specific toxins responsible for uremia remain imperfectly defined, there has never been a full understanding of the best metric for effective dialysis. Reliance on measures of small and middle molecular clearance has given us the ability to develop dialysis membranes that have become increasingly effective and provides a starting point for the evaluation of newer artificial dialysis systems. A comparison of the various physiologic functions as performed by native kidneys, conventional dialysis, and newer implantable options is outlined in **TABLE 11.1**.

TABLE 11.1 Comparison of Native Kidneys, Hemodialysis, and Implantable Artificial Kidney

Physiologic Function	Native Kidney	Conventional Dialysis	Miniaturized RAD
Toxin clearance	High-volume convective ultrafiltration, followed by active tubular electrolyte, water, organic anion, and small protein reabsorption from the ultrafiltrate with fine tuning by subsequent cellular secretion	Predominantly diffusive clearance of small water-soluble solutes from plasma water to dialysate, with some convective clearance of middle-sized molecules depending upon dialyzer flux and design	High-volume convective ultrafiltration by silicon nanoporous membrane, followed by selective reabsorption of electrolytes and water by tubule cell bioreactor or synthetic "tubular"-like membrane
Volume homeostasis	Active distant and intrarenal neurohumoral feedback systems controlling glomerular blood flow, perfusion pressure, filtration, and tubular reabsorption	Ultrafiltration volume determined clinically by assessment of dry weight and ultrafiltration rate by dialysis session time	Computerized synthesis of physiologic data and patient-entered weight data to control balance between ultrafiltration and reabsorption rates
Calcium–phosphorus metabolism	Calcium and phosphorus are filtered by the glomerulus and differentially reabsorbed by the tubule under hormonal and phosphatonin control and tubular flow rate	As dialysis does not adequately remove sufficient phosphate, patients are required to avoid phosphate-rich foodstuffs and require phosphate-binding medications. Additional active vitamin D sterols are required. Dialysate calcium is adjusted to maintain serum calcium concentration.	Calcium and phosphorus are filtered by the silicon nanoporous membrane, some calcium and phosphate is reabsorbed, and any deficiencies will be supplemented by oral medications.
Potassium regulation	Potassium is filtered by the glomerulus, then reabsorbed by the tubule, and then secreted under hormone control, and exchanged to maintain acid–base homeostasis.	Patients require a potassium-restricted diet, and then dialysate potassium is adjusted to maintain a target predialysis concentration.	Patient will self-monitor blood potassium at home by fingerstick blood sampling, and adjust diet and, if necessary, adjust ion exchange resin dose accordingly.
Red blood cell mass	Kidney tubular cells in kidney interstitium cells secrete erythropoietin in an oxygen delivery–dependent fashion regulated by hypoxia inhibitory factor (HIF).	Require exogenous erythropoiesis-stimulating agents or HIF receptor blockers. Iron supplementation is required for blood lost in dialyzer.	Require exogenous erythropoiesis-stimulating agents or HIF receptor blockers.
Acid–base balance	The kidney reabsorbs bicarbonate and excretes acid by an ammonium-based buffering system and hydrogen ion exchange for other cations.	Patients adhere to a protein-restricted diet to reduce acid generation, and dialysate bicarbonate concentration is adjusted to control pH.	A kidney tubular cell bioreactor will excrete some acid, but oral bicarbonate will be necessary to completely buffer dietary acid load.

RAD, renal assist device.

The healthy kidney (left) accomplishes critical physiology functions to maintain homeostasis: waste removal, fluid balance, electrolyte, and acid–base regulation. Hemodialysis (center) uses a combination of the procedure and drugs to approximate the same functions. The implantable artificial kidney uses a combination of technology and biology to free the patient from dialysis.

Small Molecule Clearance

Small molecules have long been the target of dialysis assessment, with a focus particularly on urea which serves as a small molecular weight marker for the variety of other uremic toxins that accumulate in ESKD. While often treated collectively, these molecules behave differently according to their molecular characteristics, interactions with the dialysis membrane and, most importantly, their kinetic behaviors between and within various body compartments. The differences in urea and phosphorus clearance are illustrative of the variance in clearance.

Urea

Having a molecular weight of approximately 60 Da and a large volume of distribution, urea is an endogenously produced molecule that is generated as a product of protein degradation. Protein metabolism leads to the endogenous production of urea at a rate of approximately 10 to 13 mg/min. Dialysis is able to remove small solutes, like urea, in direct proportion to their concentration in the blood. Typically, a single compartment model for urea removal is used to estimate the clearance of urea (**EQUATION 11.1**):

$$U_{final} = U_{initial} \times e^{-\frac{Kt}{V}} \qquad (11.1)$$

In this model, U_{final} and $U_{initial}$ represent the urea concentration at the beginning and the end of the hemodialysis session, respectively. Here, *K* is the instantaneous clearance, a parameter that is governed by the membrane characteristics, and the dialysis flow rate, though is predominately limited by the blood flow rate. Time is represented by *t*, and *V* represents the volume of distribution. The targeted urea removal for a given dialysis session is typically a single-pool Kt/V of 1.2 to 1.4. A Kt/V of one equates to the clearance of 1.0 volume of distribution. The targeted Kt/V of 1.2 to 1.4 allows for slightly greater clearance and to account for urea rebound from the unmodeled peripheral compartment. It is possible to further quantify urea removal by solving for the following (**EQUATION 11.2**):

$$U_{removed} = \int_0^T K \times U_{initial} \times e^{-\frac{Kt}{V}} \qquad (11.2)$$

Given that the urea generation between dialysis sessions is approximately 28 to 43 g, we can then determine what the expected initial urea concentration is in these patients in order for urea removal to match urea production. As noted above, K is primarily limited by dialysis blood flow, so if we assume that K = 350 to 400 mL/min, we can see that predialysis blood urea nitrogen (BUN) must rise to 70 mg/dL or higher in order to remove the urea at its production rate of 10 mg/min or greater. Indeed, in practice, it is understood that patients who do not reach this threshold in their azotemia—barring significant residual renal function—are typically suffering from being undernourished and do not have adequate protein intake. This has been found, through observational assessment of other clinical metrics, to be strongly associated with mortality in these patients.

Phosphorus

Phosphorus is another small molecule, like urea, that is able to pass through the dialysis membrane but does so slightly less ably than the slightly larger creatinine. The difference in behaviors is largely attributable to the negative charge carried by phosphorous in combination with the water of hydration.

However, unlike urea, which mobilizes relatively quickly from the peripheral compartment for dialytic clearance and approaches a one-compartment kinetic model, phosphorus is better described with two-compartment modeling and probably a multicompartment model. Phosphorus concentrations very quickly fall to a low level in the plasma compartment during dialysis but mobilize slowly from peripheral tissues and achieve a concentration postdialysis that approaches initial starting concentration.

To explore this more fully, the average dialysis patient, who is pursuing the desired 1 to 1.2 g/kg/day of protein, consumes approximately 780 to 1,450 mg of phosphorus daily, of which approximately 60% to 80% is absorbed in the gastrointestinal tract. Four-hour dialysis treatments are only able to remove approximately 1,000 mg of phosphorus per treatment, which is sufficient to maintain normal phosphorus levels in only a minority of patients. As a consequence, most dialysis patients are put on oral phosphorus binders which can reduce gastrointestinal absorption to approximately 40% or 400 to 650 mg daily.

In contrast to intermittent dialysis, continuous renal replacement therapies (CRRTs) provide significant phosphorous clearance. In these patients, the slow mobilization from peripheral tissues allows phosphorous to be removed by the dialysis modality. If critically ill patients are left on continuous therapy for any length of time, their limited oral intake often leads to profound hypophosphatemia and requires supplemental phosphorus.

Middle Molecule Clearance

Middle molecular weight molecules include those that range from approximately 2 kDa (~20 times the size of creatinine) to 45 kDa. The most commonly studied middle molecule is β_2-microglobulin. It is a component of the major histocompatibility complex and in normal physiology is shed from the cell surface during regular cell turnover and then is eliminated, almost exclusively, by the kidney (4). Despite being readily able to pass through the kidney filtration barrier, it is relatively poorly cleared by traditional hemodialysis filters. Even so-called “high-flux” dialyzers have β_2-microglobulin clearances that are only one-tenth to one-fifth that of urea (5). If serum concentrations are sufficiently high, β_2-microglobulin can go on to polymerize and coalesce in amyloid plaques that have been found in nearly every major organ system. Common manifestations include nerve entrapment syndromes like carpal tunnel syndrome and joint disease, but it has been implicated in cardiovascular disease and neurologic plaques as well in ESKD patients (6–8).

The clearance of these middle molecules is largely a consequence of the dialysis membrane “cut-off” or pore size maximum, although it is important to recognize that even in an idealized membrane, pore size is not completely uniform, and solute transport does not abruptly stop at some given or defined molecular size. That is to say that there are pores that vary around a certain mean. In order to effectively facilitate transport of these middle molecules, while avoiding transport of so-called large molecules, like albumin with a molecular weight of 66.5 kDa, the manufacturer must engineer a pore size sufficient to span the size of interest but to tail off before larger serum proteins are given passage.

Salt and Water Management

The native kidneys are wonderfully adept at managing extracellular fluid volume and osmolality within very finely regulated margins. That regulation is the product of interwoven and overlapping neurohormonal feedback loops that allow for accommodation of widely varying intake. In patients who

are dependent on dialysis, those hormonal signals that would normally influence kidney sodium handling go unanswered and salt and water removal are driven mechanically through modulation of the dialysis concentrations and ultrafiltration (UF) rates set at the bedside.

The average fluid intake in adults is approximately 1.5 L/day; an additional 350 to 400 mL/day of water is generated through the metabolism of carbohydrates. This “intake” is balanced in adults by fecal losses averaging 100 mL/day, insensible losses of about 400 to 600 mL/day, and urinary output. In balance, using the above values—which vary widely between individuals—that leaves approximately 1.3 L/day of water that must be excreted by the kidneys in order to stay in steady state. From a dialysis perspective, this means that three weekly sessions of intermittent hemodialysis must remove approximately 9 L of water per week that must be removed in dialysis-dependent patients who lack residual renal function. Thrice-weekly dialysis, then, requires 3 L be removed per treatment which, depending on the size of the patient, can be both physiologically taxing and technically challenging. The physiologic stresses, in particular, have been suggested as the primary driver behind increased cardiovascular mortality, with high UF rates showing correlation negative outcomes (9–11).

Sodium management is also intimately tied to the dialysis gradients established across the semipermeable membrane. Sodium balance is generally achieved by dialyzing patients against a dialysis bath containing 140 mmol/L of sodium, matching the serum concentration. Higher sodium baths tend to lead to higher interdialytic weight gain and higher blood pressures. Lower sodium dialysate baths on thrice-weekly hemodialysis tend to lead to intradialytic hypotension (12). There is some preliminary data on using lower sodium dialysate solutions with nocturnal or frequent dialysis to maintain slight negative sodium balance, but the long-term effects of this technique remain unknown (13). Obviously, in developing an artificial kidney, implantable, wearable, or otherwise “portable,” all of these clearances need to be collectively considered.

Wearable Dialysis Options

The first dialysis performed to treat chronic kidney disease (CKD) was performed in Seattle in March of 1960 (14). Since that time, a quest has been underway to balance the medical and mechanical demands of dialysis with the patients’ desires to live full and productive lives. It is important to realize that in the 1970s, just as the U.S. Congress was preparing to grant nearly universal health coverage to Americans with ESKD, most patients who were dependent on chronic dialysis were performing the procedure in their own homes (15) and were largely homebound. At that time, there was an interest in developing portable kidney replacement options to help liberate these patients from their homes; literature published during that era investigates the theoretical possibility of portable dialysis (16–19). However, as Medicare reimbursement allowed for a rapid growth in the CKD patient population, an extensive network of dialysis clinics was developed, which eliminated the homebound nature of the therapy by not only allowing for movement to and from treatments but also allowing for travel accommodations as needed.

Recently, however, interest in portable therapies has resumed as observational data accumulates indicating that longer dialysis sessions may be beneficial with respect to patient outcomes (20). While incompletely understood, these longer sessions likely have less negative physiologic impact through slow UF. The improved solute control—as evidenced by the superior phosphorus management seen in these patients—may also lend itself to improved outcomes. Collectively, these observations have led to renewed interest in possible slow continuous dialysis using wearable or implantable systems, which are

compared with conventional hemodialysis in **TABLE 11.2**, although these systems have their attendant challenges.

TABLE 11.2 Comparison of Conventional Hemodialysis, Wearable Artificial Kidney, and Implantable Artificial Kidney

	Conventional Hemodialysis	Wearable Artificial Kidney	Implantable Artificial Kidney
Access	Arteriovenous graft/fistula or dialysis catheter	Catheter	Permanent grafts to vasculature
Blood flow rates	High: typically 300–400 mL/min	Low: 50–100 mL/min	200–300 mL/min
Dialysis membrane	Commercial high flux dialyzers	Same	Silicon nanopore membrane
Dialysate	Large volumes of prepared dialysate	Small volumes of dialysate that are continuously regenerated	None
Treatment length	3–4 h thrice weekly	6–10 h daily	Continuous
Small molecule clearance	~200 L/wk	~200 L/wk	25 mL/min
Phosphorus clearance	Limited by intercompartmental kinetics	Limited by blood and dialysate flow	Limited by filtration rate and solute size

First among these challenges is the necessity of vascular access. Hemodialysis depends on reliable vascular access facilitating an unimpeded supply from and return to patients' circulation (21). Significant data has shown the superiority of arteriovenous fistulae or grafts to catheter access. Fistula or graft access requires needle access and secure connections. Indeed, the risk of accidental venous needle disconnect is great, given the high throughput of blood. In standard dialysis treatments, with a blood flow rate of 400 mL/min, exsanguination could occur in less than 15 minutes. In a dialysis unit, safety is ensured by stabilizing the involved limb and maintaining direct visualization through the duration of treatment. With a wearable system, the fundamental driving impetus for which is mobility to better suit patient lifestyles, this vascular might not necessarily be so stable. Indeed a dislodged line could quickly become disastrous. While catheters may provide additional stability, they have been linked to increased infectious risk and indeed may be related to ongoing inflammatory activation (22,23), and possible association with cardiovascular and other disease states (11).

The volume of required dialysate is another logistical challenge. In order to maintain the electrochemical gradients required to provide dialysis in the limited time allotted for traditional thrice-weekly dialysis, mandate that the dialysis flow rates exceed the blood flow with maximal dialysis achieved with countercurrent flows. In conventional thrice-weekly dialysis, the dialysis flow rates—typically in excess of 600 mL/min—lead to the use of approximately 200 L of dialysate per treatment. Other therapies that have allowed for less intensive but more frequent dialysis have limited the amount of dialysis needed at home, with six times weekly dialysis requiring lower dialysate flows and thus only 30 to 50 L of dialysate per treatment. One novel strategy that has been used to regenerate fresh dialysate form waste dialysate is the application of solute sorbent materials to the circuit.

Solute removal devices that utilize sorbent materials have been in commercial production for decades. Initially developed by National Aeronautics and Space Administration (NASA) for water purification on manned spaceflight missions, these solute removal devices have since been adapted for use in dialysis systems (24). The REDY system, standing for REcirculation of DialYsate, was introduced commercially in the 1970s and remains available for use. The sorbent materials are able to remove various elements of spent dialysate in several steps to regenerate usable dialysate solutions. It is worth

reviewing the details of this process briefly.

Spent dialysate, of course, contains metabolic toxins that need to be removed if that dialysate is meant to be reused. These include urea, potassium, phosphorus, and a variety of organic acids. By moving that dialysate through several steps, one can remove not only those known toxins but presumably many other metabolites that are removed by dialysis. In these systems, the dialysate is first exposed to urease, which cleaves the urea to carbon dioxide and ammonia. The newly formed ammonia scavenges free protons to form NH_4^+ given that the pK_a of the ammonia–ammonium system (NH_3/NH_4^+) of around 9, it favors a protonated form in dialysate with a neutral pH. This is the first step in excreting dietary acid. The dialysate then moves through a cation exchange resin and then an anion exchange resin to remove potassium and ammonium, and then phosphorus and sulfate, respectively. Other cationic and anionic solutes removed by dialysis are also eliminated in these columns, including calcium and magnesium. Lastly, the dialysate moves through an activated charcoal filter to remove organic solutes. Typically, because of the removal of calcium and magnesium by the cationic resin and removal of bicarbonate by the anionic resin, these must be replaced to some extent before returning the dialysate for use as well (24,25).

These sorbent systems have become an important element among the wearable dialysis options currently being explored for wider market.

Peritoneal Dialysis

Peritoneal dialysis (PD) can be described as the first “wearable” dialysis option. It only requires intermittent exchanges of peritoneal dialysate and allows patients to fit their treatment to their lives, contrary to the more rigid schedules demanded by in-center hemodialysis. PD also has drawbacks, including a significant commitment on the part of the patient with potentially many hours per week devoted to treatments, as well a large storage area and reserve for PD fluid is required. As early as 1976, Raja (25) reported the use of the REDY system to recycle spent PD fluid for reuse.

Presently, a commercially available option for PD patients is being developed by the Singapore-based Automated Wearable Artificial Kidney (AWAK) Technologies. Their device uses urease, zirconium oxide, and zirconium phosphate along with activated charcoal to facilitate peritoneal dialysate regeneration as described above. Unlike in standard hemodialysis, PD requires an osmotic gradient to facilitate water removal in these patients. The AWAK system, then, not only replaces the adsorbed salts after purification but also replaces glucose in the solution to maintain that gradient.

Another distinct difference between the standard PD routine and the AWAK system is the use of tidal dialysis. While typically, patients will infuse large volumes with long dwells, tidal dialysis allows for small volumes, with short dwells and almost continuous exchange. According to the published literature on these systems, approximately 4 L/hr is exchanged in patients using their systems (26) with achieved clearances that are superior to standard PD. Whether there is any improvement in observed patient outcomes like mortality, using this modality remain to be tested.

Ronco describes a similar device, the Vicenza Wearable Artificial Kidney for Peritoneal Dialysis (ViWAK) that also utilizes a specialized PD catheter with an inflow and outflow lumen—the Ronco catheter—and a small wearable cartridge containing the sorbent materials. The initial morning dwell is done manually by the patient, and after approximately 2 hours, when approximately 50% dialysate/plasma equilibrium has been achieved, recirculation is activated for the ensuing 10 hours or so, at a rate of 20

mL/min. Again, this allows for high daily clearances, and a weekly clearance >100 L/wk (27,28).

Hemodialysis

Just as there have been advances using these sorbent regenerated dialysis models in hemodialysis, so too have advances been made in so-called continuous ambulatory hemodialysis with two major current extracorporeal hemodialysis options being explored. The Wearable Artificial Kidney, or WAK, was trialed in Vincenza, Italy, in the mid-2000s and recently (2015) completed an initial human trial in the United States. As noted previously, while we are accustomed to high blood flow rates when patients are receiving extracorporeal kidney support, these are a mandate not of the modality but of the short treatment time offered to our outpatients. Indeed, the device currently being explored was described by Gura first in 2005 using off-the-shelf dialyzer membranes. The dialysate is circulated through a miniaturized system using the REDY components that reconstitutes the dialysate and then a series of syringes add the additional salts to the solution; heparin is added to the blood circuit. The entire device weighs approximately 5 kg.

The earliest clinical studies of this device were on patients requiring additional UF that could be provided by routine dialysis (29). This was followed by experimental use in a small cohort of ESKD patients. Blood flow rates of 50 mL/min were achieved and total urea clearances of approximately 22 mL/min. Unfortunately, access indeed proved to be a hurdle with two of the eight patients experiencing catheter thrombosis and at least one episode of needle dislodgment during treatment, although safety measures prevented significant blood loss and treatment continued after needle replacement (30). As with traditional CRRT options, phosphate and β_2-microglobulin clearances were much higher than they are on thrice-weekly dialysis, again supporting the idea that mobilization from peripheral compartments is the fundamental problem in achieving higher clearances on dialysis (31).

The Netherlands-based Nanodialysis Company has developed a slightly different approach that deviates from the REDY sorbent design described above. Instead of using disposable cartridges, a regenerable sodium polystyrene-based cartridge is used for cation exchange. With this device, the sodium polystyrene resin allows for displacement of sodium ions for cations in the dialysate that need to be expunged (potassium, ammonium, etc.). After a certain “lifetime,” the polystyrene is bathed again in a high concentration sodium bath, which displaces those cations that accumulated during dialysate exposure (32). In addition to reusable cation exchangers, they have also opted to use an electrochemical reaction to eliminate urea from the dialysate. With electrodes placed into the system, an electrical current oxidizes the spent urea into nitrogen, hydrogen, and carbon dioxide. This allows for less risk of urease failure or worse yet, urease breakthrough, but trades out that problem for the issues associated with gas production and heavy metal use with risk of metal ionization into the dialysate (33).

Implantable Renal Replacement Systems

Indeed, the pinnacle of this field’s aspiration is to achieve a bioengineered implantable device that would overcome the concerns associated with both infection and with access failure while providing adequate dialytic clearance to manage the metabolic consequences of ESKD. While wearable therapies emphasize the use of regenerable dialysate solutions and have minimized the concerns associated with dialyzer exchange simply because of accessibility, these parts would pose inherent issues to implantable devices as intermittent replacement would be necessary. While the membrane is likely a requisite piece of an

implantable strategy and its lifespan will determine the frequency of exchange, successful strategies will likely forego the use of dialysis.

Recellularization

Great interest has arisen around the prospect of rejuvenating a failed kidney by either reawakening its own cellular apparatus, or by replacing or repurposing other cell types to provide kidney function on an implanted engineered device. Both of these prospective treatment techniques share common features that lend themselves to review here.

While many different researchers have developed basic science techniques to harvest, grow, and influence differentiation of kidney tissues, those that have demonstrated the most promise include somatic cell nuclear transfer, and recellularizing organ matrices for implantation.

Somatic cell nuclear transfer involves generation of syngeneic donor tissue for a variety of uses. The tissues are generated by harvesting the nuclei of a somatic cell and then implanting that into an enucleated oocyte. The resulting embryonic or fetal tissue is then harvested for use (34). In the case of the kidney, those cells could theoretically be used to replace lost kidney tissues. More recent work has focused on using dedifferentiation signaling to change terminally differentiated cells of the host to return to pluripotency and then deliver these to the organ of interest (35). While promising, with tissues showing some histology consistent with kidney tissues, neither of these techniques have yet shown full reconstitution of the nephron.

Alternatively, some researchers have devised ways to use the matrix of an existing decellularized kidney as the structure of the kidney and then adding cellular elements in the hopes of recreating complete kidney architecture. This has the benefit of providing the superstructure necessary for nephron and vascular scaffolding. The earliest work in this area was on cardiac tissue with recapitulation of myocyte architecture and appropriate contractile orientations (36). However, the kidney architecture is significantly more complex and the process of recellularizing a bit more intensive. In 2013, Song et al. (37) published work wherein a decellularized rat kidney was seeded with human umbilical vein endothelial cells from the arterial circulation and neonatal rat kidney cells were seeded from the lower genitourinary tract. Histologically, structures similar to glomeruli and tubules were seen, though in vitro testing of the implants that were inferior to matched cadaveric kidneys with less stringent filtration specificity (37).

Implantable Devices

An alternate approach has been to develop a bioengineered device that could be implanted to permanently manage ESKD. Current concepts, being pioneered by Fissell and Roy, would involve two functional elements, similar to those in a native kidney—the first component would be akin to the glomerulus, generating a large volume filtrate. The filtrate would proceed on to the bioreactor which would function much like the tubular portion of the nephron does, modifying that filtrate through secretion and reabsorption to optimize the waste product outflow. A schematic of one possible design is seen in **FIGURE 11.1**.

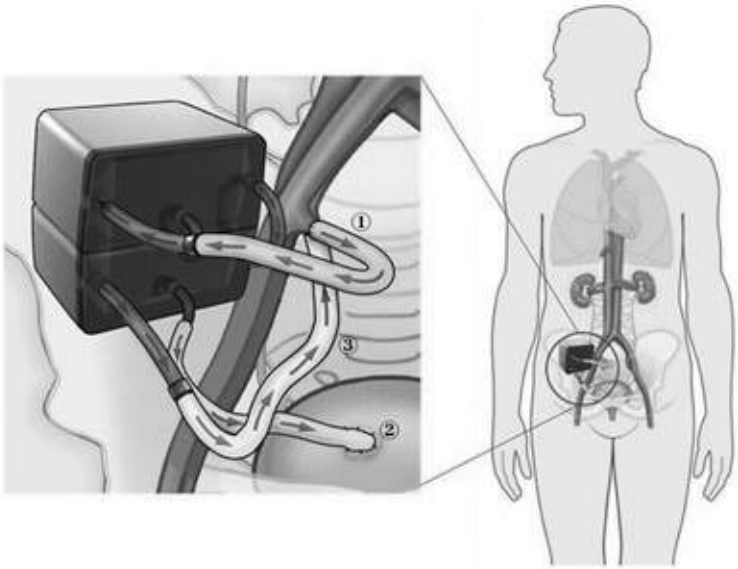

FIGURE 11.1 Schematic of implantable artificial kidney. Left, a two-stage implanted device is perfused from the iliac artery via a polytetrafluoroethylene (PTFE) vascular graft (*number 1*). The HemoCartridge filters approximately 20 to 30 mL/min from the flowing blood. Both filtrate and postfilter blood flow to a bioreactor of living human kidney cells, which return valuable fluids and electrolytes to the blood, and concentrates toxins in the ultrafiltrate, which then flows to the bladder (*number 2*). Purified blood returns to the patient's veins (*number 3*). (Courtesy of Shuvo Roy.)

Implantable Filter

Modern dialyzers, composed of hollow-fiber tubes composed of cellulosic materials, are far too bulky and have a propensity for detrimental filtration changes over time due to thrombosis and coagulation activation to be used for implantation. Instead, Roy has taken advantage of silicon micromachining to manufacture silicon chips that have very specific and controlled pore sizes (38). These can then be used in an implantable manifold to facilitate filtration. While silicon has been challenging to use in biologic models due to protein adsorption with its intended risk for pore preservation, these chips, when coated with hydrated polymers, have shown to resist this process and have reasonable half-lives (39,40). Thus far, results from *in vitro* and *in vivo* tests of the filtration apparatus have been promising.

Bioreactor

The bioreactor would then serve to modify the generated ultrafiltrate from the silicon chip by exposing it to bioengineered cell cultures. The same group that has bioengineered the silicon nanopore membrane have explored a variety of facets for bioreactor implementation, including exploring growth substrates, and tubular behaviors according to adjacent fluid mechanics (41–43) but have not yet published *in vivo* studies of a complete apparatus.

CHAPTER 12

Adequacy of Peritoneal Dialysis

John M. Burkart

Chronic dialysis is certainly a remarkable medical success story, extending the lives of some patients with kidney failure for more than 20 years (1). This success routinely occurs despite the finding that typical urea clearances for patients on renal replacement therapies (RRTs) and in particular peritoneal dialysis (PD) are only approximately one-tenth that of the normal kidney (70 L urea clearance/wk on PD vs. 750 L/wk for normal kidney function) (**TABLE 12.1**) and the fact that dialysis itself replaces only some of the typical functions of the normal human kidney. For instance, it does a fair job or replacing some of the filtration functions of the normal kidney (removal of urea and creatinine, etc.), but dialysis typically does not correct anemia and renal osteodystrophy without additional medications. Furthermore, dialysis does not replace other poorly recognized systemic metabolic functions mainly by the proximal tubules typically present in health. Despite the success of current RRTs, there is room for improvement. Mortality rates in the United States have historically been in the range of 10% to 25% per annum (2), on average, 10 times higher than that of age- and sex-matched controls in the healthy population (3).

TABLE 12.1 **Solute Removal by Dialysis and the Natural Kidney**

	Natural Solute Kidney	Hemodialysis—Standard Flux	Hemodialysis—High Flux	CAPD
Urea L/wk	750	130	130	70
Vitamin B_{12} L/wk	1,200	30	60	40
Inulin L/wk	1,200	10	40	20
β_2-Microglobulin	1,000	0	300	250

CAPD, continuous ambulatory peritoneal dialysis.
From Keshaviah P. Adequacy of CAPD: a quantitative approach. *Kidney Int* 1992;42 (Suppl 28):S160–S164.

Some have suggested that this increased rate of mortality in dialysis patients is due to inadequacies in the prescribed dose of dialysis (4,5). However, it is acknowledged that there is more to "adequacy" of dialysis than what any single yardstick for "dialysis dose" can measure. In an attempt to improve patient outcomes, both National and International Medical Societies have developed guidelines intended to standardize medical care, help practicing nephrologists, identify research needs, and ultimately improve

clinical outcomes. For PD, the first of these was the National Kidney Foundation (NKF)-sponsored Dialysis Outcomes Quality Initiative (DOQI) clinical practice guidelines for adequacy of PD (6). These have subsequently been revised twice (7,8).

This chapter discusses adequacy for PD in terms of total solute clearance, volume control, and other issues related to the PD prescription. Although it focuses on small solute clearance issues, it is acknowledged that the optimal treatment of a patient with end-stage kidney disease (ESKD) must additionally address blood pressure (BP) and volume control, treatment of acidosis, anemia, prevention of metabolic bone disease, and perhaps treatment/prevention of a chronic inflammatory state. These particular issues are discussed in other sections of this text.

WHAT YARDSTICK FOR ADEQUACY OF DIALYSIS SHOULD WE USE?

Some of the clinical manifestations of uremia or "underdialysis" are readily apparent to the clinician and/or the patient (9). These include decreased appetite, metallic taste, nausea, vomiting, pericarditis, pleuritis, and encephalopathy. Not so readily evident as a manifestation of "underdialysis," is the presence of hypertension (10), lipid abnormalities (11), and peripheral neuropathy (12). In addition, patients often underreport their symptoms. Therefore, in addition to the clinical assessment of the patient, it would be clinically helpful if nephrologists had a reliable and easily measured laboratory parameter that can be obtained during the course of chronic kidney disease (CKD) and when a patient is on dialysis that predicts the presence of uremic complications and patient outcome. There is no documented single substance that has been shown to be the "uremic" toxin. Undoubtedly, the clinical manifestations of the uremic syndrome are the result of the synergistic effect of multiple retained solutes across a broad spectrum of molecular weights. It is because retained levels (body burden) of these solutes that the uremic syndrome occurs. Therefore, because there is no single "uremic" toxin, one must rely on "surrogate" markers for "adequacy of dialysis." Current commonly used surrogates include clearances or serum levels of urea nitrogen, creatinine, phosphorous, or β_2-microglobulin. At present, if a physician was going to pick one yardstick as a measure of dialysis dose, it would be a urea-based surrogate (Kt/V_{urea}).

There are historical data which suggests that the outcome for patients on both hemodialysis (HD) (13) and PD (14) was related to total small solute clearance and to surrogates of nutritional status such as dietary protein intake (DPI), body mass, and serum albumin levels. It was not uncommon to observe an improvement in overall patient well-being and nutritional intake after small solute clearance was increased. There appeared to be a relationship between protein intake, solute clearance, and the manifestations of uremia or nutritional status that were likely to be different in each patient but, in the absence of significant comorbid disease, tended to correlate positively with solute clearance (15). As a result, in the initial clinical practice guidelines for "adequacy of PD," the recommended standard "yardsticks" for dose of PD included urea clearance normalized to its volume of distribution (Kt/V_{urea}) and creatinine clearance (Ccr) normalized to 1.73 m^2. However, as will be discussed in subsequent text, contemporary data may suggest that one may also need to refocus on other known "yardsticks" of renal replacement therapy such as sodium removal, volume control, phosphate, and β_2-microglobulin clearance.

Our historical small solute marker, Kt/V_{urea}, should just be the starting point of an adequacy of dialysis evaluation.

Correlation between Solute Clearance and Risk of Death

Steady-state serum levels of various solutes are related to their generation and removal rates. To guide dosing of dialysis, one needs to monitor serum levels and measure the amount of the surrogate solutes removed from the body. However, serum levels alone may be misleading. Take blood urea nitrogen (BUN) levels for instance. These levels are related to generation (dietary intake) and removal (native kidney function and/or dialysis). If a patient is underdialyzed, he or she may not eat well. In this case, the BUN level may look as expected or low, suggesting adequate dialysis, but the patient's dialysis dose could be low and the cause of under-eating—uremia. Similarly, if one was malnourished, one may have a low muscle mass and serum creatinine levels may look low, suggesting adequate dialysis when in fact, the low creatinine was a reflection of low production (low muscle mass) not adequate dialysis. As a result, it was felt that a surrogate for adequate dialysis should be something other than simply looking at blood levels of these two solutes. Consequently, current guidelines for "adequacy of PD" recommend obtaining a 24-hour collection of both urine and peritoneal effluent for analysis of total removal for a particular solute ($K_{renal} + K_{peritoneal} = K_{rp\ or\ total}$). Urea and Ccr are obtained and then normalized to volume of distribution (urea) and body surface area (BSA) (creatinine) to calculate weekly Kt/V_{urea} and weekly Ccr/1.73 m^2. Historically, to determine total solute removal (kidney and dialysis), it was recommended that when making these calculations, the residual kidney and peritoneal clearances was added together 1:1. This was initially based on the assumption that the potential beneficial effect on patient outcome from 1 unit of residual kidney and 1 unit of peritoneal clearances was equal. However, it is now recognized that this is not the case. Specifically, if one were to look at the benefit in terms of small solute removal only, the residual kidney component seems to be superior to that of RRTs (see subsequent text). However, because the most recent prospective randomized controlled trials (PRCTs) that have evaluated the relationship between relative risk of death and solute removal (in terms of Kt/V_{urea}) were conducted using total solute clearance adding kidney and peritoneal in a 1:1 way, current NKF Kidney Disease Outcomes Quality Initiative (KDOQI) and other guidelines still make this recommendation.

Why Small Solute Clearance as the Adequacy Surrogate?

If one was to look quantitatively at urinary solutes, you would see that urea is one of the most plentiful solutes in the urine in health. Furthermore, it is well documented clinically that in patients with advanced stages of kidney disease, some uremic symptoms are related to protein intake. It would therefore make some sense to use some index related to urea as a potential marker for dialysis dose. Multiple retrospective cohort studies, all differing in methodology and the number of patients enrolled, have examined the relationship between patient outcomes in terms of relative risk of death or morbidity and its relationship to total small solute clearance, the significance of which has been reviewed elsewhere (16,17). Historical studies tended to conclude that outcomes such as relative risk of death and hospitalizations were in some way related to total small solute clearance. These studies and more contemporary, but contradictory, PRCTs are briefly reviewed in subsequent text.

Kt/V Data

Current recommendation for PD adequacy is to target a total [PD and residual renal function (RRF)] Kt/V_{urea} of at least 1.7 per week. What are these recommendations based on?

Historical Publications

Original theoretic constructs for continuous ambulatory peritoneal dialysis (CAPD) predicted that an anephric 70-kg patient [total body water (TBW) or V = 42 L] would remain in positive nitrogen balance when prescribed five, 2-L PD exchanges per day (18). Studies using *univariate* analysis of observational data correlating outcomes with small solute clearance suggested the following: In patients with RRF, to optimize clinical outcomes, one should maintain a total weekly Kt/V_{urea} target of more than 1.5 in one (19) and more than 2.0 in another (20). A study in anuric patients suggested that patients with a Kt/V of greater than 1.89 did best (21).

Studies using the statistically more correct *multivariate* analysis of observational data to determine the predictive value of Kt/V_{urea} on survival found the following: a survival advantage in patients with a weekly Kt/V_{urea} greater than 1.89 in one study (22), and, in another study of *prevalent* PD patients [mean baseline glomerular filtration rate (GFR) 1.73 mL/min] followed up for up to 3 years, the best survival was noted in patients with a total Kt/V_{urea} of at least 1.96 with no incremental improvement in survival with higher small solute clearances (23). While the Canada–United States of America (CANUSA) study (14), a prospective, multicenter, observational cohort study of *incident* patients in North America and Canada (mean baseline GFR 3.8 mL/min), predicted that over the range of solute clearance studied every 0.1 unit increase in Kt/V would be associated with a 6% decrease in the relative risk of death. The same effect was predicted for Ccr, and there was no evidence of a plateau effect. In the original analysis, RRF was not evaluated as an independent predictor of relative risk of death.

Although in 1995, the CANUSA study provided the best historical evidence that survival on PD is related to total solute clearance, it is important to remember two points. First of all, it was not a PRCT, and secondly, the results were based on theoretic constructs and two very important assumptions: (a) Total solute clearance remained stable over time and (b) 1 unit or mL/min of clearance due to RRF is equal to 1 unit or mL/min of clearance due to PD. In actual fact, the total solute clearance decreased over time as RRF decreased with no corresponding increase in the peritoneal component. Therefore, because the peritoneal component of total solute clearance tended not to change over the course of the study, one interpretation of CANUSA would be to say that the more RRF the patient has, the better the predicted outcome (24). This was in fact confirmed with a residual renal centric reanalysis of the CANUSA data (25). Similar outcome data from CANUSA correlating patient outcome with small solute clearance in terms of Ccr are available. In some publications, total weekly Ccr/1.73 m^2 was more predictive of all-cause outcomes than total weekly Kt/V_{urea}. As will be seen, this was likely due to the residual kidney component of the total solute clearance.

On the basis of historical observational studies published before 1996, and the possible association between solute clearance and DPI (reviewed in subsequent text), the original NKF-DOQI working group on adequacy of PD recommended the following total solute clearance goals for CAPD: a total weekly Kt/V_{urea} of more than 2.0 per week and a total weekly Ccr of more than 60 L/1.73 m^2/wk. For continuous cyclic peritoneal dialysis (CCPD) and for nightly intermittent peritoneal dialysis (NIPD), slightly higher

total weekly Kt/V_{urea} and total weekly Ccr/1.73 m^2 were recommended (6). It was acknowledged that the CAPD targets were only marginally evidence-based and that there were no prospective randomized studies to support those recommendations. The original guidelines have subsequently been replaced. It was also acknowledged that targets for CCPD and NIPD were opinion-based with little to no outcome data for the recommendations. Subsequently, other medical societies recommended targeting a total weekly Kt/V_{urea} of 2.0 (Canada guidelines) (26) and 1.7 (UK guidelines) (27) for all PD therapies.

Contemporary Observational Studies

Contemporary studies have further examined the effect of increasing peritoneal clearance on survival. There are three studies from a group in China. Szeto et al. (28) retrospectively reviewed their experience in 168 prevalent CAPD patients followed up for 1 year. Outcomes for patients with a total Kt/V_{urea} of more than 1.7 per week (baseline mean total Kt/V_{urea} 2.03 ± 0.25 for patients with RRF, and a baseline mean total Kt/V_{urea} was 1.93 ± 0.18 for patients without RRF) were compared to those for patients with a total Kt/V_{urea} of less than 1.7 per week (mean total Kt/V_{urea} was 1.38 ± 0.22). Overall mortality at 1 year was 8.3%; however, although there was no statistically significant difference between the groups, 9 out of 14 deaths occurred in the anuric patients with a weekly Kt/V_{urea} of less than 1.7 per week. On the basis of this, one might infer that a weekly peritoneal Kt/V_{urea} of less than 1.7 in an anuric patient may be associated with an increased relative risk of death in the long term if these trends continued. In another study, these authors showed an association between outcome and total solute clearance, mainly due to the residual kidney component (29). In contrast, in an evaluation of 140 prevalent anuric patients, followed up for a mean of 22.0 + 11.9 months, they found a positive correlation between peritoneal clearance and survival (30). In these patients, the mean baseline peritoneal Kt/V_{urea} was 1.72 ± 0.31 per week and 42% were prescribed three 2-L exchanges per day [patients whose prescription was modified if there were ultrafiltration (UF) problems]. Each 0.1 unit decrease in Kt/V was associated with a 6% increase in mortality, similar to that predicted by CANUSA.

These data in Asian patients suggest that once a certain minimal peritoneal small solute clearance is achieved (perhaps a peritoneal Kt/V_{urea} greater than 1.7 to 1.8 per week) and the patient is on 24 per day of peritoneal clearance, that further incremental increases in small solute clearance in the range that was studied result in little increase in short-term outcome.

Davies et al. (31,32) found an association between total solute clearance and survival, and as in other studies, this was all due to variations in residual renal clearance, not peritoneal. In a study of 122 anuric Canadian patients, Bhaskaran et al. (33) reported that the best survival, representing a 58% reduction in mortality, was found in the group of patients with a Kt/V_{urea} greater than 1.8/wk (Ccr greater than 50 L/1.73 m^2/wk). There was no demonstrable incremental improvement for higher weekly clearances. However, the 95% confidence interval (CI) of the study was 0.26 to 1.13, reflecting the low statistical power achieved in this study in a relatively small number of patients.

Contemporary Prospective Randomized Trials

There are three prospective, randomized trials that evaluated the effect of an increase in peritoneal clearance on survival. In the smaller of the three studies, Mak et al. (34) prospectively evaluated the effect of an increase in dialysis dose in a controlled trial in 82 CAPD patients. Baseline, all patients were

prescribed three 2-L exchanges per day. They were then randomized to continue this regimen (mean Kt/V_{urea} of 1.67 per week) or increase their PD prescription to four 2-L exchanges per day (mean Kt/V_{urea} 2.02 per week) and were followed up for 1 year. Over short-term follow-up (1 year), there was a difference in hospitalization rates. However, hospitalization rates increased in the control group and decreased in the intervention group, so this may be misleading.

A provocative prospective, randomized, interventional study evaluating the effect of an increase in peritoneal solute clearance compared to continuing on "standard therapy" in 965 CAPD patients in Mexico, the "adequacy of peritoneal dialysis in Mexico (ADEMEX)" study, found no beneficial effect on relative risk of death for the intervention group patients who had a statistically significant increase in their peritoneal solute clearance (35). All patients had 24 h/d of peritoneal dwell, and at baseline, all were on four 2-L exchanges per day, and RRF was similar in the two groups. Averaged total solute clearances over the course of that study were total Kt/V_{urea}, 1.80 ± 0.02 in controls versus 2.27 ± 0.02 in the interventional group, whereas peritoneal-only Kt/V_{urea} was 1.62 ± 0.01 in controls versus 2.13 ± 0.01 in the intervention group. Corresponding Ccr values in L/wk/1.73 m^2 were 54.1 ± 1.0 versus 62.9 ± 0.7 and 46.1 ± 0.45 versus 56.9 ± 0.48, respectively. The distribution of prescriptions in the interventional group was 10 L/d in 37%, 11 L/d in 20%, 12 L/d in 21%, 12.5 L/d in 8%, and 15 L/d in 14%. Quality of life was also assessed in the ADEMEX trial. There were no significant differences between the two groups at any point in time for physical composite summary score, mental composite summary score, or kidney disease component summary (36). Interestingly, in a subgroup analysis of anuric patients, there was also no benefit to an increase in peritoneal clearance. Therefore, in the ADEMEX study, neither survival nor the quality of life was benefited by higher small molecule clearances.

As noted in the observational studies cited in preceding text, RRF was the main predictor of mortality, with an 11% increase in mortality for each 10 L/wk/1.73 m^2 decrease in weekly kidney Ccr and a 6% increase in mortality for each 0.1 unit decrease in weekly kidney Kt/V_{urea}. In this study, although there was a statistically significant increase in peritoneal UF volume increased in the intervention group (0.97 ± 0.05 L/d vs. 0.84 ± 0.03 L/d, $p < 0.05$), there was no demonstrable improvement in outcome with increasing peritoneal UF.

The results of the ADEMEX trial are consistent with a subsequent randomized trial done in Hong Kong comparing three total Kt/V_{urea} groups (1.5 to 1.7, 1.7 to 2.0, and more than 2.0) in CAPD patients (37). Again, despite the statistically significant differences in solute clearances, there were no differences in 2-year patient survival in the three groups. All patients at the start of the study had residual kidney Kt/V_{urea} of 1.0 or less, ensuring minimal residual kidney function. Baseline residual GFR was 2.38, 2.48, and 2.64 mL/min (representing kidney Kt/V_{urea} of 0.44, 0.46, and 0.49, respectively) in the three groups, not statistically different. Average body mass index (BMI) was 22 kg/m^2, somewhat smaller than the patients in the ADEMEX trial and the typical patient in the United States. Before randomization, the usual prescription was three 2-L exchanges per day in contrast to the "standard" prescription of four 2-L exchanges per day in the control arm of the ADEMEX trial. Dialysis adequacy was assessed every 6 months and based on the results, during the course of the 2-year follow-up in the Hong Kong study, the PD prescription was adjusted up or down, as RRF changed, to stay within the randomized total Kt/V_{urea} category. By the end of the study, residual kidney Kt/V_{urea} was at or less than 0.1 in all three categories.

This is an important distinction between the Hong Kong study and the ADEMEX study. In ADEMEX, the control group consisted of a group of patients who continued on the current "standard" therapy, whereas in the Hong Kong study, some patients randomized to the low-dose arm actually had their dialysis prescription reduced.

In summary, these data suggest that for the average patient on standard CAPD (24 h/d of peritoneal dwell time), once small solute clearance is above a certain minimal amount, further increases in small solute clearance in range easily obtained clinically with current technologies result in no demonstrable incremental increase in patient outcome. These studies did not examine a lower "dose" of PD, and therefore, the absolute minimal total delivered solute clearance in terms of Kt/V_{urea} has not been established. However, available evidence suggests that the weekly minimal delivered total solute clearance in terms of Kt/V_{urea} should be more than 1.7 per week. This is consistent with observational data in anuric patients (38). The data *do not* say that the recommended minimal prescribed total weekly small solute clearances goals should be lowered for all patients. They *do suggest* that nephrologists should be more comfortable with individualizing their prescriptions and, that if a patient is not at goal but is eating well and feeling well, that there is no reason to have to transfer the patient to HD due to inadequate dialysis. The data suggest that one also needs to consider focusing on additional "yardsticks" of adequacy of dialysis. These studies were by design relatively short term (2 years of follow-up) and did not look at differences in middle molecule clearance or volume control, other possible markers for "adequacy" of dialysis.

Creatinine Clearance Data

Current guidelines do not recommend using Ccr as the adequacy yardstick. Why not? Most of the studies reviewed earlier that examined the predictive value of total Kt/V_{urea} on outcome also evaluated the effect of total Ccr/1.73 m^2. In the CANUSA study, total Ccr predicted not only death but also technique survival and hospitalization (14). Analysis of those observational cohort data suggested that a total weekly Ccr of more than 70 L/1.73 m^2 would predict a 78% 2-year patient survival. Other studies suggested that the minimal total weekly target should be more than 58 L/1.73 m^2 (23) or more than 50 L/1.73 m^2 (2,39), whereas anuric patients did best if their clearance was more than 50 L/1.73 m^2 (33). In the ADEMEX study, there was no difference in outcome between the control group (mean total Ccr of 54 L/1.73 m^2/wk) versus the intervention group (mean total Ccr of 62.9 L/1.73 m^2/wk) (35). The Hong Kong study (36) was not analyzed in terms of Ccr.

These data suggest that as with Kt/V_{urea}, once above a certain minimal total weekly Ccr, further increases in dialysis dose were not associated with further improvement in the relative risk of death for patients as a group.

SUMMARY OF CURRENT RECOMMENDED ACCEPTABLE TOTAL SOLUTE CLEARANCE TARGETS FOR PERITONEAL DIALYSIS

In response to the ADEMEX and Hong Kong trial data, original (late 1990s) guidelines for the adequacy

of PD were revised by multiple societies and national guideline committees. Before reviewing these recommendations, it is important to remember the following caveats: First of all, it is possible that the influence of solute clearance on outcome may vary in different ethnic populations. In the United States Renal Data System (USRDS) experience, African Americans and Asians on HD tend to have a lower relative risk of death than whites, presumably with the same solute clearance. Reasons for this are unclear. Perhaps this is due to differences in protein intake. Second, patients in Mexico and Hong Kong have different DPIs than patients in North America or Europe. Third, there may be differences in compliance between countries and ethnic groups. Fourth, there may be unrecognized factors or differences in comorbid diseases (40). Fifth, the ranges of solute clearances examined may not have been sufficiently different to have been able to show a clinically significant difference in survival. More data are clearly needed.

The International Society for Peritoneal Dialysis (ISPD) commissioned a work group with representation from North America, Asia, Australia, and Europe to formulate recommendations for the delivery of adequate PD, taking into account the more recent studies cited in this chapter (41). With respect to small solute removal, it was recommended that the total (renal and peritoneal) weekly Kt/V_{urea} should be greater than 1.7/wk. If using RRF as part of the total, for simplification, the renal and peritoneal Kt/V_{urea} can be added together in a 1:1 manner, although it was acknowledged that the contribution of renal and peritoneal clearances are likely very different from each other. Although it was felt that a separate recommendation for Ccr was not necessary, it was suggested that in patients on cycler a weekly minimum clearance of 45 L/1.73 m^2 should be reached. (The reason for adding a Ccr target for the patients on cycler is because of the temptation to prescribe multiple rapid cycles overnight and a dry day—a prescription that could increase the removal of urea but compromise removal of the more slowly transported, larger uremic toxins.) PD should be carried out 24 hours a day except in special circumstances because of the time dependence for the transport of larger molecular weight toxins. Although a daily UF target was not specified, it was emphasized that maintenance of euvolemia is an important part of adequate dialysis, and attention must be given to urine and UF volume. Within the confines of financial and adherence realities and limitations, the dose of PD should be increased as a trial in any patient who is not doing well because of underdialysis or for uncertain reasons.

The NKF in the United States published similar recommendations in 2006 (8), stating that the minimal delivered total solute clearance should be a Kt/V_{urea} of 1.7 per week. The work group did not see any benefit in adding Ccr solute recommendations nor did they see any data suggesting that the minimal targets needed to be different for patients on CAPD or NIPD or CCPD. Guidelines on protecting RRF and maintaining euvolemia were also added.

The Australian guidelines formulated by a work group Caring for Australians with Renal Impairment (CARI) published on the Internet in 2005 recommends that the weekly total Kt/V_{urea} be greater than or equal to 1.6 and that the Ccr be no less than 60 L/wk in high and high-average transporters, and 50 L/wk in low and low-average transporters (www.cari.org.au). The renal association from the United Kingdom has similar recommendations (1.7 and 50 L/wk) and also recommends that if UF does not exceed 750 mL/d in an anuric patient, consideration be given to a change in therapy (www.renal.org). The European Best Practice Guidelines published in 2005 have the same target Kt/V_{urea}, while also recommending a Ccr of at least 45 L/wk/1.73 m^2 for those patients on cycler and a UF goal of 1 L/d for anuric patients

(42).

IMPORTANCE OF RESIDUAL RENAL FUNCTION

Of course, it is well recognized that in an anuric patient, there is a survival benefit associated with doing dialysis. The question is how much or are we just limited in how much we can provide given our current technologies. In contrast to the conflicting data about the benefit of increasing peritoneal clearance on survival, studies have consistently shown that the presence of residual renal clearance is associated with a decrease in the relative risk of death both for patients on PD and for patients on HD (43).

Reanalysis of the CANUSA data (25) suggested that for each 5 L/wk/1.73 m^2 increase in GFR, there was a 12% decrease in the relative risk of death. There was no demonstrable benefit from peritoneal clearance. Estimates of net fluid removal suggested that a 250 mL/d increment in urine volume was associated with a 36% decrease in the relative risk of death, whereas net peritoneal UF and total fluid removed were not predictive of outcome. In the ADEMEX study reviewed earlier, RRF, not peritoneal, was a predictor of mortality, with an 11% increase in mortality for each 10 L/wk/1.73 m^2 decrease in weekly kidney Ccr and a 6% increase in mortality for each 0.1 unit decrease in weekly kidney Kt/V_{urea} clearance. An evaluation of 673 patients followed up for 1 year reported that decreasing renal clearance, not peritoneal clearance, was statistically associated with an increased mortality rate (44). Similar findings were reported in a review of 873 patients selected for evaluation in the 2000 Health Care Financing Administration Clinical Practice Management project database (45). Other smaller observational studies have also replicated these findings (46–48).

Reasons for these observations are unclear. Some plausible hypotheses for these findings are as follows: (a) Although 1 unit of residual renal clearance may be the same as 1 unit of peritoneal clearance when measured in terms of Kt/V_{urea}, this may not be true for other solutes. For instance, as will be discussed later, if a patient has a residual kidney Kt/V_{urea} of 2.0, his or her residual kidney Ccr is likely to be approximately 120 L/wk. In contrast, an anuric patient with a peritoneal Kt/V_{urea} of 2.0/wk will likely have a peritoneal Ccr of approximately 55 L/wk (**FIGURE 12.1**). This difference may be even more pronounced for middle molecular weight solutes such as β_2-microglobulin. (b) As one increases peritoneal Kt/V_{urea}, there may not be a corresponding increase in clearance of larger solutes such as β_2-microglobulin, whereas with residual renal clearance, as Kt/V_{urea} increases, the clearance of other solutes may increase to the same degree. In fact, even with advanced CKD and severe reductions in GFR, there is relatively more removal of middle molecules than small solutes when compared to the removal by PD (49). It is well recognized that β_2-microglobulin levels are lowest in patients with RRF (50,51,52). It has been shown that increasing instilled volume is likely to relieve clinical signs and symptoms of uremia (53), although the major effect is to increase small solute, not middle molecular weight solute clearances (**FIGURE 12.2**). It is known that once on 24 h/d of peritoneal dwell time, maneuvers that result in a further increase in small solute clearance tend to have little influence on the clearance of other solutes (54,55). Perhaps alternative PD therapies such as those associated with continuous flow technologies, which appear to offer an increase in β_2-microglobulin clearance over standard technologies, will be beneficial (56). (c) Residual renal clearance may allow better control of BP and volume than what is

typically achieved in anuric PD patients. (d) It may be that intrinsically healthier patients keep their RRF longer, and they have better survival because they are healthier and not because of anything that the kidneys are contributing. (e) It is important to remember that the effect of dialysis is always a constant balance between benefit and toxicity. Is it possible that one can increase the toxicity of the therapy when increasing instilled volume or when attempting to increase UF with current therapies? When using 2.5-L exchanges versus 2.0-L exchanges, there is increased glucose absorption from the peritoneal cavity. (f) There may be unrecognized intrinsic "anti-inflammatory" effect of functioning renal parenchyma (perhaps by the proximal tubules) that has been described in the general nondialysis population, which may also apply to RRF in those on dialysis. Studies in the general population have shown that loss of kidney function is associated with an increased risk of cardiovascular (CV) death, in a way that cannot be fully explained by "conventional" risk factors (57).

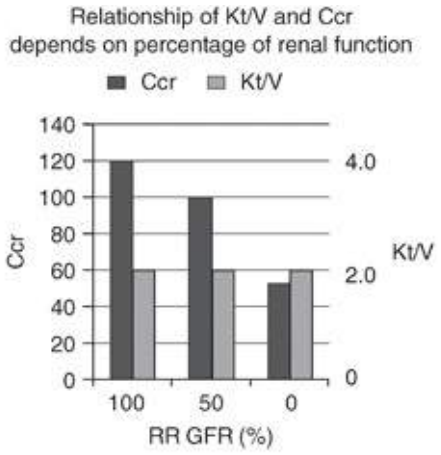

FIGURE 12.1 Relationship between creatinine clearance and Kt/V based on percentage of total clearance that is residual renal (*dark bars*) versus peritoneal (*light bars*). Ccr, creatinine clearance; RR GFR, residual renal glomerular filtration rate.

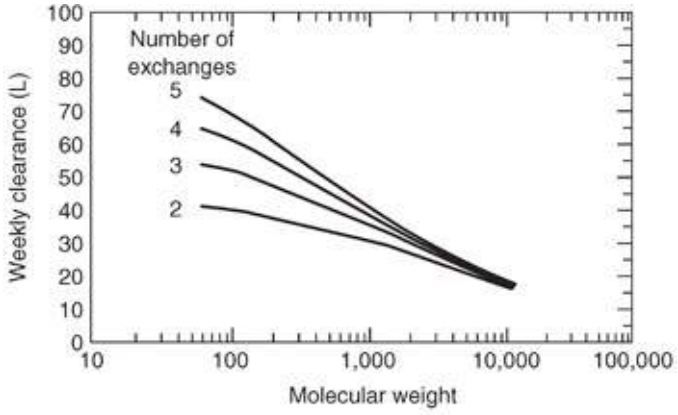

FIGURE 12.2 Effect of increasing number of peritoneal dialysis exchanges on removal of various solutes. The influence of the number of continuous ambulatory peritoneal dialysis exchanges on the weekly solute clearance for a range of solute molecular weights derived from a computerized model of peritoneal transport. [From Keshaviah P. Adequacy of CAPD: a quantitative approach. *Kidney Int* 1992;42(Suppl 38):S160–S164.]

Interestingly, neither a prospective multicenter study in The Netherlands (47) nor data from the ADEMEX study (35) was able to show an association between dose of PD and benefit in quality of life. In these studies, however, there was a correlation between the amount of RRF and quality of life.

Because of the observational cohort data reviewed in the preceding text, it is important to preserve RRF when possible. One should avoid the use of nephrotoxins (such as NSAIDs, intravenous contrast dye, prolonged aminoglycoside use) whenever possible. In an open label controlled trial of 60 patients on

CAPD randomized to ramipril 5 mg daily versus no additional treatment, residual Glomerular Filtration Rate (rGFR) at 1 year (primary outcome) was higher among those randomized to receive ramipril (adjusted GFR: 1.72 vs. 0.64 mL/min). There also was less likelihood of anuria (58). Similarly, in a prospective randomized trial of 34 CAPD patients randomized to valsartan (40 to 80 mg/d; *n* = 18) or no additional treatment (*n* = 16), better preservation of residual Ccr and urine volume were observed after 2 years in the valsartan group (59). Hence, the last KDOQI guidelines recommended "use of ACE inhibitors or angiotensin II inhibitors in PD patients who need an antihypertensive medication and that there use be considered for renal protection among normotensive patients."

IMPACT OF NUTRITIONAL STATUS ON PATIENT OUTCOME

It is well known that nausea, vomiting, and appetite suppression are symptoms of uremia and patients with uremia tend to have decreased DPI (60). Furthermore, spontaneous DPI decreases as residual kidney GFR decreases to less than 50 to 25 mL/min (61). These tendencies may be exacerbated during the period before the initiation of dialysis when many patients are not only anorexic but also acidotic and often treated with low-protein "kidney protective" diets. Consequently, patients may exhibit signs of protein malnutrition when they present for dialysis. A more "timely" start of dialysis may prevent this.

As a result of these observations, the working hypothesis has been that underdialysis or uremia leads to a decreased appetite, malnutrition, and decreased albumin synthesis. However, cross-sectional studies have provided contradictory results regarding the potential association between nutrition and dialysis dose (15,62–65). Some investigators believe that this relationship is simply mathematical coupling of data (66). Prospective studies, however, have demonstrated that in appropriate cohorts of patients, increasing the dose of dialysis tended to result in an increase in normalized protein equivalent of nitrogen appearance (nPNA) values, an increase in energy intake (31), and increase in percent lean body mass (LBM). These findings are in accordance with the observation that the relationship between dose of dialysis and protein intake seems to level off at a weekly Kt/V_{urea} level greater than approximately 1.9 (67,68) and are the basis for the clinical recommendation that suggests that a malnourished dialysis patient may be malnourished because of "underdialysis."

Studies in both ESRD (69–73) and non-ESRD (74) patients have shown that one of the most important predictors of a patient's relative risk of death is the patient's underlying nutritional status. In HD patients, as the serum albumin decreases from the reference value of 4.5 to 4.0 g/dL to an albumin of less than 2.5 g/dL, the risk of death increased to 18 times that of the reference group (68). Malnutrition is also a significant risk factor for mortality and hospitalizations in chronic PD patients (75,76). Estimates of malnutrition in chronic PD patients ranges from 40% to 76%, with the variability in prevalence due to differing definitions of malnutrition as well as differences in the patient population studied (77–79). There are few studies that provide data on longitudinal changes in nutritional parameters. A prospective study performed in 118 patients who were started on PD found that mean serum albumin levels increased by approximately 0.2 g/dL over 24 months, nPNA declined by approximately 0.1 g/kg/24 h, whereas BMI and body fat were essentially unchanged (80).

The link between malnutrition and poor clinical outcome was not established using serum albumin

alone as a marker for nutritional status. Other surrogates for nutritional status such as loss of muscle mass as indicated by lower serum creatinine levels, lower creatinine generation rates, or total body nitrogen levels as well as low serum albumin levels, low prealbumin levels, and subjective global assessment (SGA) score are all good predictors of morbidity and mortality.

These data suggest that death risk is related to nutritional status, a parameter that may be influenced by a patient's total small solute clearance. However, it is important to remember that nutritional status is dependent not only on the prevention of or treatment of uremia but also on many non–ESRD-related factors (comorbid diseases, depression, gastroparesis, etc.). It is now noted that malnutrition can be reflective of poor nutritional intake, inflammation (81–83), or both (84,85). Serum albumin levels are known to be an acute phase reactant, decreasing in the face of inflammation. C-reactive protein (CRP) levels are abnormally high in most PD patients, and there is a direct association between elevated CRP levels and increased rates of mortality (86,87) and CV disease (88–90).

The International Society for Renal Nutrition and Metabolism (ISRNM) published standardized criteria for the diagnosis of protein-energy wasting in 2008. Those criteria define a serum albumin concentration of less than 3.8 g/dL, not an uncommon finding in a PD patient, as consistent with protein-energy wasting (91). Using the plasma albumin concentration, creatinine production, or other nutritional parameters, historical publications have estimated that 40% to 66% of PD patients in the United States are malnourished (75,77), whereas in a more recent cohort study using the ISRNM definition of protein-energy wasting (serum albumin of <3.8 g/dL), it was noted that 63% of PD patients compared to 55% of HD patients were malnourished (92). The ISRNM has suggested that there are four categories of protein-energy wasting. These are (a) evidence of biochemical abnormalities, (b) reduced body mass, (c) reduced muscle mass, and (d) unintentionally low dietary caloric intake.

Dialysis itself is associated with unique metabolic and nutritional problems that may cause one of the four conditions listed by the ISRNM. As mentioned earlier, they could be "underdialyzed" which may suppress appetite. It has been noted that PD patients often have a decreased appetite and early satiety (93,94). Perhaps, this is due to the presence of dialysate in abdomen which imparts a feeling of fullness, perhaps related to the continuous infusion of glucose which may suppress appetite. PD patients typically lose 5 to 15 g of protein and 2 to 4 g of amino acids per day in their dialysate (95). These losses amount to a net loss equivalent to 0.2-g protein/kg/d and tend to be higher in rapid transporters than in low transporters (96). They also are increased during episodes of peritonitis (97), at times doubling even after a mild episode. Although peritoneal losses of protein may correlate with serum albumin levels, they do not seem to correlate with other surrogates for nutritional status of chronic PD patients (98). The PD fluids may cause a chronic inflammatory state. Finally, one must remember, many new dialysis patients still have significant urine volumes and may have proteinuria causing a low albumin.

MEASUREMENTS OF NUTRITIONAL STATUS

Of the readily available measures of nutritional status, serum albumin levels, protein equivalent of nitrogen appearance (PNA), and SGA scores have traditionally been used.

Serum Albumin Levels

Serum albumin levels, in part a reflection of visceral protein storage, predict patient outcome in

populations with ESKD, no matter if obtained at the initiation of therapy (14,99) over the duration of dialysis (100) or measured at a stable period while on dialysis (101,102). Different assays for serum albumin give markedly different results (103). The Bromocresol green assay is preferred. Using this, the mean serum albumin level in 1,202 PD patients in late 1994/early 1995 was 3.5 g/dL (104). In an individual PD patient, the significance of an isolated serum albumin level must be viewed with caution. An isolated low level does not necessarily predict a high risk of death or malnutrition. Levels must be followed up over time and interpreted in context of other patient-related issues such as trends in the level, transport type, solute clearance, comorbid diseases, and so on.

We now have a better understanding of the causes of hypoalbuminemia. They are multifactorial (**TABLE 12.2**). When evaluating an individual patient, all causes must be considered, including the possibility that a chronic inflammatory state exists. Evolving data suggests that ESKD or perhaps the treatment of ESKD represents a chronic inflammatory state. During PD, the peritoneal cavity is repeatedly exposed to unphysiologic fluids (105,106), which may (107) or may not (108) induce a chronic inflammatory state.

Chronic inflammatory states

Dietary Protein Intake

Most (95%) nitrogen intake in humans is in the form of protein. Therefore, when the patient is in a steady state (not catabolic or anabolic), total nitrogen excretion multiplied by 6.25 (there are approximately 6.25 g of protein per gram of nitrogen) is thought to be an estimation of a person's DPI (109). Estimated DPI is calculated from urea nitrogen appearance (UNA) in dialysate and urine. Multiple equations have been derived, some of which have been validated in CAPD (not NIPD) patients (PNA = PCR + protein losses) (**TABLE 12.3**). These estimations were initially called the *protein catabolic rate* (*PCR*). However, PCR actually represents the amount of protein catabolism exceeding synthesis required to generate an amount of nitrogen that is excreted. PCR is actually a net catabolic equivalent. Therefore, because these calculations are based on nitrogen appearance, the term is more appropriately called the *PNA*.

TABLE 12.3 Commonly Used Formulas for Calculating Dietary Protein Intake

Formula for Calculating PNA	
Randerson I	PNA = 10.76 (UNA / 1.44 + 1.46), where UNA is in g/d
Randerson II	PNA = 10.76 (UNA + 1.46), where UNA is in mg/min
Modified Borah	PNA = 9.35 G_{un} + 0.294 V + protein losses
Teehan	PNA = 6.25 (UN_{loss} + 1.81 + 0.031 BW)
Kjeldahl	PNA = 6.25 × N. loss
Bergstrom	PNA = 19 + 7.62 × UNA

PNA, protein equivalent of nitrogen appearance; UNA, urea nitrogen appearance; BW, body weight.
Modified from Kopple JD, Jones MR, Keshaviah PK, et al. A proposed glossary for dialysis kinetics. *Am J Kidney Dis* 1995;26:963–981; Keshaviah P, Nolph K. Protein catabolic rate calculations in CAPD patients. *ASAIO Trans* 1991;37:M400–M402.

Keshaviah and Nolph (110) have compared these formulas and recommended the Randerson equation (111), where PNA = 10.76 (UNA + 1.46), and UNA is in milligram per minute, or PNA = 10.76 (UNA / 1.44 + 1.46), and UNA is in gram per day. These equations assume that the patient is in a steady state where UNA = urea nitrogen output which equals urea generation. The Randerson equation also assumes that the average daily protein loss in the dialysate is 7.3 g/d. In dialysis patients with substantial urinary or dialysate protein losses, these direct protein losses must be added to the equation to yield a true PNA. Most societies had historically recommended monitoring a patient's estimated DPI over time to assure adequate nutritional status. This was not recommended in the most recent KDOQI guideline for adequacy of PD. If used, a baseline PNA should be obtained during training. These should then be recalculated every 4 to 6 months using the same 24-hour dialysate and urine collections used to monitor solute clearances. Decreasing values would then suggest a decreasing protein intake. One cause for this may be a suboptimal total solute clearance.

For comparison purposes, it is recommended that PNA be normalized for patient size (nPNA). The weight to use for that normalization is contested. Depending on what weight is used in calculating nPNA, there may or may not be a statistical relationship between clinical evidence of malnutrition and nPNA values below target. The PNA normalized by actual weight tends to be high or may appear to be increasing over time in malnourished individuals who are losing body weight if normalized (divided) by a smaller malnourished weight when compared to the patient's baseline weight (112). This fact is important not only for evaluating patient to patient comparisons but more importantly when comparing serial measurements in an individual patient. The DOQI working group and others have recommended using standard weight or V/0.58 for normalization (113). In this case, the weight used for normalization does not change over time so that nPNA is more likely to reflect actual changes in DPI. Although most guidelines recommend monitoring estimated nPNA over time, looking for changes, it has been suggested that in cross-sectional analysis that the absolute amount of protein intake, not nPNA, correlated best with outcome and signs of malnutrition.

Data from the Centers for Medicare & Medicaid Services–Clinical Performance Measures (CMS–CPM) project for the year 2000 found that in chronic PD patients, the mean nPNA was 0.95 ± 0.31 g/kg/d, their normalized creatinine appearance rate was 17 ± 6.5 mg/kg/d, and the mean percentage of LBM was 64% ± 17% of actual body weight (ABW) (114).

There is some controversy as to what amount of DPI, in terms of grams of protein per kilogram of body weight, is needed to maintain positive nitrogen balance in PD patients. Early studies suggested that a DPI of at least 1.2 g/kg/d was needed to maintain nitrogen balance (115,116), a value considerably higher than that recommended for normal individuals. The 2001 NKF Clinical Practice DOQI guidelines recently recommended a DPI for chronic PD patients of 1.2 to 1.3 g/kg/d (117). Cross-sectional studies by Bergstrom and Lindholm (64) and Nolph (118) suggest that their patients who show no signs of malnutrition seem to eat less (0.99, 0.88 g protein/kg/d, respectively). The results are likely due to variations in the patient populations studied, historical dietary patterns, and amounts of RRF present. Therefore, several investigators have proposed that the daily protein intake in these patients should be in the range of 0.9 to 1.1 g/kg/d (119,120). It is interesting to note that the 2006 KDOQI guidelines do not have a guideline for protein intake due to the fact that there are no recent PRCTs that have evaluated the effect of increasing protein intake on relative risk of death.

Patients undergoing chronic PD should target a total daily energy intake of at least 35 kcal/kg/d for patients who are younger than 60 years and 30 kcal/kg for patients 60 years or older (117,121,122). This includes both dietary intake and the energy intake derived from glucose absorbed from the peritoneal dialysate. Many patients will typically eat less (122,123). Food supplements, enteral tube feedings, and both intradialytic and total parenteral nutrition have been used to treat malnutrition (124). Percutaneous endoscopic gastrostomy tubes should be used cautiously, however, as their use has been associated with a high rate of peritonitis. In addition, bicarbonate supplementation can result in improvements in weight and BMI (125). It is important to note however that for many PD patients, the dialysate glucose that is absorbed is a significant portion of their total caloric intake.

Subjective Global Assessment Score

One instrument that assesses nutritional status, the SGA score (126) has been modified for PD and was shown to be a valid estimate of nutritional status in PD patients (127). In the CANUSA study, a modified SGA using a 7-point scale addressing four items (weight change, anorexia, subcutaneous tissue, and muscle mass) predicted outcome (14). On multivariate analysis, poorer SGA scores were associated with a higher relative risk of death. It is recommended that this simple test be obtained sequentially (twice a year) in PD patients to evaluate nutritional status. If a decline is noted, evaluate for comorbid diseases and consider a suboptimal total solute clearance as the cause.

Possible Interventions for Suspected Malnutrition

Possible interventions when albumin is low include increasing the dialysis dose if “underdialysis” is suspected; restricting dietary sodium intake, water intake, or consider use of diuretics to increase urine volume and minimize use of hypertonic glucose if satiety from glucose is suspected (remember that the absorbed glucose is actually a source of calories); treating any poor dentation that is present; and if available, considering use of alternative dialysate solutions such as amino acid solutions. Initial observations suggest that use of amino acid–containing fluids can lead to an elevation in the plasma albumin concentration and improvement in other biochemical parameters of nutritional status (128,129); however, data are conflicting as to if this can be sustained without side effects if more than one exchange per day are used. Consensus exists that if used only once a day, they are generally safe and are associated with daily protein and amino acid gains that exceed daily amino acid losses although they may not

significantly improve albumin concentrations (130).

MAJOR DETERMINANTS OF TOTAL SOLUTE CLEARANCE

Small solute clearance is typically measured in terms of urea kinetics (Kt/V_{urea}) and Ccr/1.73 m^2. Guidelines (reviewed earlier) recommend attaining certain minimal "total" (peritoneal and residual kidney) clearances per week.

Residual Renal Function

Creatinine and urea are used as surrogate markers for small molecular weight clearance. When calculating the Ccr due to RRF, it is important to remember that at very low GFRs or Ccrs, much of the creatinine in the urine is due to proximal tubular secretion rather than actual glomerular filtration. As a result, traditional measurements of Ccr (24-hour collection) can significantly overestimate the true GFR. If using creatinine kinetics as the surrogate, it is recommended that the sum of the measured urea clearance and Ccr divided by 2 be used to approximate underlying residual kidney GFR. This amount in liters per day is then added to the daily peritoneal Ccr to determine total daily Ccr. The clearance of most other small molecular weight substances such as urea by the kidney only involves glomerular filtration and little to no tubular secretion. Therefore, if one is measuring dialysis dose using urea kinetics, no adjustment for tubular secretion is needed.

Each 1 mL/min of corrected residual kidney Ccr (measured as GFR) adds approximately 10 L/wk/1.73 m^2 of Ccr for the average patient with a BSA of 1.73 m^2. Similarly, each 1 mL/min of residual renal urea clearance adds approximately 0.25 Kt/V_{urea} units to the total weekly Kt/V_{urea} urea for a 70-kg male. At the initiation of dialysis, residual kidney function often represents a significant amount of the recommended minimal solute clearances. In one report, the residual kidney component represented 39% of total clearance (131), while representing 25% of the total in another review (132). If a patient starts PD with a residual kidney Ccr of 5 mL/min (not an unusual scenario), the corrected kidney CCr (GFR) may be approximately 4 mL/min, adding approximately 40 L/wk of Ccr to overall solute clearance, whereas the residual kidney urea clearance might be approximately 3 mL/min (a weekly RRF Kt/V_{urea} of about 0.75 for a 70-kg male). In this instance, a patient may only need to do one or two exchanges per day at the start of dialysis.

Some have suggested that RRF is better preserved with PD than with HD (123–136). It is acknowledged that residual renal clearance is an important supplement to that provided by dialysis and is an important predictor of outcome. As RRF decreases, total clearance expressed as Kt/V_{urea} or Ccr will decrease unless replaced by an increase in the peritoneal component. Tattersall et al. (137,138) have shown that it was possible to compensate for declining RRF and maintain minimal solute clearance goals by increasing dialysis dose as residual kidney function declines. This is a common practice in PD units where "incremental dialysis" is prescribed and dialysis dose increased over time as RRF decreases.

Peritoneal Membrane Transport Characteristics

The first step in tailoring an individual patient's PD prescription is to know that patient's peritoneal membrane transport characteristics. Unlike HD, where the physician has a wide menu of dialyzers to

choose from for each individual patient, PD patients are "born" with their membrane. At present, there is no clinically proven way to favorably change membrane transport or predict transport type before beginning PD.

The peritoneal equilibration test (PET) (139) is the standard way to characterize peritoneal membrane transport properties of an individual patient. It is a standardized test in which, after an overnight dwell, 2 L of 2.5% dextrose dialysate is instilled (time 0) and allowed to dwell for 4 hours. Dialysate urea, glucose, sodium, and creatinine are measured at time 0, and after 2 and 4 hours of dwell time. Serum values are drawn after 2 hours. Dialysate is drained after 4 hours of dwell, and drain volume (DV) is measured. Dialysate to plasma (D/P) ratios of creatinine and urea are determined after 2 and 4 hours of dwell, as is the ratio of dialysate glucose at a particular drain time to the initial dialysate glucose concentration (D/Do) (**FIGURE 12.3**). On the basis of published data, the patient's peritoneal membrane type is then characterized as high, high average, low average, and low. In a review of 806 patients, 10.4% were found to be high transporters, 53.1% high average, 30.9% low average, and 5.6% low transporters (140). Once characterized, the PD prescription that would best match the patient's transport characteristics can be then chosen.

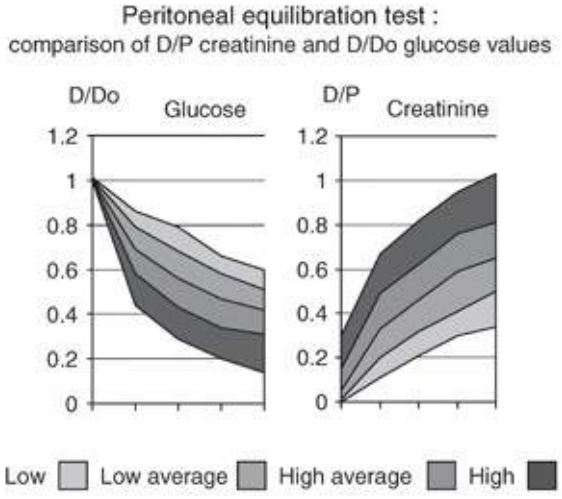

FIGURE 12.3 Dialysate to plasma (D/P) ratio urea and dialysate glucose at time of sampling to dialysate glucose at time zero ratios for glucose during typical 4-hour dwell with 2.5% dextrose. D/Do, dialysate glucose concentration. (Modified from Twardowski ZJ, Nolph KD, Khanna R, et al. Peritoneal equilibration test. *Perit Dial Bull* 1987;7:138–147; Twardowski ZJ, Khanna R, Nolph KD. Peritoneal dialysis modifications to avoid CAPD dropouts. In: Khanna R, Nolph KD, Prowant BF, et al, eds. *Advances in Continuous Ambulatory Peritoneal Dialysis*. Proceedings of the Seventh Annual CAPD Conference, Kansas City, Missouri, February 1987. Toronto, Canada: Peritoneal Dialysis Bulletin, 1987:171–178.)

These D/P ratios can be calculated for any solute. By doing so, one can appreciate the difference in expected clearances for various sized solutes. For instance, as noted in **FIGURE 12.4** urea (molecular weight: 60 Da) is transported faster than creatinine (molecular weight: 112 Da). Most patients are greater than 90% equilibrated for urea after a 4-hour dwell, whereas for creatinine, the average patient is only 65% equilibrated at 4 hours. As noted in the figure, these differences are even more marked for low transporters and is clinically most noted when using a therapy that utilizes multiple short dwells (CCPD, NIPD). Phosphate has a larger molecular weight than creatinine but is similar in size, so creatinine removal can be used as a surrogate for phosphate removal (**FIGURE 12.5**).

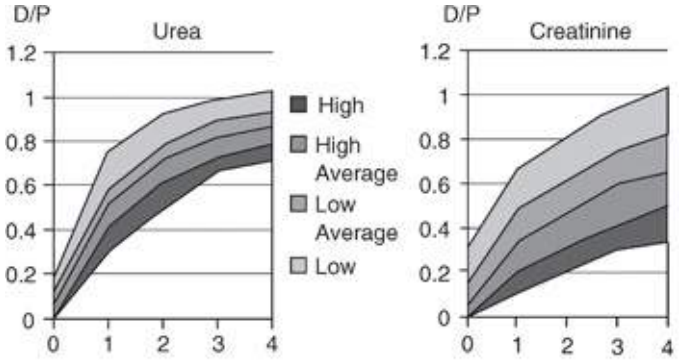

FIGURE 12.4 Dialysate to plasma (D/P) ratios for creatinine and urea. D/P ratios for urea and creatinine during the standard peritoneal equilibration test. Exact values at 2 and 4 hours are shown. (Modified from Twardowski ZJ, Nolph KD, Khanna R, et al. Peritoneal equilibration test. *Perit Dial Bull* 1987;7:138–147; Twardowski ZJ, Khanna R, Nolph KD. Peritoneal dialysis modifications to avoid CAPD dropouts. In: Khanna R, Nolph KD, Prowant BF, et al, eds. *Advances in Continuous Ambulatory Peritoneal Dialysis*. Proceedings of the Seventh Annual CAPD Conference, Kansas City, Missouri, February 1987. Toronto, Canada: Peritoneal Dialysis Bulletin, 1987:171–178.)

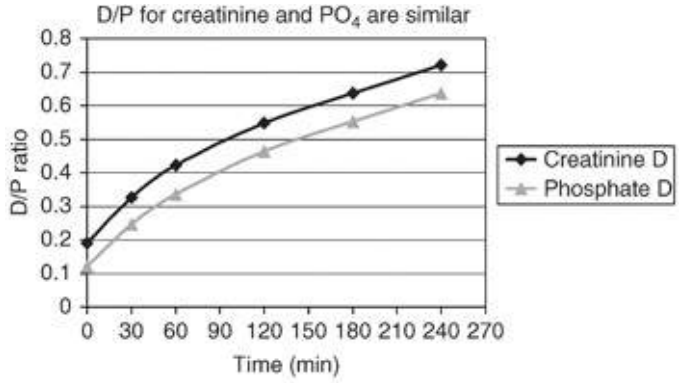

FIGURE 12.5 Theoretic constructs for dialysate to plasma (D/P) ratios of creatinine and phosphorous (PO_4) during a peritoneal dialysis dwell.

Solute removal by PD is related to the concentration of the solute in question in the dialysate (D/P ratio) and the dialysate DV. Patients with small DVs tend to have lower clearances. UF during a dwell is related to crystalloid (glucose, amino acid) or colloid (icodextrin)-induced osmotic forces. It is important to point out that rapid transporters of creatinine/urea also tend to be rapid absorbers of dialysate glucose. Once the osmotic glucose gradient is mitigated by absorption, UF ceases and lymphatic absorption of fluid predominates (**FIGURE 12.6**). Therefore, in rapid transporters, although the D/P ratios of urea and creatinine at 4 hours or longer dwells tend to be close to unity, their DVs tend to be small and hence their solute removal is less than optimal due to the small DVs (141). In fact, during the long overnight dwell of CAPD (9 hours) or during the long daytime dwell of classic CCPD (15 hours), rapid transporters may have DVs that are actually less than the *instilled* volume. For these patients, short dwell times are needed to reduce or minimize fluid reabsorption and optimize clearances. In patients who are low transporters, intraperitoneal glucose is slowly absorbed; hence, peak UF occurs later during the dwell and net UF can be obtained even after prolonged dwells. In these patients, the D/P ratio increases almost linearly during the dwell. It is not until 8 to 10 hours that the D/P ratio reaches unity.

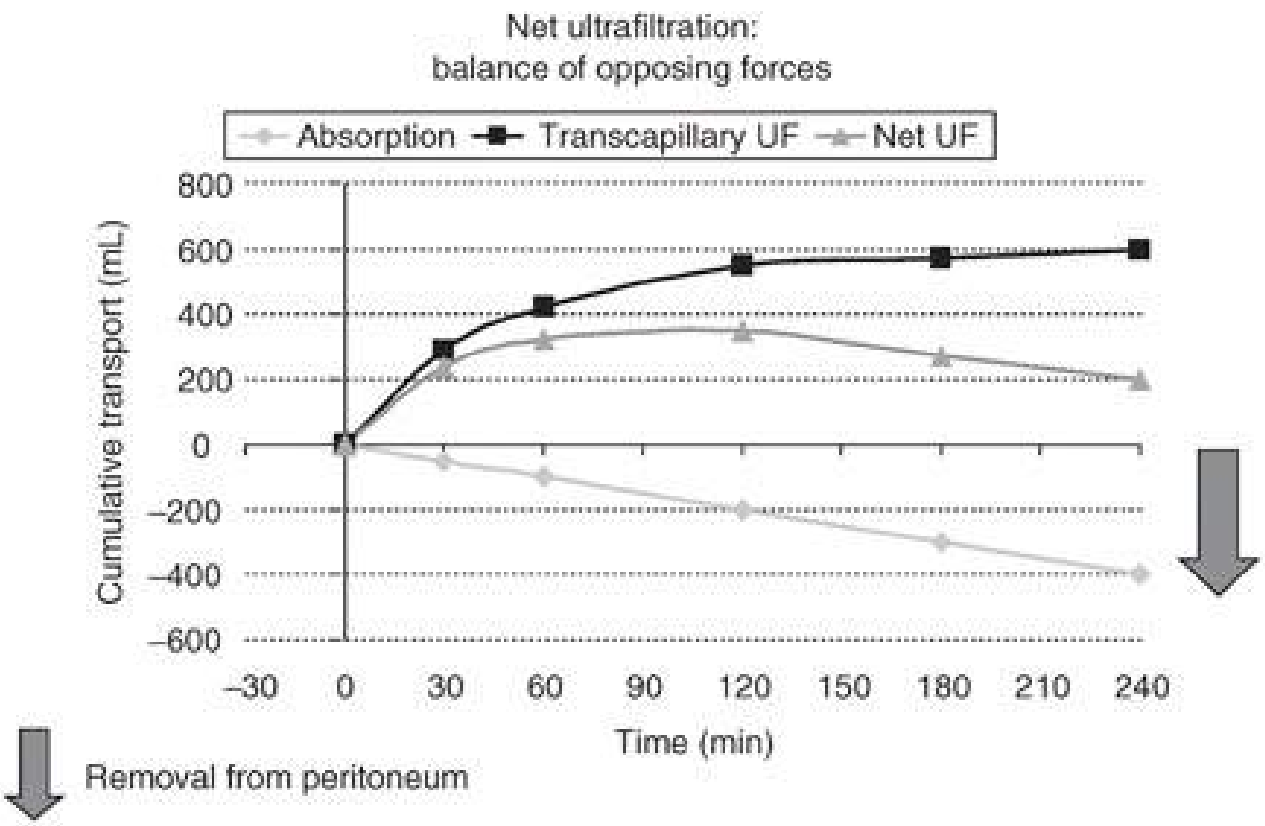

FIGURE 12.6 Time profiles of opposing forces governing ultrafiltration (UF) (transcapillary UF) and lymphatic absorption. *Diamond*, lymphatic absorption; *square*, transcapillary ultrafiltration; *triangle*, net ultrafiltration. (Modified from Mactier RA, Khanna R, Twardowski ZJ, et al. Contribution of lymphatic absorption to loss of ultrafiltration and solute clearances on continuous ambulatory peritoneal dialysis. *J Clin Invest* 1987;80:1311–1316.)

To put these differences in perspective, one can appreciate that after only a 2-hour dwell time, a rapid transporter likely will have achieved 2 L of Ccr, whereas the Ccr in a low transport individual may be only 1 L or less, despite a larger DV (**FIGURE 12.7**). It may take the low transporter up to 7 or 8 hours of dwell time to achieve the same clearance that a rapid transporter achieves after only a 2-hour dwell. These differences must be taken into account when attempting to tailor an individual patient's PD prescription.

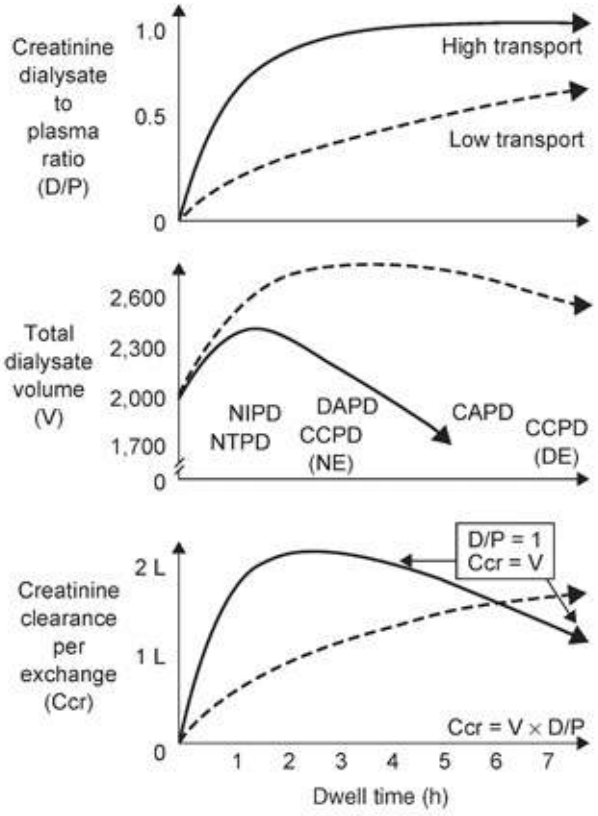

FIGURE 12.7 Comparison of idealized curves for solute and water transport during an exchange in patients with low and high transport characteristics. Idealized curves of creatinine and water transport during an exchange with 2 L of 2.5% glucose dialysis solutions in patients with extremely low and high transport characteristics. NIPD, nightly intermittent peritoneal dialysis; DAPD, daytime ambulatory peritoneal dialysis; CAPD, continuous ambulatory peritoneal dialysis; NTPD, nightly tidal peritoneal dialysis; NE, nightly exchange; DE, daytime exchange; CCPD, continuous cyclic peritoneal dialysis. [From Twardowski ZJ. Nightly peritoneal dialysis (Why? who? how? and when?). *ASAIO Trans* 1990;36:8–16.]

Peritoneal membrane transport tends to remain stable over time. Rippe and Krediet (142) reviewed 9 cross-sectional and 16 longitudinal studies of peritoneal transport. In 14 out of 25 studies, there tended to be no change in peritoneal transport over time on PD; in the other 11 out of 25 studies, there was a slight increase in low/medium molecular weight solute transport over time. Others found no change in peritoneal transport in 23 patients followed up for at least 7 years (143), especially in patients with low peritonitis rates (144). In contrast, there was a tendency toward increase in small solute transport and loss of UF, especially in patients with frequent peritonitis (145,146). Others have noted that up to 30.9% of patients developed UF failure (change in transport) after 6 years on PD (147). These data emphasize the importance of monitoring membrane transport (usually with PET testing) over time to optimize solute clearance, DVs, BP, and UF, while minimizing hypertonic glucose use. If peritoneal transport type changes, the patient's prescription may need to be altered.

The PET is the most practical and widely used method to classify peritoneal transport; however, there are also other ways. In these other tests, instead of using D/P ratios, these tests use mass transfer area coefficients (MTACs) (148,149), which are more precise and more succinctly define transport. The MTACs define transport independent of UF (convection-related solute removal) and hence in theory are not influenced by dwell volume or glucose concentration. The practical use of MTAC for modeling a PD prescription requires additional laboratory measurements and computer models but once obtained, MTAC can be easily used in the clinical setting (150). The standard peritoneal permeability analysis is another less often used test to follow transport and UF characteristics (151). The test not only determines

transport characteristics but also better evaluates lymphatic reabsorption. If one does a PET using 4.25% dextrose dwell rather than the classic 2.5% dextrose dwell to maximize UF, one is better able to determine actual UF properties of the membrane the amount of sodium sieving and can better differentiate the causes of UF failure (152,153).

Normalization and Influence of Body Size on Solute Clearance

Removal of the same absolute amount of solute from a 55-kg elderly woman as from an 80-kg muscular man may not result in the same control of uremia. These patients likely have different metabolic rates and protein intakes. Therefore, the absolute amount of daily solute removed or cleared must be normalized for differences in body size (traditionally when using urea as a surrogate, it is normalized by V or volume of distribution for Kt/V_{urea} and by BSA for Ccr/1.73 m^2).

Kt/V_{urea} is normalized by V, whereas Ccr in L/wk/1.73 m^2 by BSA. For recommended formulas, see **TABLE 12.4**. TBW (V) can be estimated as a fixed percentage of body weight, or more accurately, by using anthropometric formulas based on sex, age, height, and weight such as the Watson et al. (154) or Hume and Weyers (155) formulas in adults. These equations provide unrealistic estimates for V in patients whose weights are markedly different than normal body weight (NBW). BSA is usually calculated using the formula by Dubois and Dubois (156).

TABLE 12.4 Equations for Normalization (Calculating V for Kt/V or BSA for Creatinine Clearance)

Formula for Estimating BSA		
For all formulas, weight (Wt) is in kilogram and height (Ht) is in centimeter:		
DuBois and Dubois method:		$BSA\ (m^2) = 0.007184 \times Wt^{0.425} \times Ht^{0.725}$
Gehan and George method:		$BSA\ (m^2) = 0.235 \times Wt^{0.51456} \times Ht^{0.42246}$
Haycock method:		$BSA\ (m^2) = 0.024265 \times Wt^{0.5378} \times Ht^{0.3964}$
Formulas for Estimating V		
Watson Method		
For men:	V (L)	$= 2.447 + 0.3362 \times Wt\ (kg) + 0.1074 \times Ht\ (cm) - 0.09516 \times Age\ (yr)$
For women:	V	$= 2.097 + 0.2466 \times Wt + 0.1069 \times Ht$
Hume Method		
For men:	V (L)	$= -14.012934 + 0.296785 \times Wt + 0.194786 \times Ht$
For women:	V	$= -35.270121 + 0.183809 \times Wt + 0.344547 \times Ht$
Mellits-Cheek Method for Children		
For boys:	V (L)	$= -1.927 + 0.465 \times Wt\ (kg) + 0.045 \times Ht\ (cm)$, when height is ≤ 132.7 cm
	V	$= -31.993 + 0.406 \times Wt + 0.209 \times Ht$, when height is ≥ 132.7 cm
For girls:	V	$= 0.076 + 0.507 \times Wt + 0.013 \times Ht$, when height is < 110.8 cm
	V	$= -10.313 + 0.252 \times Wt\ 0.154 \times Ht$, when height is ≥ 110.8 cm

BSA, body surface area.

Relationship between total body water and surface area in normal and obese subjects. *J Clin Pathol* 1971;24:234–238; Mellits ED, Cheek DB. The assessment of body water and fatness from infancy to adulthood. *Monographs Soc Res Child Dev* 1970;35:12–26.

In a review of 806 patients with PD, the median BSA was 1.85 m^2 (not 1.73 m^2), the 25th percentile was 1.71 m^2, and the 75th percentile was 2.0m^2 (140), whereas data from the CMS–CPM project for the year 2000 found that chronic patients with PD had a mean body weight of 76 ± 19 kg and BMI of 27.5 ± 6.4 kg/m^2 (109). Despite the finding that most PD patients are larger than the "standard" BSA of 1.73 m^2,

a review of the predicted clearances for Kt/V_{urea} for an average transporter over a broad range of BSA suggests that if one was able to individualize therapy (increased instilled volumes, daytime exchange for CCPD, nightly exchange device), one should be able to achieve the recommended acceptable target total Kt/V_{urea} clearances for most patients on PD (157). On the basis of the patient's body size, one can predict whether or not an individual patient who is an average transporter would meet NKF-DOQI targets for small solute clearance using four 2-L exchanges/d once they were anuric (158–160) and also what instilled volume/prescription would be needed to achieve the small solute clearance targets. Only anuric patients who are low transporters and who have large BSAs (greater than 1.8 m^2) would not be likely to achieve these targets.

For malnourished patients whose weight is more than 10% below than their ideal weight, the NKF-DOQI guidelines recommend adjusting total solute clearance targets by the ratio of ideal/actual weight. In this case, a relatively higher target solute removal to promote anabolism and an increased protein intake is targeted. Jones (161) noted that when ABW was used for normalization, there was no difference in total solute clearance (Kt/V or Ccr) between patients who were well nourished and those who were malnourished. However, when calculated V and BSA were determined using desired body weight (dBW), there was a statistically significant difference between the groups for both weekly Kt/V_{urea} (1.68 ± 0.46 vs. 1.40 ± 0.41, $p < 0.05$) and for Ccr in liters per 1.73 m^2 per week (52.5 ± 10.3 vs. 41.6 ± 19.0, $p < 0.01$).

It is noted that large patients (BMI greater than 27.5) on PD tend to do as well as or better than patients who are within 10% of their ideal weight (162). If one uses actual weight versus ideal weight, there is a marked difference in adequacy calculations (**TABLE 12.5**). Some have managed their patients, adjusting the PD prescription based on Kt/V urea and Ccr/1.73 m^2, where the normalization calculations were done using ideal weight when calculating V or BSA found no difference in survival for patients whose actual weights were more than 10% above their ideal weight when compared to those whose weights were within 10% of ideal weight (34). Currently, it is still unclear what weight to use when calculating Kt/V or Ccr in obese individuals. However, it is clear that many obese patients do very well on PD and if clearances are individualized, most are able to achieve target. Unfortunately, this often results in transfer from PD to HD because the adequacy number is not above target despite fact that the NKF-DOQI guidelines suggested to attempt to reach recommended targets. If one cannot, look at the individual and decide how they are doing clinically before one automatically transfer the patient to HD.

TABLE 12.5 Adequacy Calculations: What Weight Should You Use?

BW Ratio	<0.9	0.9–1.1	>1.1
Percentage	19	33	48
BWa/BWd	0.82	1.01	1.37
Kt/Va	1.95	2.08	1.94
Kt/Vd	1.74	2.08	2.25
Ccra (L/wk)	68.1	71.5	64.1
Ccrd (L/wk)	62.6	71.7	72.4

BW, body weight; a, actual; d, desired; Ccr, creatinine clearance.

SPECIAL CONSIDERATIONS

Rapid Transporters

Rapid transporters tend to optimize both solute clearance and UF after a short dwell time (approximately 2 hours) and, therefore, are likely to do well on short dwell therapies such as NIPD, with or without one or two 2- to 4-hour daytime dwells. One would predict that they would easily reach total small solute clearance goals for Kt/V_{urea} and Ccr, at times reaching that goal while only doing nightly dwells. Despite this relative ease in the ability to achieve recommended minimal total solute clearance goals, some (163–165) but not all (35,166–168) studies have suggested that after controlling for urea clearance rapid transporters tended to have a higher relative risk of death. In the CANUSA study, patients with a 4-hour D/P creatinine of greater than 0.65 (high) were compared to those with a 4-hour D/P creatinine of less than 0.65 (low). The 2-year probability for technique survival was 79% among low transporters compared to 71% for high transporters. The probability of 2-year patient survival was 82% among low transporters versus 72% for high transporters with a relative risk of death of 2.18 for high versus low transporters. Heaf (165) noted increased morbidity in rapid transporters.

The reason(s) for this possible increased relative risk while on CAPD are unclear and may be related to malnutrition (169), increased protein losses in the DV (170–172), or overt or subtle volume overload. This volume overload may lead to increased BP and/or increased left ventricular hypertrophy (LVH) with its associated increased risks of death. Furthermore, to optimize UF, these patients will likely increase their percentage of glucose in fluids, leading to better UF but increased glucose absorption with its associated side effects. A meta-analysis of studies published between 1987 and end of December 2005 that correlated membrane transport and relative risk of death was conducted. Twenty studies were identified, 19 of which were pooled to generate a summary mortality relative risk of 1.15 for every 0.1 increase in the D/P creatinine (95% CI 1.07 to 1.23; p <0.001) (173). They concluded that higher peritoneal membrane status is associated with a higher mortality risk (increased mortality risk of 21.9%, 45.7%, and 77.3% in low-average, high-average, and high transporters, respectively) as compared to low transport status. Note that these historical data tend to be mainly from patients on CAPD. They do not include more contemporary advances in therapy such as newer innovations in automated peritoneal dialysis (APD) therapy and alternative PD solutions designed for better UF such as icodextrin. Contemporary data has evaluated the death risk for rapid transporters on APD.

Studies that have evaluated a greater proportion of patients on cycler therapy demonstrated a lower mortality risk for a given increase in D/P creatinine compared to studies that mainly enrolled CAPD patients. This is consistent with the reported observational finding that in patients all given the same CAPD prescription, those with high transport status were more likely to be hypertensive (100% vs. 0%) and have LVH (100% vs. 33%) than the low transporters on the same prescription (3 × 1.36% G daytime dwells and 1 × 3.86% G overnight) (174). In these patients, when prescription was altered to increase UF, their BP improved. When these observations were noted, more attention was paid to individualizing the PD prescription for patients with high peritoneal membrane transport. With such maneuvers, it has been shown that patients with high membrane transport can be managed on PD without the increased mortality risk demonstrated in historical studies (175) (**FIGURE 12.8**). Current data would suggest that patients who are baseline high transporters are not at increased relative risk of death as long as their

prescription is managed appropriately.

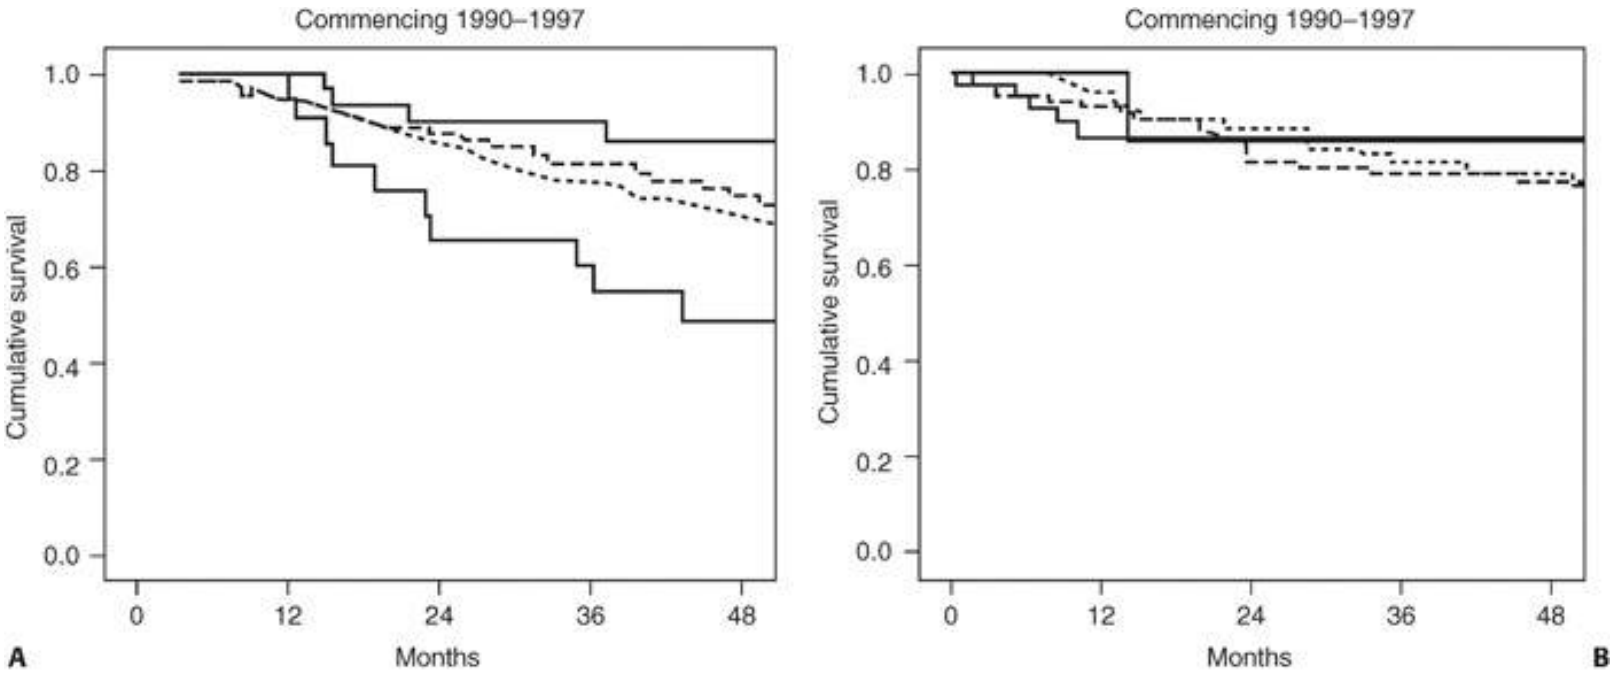

FIGURE 12.8 Correlation between transport type and survival in two peritoneal dialysis (PD) cohorts commencing therapy during different years. Survival on PD [patients censored at transplant or transfer to hemodialysis (HD)] according to transport category at start of treatment comparing two cohorts commencing therapy between **(A)** 1990 to 1997, $n = 320$, and **(B)** 1998 to 2005, $n = 300$. Low (*solid line*), low average (*dotted line*), high average (*dashed line*), and high (*solid bold line*). In the first cohort, transport category was significantly ($p = 0.0009$) associated with survival, whereas in the more recent cohort, transport type was not associated with survival. (From Davies SJ. Mitigating peritoneal membrane characteristics in modern peritoneal dialysis therapy. *Kidney Int* 2006;70:S76–S83.)

Acid–Base Metabolism

An essential component of providing "optimal" dialysis is correction of acidosis. Chronic acidosis has a detrimental effect on protein, carbohydrate, and bone metabolism. In patients with CAPD, body base balance is self-regulated by feedback between plasma bicarbonate levels and bicarbonate gain/loss (176). Dialysis must provide sufficient replenishment of buffers to compensate for the daily acid load. Lactate (concentration 35 to 40 mmol/L) is the standard buffer in PD fluids. Lactate is converted to pyruvate and oxygenated or used in gluconeogenesis with the consumption of H+ and the generation of bicarbonate (177). With lactate-containing buffer solutions, buffer balance is governed by the relative amounts of H+ generation, bicarbonate loss, lactate absorption, and lactate metabolism (178–180). Newer bicarbonate-based solutions are in use in some countries but mainly for their "biocompatibility" properties and not to better treat acidosis (181). Most patients with CAPD have stable mean plasma bicarbonate levels of approximately 25.6 mmol/L using a dialysate lactate of 35 mmol/L, although some patients with CAPD remain mildly acidotic. Increasing dialysate lactate results in a higher serum bicarbonate level (182).

Control of acidosis is important to prevent protein catabolism (183–185); however, two studies have found no correlation between serum albumin levels and bicarbonate concentration (186,187). A recent survey of serum bicarbonate levels in patients with PD showed that only consumption of the phosphate binder sevelamer hydrochloride was associated with a decline in serum bicarbonate concentration (188).

Which Is the Preferred Target—Kt/V or Creatinine Clearance?

Both total Kt/V_{urea} and total Ccr/1.73 m^2 can be used to monitor solute clearance. There are no data to

suggest that one index is better than the other. Of course, these solutes are just surrogates for small solute removal; other solutes could be used, but there are currently no data to correlate relative risk of death with the removal of other solutes. Although these two yardsticks do not fall on the same linear scale, the two values usually correlate (189).

If one uses residual kidney and peritoneal clearance of these solutes, it is important to remember the following caveats: Residual renal clearance of a solute is the result of glomerular filtration and tubular manipulation of that filtrate. Ccr by the kidneys is due to glomerular filtration and proximal tubular secretion, especially in advanced stages of kidney insufficiency where the absolute amount tubular creatinine secretion can increase by as much as 30% accounting for up to 35% of total urinary creatinine (190). In contrast, with urea, there is glomerular filtration but also tubular reabsorption. Therefore, in advanced stages of kidney disease, residual renal clearance of creatinine will be relatively greater than that for urea. Peritoneal clearance is predominantly diffusion-driven. (There is also a component of convective clearance due to UF, but this contribution is relatively smaller than that due to diffusion.) Therefore, because urea is a smaller molecular weight solute than creatinine, the numerical value for peritoneal clearance of urea tends to be relatively greater than that for Ccr. This difference is most pronounced in patients who are low transporters (**FIGURE 12.9**).

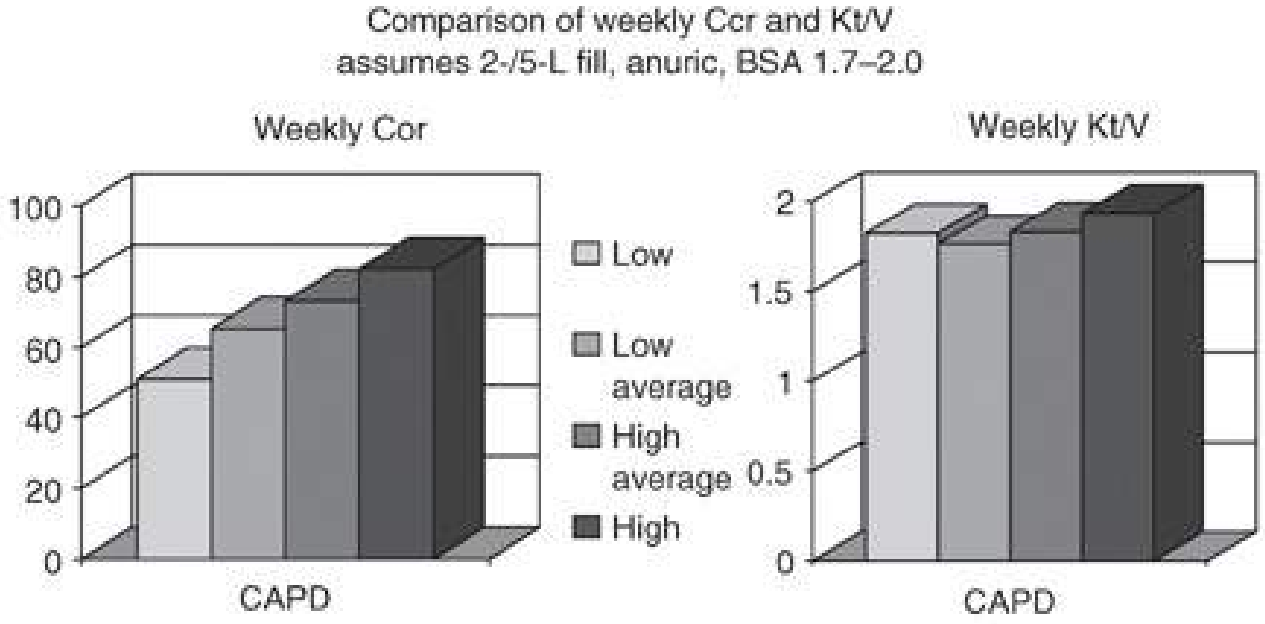

FIGURE 12.9 Representative total weekly Kt/V_{urea} and Ccr/1.73 m^2 for an average 70-kg male, who is an average transporter with various amounts of residual renal function contributing to total solute clearance (100%, 50%, 0%). Ccr, creatinine clearance; BSA, body surface area; CAPD, continuous ambulatory peritoneal dialysis. (Modified from Blake P, Burkart JM, Churchill DN, et al. Recommended clinical practices for maximizing PD clearances. *Perit Dial Int* 1996;16:448–456.)

Peritoneal membrane transport characteristics may also explain this discrepancy. The diffusive clearance for urea is relatively greater than that for creatinine. During the typical dwells associated with CAPD, the D/P ratio for urea tends to reach unity (equilibration between blood and dialysate) in all patients, whereas the D/P for creatinine tends to reach unity only in high transporters. Therefore, the urea clearance/dwell tends to be greater than that for creatinine. This is most pronounced in low transporters.

The guidelines do not differentiate between genders. The patient's weight has a different effect on normalization (V or BSA) for male or female and for Ccr versus Kt/V. In patients with similar BSA, instilled volume, transport type, and gender all have a significant effect on Kt/V calculations but not on

Ccr calculations. The mathematical relationship between BSA and V is not fixed. It is disturbed by both gender and obesity. Furthermore, the actual V is different if "obesity" is due to a change in body fat versus a change in body water (overhydration) (191) and if the patient has had an amputation (192). Therefore, in the average anuric patient on 5- to 2-L exchanges per day with average peritoneal transport characteristics, peritoneal Ccr will be 73% of urea clearance (193). Therefore, in an anuric average transporter with a weekly peritoneal Kt/V of 2.0, the expected Ccr is approximately 55 L/1.73 m^2/wk in males and 47 L/1.73 m^2/wk in females. Similarly, for NIPD patients with average transport, the peritoneal Ccr will be 64% of urea. Therefore, for an anuric average transporter on NIPD, with a weekly Kt/V of 2.2, the expected weekly Ccr will be 53 L/1.73 m^2 in males and 45 L/1.73 m^2 in females (**TABLE 12.6**).

TABLE 12.6 Creatinine Clearance (L) at Kt/V of 2.2 in Nightly Intermittent Peritoneal Dialysis (NIPD) and 2.0 in Continuous Ambulatory Peritoneal Dialysis (CAPD)

	NIPD		CAPD	
Transport Category	**Females**	**Males**	**Females**	**Males**
Minimal value	32.90	38.80	30.70	36.30
Low transporters	33.70	39.80	35.70	41.60

Mean + SD	50.80	59.90	53.20	62.80[a]
High transporters	55.60	65.60	58.10	68.50[a]
Maximal value	59.40	70.00[a]	62.70[a]	73.90[a]

Assumptions: Total body water in males = 41.7 L; total body water in females = 32.1 L; body surface area in males = 1.92 m^2; body surface area in females = 1.74 m^2; NIPD (nocturnal intermittent peritoneal dialysis): hourly 2-L exchanges. CAPD (continuous ambulatory peritoneal dialysis): five 2-L exchanges. SD, standard deviation.

[a]Values are above the Dialysis Outcomes Quality Initiative guidelines for creatinine clearance at recommended Kt/V.

From Twardowski ZJ. Relationships between creatinine clearances and Kt/V in peritoneal dialysis patients: a critique of the DOQI document. *Perit Dial Int* 1998;18:252–255.

There are no clinical outcome data to support the use of one solute clearance yardstick (Ccr or Kt/V) over the other. Most of the published outcome data is related to Kt/V_{urea}. NKF-DOQI guidelines and others (194) have historically suggested that one should always strive to at least have Kt/V_{urea} above target, stating that there was no additional benefit to using Ccr. As reviewed earlier, current guidelines use Kt/V_{urea} as the "dose surrogate."

VOLUME AND BLOOD PRESSURE CONTROL ISSUES

CV disease continues to be the leading cause of death in patients with ESKD. There is a high prevalence of LVH and congestive heart failure (CHF) in patients initiating dialysis. The prevalence of LVH is higher

in the elderly population and is increasing yearly (195). It is well known that predisposing factors for the development of LVH include volume overload and hypertension.

Multiple observational studies have compared BP and volume status in PD and HD patients. Counterintuitive to what would be expected in a PD patient where there is an opportunity for daily control of extracellular volume, PD patients tend to be volume expanded (**FIGURE 12.10**). Using bioimpedance measurements (BIA) to determine intracellular and extracellular fluid spaces, it was noted that both TBW and extracellular fluid volume (Vecf) were actually greater in PD patients than both before and after dialysis values in chronic HD patients and baseline values of healthy controls (196). Furthermore, the ratio of Vecf/TBW positively correlated with systolic BP and negatively correlated with serum albumin levels. Others have shown that CAPD patients have an increase in mean pulmonary artery pressure when compared to HD patients. In that study, pulmonary artery pressures were measured pretransplant in both PD and HD patients and found to be a mean of 22 + 7 mm Hg in 56 CAPD patients and 16.3 + 7.2 mm Hg in 296 HD patients (p <0.01) (197). In another study, it was shown that CAPD patients (n = 28) had a considerable fall in "dry weight" (66.6 + 2.3 kg on PD vs. 62.4 + 2.4 kg on HD, p <0.05) after transfer to HD (3). This was associated with no change in systolic BP but a significant improvement in diastolic BP. These observations suggest that PD patients tend to be chronically plasma volume overloaded.

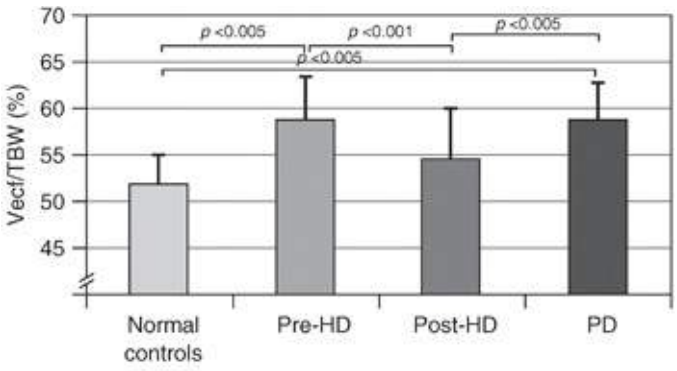

FIGURE 12.10 Volume status in peritoneal dialysis (PD) and hemodialysis (HD) (both pre- and postdialysis). Ratio of Vecf/TBW in HD patients (measured pre- and postdialysis, in PD patients and in healthy subjects. Measurements were performed after 20 minutes in the supine position using multifrequency bioimpedance. Vecf, volume of extracellular fluid; TBW, total body water. (From Plum J, Shoenicke G, Kleophas W, et al. Comparison of body fluid distribution between chronic hemodialysis and peritoneal dialysis patients as assessed by biophysical and biochemical methods. *Nephrol Dial Transplant* 2001;16:2378–2385.)

Uncontrolled hypertension due to volume overload is thought to contribute to higher left ventricular mass in CAPD patients (198). Some have demonstrated that long-term PD patients were more likely to have LVH than long-term HD patients (199). In that study, 51 CAPD patients were compared to a group of 201 HD patients. LVH was more severe in CAPD patients than in HD patients (p <0.0001), and CAPD patients were more likely to need antihypertensive medications (65% vs. 38%, p <0.001) despite CAPD patients being younger. Note this study was done in CAPD patients, and it is uncertain if individualization of prescription and use of APD would alter the results. Hypertension is a common finding in the PD patient with reported prevalence in PD populations of between 29% and 88% (104,200,201) (**FIGURE 12.11**). Conventional wisdom would suggest that hypertension in patients with ESKD is in part related to volume expansion and presumably excess total body sodium. As will be discussed, due to "sodium sieving" across aquaporins, it is important to remember that with PD, not all of the UF volume is always sodium replete. In fact, the UF volumes of the short dwells of APD when using dextrose-based solutions

may be up to 50% sodium-free.

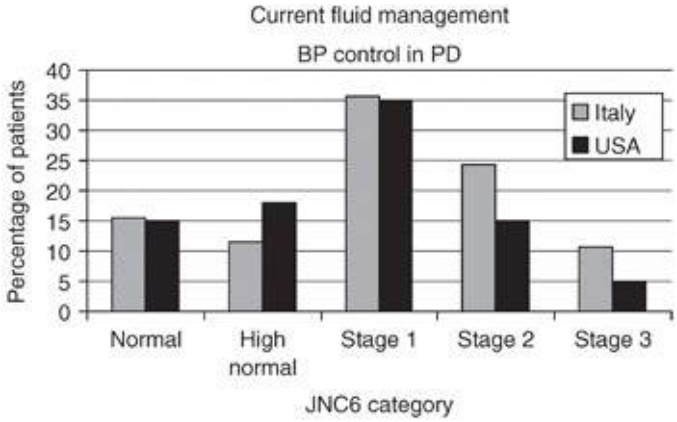

FIGURE 12.11 Blood pressure (BP) control in peritoneal dialysis (PD) patients. BP control in PD patients in Italy and the United States per Joint National Commission recommendations version 6. (Modified from Frankenfield DL, Prowant BF, Flanigan MJ, et al. Trends in clinical indicators of care for adult peritoneal dialysis patients in the United States from 1995 to 1997. *Kidney Int* 1999;55:1998–2010; Cocchi R, Degli Esposti E, Fabbri A, et al. Prevalence of hypertension in patients on peritoneal dialysis: results of an Italian multicentre study. *Nephrol Dial Transplant* 1999;14:1536–1540.)

Interestingly in HD patients, it has been noted that with chronic expansion of extracellular space, BP increases slowly over weeks to months (202). Short-term expansion of extracellular space tended not to have a major effect on BP and slow reduction in dry weight was associated with a gradual decrease in BP (203). This suggests that acute volume expansion *per se* may not be the only mechanism that causes hypertension in patients with ESKD, rather the increase in peripheral vascular resistance associated with chronic volume expansion (a situation not uncommon in a PD patient) may play a key role, and therefore, close attention to dry weight and patient's BP needs to be addressed in every PD patient.

The relationship between BP control and risk of death in patients with ESKD is controversial. Some observational studies suggest that in fact, there seems to be a reverse epidemiology, where in contrast to what is noted in the general population, the lower the systolic BP, the higher the relative risk of death in patients with ESKD (204,205). Others have shown a "U"-shaped curve, wherein patients with both the lowest and highest postdialysis systolic BP have an increased relative risk of death (206). This observation could be due to the fact that in the population with ESKD, it is a "selective" cohort and in fact patients with the lowest BP may have comorbidities (CHF, malnutrition) that contribute to this increased risk; alternatively, this finding may be related to the HD procedure itself. If due to the HD procedure itself, PD patients would not have this reverse epidemiologic observation. In a prospective observational study of 125 PD patients where the mean BP was 131.2 ± 17.4/83.4 ± 9.8 mm Hg, BP was found to be an independent predictor of mortality—no reverse epidemiology was seen. Hypertensive patients (not defined) had a significantly worse 3-year survival than normotensives (60.5% vs. 92.1%, respectively; $p = 0.0001$). Similarly, total ($p = 0.001$) and CV ($p < 0.01$) hospitalizations were significantly worse in hypertensive patients (207). This study did not define a BP target. To examine the association between BP control and various clinical outcomes, 1,053 random PD patients from the USRDS Dialysis Morbidity and Mortality Study (DMMS) wave 2 study were evaluated (208). Using a Cox model and adjusting for covariates and a mean follow-up of only 23 months, these authors found that the two lowest BP categories (systolic BP less than 100 mm Hg and systolic BP 101 to 110 mm Hg) were associated with an increased all-cause and CV-related mortality. They did not find a similar association

for diastolic BP. This study could not evaluate for the development of comorbidities during follow-up (new-onset CHF), nor were they able to adjust for differences in confounding factors between groups or over time. Higher systolic BP was associated with shorter duration hospitalization. They concluded that based on their data, aggressive treatment of hypertension should be done with caution in the PD population and again did not establish a BP target. In the European Automated Peritoneal Dialysis Outcomes Study (EAPOS), there was no significant relationship between BP and survival when examined as a continuous variable [relative risk (RR) 0.99/mm Hg, $p = 0.188$]. When evaluated by tertiles, there was no significant difference by category ($p = 0.23$), although there was a tendency toward an earlier death in the lowest BP tertile (209).

As a result of these studies, a specific "target" BP for PD patients cannot be recommended. In fact, there have been no prospective randomized trials done in an attempt to identify what BP should be targeted in an attempt to improve an individual patient's outcome as there has been in the general population. Furthermore, there is little evidence to show which antihypertensive would be "best" to use in the PD patient for BP control. However, because there are data to suggest using an angiotensin-converting enzyme (ACE) or adrenergic receptor binder (ARB) for CV protection, preservation of RRF (58,59,210), or stabilization of peritoneal membrane transport characteristics, it is recommended that one consider giving preference to using these agents. The 2006 NKF-DOQI guidelines did not give a target BP but recommended that one should try to control BP with less aggressive approaches than used in the general population and that one should consider use of an ACE or an ARB. They further recommended that "one should optimize volume status because of the detrimental effect of volume overload on CHF, LVH, and BP control," stating, "Each facility should implement a program that monitors and reviews peritoneal dialysate DVs, RRF and BP control on a monthly basis, and that some of the therapies one should consider to optimize extracellular water and blood volume include but are not limited to restricting dietary sodium intake, use of diuretics in patients with RRF and optimization of peritoneal UF volume and sodium removal" (8).

How Does One Achieve Euvolemia in Peritoneal Dialysis?

A rational approach to fluid management in PD has been reviewed elsewhere (211,212). In the reevaluation of the CANUSA study, it was shown that residual kidney volume, not peritoneal UF, was predictive of outcome (25). In another study, both fluid and sodium removal were independent predictors of death (207). The survival rate increased linearly with both fluid and sodium removal. Elevated systolic BP correlated positively with risk of death and negatively with salt and water removal. In a cohort of anuric APD patients, all obtaining a certain minimal small solute clearance, peritoneal UF not small solute clearance was predictive of outcome (213). Some have shown that aggressive interventions directed at controlling blood volume using salt restriction and, if needed, alterations of the PD prescription to improve UF can result in control of BP in most patients without the need to use antihypertensive medications (214). More data relating to the effect of fluid removal on outcome are needed; however, these preliminary data do underscore the clinical significance of including BP and volume control as part of adequacy of any dialysis therapy. As with small solute clearance issues, what is not as clear is if the same volume removed by PD alone is as predictive as that removed by the native kidney.

As with any other solute, achievement of a steady state is related to removing the same amount of

solute that is either ingested or produced/generated during a specified time. So if one is interested in controlling BP and volume in patients on PD, then obtaining the desired steady state for sodium and TBW are key to success. It is important therefore not to forget dietary restrictions if indicated. Although historically one tended to be less restrictive of sodium intake in a PD patient, one should always consider dietary sodium restriction as an intervention. One also needs to consider all the ways that sodium and water are removed. Again, remember the importance of urine volume and use of diuretic when possible. One should also be cognizant of how sodium and water are removed with PD and how they cross from the blood side to the dialysate. It is best to picture the pathways as a series of pores, some of which are functional aquaporins similar to what are found in the kidney. These aquaporins only allow the passage of water, whereas other "pores"—the so-called small and large pores—allow passage of water and any solute in that water fits through the pore (convective removal) as well of passage of a solute down concentration gradients (diffusion) independent of any water movement. Both of these processes (diffusion and convection) and both of these pathways (pores and aquaporins) are important factors when considering BP and volume control in PD patients. During a typical glucose dwell, water moves from the blood side to dialysate via small pores, large pores, and aquaporins. Given the fact that glucose is also absorbed via small and large pores and therefore exerts very little osmotic gradient across those pores and that aquaporins only allow passage of water, it turns out that about 50% of the UF volume during a dextrose dwell is sodium-free or "free water." If the dwell time is long enough, sodium can catch up to that free water by diffusion and if long enough, all the UF will be sodium replete. In contrast with icodextrin, the gradient is the same across all pores (small and large and aquaporins). In this case, because greater than 95% of the pore surface area are the small and large pores, the UF with icodextrin is essentially sodium replete. These differences are important when managing a PD patient and trying to control BP and volume.

Classic PD solutions contain glucose as the osmotic agent. Glucose is readily absorbed from the peritoneal cavity, and as it is, the osmotic concentration of the intraperitoneal dialysate approaches that of blood. When there no longer is an osmotic gradient for crystalloid-induced UF, lymphatic reabsorption of fluid predominates and the intraperitoneal and eventual DV decreases. As a result, during the long dwell (overnight) in CAPD or during the long daytime dwell of APD, this phenomenon is likely to occur. Up to 30% of CAPD patients actually absorb fluid during their overnight dwell if using 1.5% dextrose PD solutions. Increasing the percentage of dextrose from 1.5% to 2.5% or 4.25% decreases the percentage of patients with negative net UF to approximately 20% and 5%, respectively, whereas if on APD therapies, 80% of patients may have fluid adsorption during the "long" daytime dwell if using 2.5% dextrose versus 20% of patients using 4.25% dextrose (211). This means that in an anuric patient on APD, the remaining night dwells must first remove this "absorbed" fluid before removing any fluids taken by mouth during the day to maintain fluid balance. However, as discussed earlier, this approach of increasing all the UF during the night results in UF volumes that may be up to 50% sodium-free or "free water." If overnight dwell times are short and multiple dwells are done, this "free water" volume minimally may elevate serum sodium causing thirst when patient wakes up. Because of the known effect of hypertension and volume overload on left ventricular function and risk of death, it is important to focus on maintaining positive UF during the long dwell. This can be done by increasing the tonicity of the dialysate; modifying the dwell time, at times by breaking up the dwell; and by doing two dwells during that same time period

or by just doing one short dwell with some dry time. Having dry time may solve the UF problem and maintain small solute clearance but will likely compromise peritoneal middle molecular weight clearance. If available, an alternative would be to use other osmotic agents which result in more sustained UF during the long dwell.

Polyglucose (icodextrin) is a macromolecule and can be used as an alternative osmotic agent (215). It is a mixture of high molecular weight, water-soluble, glucose polymers isolated by fractionation of hydrolyzed starch ranging in molecular weight from 13,000 to 19,000 Da. It is very slowly absorbed from the peritoneal cavity by direct absorption into the peritoneal lymphatics, not by diffusion because it is too large to move across small pores. Because of the slow absorption, there is sustained UF even during long dwells of up to 15 hours. The differences between expected UF with the different solutions are especially apparent in patients who are high and high-average transporters. This UF is achieved while using isotonic solutions (216). The reason one can obtain sustained UF with icodextrin solutions is because the force driving the UF is due to colloid osmotic differences between the peritoneal cavity and blood. These colloid osmotic forces are due to the difference between the number of large molecular weight solutes between the two compartments (polyglucose vs. albumin). The clinical differences in UF profiles between dextrose solutions and polyglucose in CAPD and APD have been reviewed elsewhere (217–220). **TABLE 12.7** outlines the reason for these differences, and **FIGURE 12.12** illustrates the UF profiles of typically available dialysis fluids. Also an important consideration when using icodextrin is that, because >95% of the UF volume comes across small or large pores and NOT the aquaporins, all of the UF volume with icodextrin contains sodium in contrast to what happens initially in the dwell with dextrose solutions.

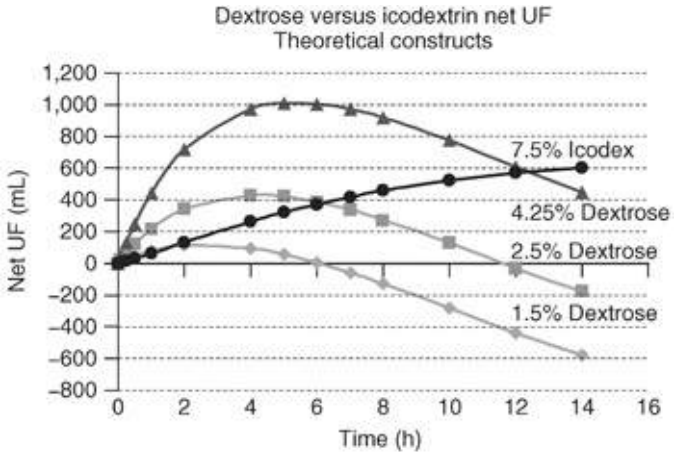

FIGURE 12.12 Temporal profile of net ultrafiltration (UF) in high-average transport patients with use of 1.5% dextrose (*diamonds*), 2.5% dextrose (*squares*), 4.25% dextrose (*triangles*), or 7.5% icodextrin (*circles*) solutions. [From Mujias S, Vonesh E. Profiling of peritoneal ultrafiltration. *Kidney Int* 2002;62(Suppl 81):S17–S22.]

TABLE 12.7 Likely Pathways for Peritoneal Fluid and Solute Removal

Glucose-Based Solutions	Icodextrin-Based Solutions
Crystalloid-induced osmosis	Colloid-induced osmosis
Water transport through	Water transport through
Small and ultrasmall pores	Small pores predominantly
Small solute movement	Small solute transport
By diffusion through small pores	By diffusion through small pores

Macromolecule movement	Macromolecule movement
Across large pores and into lymphatics	Across large pores and into lymphatics
Osmotic agent (glucose)	Osmotic agent (icodextrin)
Rapidly absorbed by diffusion	Slowly absorbed into lymphatics
Across small and large pores	

Although not available in the United States, lowering dialysate sodium allows for more diffusive removal of sodium independent of convective sodium removal. Although not currently available in the United States, many investigators have evaluated the use of low sodium solutions. Ahearn and Nolph (221) found that using 7% dextrose dialysis solutions with sodium concentration of 100 to 130 mmol/L compared to 140 mmol/L resulted in increased sodium removal/exchange. In another study, the authors have shown that one could increase total sodium removal without any change in UF volume by lowering dialysate sodium. Nine anuric patients were studied in a crossover trial in patients on APD. A dialysate sodium of 132 mmol/L was compared to one with a sodium concentration of 126 mmol/L. On the lower sodium solution, daily sodium removal increased to 94 mmol/L of UF compared to 32 mmol/L while on standard dialysate sodium solutions. Four patients experienced an improvement in BP, and three were able to discontinue BP medicines. There was no significant change in UF or body weight during the study (222). In another study, the effects of ultralow sodium dialysis solutions (Na 102 mmol/L) were compared to baseline (when at least one exchange was 3.86% glucose/4.25% dextrose and one exchange with icodextrin) in five anuric PD patients (223). The better sodium removal (80 + 14 mEq vs. 56 + 15.9 mEq/d, p <0.05), the better BP control (mean BP 98 + 5.5 mm Hg vs. 109 + 7.6 mm Hg, p + 0.046) with the ultralow sodium solutions. Clearly, these solutions may work, but current data is limited and more studies are needed. Generally, if dialysate sodium is lowered, one would need to increase dialysate glucose to maintain UF. For a further review of low sodium dialysate solutions, see Khandelwal et al. (224).

HOW TO MONITOR DIALYSIS DOSE?

The most accurate way to measure dialysis dose is to measure the total amount of the solute in question cleared from the body during a specific time interval. In practice, for patients on PD, this means that 24-hour collections of dialysate and urine (if included in dose calculations) should be obtained. Total solute clearance is then calculated. An alternative would be to estimate the daily clearance either

mathematically or with the use of computer-assisted kinetic modeling programs. However, although the estimations do tend to correlate with the actual clearance measured from 24-hour collections, there is a high degree of discordance (225,226). Therefore, the gold standard for measurement of dialysis dose is to obtain 24-hour collections of both urine and dialysate to document the actual amount of solute removed. These studies should be obtained at baseline and then every 4 months and within 1 month of any prescription change. If RRF is included, then the RRF component should be measured every 2 months—as it is the most likely component of the two to change—and that value is then added to the prior 24-hour dialysate collection. The 2006 NKF-DOQI guidelines recommend that one only uses residual kidney component if (for simplicity) urine volume is more than 100 mL/d.

PET is obtained to characterize the patient's peritoneal membrane transport characteristics, not to determine clearance or any other clinical outcome. The two tests (24-hour collections and PET) are complementary to each other and are routinely used together for developing a patient's dialysis prescription and for problem solving. Several studies have documented that an individual patient's peritoneal membrane tends to be stable over time (227). However, in some patients, it may change. Therefore, peritoneal transport should be monitored to optimize clearance and UF. The PET is the most practical way to do this, and originally, it was recommended that it be obtained twice a year. It has been shown that over time, if there tends to be any change in transport characteristics, the D/P ratios were likely to increase slightly, associated with a small decrease in UF. Alternatively, one can estimate D/P values for PET from D/P values on 24-hour dialysate collections (*D*ialysis *A*dequacy and *T*ransport *T*est, or DATT) when followed sequentially in an individual patient (228). Because of the stability over time, current recommendations are to obtain a baseline PET approximately 1 month after starting dialysis and only repeat the PET when clinically indicated (such as unexplained inadequate dialysis, unexplained volume overload, failure to thrive). Dialysate collections over 24 hours can also be used to calculate LBM, creatinine generation rates, and estimate protein intake (**TABLE 12.8**).

TABLE 12.8 Usefulness of 24-Hour Collections of Dialysis and Urine Collection

Creatinine Kinetics	Urea Kinetics
Creatinine clearance^{D}	Urea clearance^{D}

NONCOMPLIANCE

Noncompliance with a medical regimen is not uncommon and is a real issue for PD as documented by patient questionnaires (229) and by looking at patient home inventories (230). Because PD is a home

therapy, it is not easy to document the degree of noncompliance with a patient's prescription. In contrast, the degree of noncompliance with the dialysis prescription itself is easily documented in in-center HD populations (5,231). Historic publications have suggested that a value above unity for the ratio of measured to predicted creatinine production may be an indication of recent periods of noncompliance (232–234). These authors speculated that if the patient had been noncompliant before obtaining the 24-hour dialysate and urine collection but was compliant on the day of collection, then a "washout" effect would occur. In such a case, the creatinine production would be higher than would be predicted from standard equations, resulting in an elevated ratio of measured to predicted creatinine production. From these studies, it has been estimated that only 78% of the prescribed therapy is actually delivered. Others have shown that the index is *not* a good indicator of patient compliance (235,236). Perhaps sequential rather than individual ratios will be helpful. At the moment, there is no recommended test as a measurement of compliance other than index of suspicion based on how the patient is doing and clinical studies. In the United States, most patients use an automated device to do their PD, most of which have a card to record actual prescription history; therefore, compliance can be evaluated this way. Interestingly, noncompliance may be more of an issue in the United States than in other countries such as Canada.

To minimize noncompliance, one should be sure to design PD prescriptions with the patients' lifestyle needs and abilities in mind. To do five manual exchanges per day is not realistic for most patients. Automated therapies may be. Education and importance of compliance with prescription should be emphasized.

PRESCRIPTION DIALYSIS

Timing of Initiation

The NKF-DOQI guidelines (8) and Obrador et al. (237) have highlighted the need to treat patients throughout all the stages of CKD as a continuum. The traditional indications for initiation of dialysis such as pericarditis, encephalopathy, refractory hyperkalemia, nausea, vomiting, and volume overload raise little controversy. Weight loss and signs of malnutrition are other more subtle, "relative" indications for initiation. Interestingly, as opposed to ESKD when minimal target values for weekly total solute clearance have been established (i.e., Kt/V_{urea} greater than 1.7), minimal values for solute clearance by RRF alone have not been established. This seems paradoxical. There are data to suggest that patients are starting dialysis with a higher serum creatinine, but this is likely a surrogate for number of comorbidities and sickness, not an indication that patients are starting dialysis in a healthier state. At the moment, the timing of when to start dialysis should not be driven by a number—eGFR, Ccr, serum creatinine. Rather, a constellation of clinical signs and symptoms along with input from the patient.

Initial Prescription

When a patient presents with near-ESKD or ESKD, and PD is elected, two alternatives for writing the initial prescription exist. For those patients with minimal RRF, the initial prescription should consist of a "full dose" of PD dialysis to meet minimal total solute clearance goals. If the patient has a significant amount of RRF (defined by the 2006 NKF-KDOQI guidelines as a residual urine volume of more than 100 mL/d and a residual kidney Kt/V_{urea} of less than 1.7 per week) less dialysis is needed. In this, an

"incremental" approach to the dosage of PD can be used (238,239).

In both instances, the initial prescription is based on the patient's body size and amount of RRF (both potentially known variables at initiation of dialysis). At initiation, peritoneal transport is not known. Initial prescriptions are based on the assumption that the patient's peritoneal transport is average. Once stable on PD, a PET can be obtained (usually after 1 month) determining an individual patient's transport type, so that his or her prescription can be more appropriately tailored. During training, transport type can be predicted from DV during a timed (4-hour) dwell with 2.5% glucose and compared to those predicted by PET.

Pitfalls in Prescribing Peritoneal Dialysis

There are some common pitfalls in prescribing the peritoneal component of total solute clearance. The following is a brief summary of some of these and should be considered whenever a patient appears underdialyzed.

For patients on standard CAPD, these include (a) inappropriate dwell times (a rapid transporter would do better with short dwells), (b) failure to increase dialysis dose to compensate for loss of RRF, (c) inappropriate instilled volume or dialysis "dumping" (patient may only infuse 2 L of a 2.5-L bag) (240), (d) multiple rapid exchanges and one very long dwell (patient may do three exchanges between 9 AM and 5 PM and a long dwell from 5 PM to 9 AM (241), (e) inappropriate selection of dialysate osmotic agent for long dwells which may not maximize UF and consequently clearance, and (f) noncompliance.

Other problems are specific for those patients on cycler or APD therapy; these would include the following: (a) The drain time may be inappropriately long (more than 20 minutes), thereby increasing the time the patient must be connected to the cycler, perhaps limiting the number of exchanges a patient would tolerate and spending more time in fill and dwell than needed. (b) Inappropriately short dwell times may also be prescribed, making the therapy less effective for the average patient where length of dwell is crucial. (c) Failure to augment total dialysis dose with a daytime dwell ("wet" day vs. "dry" day) could also result in underdialysis. APD patients are typically on the cycler for 9 to 10 hours per night. Therefore, the daytime dwell is long (15 to 14 hours). During this long dwell (longer than the long nighttime dwell for typical CAPD patients), diffusion stops and reabsorption often begins, minimizing clearance. (d) Failure to consider using a midday exchange to augment clearances. Use of a mid day exchange is an effective way to optimize both clearance and UF in these patients. (e) Failure to consider use of alternative osmotic agents such as icodextrin, which maintain UF during long dwells (242). These optimize both clearance and UF without hypertonic glucose. (f) Poor selection of dialysate glucose may not allow maximization of UF with subsequent reabsorption of fluid and solutes. (g) Noncompliance.

When changing from standard CAPD (long dwells) to cycler therapy (short dwells), it is important to remember the difference in transport rates of urea and creatinine and the effect that this change will have on the patient's overall clearance. These differences and their relevance for CAPD, CCPD, NIPD, and other modifications are reviewed by Twardowski (243). Transport of urea into the dialysate tends to occur faster than for creatinine. Therefore, if total solute clearance targets are measured using urea kinetics, keeping Kt/V constant going from long to short dwells may decrease Ccr. In contrast, if Ccr is the total solute clearance target, keeping Ccr constant when changing from long to short dwells will keep Kt/V constant or even increase it. This concept has been termed *horizontal modeling* (244). Knowledge

of the individual patient's peritoneal transport characteristics and familiarity with the differences in dialysis needs for rapid versus slow transporters is imperative to avoid problems or confusion.

Adjusting Dialysis Dose

When determining an individual patient's prescription, one should aim for a total solute clearance that is not only above target but also allow for other indices of adequate dialysis such as quality of life issues, BP control, volume control, and DPI. If during routine monitoring or clinical evaluation of the patient the delivered dose of dialysis needs to be altered, this can easily be done in a scientific manner if one knows the patient's present transport characteristics (PET), the present total clearance of urea or creatinine, and one understands the relationship between dialysis clearance, DV, and dwell time based on the measured D/P ratios. In general, when the goal is to increase total solute clearance, it is best to increase dwell volume, not number of exchanges. Increasing the number of exchanges decreases dwell time/exchange, making the therapy less effective for the average patient.

It is important that these relationships are understood because increasing the total instilled volume per day does not always result in an increase in clearance. For instance, in a patient who is a low transporter and in whom clearance is critically dependent on dwell time, changing from standard CAPD (infused volume—8 L) to a form of cycler therapy using 2-hour dwells where the infused volume may be as high as 10 to 14 L may not always result in an overall increase in that patient's clearance.

Once familiar with these relationships, to adjust the dialysate prescription, one would need to know the D/P ratios at the anticipated dwell time and the patient's DV for that dwell time. By altering dwell time, you change the D/P ratio and the DV. By altering instilled volume, you will also affect total DV and therefore clearance. In general, just increasing the instilled volume without changing dwell time will result in an increase in solute clearance.

Another means to tailor a dialysis prescription would be with the use of computer-assisted kinetic modeling programs (245,246), which allows for ease in adjusting a patient's dialysis prescription. Baseline PET data, DVs, and patient weights are needed for input data. Use of these programs usually allows one to set targets for solute clearance, glucose absorption, and anticipated DPI. These computer simulations then give you a menu of prescriptions that should achieve these targets, and you can choose the one that would best suit the patient's lifestyle.

Tidal PD is a form of automated dialysis in which, after an initial dialysate fill, only a portion of the dialysate is drained from the peritoneum and is replaced with fresh dialysate after each cycle. This leaves most dialysate in constant contact with the peritoneal membrane. A typical tidal dialysis prescription would usually require 23 to 28 L of instilled volume, but preliminary studies suggest that tidal dialysis may be approximately 20% more efficient than nightly PD at dialysate flow rates of approximately 3.5 L/h (247) and are therefore not cost effective and very seldom used in clinical practice.

SUMMARY

The delivered dose of dialysis does have an influence on certain patient outcomes. When considering adequacy of dialysis, one must not only maintain a minimal total solute clearance but also monitor other parameters such as overall clinical assessment, BP, and volume control, treatment of anemia, osteodystrophy, and other comorbid diseases. Periods of inadequate dialysis can result in subtle

symptoms of uremia that are insidious in onset and may not be reversible. These can influence outcome in a negative way. To prevent this symptomatology and provide as close to optimal dialysis as possible, it is important to monitor dialysis dose so that changes in dialysis prescription can be made proactively rather than reactively. There does appear to be a "minimal" dose of dialysis measured in terms of small solute clearance that one should obtain to optimize outcomes (near a Kt/V_{urea} of 1.7/wk). When tailoring PD prescriptions, it is important that the prescribed dialysis dose be targeted to at least achieve these minimal doses. What is still unknown is if one was to achieve markedly higher small solute clearances with PD would this result in an incremental improvement in outcome. Preliminary data would suggest no, but it is important to remember that these maneuvers did not concomitantly increase or improve other "adequacy" parameters such as middle molecular weight solute clearance or volume control. Further studies, which specifically address these issues, are needed.

CHAPTER 13

Causes, Diagnosis, and Treatment of Peritoneal Membrane Failure

Shweta Bansal and Isaac Teitelbaum

Over the last several decades, peritoneal dialysis (PD) has become an established alternative to hemodialysis (HD) for the treatment of end-stage kidney disease (ESKD), and the number of patients and PD programs have grown rapidly recently with implementation of bundle payment programs. A number of studies, including the most recent ones, have confirmed its equivalent dialysis adequacy, somewhat better mortality and fluid balance status, at least for the first 4 to 5 years of renal replacement therapy (1,2). The success of PD as a long-term therapeutic option in the treatment of ESKD depends on the efficient removal of both solute and fluid. The ability to provide "adequate" dialysis (see Chapter 12) is a function of patient compliance, residual renal function (RRF), the transport characteristics of the peritoneal membrane, and the capacity to deliver a required dialysate flow rate in a manner that is tolerable to the patient. Therefore, alterations in any of these factors, not only in the characteristics of the peritoneal membrane, can significantly influence the efficiency of PD (**TABLE 13.1**) leading to "inadequate" dialysis and perceived "failure" of PD as a technique.

TABLE 13.1 Factors Influencing Peritoneal Dialysis Efficiency

- Residual renal function
- Patient compliance
- Peritoneal membrane characteristics
  - Permeability
  - Effective surface area
- Lymphatic absorption
- Dialysate volume/osmolarity/flow
- Effective blood flow

From Twardowski ZJ. The fast peritoneal equilibration test. *Semin Dial* 1990;3:141–142.

Owing to improved technology and the decline in peritonitis rates, ultrafiltration failure (UFF)/membrane failure has now become one of the major factors leading to technique failure in PD patients. Typically, alterations in peritoneal membrane function have a disproportionately greater effect on fluid removal than solute removal and therefore the most overwhelming cases of membrane failure are

due to inability to achieve adequate ultrafiltration (UF), whereas the inability to achieve adequate solute removal is relatively uncommon. In most patients maintained on PD for 4 or more years, peritoneal clearance of small solutes is stable or increases, whereas net UF has been shown to decrease by as much as 40% from baseline (3–5).

Although UFF can occur in any stage of PD, it develops over time, and is, therefore, especially important in long-term PD. The exact prevalence of UFF in patients treated with PD is not known. Heimbürger et al. (6) demonstrated the cumulative risk for permanent loss of net UF capacity to be 2.6% at 1 year, 9.5% at 3 years, and in excess of 30% for those patients on continuous ambulatory peritoneal dialysis (CAPD) for 6 years or more. Similarly, in a Japanese long-term study, dropout because of UFF was as high as 51% after 6 years (7). Over an 18-month period, Davies et al. (8) observed UFF in 14% of their patients. Inadequate dialysis including UFF was responsible for transfer to HD in 18% of the patients in one series, whereas infection was responsible for 28% of the transfers (9). All the studies were based on clinical signs of UFF and not on a standardized test.

The definition of UFF had been under discussion over the past years. Some applied a clinical definition: the inability to remain at a certain dry weight and the use of more than two hypertonic (3.86%) bags per day had been considered as UFF (10–12). Others used a definition based on a standardized exchange and considered UFF to be present, for instance, when there was negative net UF with a 1.36% glucose dwell (13,14). In 2000, the International Society for Peritoneal Dialysis (ISPD) committee on UFF advised performing a standardized test with 3.86% glucose and considered a net UF of less than 400 mL after a 4-hour dwell as UFF (15). A cross-sectional study in a small number of PD patients, using the 400 mL/4 h on 3.86% glucose definition, reported a prevalence of 23% (14). Smit et al. (16) reported prevalence of 36% in 55 patients after a median period of 61 months.

Although the inability to achieve adequate solute and fluid removal is often attributed to a “failure” of the peritoneal membrane, it must be remembered that this is but one of several factors that affect the efficiency of PD (**TABLE 13.1**). It is therefore critical that nephrologists consider and understand these issues when evaluating patients with signs and symptoms of UFF. In this chapter, we review the factors that influence UF efficiency and present an approach to evaluating and treating these patients in clinical practice.

SOLUTE AND FLUID TRANSPORT IN PERITONEAL DIALYSIS

The Peritoneal Membrane

Solute and fluid transport in PD results from the development of concentration and pressure (hydrostatic and osmotic) gradients between blood and dialysate across the semipermeable peritoneal “membrane.” Therefore, the physical characteristics (surface area and permeability) of the peritoneal membrane become major determinants in solute and fluid transport. The physical features of HD membranes are known by design; however, these properties are unknown for the peritoneal membrane and have largely been determined indirectly based on conceptual models and mathematical analyses. From these efforts, our concept of the transport physiology of the peritoneal membrane is evolving.

Originally, peritoneal transport properties were based on a “membrane model” in which the

peritoneum was simply viewed as a single membrane comprising capillary wall, interstitium, and mesothelium. In this model, a concentration gradient exists from the capillary lumen on one side of the membrane to the peritoneal cavity on the other (17). More recently, the concept of a "distributed model" was proposed to better explain the observed transport properties of the peritoneum. Here, the capillaries are viewed as "distributed" throughout the interstitium, resulting in varying distances between capillary lumens and the peritoneal cavity (18). The contribution of a given capillary depends on the proximity of that capillary to the dialysate interface.

The "anatomic" surface area of the peritoneal membrane correlates best with body surface area (BSA) and is estimated to range from 1.7 to 2.0 m^2 (19). However, it is the "effective" surface area of the peritoneal membrane that is important in determining solute and fluid transport in PD. The effective peritoneal surface area is defined as that area of peritoneal membrane perfused by capillaries that comes into contact with dialysate and contributes to solute and fluid transport (20–22). The effective peritoneal surface area therefore depends not only on the volume of dialysate used but also on the effective peritoneal blood flow (that portion of the peritoneal microcirculation that actually comes into contact with dialysate and participates in solute and fluid transport). The largest portion (47%) of the overall small solute diffusive transport is across the peritoneal membrane associated with hollow viscera. However, as much as 43% of diffusive transport during PD occurs across the peritoneum associated with the liver (abdominal wall 6% and diaphragm 4%) (23).

The permeability of the peritoneal membrane is determined by the resistances created by the capillary wall, interstitium, and mesothelium. Of these, the capillary wall is the most important and the mesothelium the least important as barriers to transport. On the basis of the three-pore model of the peritoneal membrane, initially derived from a computer model for peritoneal transport mechanisms, solute and water transport occurs through three different pore types located in the capillary endothelium (24). "Large pores" are believed to correspond to interendothelial gaps (radius 12 to 15 nm) and are responsible for transport of macromolecules (e.g., albumin) across the membrane. Large pores account for less than 1% of the effective pore area for small solute diffusion, and, to a minor extent, they account for UF through fluid convection. "Small pores" (radius 4 nm) represent intercellular endothelial clefts and account for approximately 90% of total pore area. They are the primary route for the diffusive and convective transport of small molecular weight solutes (e.g., urea, creatinine, and electrolytes). More than 50% of glucose-induced UF occurs through small pores. It is through back diffusion across these pores that glucose absorption from the peritoneal cavity also occurs. However, small pores are essentially impermeable to macromolecules such as proteins. The third pore type is a water-selective, intracellular, so-called ultrasmall pore (radius less than 0.5 nm). The "ultrasmall pore" is the only pore type that is molecularly defined and corresponds to aquaporin 1 (AQP-1). The AQP-1 channel is located in endothelial and mesothelial cells (MCs) of the peritoneal wall. Although these pores comprise only 1% to 2% of the total pore area, they contribute up to 40% of the ultrafiltrate (25). Because the ultrafiltrate generated by the ultrasmall pores is solute-free, the concentration of solutes in the ultrafiltrate is less than that in the plasma, a phenomenon called *solute sieving*, usually referred as *sodium sieving* (see section "Convective Transport" in subsequent text).

Although the three-pore model has proven successful for modeling purposes in several physiologic and pathophysiologic conditions and for various osmotic agents, it does not take into account of the

distributed nature of the peritoneal capillaries and also of the influence of the peritoneal tissue interstitium as explained in the distributed model (18). The pore-matrix model explains the complex nature of distributed peritoneal barrier by incorporating the concepts from these two models (26). As mentioned in three-pore model, small and large pores have not been found to be distinct anatomic entity. Rather, these are interendothelial spaces filled with a luminal glycocalyx that restricts passage of solutes and sets up alternative pressure forces. Large pores have a very sparse glycocalyx that permits transport of macromolecules, while small pores have a denser glycocalyx that are more restrictive. In addition to the aquaporins and glycocalyx-filled pores, the integrated cellular-interstitial matrix also makes the peritoneal barrier. According to this model, the distributed geometry of the capillary bed yields a substantial decrease in the effective reflection coefficient for crystalloid osmotic agents compared with their reflection coefficient in the capillary wall.

Solute Transport

Diffusive Transport

In PD, solute removal results from a combination of diffusive and convective transport. Diffusion, the primary mechanism for small solute removal, results from the concentration gradient between blood and dialysate created across the peritoneal membrane by the instillation of dialysate into the peritoneal cavity. The rate of diffusion for a solute (J_s) depends on the product of the peritoneal membrane solute permeability (P_s), effective peritoneal surface area (A), and the magnitude of the plasma to dialysate concentration (DC) gradient for that solute (**EQUATION 13.1**):

$$J_s = P_s \times A \times DC \qquad (13.1)$$

The intrinsic permeability of the peritoneal membrane for a given solute is relatively constant and is determined by its molecular weight. The peritoneal membrane is therefore highly permeable to low molecular weight solutes such as urea and creatinine but has a low permeability to high molecular weight solutes such as β_2-microglobulin and other large proteins.

Increasing the effective peritoneal surface area, by increasing the intraperitoneal volume of dialysate, can significantly improve the rate of diffusive transport for small solutes (**FIGURE 13.1**) (4). Keshaviah et al. (27) demonstrated that transport rates for urea, creatinine, and glucose doubled as infused volumes of dialysate were increased from 0.5 to 2.5 L. The infused volume producing the maximal diffusive transport rate for a given patient increased with increasing BSA, being 2.5 L for an average-sized person (BSA 1.7 m^2) and 3 to 3.5 L for a person with a BSA of more than 2 m^2. The improved transport with larger volumes is felt to result from an increase in contact between dialysate and peritoneum, thereby increasing the effective peritoneal surface area by recruiting more peritoneal membrane. Beyond these maximal volumes, little to no improvement in diffusive transport is attained as the effective peritoneal surface area is completely exposed to dialysate and any further increases in volume results in “pooling” of dialysate.

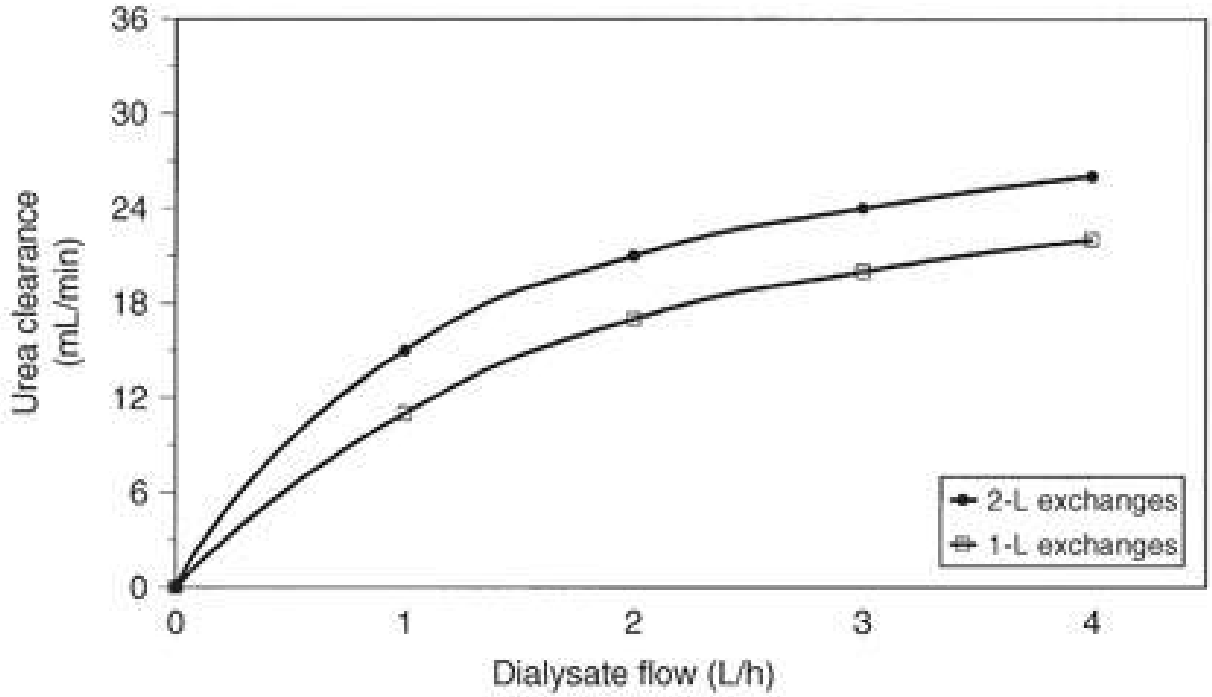

FIGURE 13.1 Effect of dialysate flow rate and volume on small molecular weight solute clearance. With an increase in dialysate flow clearances increase, but at a given flow rate, the clearances are even better with the use of larger fill volumes. This results from an increase in diffusive transport due to the increase in effective peritoneal surface area with larger fill volumes. *Open circle*, 2-L volumes; *open square*, 1-L volumes. (Modified with permission from Robson M, Oreopoulos DG, Izatt S, et al. Influence of exchange volume and dialysate flow rate on solute clearance in peritoneal dialysis. *Kidney Int* 1978;14:486–490.)

Maintaining a maximal concentration gradient also enhances the rate of diffusive transport. This is dependent on the effective peritoneal blood flow as well as dialysate flow. The concentration gradient (ΔC) across the peritoneum is maximal early in the dwell cycle but decreases over time as solute diffuses from blood to dialysate. As the gradient decreases, the rate of diffusion decreases. Increasing the dialysate flow rate (shorter dwell times) and/or volume (increased exchange volumes) enhances the gradient, and therefore, the rate of diffusion can be increased (**FIGURE 13.1**). Diffusion ceases when the concentration gradient between blood and dialysate no longer exists. Smaller molecules cross the peritoneal membrane more easily, equilibrate faster, and are influenced more by dialysate flow rates than are larger molecules (28,29).

It has generally been accepted that effective peritoneal blood flow is not a rate-limiting factor for the diffusive transport of small molecular weight solutes, as estimates of peritoneal blood flows are more than two to three times that estimated for the transport rates of small solutes like urea (17,18,30,31). However, given the large contribution of the liver-to-sinusoid transport and the fact that the liver may be more permeable to small solutes than other vascular beds in the abdomen, the rate of transport across the sinusoids may be so rapid that blood flow could be a limiting factor for this vascular bed (23). The major contribution of the liver to small solute clearance may account, in part, for the increased solute transport observed in the supine position or with increased dwell volumes as these maneuvers increase the contact of dialysate with the liver (23,29,32,33).

Convective Transport

Solute removal also occurs through convection. As osmotic forces cause water to move across the

peritoneal membrane and into the peritoneal cavity, frictional forces between the solvent (water) and solutes (e.g., Na^+, urea) result in these solutes being convectively carried along with water. This is referred to as *solvent drag*. Because the peritoneal membrane provides greater resistance to solutes than to water (particularly by way of fluid transport across ultrasmall or transcellular pores), the concentration of solutes in the ultrafiltrate is less than that in plasma; this is referred to as *solute sieving*. The sieving coefficient for a given solute is the ratio of the solute concentration in the ultrafiltrate to that in the plasma. The rate of solute transport by convection (J_s) is therefore related not only to the transcapillary ultrafiltrate rate or water flux (J_w) but also to the serum concentration (C_s) and sieving coefficient (S) for that solute (**EQUATION 13.2**);

$$J_s = J_w \times C_s \times S \qquad (13.2)$$

Because the rate of UF decreases over the time course of a dwell (see section "Fluid Transport" in subsequent text), the relative contribution of convective transport to overall solute removal also decreases during the same time period. The percentage of total solute transfer that is provided by convective as compared with diffusive transport increases significantly as the molecular size increases. It may be responsible for as little as 10% of total urea transport but may be responsible for more than 80% of protein transport (34,35).

Fluid Transport (Ultrafiltration)

Ultrafiltration occurs primarily through osmosis, as a consequence of the osmotic gradient created between the peritoneal blood compartment and the intraperitoneal dialysate compartment. This is achieved by utilizing hyperosmolar dialysate created by the addition of an osmotically active substance, usually dextrose, to the solution. The rate of transcapillary UF or water flux (J_w) is dependent on the peritoneal membrane hydraulic permeability (L_p) and effective surface area (A), as well as the transmembrane osmotic ($\Delta\pi$) and hydrostatic pressure gradients (ΔP) (**EQUATION 13.3**):

$$J_w = L_p \times A\,(\Delta\pi + \Delta P) \qquad (13.3)$$

Transcapillary UF is highest at the beginning of a peritoneal exchange when the osmotic gradient is greatest. As a result of dilution of glucose by the ultrafiltrate and glucose absorption from the peritoneal cavity, as the osmotic gradient decreases over time, the rate of UF declines. The transcapillary UF rate (and therefore net UF—see later) can be increased by either the use of larger dialysate volumes (which decreases the rate of dilution) or more hypertonic solutions (which increases the osmotic gradient) or both (**FIGURE 13.2**). Factors that lead to an increase in peritoneal membrane permeability or effective surface area (e.g., peritonitis) increase solute transport (e.g., glucose absorption), resulting in a more rapid decline in the osmotic gradient and therefore decrease the rate of UF (36).

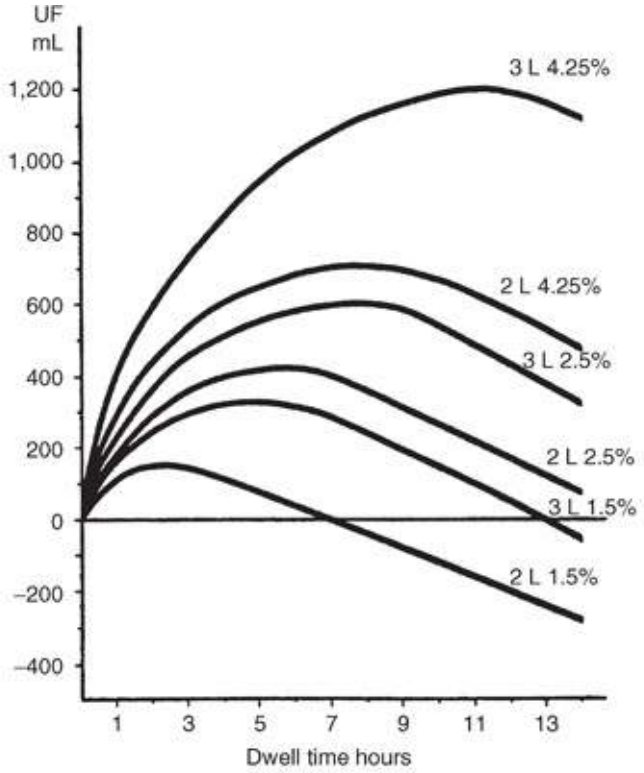

FIGURE 13.2 Effect of osmolality and volume of dextrose dialysis solutions on net ultrafiltration (UF). (Reproduced with permission from Twardowski Z, Khanna R, Nolph KD. Osmotic agents and ultrafiltration in peritoneal dialysis. *Nephron* 1986;42:93–101.)

Lymphatic absorption (LA) of fluid from the abdominal cavity opposes the effects of transcapillary UF. As shown in **FIGURE 13.3**, the combined effects of these two forces determine the ultimate drain volume or net ultrafiltration (net UF) (**EQUATION 13.4**):

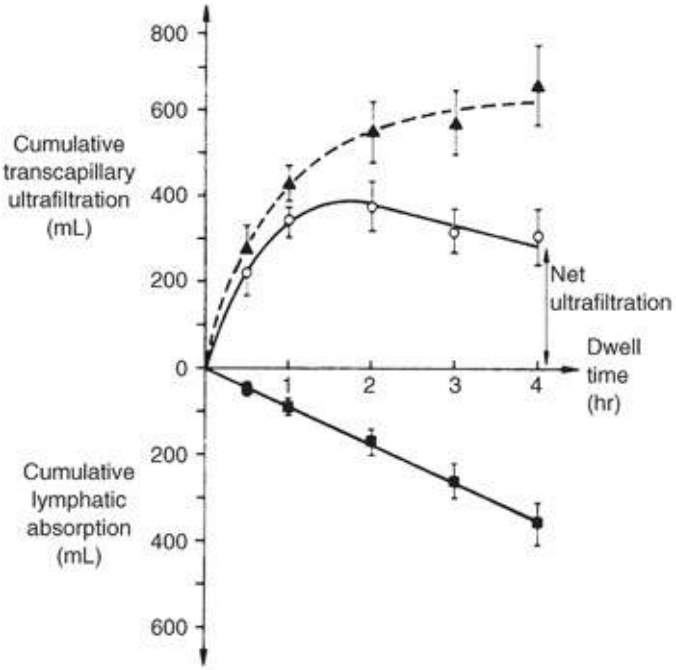

FIGURE 13.3 Net ultrafiltration (*open circle*) is a result of the additive effects of transcapillary ultrafiltration (*solid triangle*) and the negative effects of lymphatic absorption (*solid square*). Net ultrafiltration actually decreases as lymphatic absorption rate exceeds transcapillary ultrafiltration. (Solution used is 2.5% dextrose.) (Reproduced with permission from Mactier RA, Khanna R, Twardowski Z, et al. Contribution of lymphatic absorption to loss of ultrafiltration and solute clearances in continuous ambulatory peritoneal dialysis. *J Clin Invest* 1987;80:1311–1316.)

$$\text{Net UF} = \text{TCUF} - \text{LA} \qquad (13.4)$$

LA rates appear to be constant, regardless of the initial volume or tonicity of the dialysate instilled, and have been estimated to average from 1 to 1.5 mL/min (22,37,38). As long as the rate of transcapillary UF is greater than the rate of LA, intra-abdominal fluid volume or net UF increases above the initial fill volume (38,39). Peak intraperitoneal volume (net UF) is reached when the rate of transcapillary UF equals the rate of LA (**FIGURE 13.4**). This actually precedes the point in time at which osmotic equilibration of dialysate and plasma occurs. However, once the LA rate exceeds the rate of UF, a net absorption of fluid from the peritoneal cavity occurs, causing a decline in the intraperitoneal volume (declining net UF). Net UF can be increased by measures that increase the transcapillary UF rate (hypertonic dextrose solutions and/or increasing dialysate volume, as noted earlier), or by taking advantage of the time of peak UF (decrease the dwell time) (**FIGURES 13.2** and **13.3**). In addition to decreasing net UF, absorption of peritoneal fluid by lymphatic uptake impairs overall solute removal by partially negating the effects of both diffusive and convective transport.

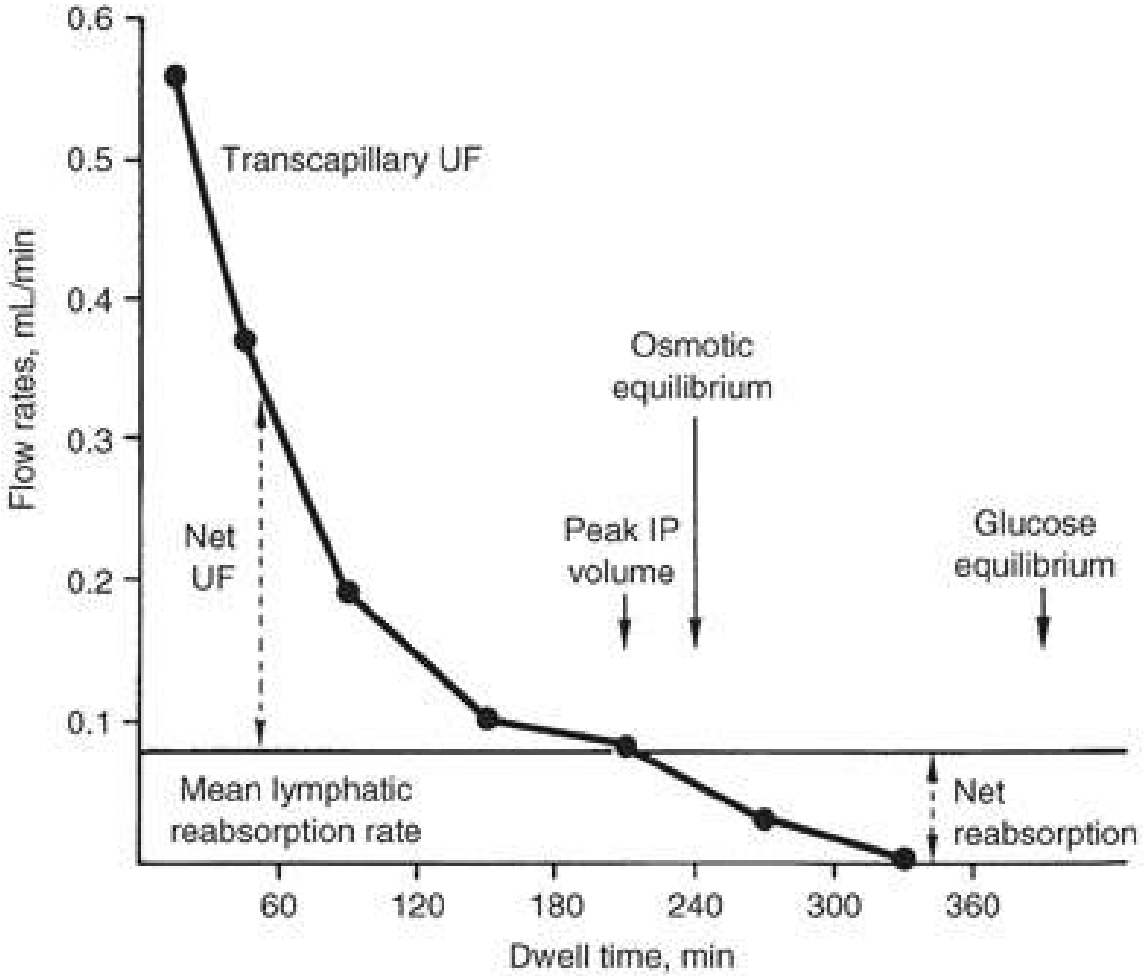

FIGURE 13.4 Transcapillary ultrafiltration (UF) and lymphatic absorption rates related to dwell time during an exchange using 2 L of 1.5% dextrose. Peak intraperitoneal volume occurs when the rate of transcapillary UF equals the rate of lymphatic absorption of fluid from the peritoneal cavity. This precedes osmotic equilibrium (there is still an osmolar gradient, although markedly attenuated because of the combined effects of dilution by ultrafiltrate and absorption of glucose from dialysate to blood) and glucose equilibration. IP, intraperitoneal pressure. (Reproduced with permission from Nolph KD, Mactier R, Khanna R. The kinetics of ultrafiltration during peritoneal dialysis: the role of lymphatics. *Kidney Int* 1987;32:219–226.)

EVALUATION OF PERITONEAL MEMBRANE FUNCTION

Unlike HD membranes, the solute and fluid transport characteristics (surface area and permeability) of the

peritoneal membrane in a given patient are unknown. Because of the alterations in transport parameters during the course of PD, regular follow-up is necessary to assess the delivered dialysis dose and, if needed, to characterize the functional status of the membrane. As a result, several indirect methods of evaluating the transport properties of the peritoneal membrane have been established. These protocols usually require that a PD exchange be performed with a specified dialysate volume and dextrose concentrations, assessing solute concentrations in serum and dialysate at specific points in time during a set dwell period, as well as determining the final drain volume. Through the information derived from these studies, a patient's transport characteristics can be established. This is most often done by determining either the dialysate to plasma (D/P) ratio—best standardized by the peritoneal equilibration test (PET) (40) or the peritoneal membrane mass transfer area coefficient (MTAC) (35,41,42) for various solutes. Because the D/P ratio of a given solute (the measure of transport utilized in the PET) depends upon both diffusive and convective transport, the MTAC was introduced to separate those influences on solute transfer from membrane function alone. From a practical perspective, information on peritoneal membrane function that is gained by the MTAC adds little to that of the PET and the MTAC is therefore not commonly utilized in clinical practice (43).

Peritoneal Equilibration Test

We are all indebted to Twardowski for his seminal observation of the variability of small solute transport rate and UF capacity within the PD population when he initially described the PET (44). This test semiquantitatively measures the peritoneal membrane transfer rates for solutes (usually urea and creatinine), based on the ratio of their concentration in D/P ratio at specific times (t) during the dialysate dwell, and for glucose, based on the ratio of dialysate glucose at dwell times t to dialysate glucose at 0 dwell time (D_t/D_0). The procedure for performing PET is outlined in **TABLE 13.2**.

TABLE 13.2 Standard Peritoneal Equilibration Test (PET)[a]

1. An 8- to 12-h exchange with 4.25% dialysate precedes the test exchange.
2. Drain pretest exchange over 20 min in the vertical position (sending a sample for creatinine and glucose will allow for the determination of residual volume).
3. Infuse 2 L of 2.5%[a] dextrose dialysate over 10 min with patient supine.
4. After each volume of 400 mL is infused, have patient roll from side to side.
5. At the completion of the infusion, or 0 dwell time, and at 120 min dwell time, 200 mL of dialysate is drained, 10 mL is taken, and the remaining 190 mL is reinfused.
6. The patient is otherwise ambulatory during the dwell period.
7. At 120 min dwell time, a serum sample is obtained.
8. At 240 min dwell time, with the patient in the vertical position, the dialysate is drained over 20 min, the volume is measured, and a final sample is obtained.
9. All samples are sent for glucose and creatinine concentrations[b].

[a]The modified PET uses a 4.25% exchange.
[b]Sodium concentration may also be assessed when pursuing an abnormality in transcapillary ultrafiltration (type I ultrafiltration failure or an abnormality in transcellular pore function) versus an increase in lymphatic absorption rate. In this case, an additional dialysate sample at 60 minutes may also be helpful.
Twardowski ZJ. Peritoneal equilibration test. *Perit Dial Bull* 1987;7:138–147; Twardowski ZJ. Clinical value of standardized equilibration tests in CAPD patients. *Blood Purif* 1989;7:95–108.

In determining the D/P creatinine ratio, it must be appreciated that high glucose levels will falsely

elevate creatinine measurements when determined by the picric acid method. As a result, creatinine levels must be corrected for the glucose level using a correction factor (**EQUATION 13.5**):

$$\text{Corrected Creatinine (mg/dL)} = \text{Creatinine (mg/dL)} - [\text{Glucose (mg/dL)} \times \text{Correction factor}] \quad (13.5)$$

The correction factor in our laboratory is 0.00053, but this may differ from one laboratory to another, depending upon the analyzer used. Enzymatic methods for determining creatinine are not altered by glucose concentration and therefore do not require the use of a correction factor.

From 103 PETs performed in 86 patients on PD from 0.1 to 84 months at the time of the PET, Twardowski (40) categorized patients according to transport rates (based on the relationship of ±1 standard deviation from the mean) as low, low average, high average, and high (**FIGURES 13.5** and **13.6**). The PET results have been found to be highly reproducible, varying by less than 3% in repeated studies (8,45). The PET provides a valuable tool for categorizing and monitoring changes in peritoneal membrane transport (solute transport). Although the standard PET is also useful in assessing UF (water transport), it is limited by the fact that the use of a 2.5% exchange does not create a maximal osmotic gradient (15) (see section "Modified Peritoneal Equilibration Test" in subsequent text where 4.25% exchange is used). Nonetheless, information from the PET, in conjunction with clearance studies, aids in choosing an appropriate dialysis technique, developing a PD prescription, as well as following peritoneal membrane function (46). Because of the labor-intensive and time-consuming requirements of the standard PET, a "fast PET" was devised (47) (**TABLE 13.3**). The fast PET allows assessment of net UF and categorization of solute transport status using only the 4-hour D/P creatinine ratio (**FIGURE 13.5**) and glucose concentration (**TABLE 13.4**). The reproducibility of the fast PET results has also been shown to be quite good with coefficients of variation of less than 5% for the D/P creatinine and drain volumes (48). Transport category determinations obtained utilizing the results of the fast PET have been shown to correlate extremely well with those obtained by the standard PET method (49). One can therefore accurately follow up patients using the more labor-efficient fast PET. One disadvantage of the fast PET is that intermediate evaluation points at 1-, 2-, or 3-hour dwell times are not obtained; this may pose a problem when using this test for planning or altering dialysis prescriptions that use shorter dwell times such as continuous cyclic peritoneal dialysis (CCPD) regimens. Therefore, its primary value is as a tool for evaluating changes in membrane permeability over time.

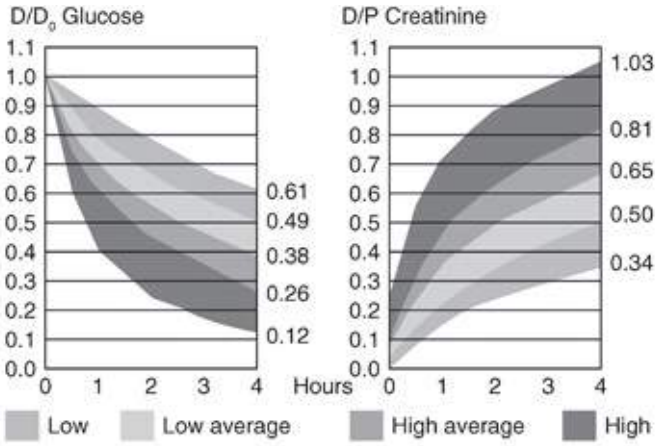

FIGURE 13.5 Results of 103 peritoneal equilibration tests (PETs) done in 86 patients. Areas shaded in different patterns portray results representing peritoneal transport rates that are high, high average, low average, and low. Creatinine concentrations in dialysate and plasma are corrected for glucose (see text). D/D_0, dialysate glucose concentration; D/P, dialysate to plasma. The numbers to the right separate the categories. (Reproduced with permission from Twardowski ZJ. Clinical value of standardized equilibration tests in CAPD patients. *Blood Purif* 1989;7:95–108.)

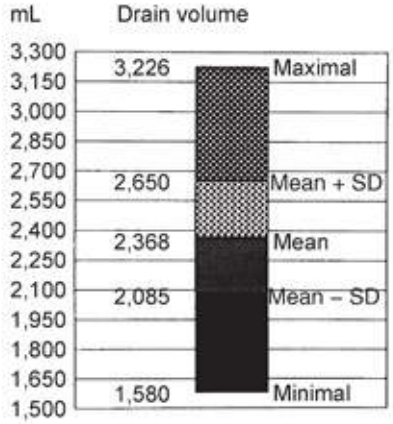

FIGURE 13.6 Drain volumes after standardized 4-hour dwell time test exchanges (PET), $n = 94$. Patients with high solute transport rates usually have low drain volumes, and *vice versa*. SD, standard deviation. (Reproduced with permission from Twardowski ZJ. Clinical value of standardized equilibration tests in CAPD patients. *Blood Purif* 1989;7:95–108.)

TABLE 13.3 Fast Peritoneal Equilibration Test (PET)

1. Steps 1, 2, and 3 of the standard PET are performed by the patient at home.
2. The exact time the infusion ended is noted by the patient.
3. The patient comes to the clinic at 240 min dwell time; in the vertical position, the dialysate is drained over 20 min.
4. The drained dialysate amount is measured and a sample is obtained.
5. A serum sample is obtained at 240 min dwell time.
6. All samples are sent for glucose and creatinine concentrations.

Factors Influencing the Accuracy of Peritoneal Equilibration Test

The accuracy and reproducibility of the PET depend on its being performed exactly as outlined in **TABLE 13.2**. Any alteration in the method (e.g., dialysate volume) could significantly alter the results. For example, a larger instilled volume of dialysate may delay equilibration and lead to a lower D/P ratio and *vice versa*. Although using a more hypertonic exchange (4.25%) compared to 2.5% exchange has been shown to significantly change the D/D_0 glucose and drain volume, the effect on D/P ratios for creatinine and designated transport category has been insignificant (50).

TABLE 13.5 outlines common errors in performing the PET. One additional note of caution is the use of the PET in patients with serum glucose concentrations of more than 300 mg/dL, as this can lead to unreliable results (47). Hyperglycemia decreases the D/P glucose (osmotic) gradient, thereby reducing the transcapillary UF rate as well as the rate of diffusion of glucose. This results in drain volumes that are less than expected and D/D_0 glucose concentrations that are higher than expected based on the patient's 4-hour D/P creatinine transport categorization. Finally, peritoneal surface area is larger relative to body weight in infants and children as compared with adults, and correlates more closely to BSA. Therefore, when performing the PET in infants and children, an exchange volume of 1,100 to 1,200 mL/m^2 BSA is recommended. This allows the use of the same transport categories defined for adults (40,43) to be applied to infants and children (51–53).

TABLE 13.5 Common Errors in Performing the Peritoneal Equilibration Test (PET)

Incomplete drainage of the overnight exchange
Incomplete final drainage of the PET exchange
Poor mixing of the dialysate during PET
Allowing fresh dialysate to flow into the drain bag
Errors in calculation

Modified Peritoneal Equilibration Test

Although standardized and highly reproducible, the use of standard PET may not be optimal in determining UFF because the osmotic gradient created by the use of a 2.5% exchange is modest and does not test maximal UF, as would be seen using a 4.25% exchange. The large drained volume with a 4.25% exchange makes the result less subject to measurement errors and more sensitive to detect clinically significant UFF. Therefore, it has been recommended that a modification of the standard PET be made and that a 4.25% exchange be used rather than a 2.5% exchange. The use of a 4.25% exchange does not result in any significant difference in MTAC or D/P creatinine (D/P_{Creat}) transport group characterization compared with that determined using a 2.5% exchange (50). The "modified PET" is currently considered the procedure of choice in the evaluation of UFF (water transport) and can be used to define peritoneal membrane function (solute transport) as well (14,15,54,55).

Miniperitoneal Equilibration Test

During a hypertonic dwell, approximately 60% of total UF is dependent on transport through small pores [ultrafiltration through small pores (UFSP)], which is coupled to the transport of small solutes, whereas approximately 40% of UF occurs through aquaporins resulting in the transcellular transport of free water without solutes (56–58). Estimation of free water transport can help in determining whether the cause of

apparent UFF is due to decreased osmotic conductance in response to glucose or to a deficiency of aquaporins. A semiquantitative assessment of free water transport may be obtained by performing a 3.86% PET and examining either the D/P sodium concentration ratio (D/P_{Na}) or the magnitude of the dip in D/P_{Na} (15). However, even after correction for sodium diffusion (59), D/P_{Na} and the dip in D/P_{Na} are only approximate estimates of free water transport. Another indirect method to estimate free water transport is the comparison of net UF obtained during two modified PETs (standard peritoneal permeability analysis) performed with a PD solution with a glucose concentration of 1.36% or of 3.86% (54), but this method is complicated, time consuming, and not easily applicable in everyday clinical practice. In addition, it cannot properly quantify free water transport because the difference in net UF during a 1.36% or 3.86% test is the sum of the contribution of free water transport and of UFSP during the 3.86% test.

La Milia et al. (60) suggested another method with the consideration that during the first hour of a 3.86% exchange the free water transport is maximal—as glucose in the dialysate is at its highest concentration and diffusive sodium transport is very low—because of low plasma to dialysate sodium gradient. Therefore, if one shortens the duration of the 3.86% PET from 4 to 1 hour, UF through the large pores and reabsorption through lymphatics are both low (61); sodium transport is due mainly to convective transport through small pores. It is then possible to estimate UFSP as the sodium removal divided by the plasma water sodium concentration; free water transport is easily calculated by subtracting UFSP from total UF. This is referred to as the *3.86% mini-PET*. The values of D/P_{Creat} during the 3.86% PET and the 3.86% mini-PET were well correlated (**FIGURE 13.7**). Computer simulations by Venturoli and Rippe (62) showed that the La Milia method leads to reliable results and is easy to use in common practice. Furthermore, the free water transport calculated by this method was correlated to vascular AQP-1 expression (25). The mini-PET is a promising new tool, but its utility in the follow-up of prevalent patients' needs to be explored.

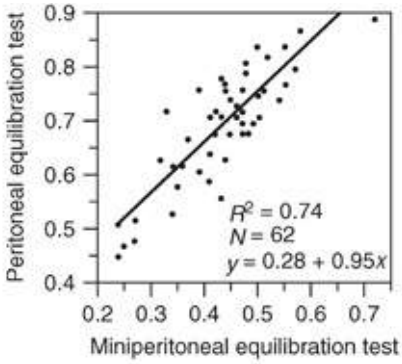

FIGURE 13.7 Linear correlation between the values of D/P (dialysate to plasma) creatinine during the 3.86% peritoneal equilibration test and the 3.86% miniperitoneal equilibration test. [From La Milia V, Di Filippo S, Crepaldi M, et al. Mini-peritoneal equilibration test: a simple and fast method to assess free water and small solute transport across the peritoneal membrane. *Kidney Int* 2005;68(2):840–846.]

Alternative Methods for Evaluating Peritoneal Membrane Function

A number of authors have offered alternative approaches to evaluating and monitoring peritoneal transport. These are all variations on the principles of the PET but are felt to offer either greater accuracy or ease than the standard PET. These include the standardized peritoneal permeability analysis (SPA), a modification of the PET using 1.5% dextrose to which dextran is added (63); the dialysis adequacy and

transport test (DATT), which utilizes the D/P creatinine and urea ratios established by the 24-hour dialysate collection available from clearance studies (64); and the peritoneal permeability and surface area (PSA) index, which separates the contribution of diffusive and convective transport to the D/P ratio (65). But their complexity, accuracy, or reproducibility make them inferior substitutes for the PET, and they are not commonly used in clinical practice.

DIAGNOSTIC APPROACH, DIFFERENTIAL DIAGNOSIS, AND TREATMENT OF THE PATIENT WITH ULTRAFILTRATION FAILURE

UFF is suspected clinically when patients cannot maintain an edema-free state or their target weight despite frequent use of hypertonic exchanges and dietary restriction. The observed increase in solute transport with time on dialysis explains, in part, the more frequent occurrence of signs and symptoms of UFF rather than that of inadequate solute removal (**TABLE 13.6**) (66–68). However, a change in peritoneal membrane function is only one of a number of possible factors that must be considered in a patient with suspected evidence of UFF (**TABLE 13.1**). A diagnostic approach (**FIGURE 13.8**) directed to the patient with possible UFF is therefore particularly germane.

TABLE 13.6 Signs and Symptoms of Inadequate Dialysis

Ultrafiltration failure
Increasing hypertension or edema
Increasing requirement for hypertonic exchanges
Solute removal failure
Increasing creatinine
Increasing or decreasing blood urea nitrogen
Worsening anemia or neuropathy
Anorexia, nausea, vomiting, lethargy, insomnia

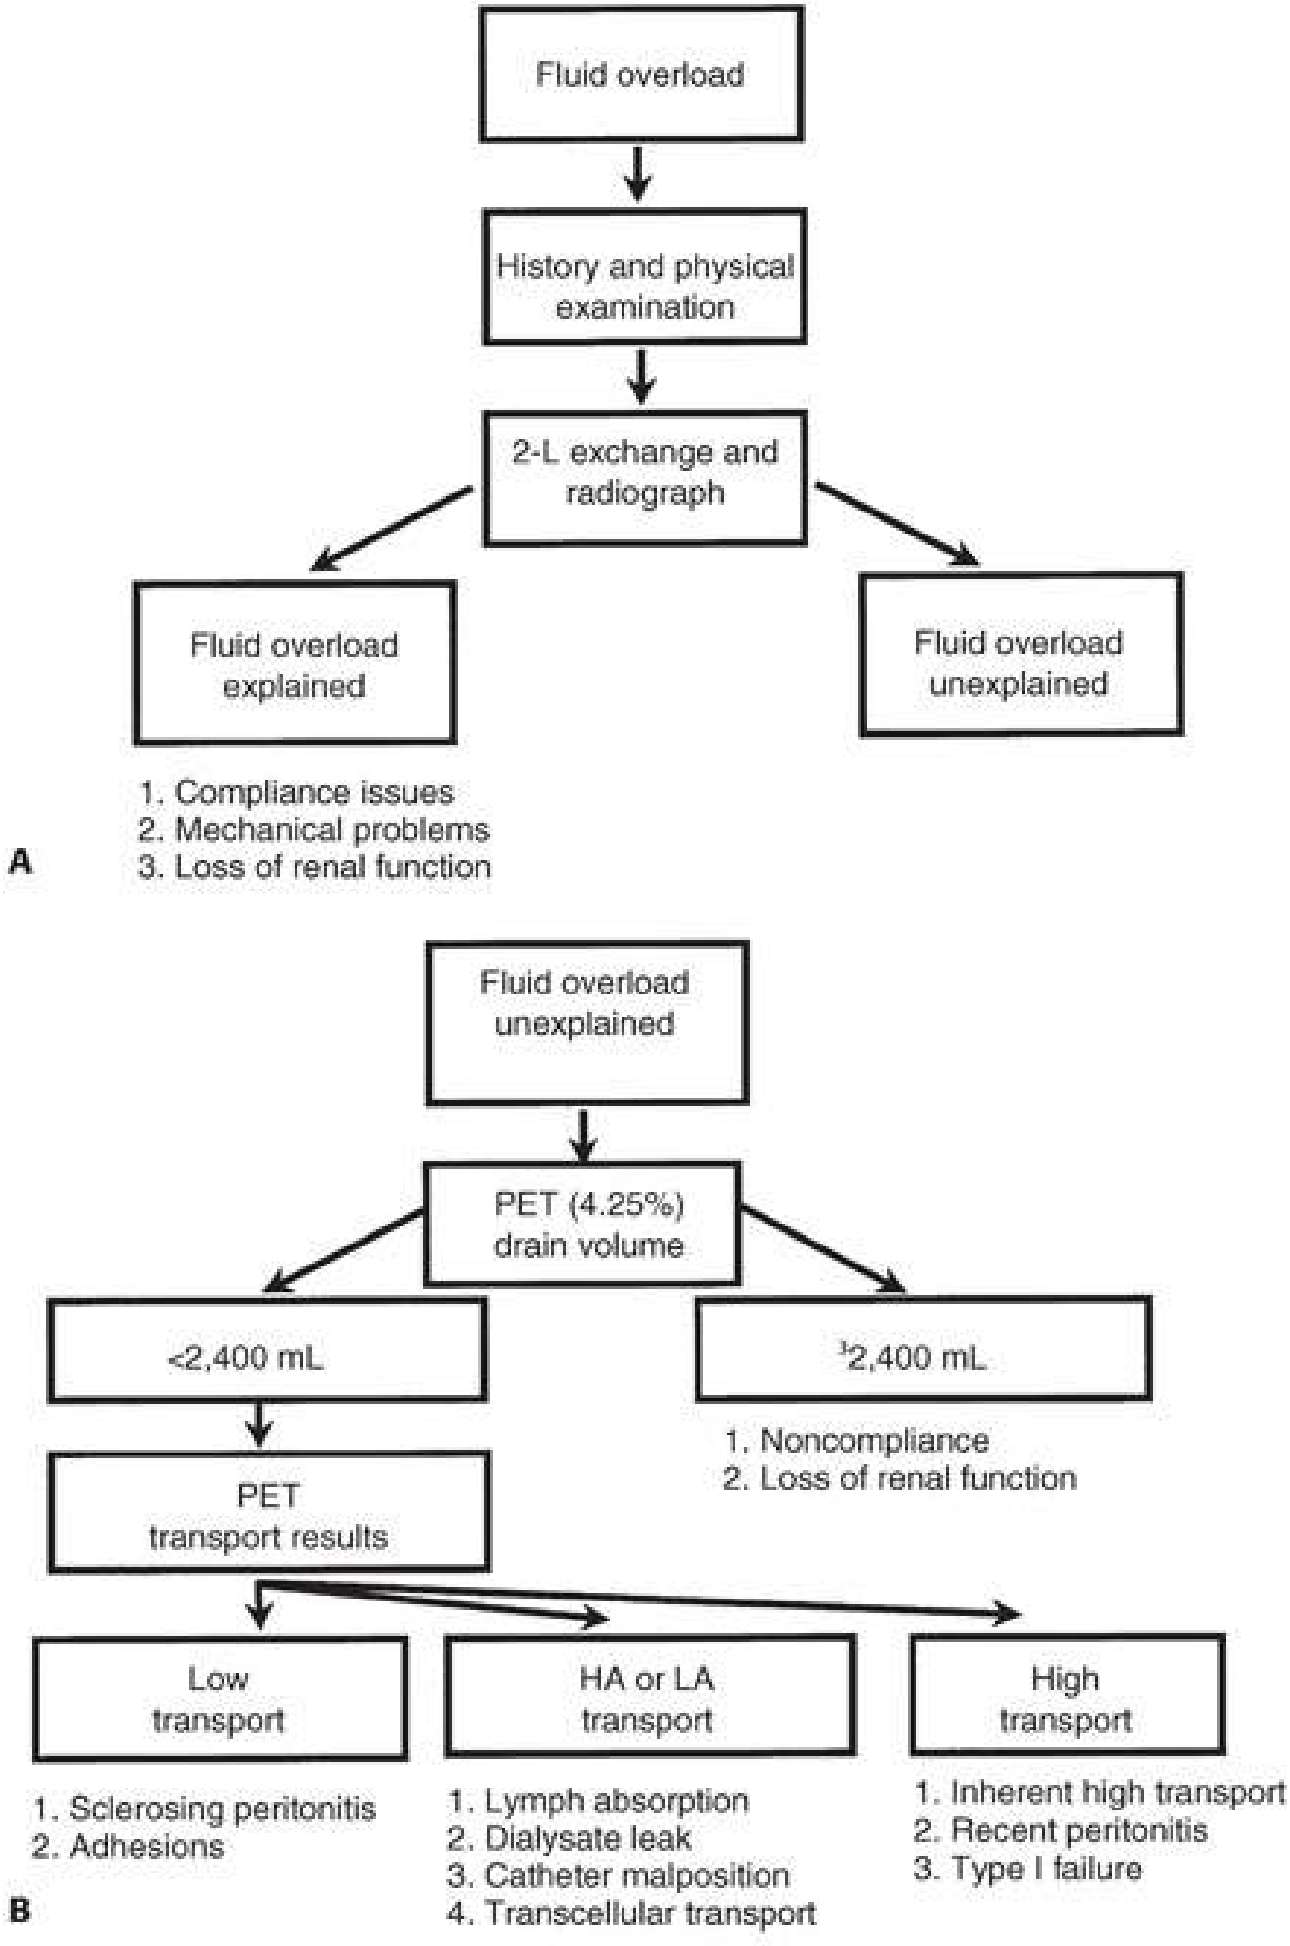

FIGURE 13.8 Initial approach **(A)** to patients with fluid overload and **(B)** an algorithm incorporating the modified (4.25%) peritoneal equilibration test (PET) to further evaluate those patients in whom the cause of fluid overload remains unexplained after the initial assessment. HA, high average; LA, low average.

When a patient presents with signs or symptoms of fluid overload, it is important to obtain a good medical history and to perform a thorough physical examination (**FIGURE 13.8**). Issues such as compliance with diet and dialysis are obviously critical, and a significant reduction in urine output may identify another potential reason for this problem. In addition, knowing the time frame over which the fluid accumulation occurred may be extremely helpful; patients with membrane failure as well as those with increased LA usually develop symptoms of UFF gradually, whereas those with mechanical problems (malpositioned catheter or dialysate leak) have a more acute presentation. When the dialysate flow is described as positional, this suggests a malpositioned catheter. Findings of edema localized to the abdomen or inguinal area can be important clinical clues to the presence of a peritoneal leak.

At the time of the initial evaluation of a patient with fluid overload, a quick "fill and drain" with 2 L of dialysate is beneficial to directly observe the nature and rate of inflow and outflow. Usually, the inflow rate for dialysate is approximately 1,700 mL over 10 minutes and the outflow rate is similar. The presence of fibrin clots may explain abnormalities with flow that reduce the efficiency of drainage and volume removal and can often be resolved with intraperitoneal heparin. If incomplete drainage or positional drainage is observed, a flat-plate radiograph of the abdomen should be performed to determine catheter position and to assess the degree of stool in the bowel as the distension of bowel loops because feces is the single most common cause of poor catheter drainage (**FIGURE 13.9**). When a peritoneal leak is suspected by clinical examination, computed tomography or magnetic resonance imaging (MRI) of the abdomen—even without contrast—will often confirm its presence (**FIGURES 13.10** and **13.11**). It is extremely important to communicate to the radiologist the purpose of any radiographic procedure used in assessing problems with PD, as well as to review the radiograph(s) personally.

FIGURE 13.9 Plain roentgenogram (flat plate) of the abdomen demonstrating malpositioned catheter. Catheter tip can be seen in left upper abdomen (*arrow*).

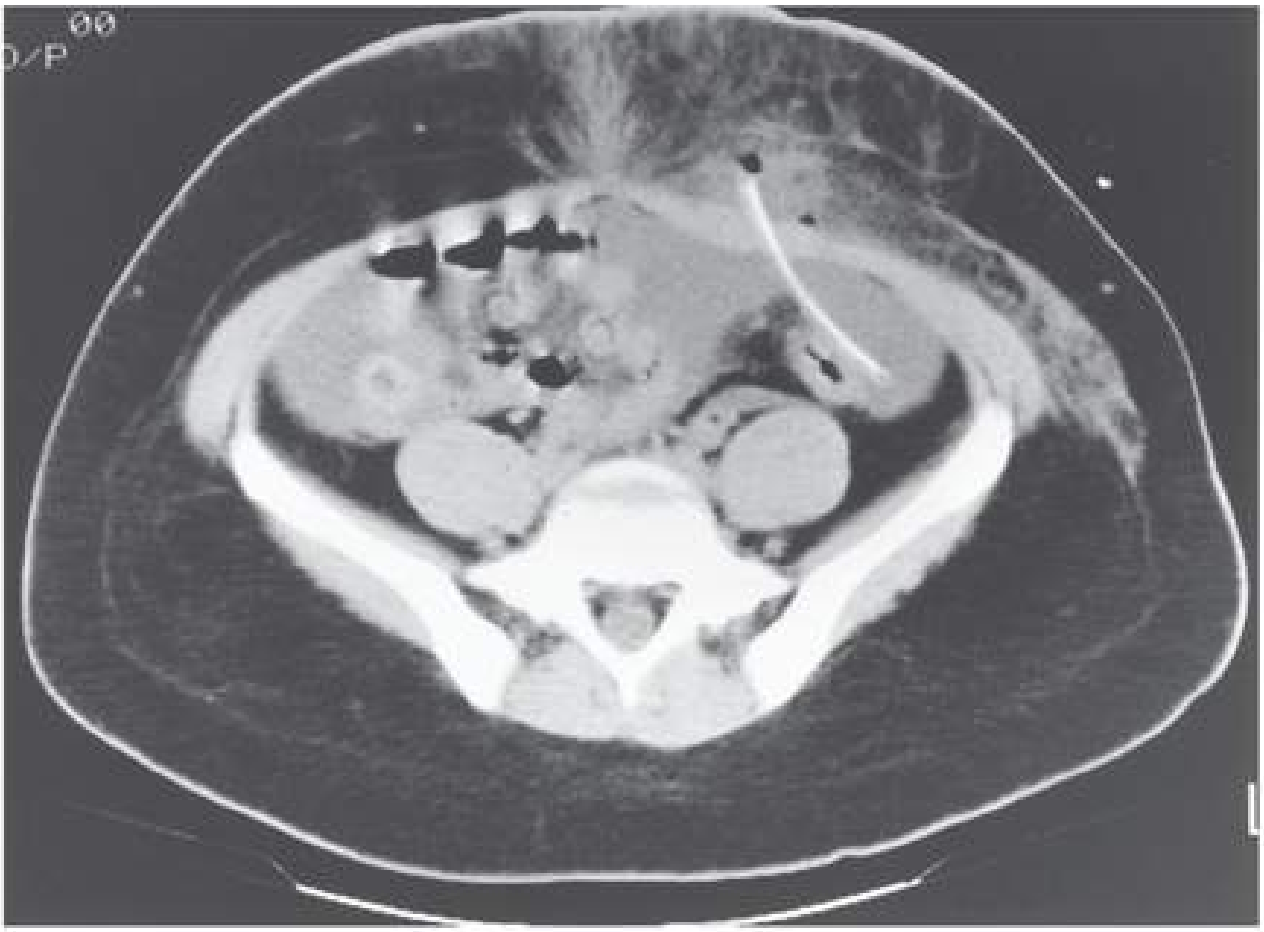

FIGURE 13.10 Computed tomographic scan of abdomen without intraperitoneal contrast in a patient with ultrafiltration failure and abdominal wall edema. Increased markings, representing fluid, can be seen within the anterior and left lateral subcutaneous tissues adjacent to the Tenckhoff catheter and indicate a dialysate leak.

FIGURE 13.11 Computed tomographic scan of abdomen in patient with ultrafiltration failure and abdominal wall swelling. Radiocontrast material has been injected into dialysate to facilitate tracking. A large collection of contrast material can be seen in the anterior abdominal wall and subcutaneous tissues (*), indicating a dialysate leak.

When the etiology of fluid overload is not apparent after the initial clinical assessment and mechanical causes have been ruled out, the use of the modified PET is recommended as the best way to evaluate patients suspected of having UFF (15). The modified PET allows one to construct a logical approach to the differential diagnosis and treatment of this common problem (**FIGURE 13.8**).

FLUID OVERLOAD WITHOUT ULTRAFILTRATION FAILURE

When a patient presents with unexplained fluid overload without UFF (drain volume greater than or equal to 2,400 mL), the possibility of noncompliance with diet or dialysis prescription must be entertained (**FIGURE 13.8**). In addition, the unrecognized and therefore uncompensated loss of RRF is a common cause for signs and symptoms of inadequate fluid removal, particularly in high-transport patients.

Patient Compliance

Noncompliance with the dialysis prescription and/or diet is a common problem that is often difficult to diagnose, as it is almost totally dependent on the patient's willingness to be honest. Estimates of the rate of noncompliance with the dialysis prescription range from 13% to 78% (69–71). Unfortunately, the methods presently used in documenting dialysis noncompliance such as comparing measured to calculated creatinine production are highly inaccurate (70). An estimate of dialysate use can be obtained through the shipping records of the dialysate supply company and therefore may allow an objective parameter by

which to judge a patient's compliance. Although difficult to resolve, education and positive reinforcement may help improve this problem in a motivated patient.

Residual Renal Function

At the initiation of chronic dialysis, most patients still have RRF that may contribute as much as 30% to the overall maintenance of solute and fluid balance (72). Outcome studies in PD patients have clearly demonstrated a significant survival benefit with preservation of RRF (73). The potential benefits include better clearance of middle and larger molecular weight toxins, better volume and blood pressure control, decreased inflammation, improved appetite and nutritional status, relative preservation of kidney endocrine functions, and improved phosphate control and quality of life. However, RRF [glomerular filtration rate (GFR)] continues to decline on dialysis, which is associated with a significant decrease in urine volume. As a result, measures to preserve RRF are an important target in the treatment of patients receiving dialysis. Aggressive measures taken before initiation of dialysis to preserve kidney function, such as avoidance of nephrotoxic insults including intravenous contrast, antibiotics (e.g., aminoglycosides), and prevention of hypotensive episodes, should continue to be addressed once dialysis has been initiated. Randomized trials have shown that use of an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker reduces the rate of decline in RRF and possibly delays the development of complete anuria in patients performing PD, although these trials were of small size (74,75). Another intervention which may be useful for preservation of RRF has been the use of biocompatible PD solution. Several trials comparing biocompatible solutions based on (a) neutral pH with low glucose degradation product (GDP) (balANZ trial), (b) 1.1% amino acids, or (c) 7.5% icodextrin with conventional dextrose-based dialysate recently have been shown to decrease the rate of decline in RRF, with a smaller decline in urine volume or longer time to the development of anuria (76–79). To closely monitor for changes in kidney function, the ISPD recommends that 24-hour urine volumes and clearances be assessed regularly and at an appropriate frequency (every 1 to 2 months if practicable, otherwise no less frequently than every 4 to 6 months) so that the PD prescription can be adjusted in a timely manner (evidence level C). If there is a decrease in urine volume or a change in blood chemistries suggesting a decline in RRF, it should be measured sooner (80).

FLUID OVERLOAD WITH ULTRAFILTRATION FAILURE

A drain volume of less than 2,400 mL following a 4-hour 4.25% exchange defines the patient with UFF. UFF occurs when the balance between the transcapillary UF and LA rates has been altered, resulting in a decrease in drain volume (**FIGURE 13.8**). Clinically, this is identified by the need for more hypertonic exchanges to resolve signs of volume overload. These changes can be the result of (a) an increase in surface area/permeability leading to greater glucose absorption and a more rapid dissipation of the osmolar gradient (type I UFF), (b) a decrease in the osmotic conductance of glucose that leads to inadequate water removal (type II UFF), (c) a severe decrease in effective peritoneal surface area/permeability that significantly restricts the transport of both solute and fluid (type III UFF), (d) an increase in LA (type IV UFF), or (e) an increase in residual volume that leads to a more rapid loss of osmotic gradient by dilution (4). Therefore, a number of factors, in addition to changes in the peritoneal membrane, must be considered in the differential diagnosis of patients with UFF (**TABLE 13.7**). The PET

allows an important assessment of both water and solute transport, which aids in the evaluation of UFF.

TABLE 13.7 Factors Resulting in Ultrafiltration Failure

I. Peritoneal membrane function
  A. Increased effective surface area/permeability
    1. Peritonitis
    2. Type I ultrafiltration failure[a]
  B. Decreased osmotic conductance to glucose
    1. Type II ultrafiltration failure[b]
  C. Decreased effective surface area/permeability
    1. Type III ultrafiltration failure[c]
      a. Sclerosing peritonitis
      b. Adhesion
II. Lymphatic absorption
  A. Increased
    1. Primary increase (type IV ultrafiltration failure[d])
    2. Secondary increase (dialysate leak)
III. Dialysate volume/osmolarity/flow
  A. Increased residual volume (diluting osmotic gradient)
    1. Malpositioned catheter
    2. Loculations from adhesions
IV. Peritoneal blood flow
  A. Decreased
    1. Vascular disease

[a]The term applied to ultrafiltration failure when unexplained changes in membrane properties result in high solute transport. This has also been referred to as *type I membrane failure*.
[b]The term applied to ultrafiltration failure when changes in function of ultrasmall pore (aquaporins) cause decrease in osmotic conductance of glucose and leads to inadequate water removal.
[c]The term applied to ultrafiltration failure when changes in membrane properties result in decreased water and (low) solute transport as seen with sclerosing peritonitis or severe abdominal adhesions. This has also been referred to as *type III membrane failure*.
[d]The term applied to ultrafiltration failure as a result of a primary increase in lymphatic absorption.

Patients with High Solute Transport (D/P Creatinine Greater Than 0.81)

Patients with a low drain volume (less than 2,400 mL/4 h with a 4.25%/3.86% modified PET) and a D/P creatinine greater than 0.81 likely represent the largest group of patients with inadequate filtration due to peritoneal membrane characteristics. These patients tend to have good low molecular weight solute transport but have poor UF during standard CAPD or CCPD using glucose-containing dialysate, due to rapid absorption of glucose and dissipation of the osmotic gradient. If their dwell times are mismatched for their membrane transport characteristics, they often appear to have inadequate UF as they lose RRF and no longer have urine flow to supplement net daily peritoneal fluid removal. This clinical picture may develop over the course of months to years (so-called type I UFF), may be the consequence of a recent episode of peritonitis, or may be intrinsic to a particular patient's peritoneal membrane.

Type I Ultrafiltration Failure

This is the most common cause of UFF and is due to large effective peritoneal surface area with subsequent hyperpermeability of the membrane. Unfortunately, the development of slowly increasing hyperpermeability is a typical feature of chronic PD. The pathomorphologic cause of type I UFF is probably both fibrosis and, especially, angiogenesis, resulting in a large effective surface area (**FIGURE 13.12**). The avascular submesothelial fibrotic layer results in decreased osmotic pressure toward the endothelial exchange area of the capillaries. Additionally, by angiogenesis, an increased number of perfused capillaries under the fibrotic matrix rapidly dissipate the glucose-driven osmotic pressure. In an excellent animal model, an adenovirus-mediated gene transfer of angiostatin, a highly potent inhibitor of

angiogenesis, resulted in higher UF by suppressing angiogenesis. An inverse correlation was found between the number of vessels and UF, underlining the important role of increased effective peritoneal surface area by angiogenesis in decreasing UF (81).

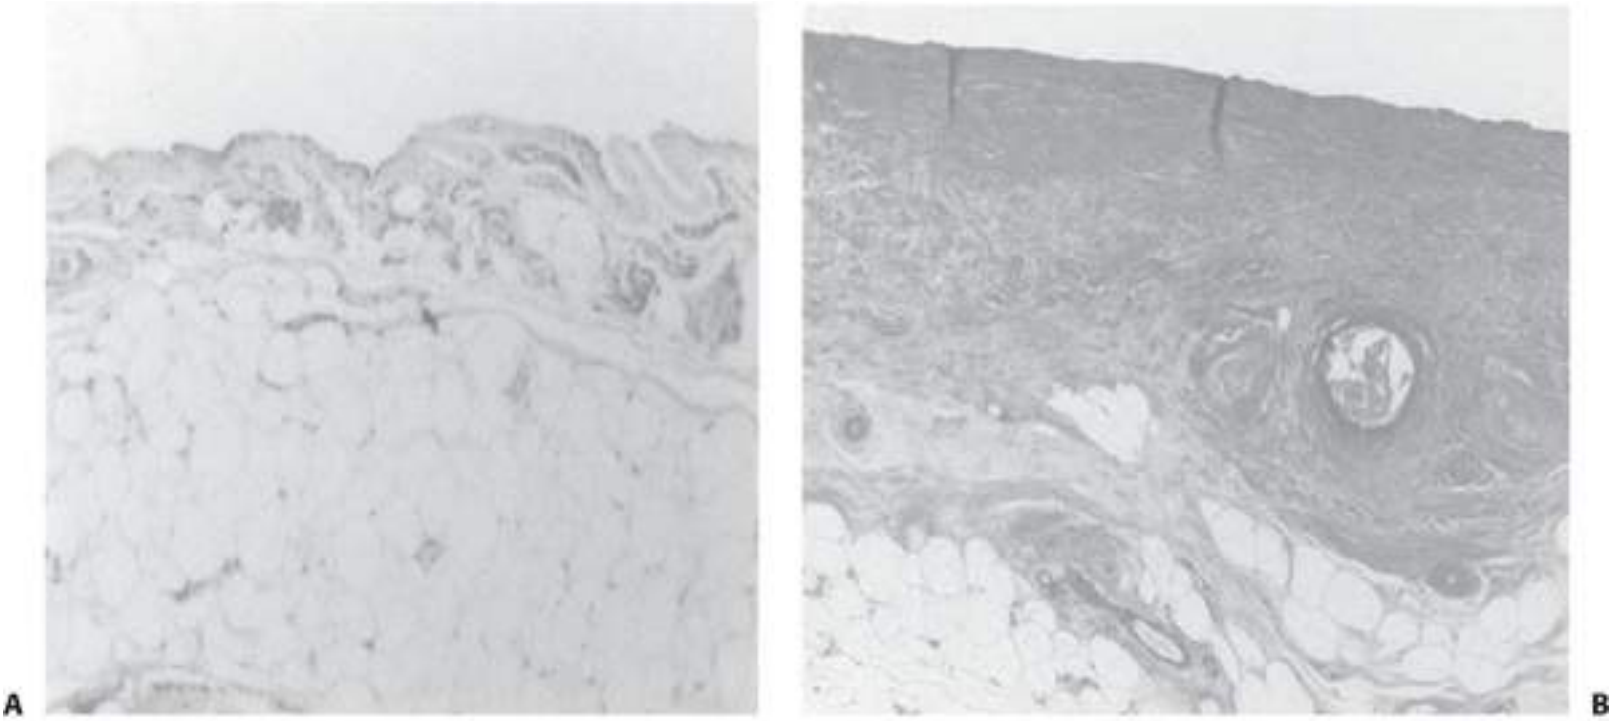

FIGURE 13.12 **(A)** Peritoneal histomorphology at the beginning of peritoneal dialysis (PD) and **(B)** after 6 years of PD, with submesothelial fibrosis, increased numbers of vessels, and vasculopathy. [From Fusshoeller A. Histomorphological and functional changes of the peritoneal membrane during long-term peritoneal dialysis. *Pediatr Nephrol* 2008;23(1):19–25.]

Hyperpermeability is a predictor of higher mortality in long-term PD patients (80). In 1998, the single-center Stoke PD study (83,84) and the multicenter Canada–United States of America (CANUSA) study (85), both prospective cohorts adequately powered to look at mortality, demonstrated that high transport was associated with worse patient and technique survival independent of other important predictors, such as age, comorbidities, and RRF. Later analysis from the Australian and New Zealand Dialysis and Transplant (ANZDATA) registry, by far the largest study published to date, also reported the association of high transport rates with increased mortality and technique failure (86). Moreover, further analyses of these studies exhibited that relationship between high transport and survival was confined to CAPD and not apparent in CCPD patients (87). Similarly, ANZDATA reported a high transport-modality interaction supporting higher mortality in CAPD patients. These analyses clearly suggest that excess mortality associated with high permeability is related to impaired ultrafiltration, which is better managed by CCPD.

Etiology and Pathogenesis

Recently, much work has been done to identify the mechanisms that are involved in the pathogenesis of peritoneal membrane failure during long-term PD (**FIGURE 13.13**). The major studied factors contributing to morphologic and functional alterations of the peritoneal membrane have been uremia, peritonitis, and the nonphysiologic nature of dialysis fluids. In uremia circulating nitric oxide (NO), advanced glycation end-products (AGEs), vascular endothelial growth factor (VEGF), and inflammatory cytokines [interleukin (IL)-1β, tumor necrosis factor alpha (TNF-α), and IL-6] are all significantly increased (88).

The increase in effective peritoneal surface area is strongly related to VEGF and NO. The peritoneal expression of VEGF has been reported to correlate with the permeability of the peritoneal membrane and the degree of angiogenesis (89). In addition, during chronic PD, endothelial nitric oxide synthase (eNOS) is significantly upregulated, which may contribute to an increase in vascular density and endothelial area (90). Data from the peritoneal biopsy registry confirmed that uremia *per se* leads to thickening of the submesothelial zone and mild vasculopathy (91).

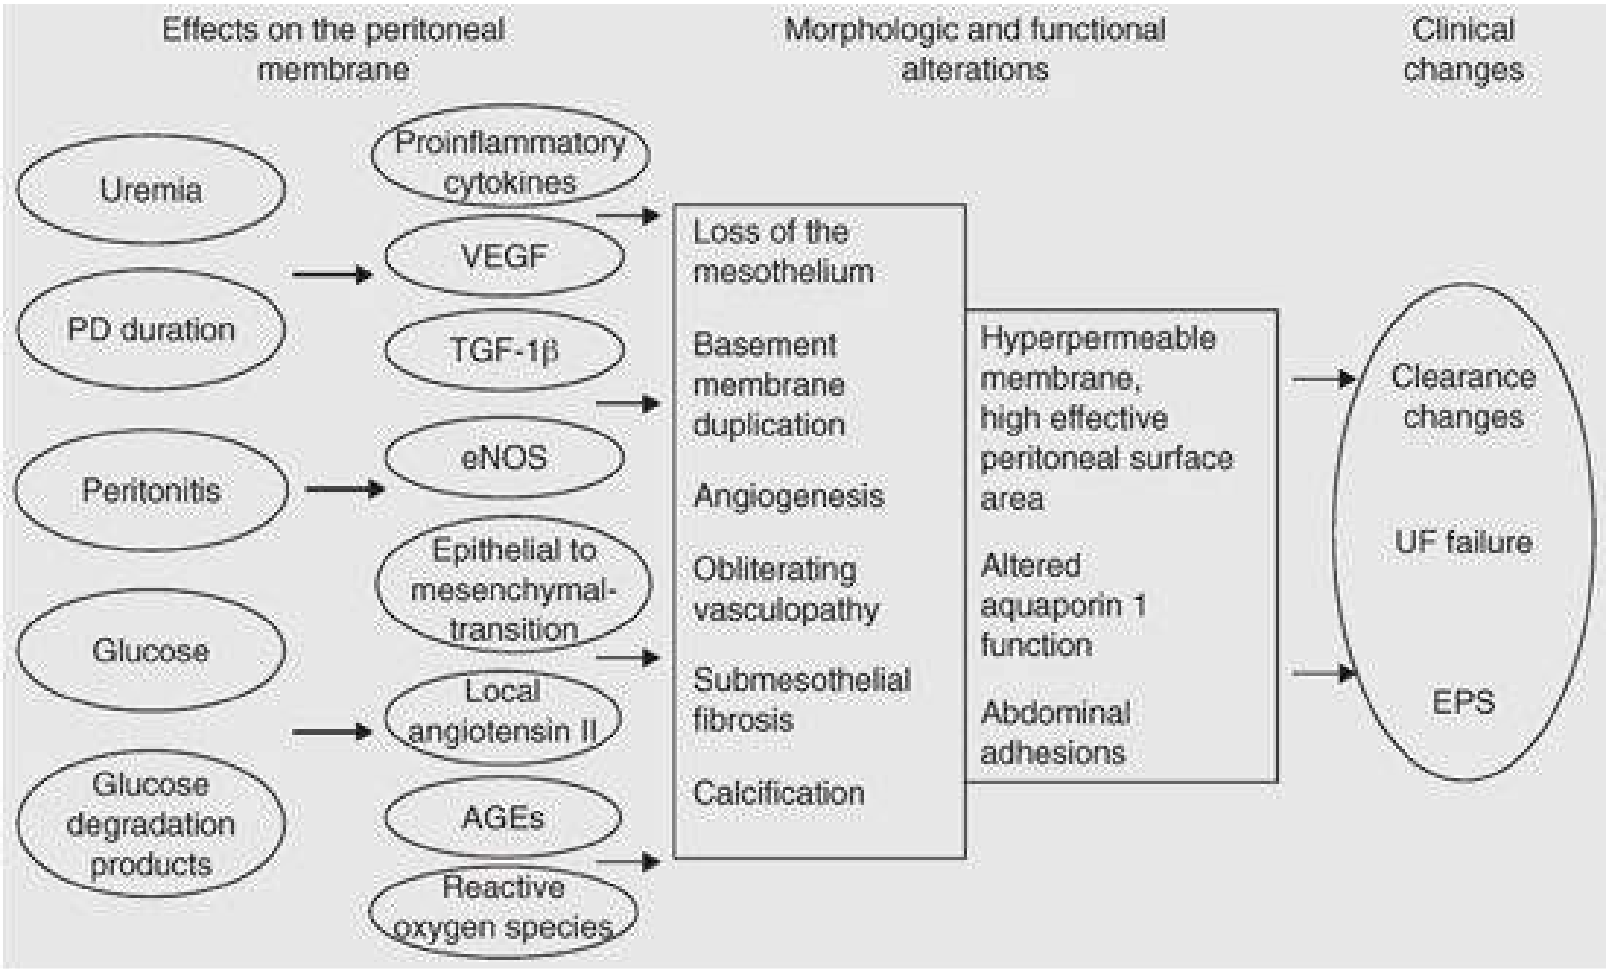

FIGURE 13.13 Effects of long-term peritoneal dialysis (PD) on the peritoneal membrane, and the subsequent morphologic, functional, and clinical consequences. VEGF, vascular endothelial growth factor; TGF, transforming growth factor; eNOS, endothelial nitric oxide synthase; AGE, advanced glycation end-product; UF, ultrafiltration; EPS, encapsulating peritoneal sclerosis. [From Fusshoeller A. Histomorphological and functional changes of the peritoneal membrane during long-term peritoneal dialysis. *Pediatr Nephrol* 2008;23(1):19–25.]

To provide a stable peritoneal solution with a practicable shelf life, the pH of the solution is kept moderately acidic at approximately 5.2. This prevents the formation of GDPs. Moreover, standard peritoneal dialysate is buffered with lactate rather than bicarbonate as the latter has the potential to react with calcium and form calcium carbonate precipitate. Given the acid pH (but not sufficiently acidic to halt completely the formation of GDPs), high lactate and absent bicarbonate, peritoneal dialysate is not completely physiologic or "biocompatible." In an international peritoneal biopsy registry, more than 130 biopsies of long-term PD patients were compared with healthy controls and uremic patients not undergoing PD to evaluate the role of PD fluid as a cause for functional and morphologic alteration of the peritoneal membrane (91). In uremic patients, the submesothelial zone was three times thicker than in healthy individuals, and, in PD patients, it was even five times as thick. Both the thickness of the submesothelial zone and the degree of obliterating vasculopathy correlated directly with the duration of

PD (**FIGURE 13.14**). The number of vessels (angiogenesis) was increased, especially in patients with clinical UFF and in patients with severe fibrosis. Patients on high-volume automatic peritoneal dialysis (APD) tended to have even more peritoneal fibrosis after shorter times on PD, which underlines the effect of cumulative glucose exposition. Glucose is a proinflammatory agent and has an additional profibrotic effect, especially through transforming growth factor (TGF)-1β stimulation and activation of protein kinase C. Glucose further stimulates the production of reactive oxygen species (ROS) causing oxidative stress and induces local angiotensin II production (92), which can also promote fibrosis through TGF-1β and fibronectin. GDPs and AGEs (AGEs form when GDPs link with proteins) are potent proinflammatory agents and strong inducers of angiogenesis through VEGF (93). Through stimulation of plasminogen activator inhibitor (PAI)-1, additional fibrosis is promoted (94). Peritoneal AGE depositions correlate directly with the degree of fibrosis, the increase in effective peritoneal surface area, and functionally with the decline in UF. Diabetic rats have been shown to have a much higher density of small blood vessels in their peritoneum than nondiabetic rats (95). This neovascularization resembles that seen in proliferative diabetic retinopathy. However, among the small number of biopsies from diabetic patients represented in the peritoneal biopsy registry, there did not seem to be an increased incidence of vasculopathy (91).

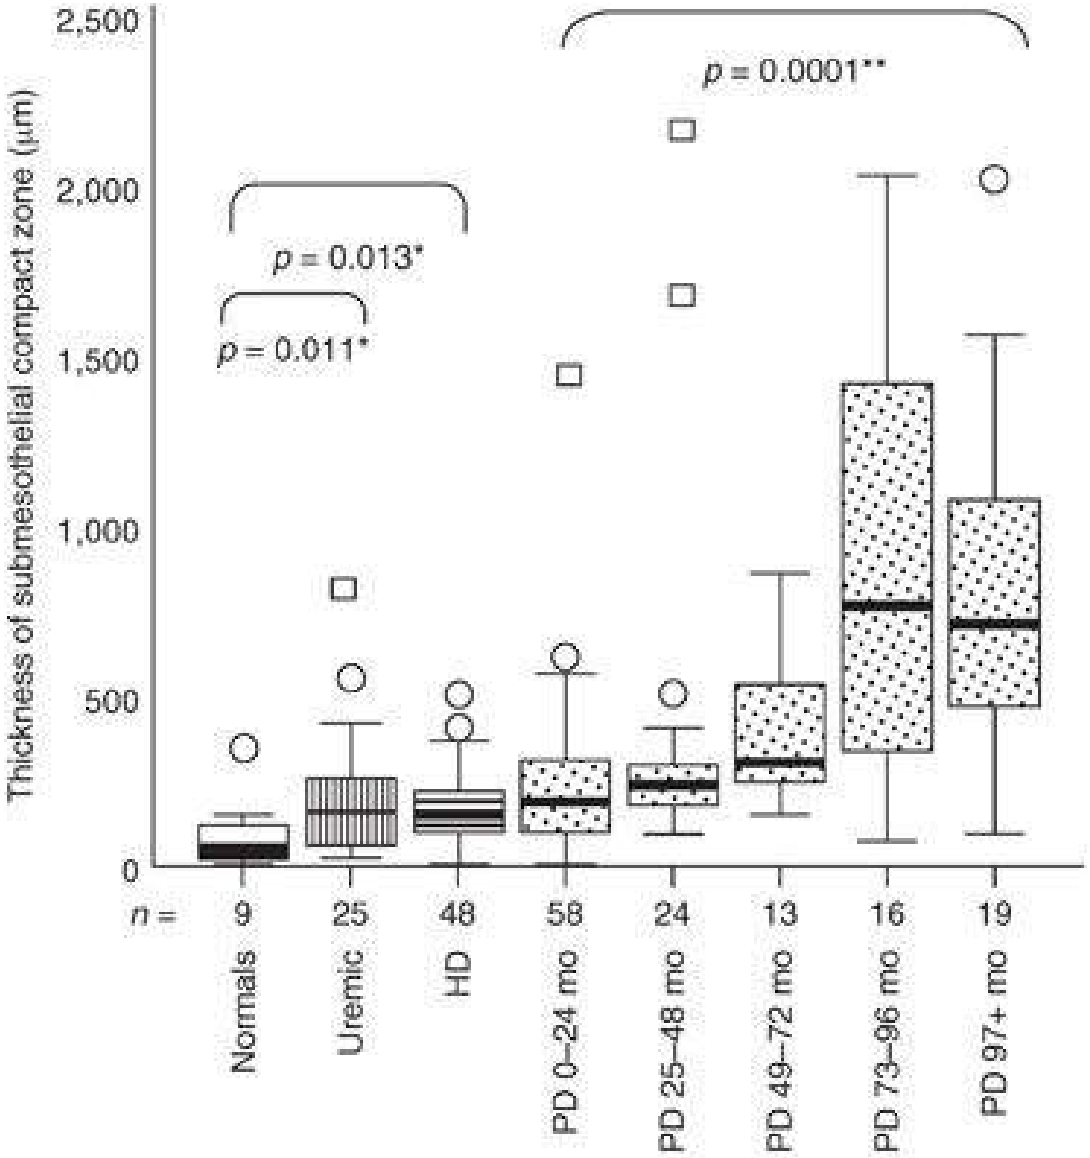

FIGURE 13.14 Changes in the submesothelial compact zone with biopsy origin and with peritoneal dialysis (PD) duration. The thickness of the submesothelial compact zone (in micrometers) was measured in biopsies from normal individuals, uremic patients, patients undergoing hemodialysis (HD), and patients undergoing PD, grouped according to the duration of dialysis. Data are presented as box plots, with the boxes representing the interquartile range (IQR). Lines extend from the box to the highest and lowest values, excluding outliers. The median value is represented by the thick line across each box. *, statistical comparisons made using the Mann-Whitney U test; **, statistical comparison made using Kruskal-Wallis one-way analysis of variance; ○ outliers; □ extremes. [From Williams JD, Craig KJ, Topley N, et al. Morphologic changes in the peritoneal membrane of patients with renal disease. *J Am Soc Nephrol* 2002;13(2):470–479.]

Classically, resident stromal fibroblasts and inflammatory cells have been considered the main cells responsible for structural and functional peritoneal alterations, whereas MCs have been considered mere victims of peritoneal injury. However, recently, it has been shown that MCs also play an active role in peritoneal membrane alteration. It has been demonstrated that soon after PD is initiated, peritoneal MCs show a progressive loss of epithelial phenotype and acquire myofibroblast-like characteristics by an epithelial-mesenchymal transition (EMT) (96). MCs that have undergone an EMT acquire higher migratory and invasive capacities, which allow these cells to invade the submesothelial stroma, where they contribute to peritoneal fibrosis and angiogenesis and ultimately lead to peritoneal membrane failure (96–98). The myofibroblastic conversion of MCs has been confirmed in an *in vivo* animal model based on the injection of an adenovirus vector that transferred active TGF-β1 in rat peritoneum (99). In these studies, EMT appears as the central point in the early pathogenesis of peritoneal damage associated with

PD. All the factors described earlier such as inflammation, uremia, and glucose stimulate the MCs to undergo EMT. MCs that have undergone EMT produce higher amounts of extracellular matrix component, including fibronectin and collagen I (98), and display less fibrinolytic capacity as a result of unbalanced ratio between tissue plasminogen activator and PAI-1 (100). The transdifferentiated MCs are also an important source of VEGF in PD patients; in fact, mesenchymal conversion of these cells appears to be the mechanism underlying upregulation of VEGF in PD (98). This suggests a direct and active role of MCs not only in fibrosis but also in peritoneal angiogenesis. Previous studies remained inconclusive regarding an association between markers of chronic inflammation and membrane transport failure (16,101,102); however, the most recent analysis of Global Fluid study, a multinational, multicenter, prospective, combined incident and prevalent cohort study (n = 959 patients) with up to 8 years of follow-up, reports that local subclinical intraperitoneal inflammation, as determined by dialysate IL-6 concentration, is the most significant known predictor of peritoneal solute transport rate (PTSR). Nonetheless, association of higher PTSR with worse survival remained independent of inflammation (103). The relevance of membrane inflammation is yet to be determined.

Treatment

Discontinuing PD and resting the peritoneum for at least 4 weeks by a temporary transfer to HD has been associated with significant improvement in UF capacity and normalization of solute transport characteristics in more than 81% of patients (104,105). A latest study reports that peritoneal rest enabled patients with UFF to continue on PD for a median time of 23 months (range, 13 to 46 months), although this beneficial effect was not be seen in patients with more than 6 months of UFF (106). This discontinuation of PD is felt to allow time for repair and remesothelialization of the damaged peritoneal membrane. Cancer antigen 125 (CA125) is a high molecular weight glycoprotein that is secreted by MCs. The level in PD fluid is considered a marker of MC mass (107). A decrease in CA125 levels in the absence of peritonitis has been seen before the development of type I membrane failure. Serial evaluations of CA125 may therefore provide a means by which to monitor mesothelial mass, allowing for peritoneal resting before the development of type I membrane failure. More research is required, however, to determine the best method for measuring CA125 and to establish normal values.

In most patients with type I UFF, especially those previously managed on standard CAPD, a change in the PD prescription to a regimen that takes advantage of shorter dwell times [e.g., nightly intermittent peritoneal dialysis (NIPD) and CCPD] may improve UF. Recent experience with the glucose polymer solution icodextrin 7.5% has proved beneficial in enhancing UF due to a modest oncotic pressure gradient that is sustained because of its relatively slow absorption and metabolism during the dwell period. This more than counterbalances Starling's forces (108,109), and it enables a slow but linear UF combined with almost complete prevention of fluid reabsorption during the long daytime dwell of CCPD or nighttime dwell of CAPD. Some patients cannot be maintained with these measures, fail PD, and require a transfer to HD for better volume control. The peritoneal catheter may be left in place and the PET may be repeated after a peritoneal rest period of 1 to 2 months. If solute transfer and UF normalize, PD may be reinitiated. If the patient's peritoneal membrane remains hyperpermeable, the transfer should be considered permanent and the PD catheter should be removed. An additional concern for patients with type I UFF is the fact that some patients have been reported to progress to type II UFF or sclerosing

peritonitis (see subsequent text) (110).

Prevention

As alterations in membrane characteristics are a major cause of UFF, their prevention has been much emphasized. Davies et al. (111) reported stable peritoneal permeability and better volume control in long-term PD patients using icodextrin in contrast to increasing hyperpermeability in “no-icodextrin” patients. They examined the longitudinal changes in membrane function and divided the patients according to baseline glucose concentration of dialysate and reported decreased UF capacity even during the short study period of 24 months, more marked and with earlier onset in patients using greater than or equal to 2.27% solution, least apparent in the patients using icodextrin from the start of the study (111). Systemic review of 11 randomized controlled trials confirmed the previously described observation and demonstrated that use of icodextrin resulted in significant reduction in episodes of uncontrolled fluid overload and improvement in peritoneal ultrafiltration without any complications (79). New biocompatible, double-chamber dialysates, which have normal pH, low GDP, and are buffered with bicarbonate rather than lactate, demonstrate reduced inflow pain, improved correction of acidosis (112,113), and a survival benefit (114). Recent analysis of balANZ trial revealed that patients who performed PD with the neutral pH, lactate buffered, and low GDP solution initially had a higher rate of peritoneal membrane transport. This rate remained stable over the 2-year observation compared to a progressive increase in peritoneal membrane permeability with conventional solutions (115). Long-term histomorphologic and functional data are lacking so far.

Another possibility for reducing GDP formation in PD solutions is sterilization by filtration. *In vitro* studies showed a significant increase in cell viability, equivalent to that of control cells, following exposure to filter-sterilized PD fluids (116). To date, only a few reports regarding the utilization of filter-sterilized PD solutions have been published, and they date some years back (117,118). Another approach to reducing glucose-related toxicity is the replacement of glucose with other osmotic agents. The use of amino acids (not yet available in the United States) is relatively well established for this purpose. Exposure of human peritoneal MCs to amino acid–based solutions resulted in better preservation of ultrastructure, viability, and protein synthesis compared with conventional glucose-based PD fluids (119). Animal studies with amino acid–based PD fluids showed reduced activation of the peritoneal immune system as well as reduced peritoneal neoangiogenesis, fibrosis, and damage to MCs (120). Although not well studied, some data suggest that these solutions may also have a protective effect on the peritoneal membrane in humans (77,121). There have been no serious side effects seen and no differences in UF, dialysis efficiency (Kt/V) (122), mortality, hospital duration, or serial C-reactive protein levels (123) compared to the particular controls. Yet, no impact on long-term technique survival has been reported to date. Upregulation of renin-angiotensin-aldosterone system (RAAS) in response to acute inflammation and chronic exposure bioincompatible PD solution play an important role in the morphologic alteration of peritoneal membrane. Beneficial effects of ACE inhibitors on the development of these alterations have been reported in experimental models (124,125) and were also shown in few retrospective controlled trials of patients on PD treated with 2 years of ACE inhibitors/angiotensin receptor blockers (ARBs) (126,127).

Recent Peritonitis

Acute peritonitis is associated with an enormous intraperitoneal network of pro- and anti-inflammatory cytokines and a complex interaction of peritoneal cell lines (128). A rapid and reversible increase in the effective peritoneal surface area occurs, most likely under the influence of NO, proinflammatory cytokines (IL-1β, TNF-α, IL-6), and prostaglandins (129). This results in an increase in the D/P creatinine, a proportionate decrease in the D/D_0 glucose, and a significant reduction in net UF as compared with baseline (130). As a result, patients frequently become fluid overloaded, requiring a change in their dialysis prescription to improve UF. This may be achieved by an increase in the hypertonicity or number of hypertonic exchanges, the use of icodextrin, or a regimen that utilizes shorter dwell times [e.g., NIPD and daytime ambulatory peritoneal dialysis (DAPD)]. Fortunately, these membrane permeability changes are generally transient and patients are usually able to resume their previous PD prescription within a month of the peritonitis episode. Similar to acute peritonitis, recurrent peritonitis is also reported to affect peritoneal structure and function in PD. Again, hyperpermeability of the membrane and morphologic changes such as submesothelial fibrosis and angiogenesis are typical and important results of recurrent infectious episodes and may lead to type I UFF (131). It seems that the increased intraperitoneal release of IL-1β–stimulated TGF-β plays an important role in the development of fibrosis. Additionally, IL-1β, IL-6, and TNF-α are also strong stimulators of angiogenesis.

Recovery of peritonitis may not be associated with significant remesothelialization of the peritoneum until 6 weeks or more have elapsed, although clinical recovery of peritonitis may occur within days (132). Therefore, the PET should be delayed for at least 4 weeks after an episode of peritonitis as it may otherwise not be representative of a patient's true peritoneal transport characteristics.

Inherent High Transporter

Ten percent of patients starting PD display this transport profile. When patients originally defined as high transporters present with volume overload, it may be the result of a loss of RRF. When this occurs, a change in the dialysis regimen (similar to that for type I membrane failure) and strict dietary restrictions are required. If there has been no loss of RRF, an evaluation for mechanical problems as well as compliance issues must be pursued.

Patients with Average Solute Transport (D/P Creatinine 0.5 to 0.81)

A low drain volume coupled with either high-average or low-average transport (D/P creatinine 0.5 to 0.81) can result from mechanical problems (e.g., a peritoneal leak or malpositioned catheter), a decrease in transcellular water transport, or an increase in LA (**FIGURE 13.8B**).

Dialysate Leak

Dialysate leaks from the intra-abdominal cavity to extra-abdominal tissues, usually the abdominal wall, result in a decrease in UF drain volume. Although the reason drain volume is lowered is obvious, the fluid leaked into the interstitium is subsequently removed by the lymphatic system and therefore technically falls into the category of UFF secondary to increased lymphatic flow. An extraperitoneal dialysate leak is frequently accompanied by an abdominal wall hernia, history of multiple abdominal surgeries, or a patent processus vaginalis (133). Some systemic conditions of ESKDs, including uremia, obesity, transperitoneal protein loss, and anemia, also contribute to these problems.

Extraperitoneal leakage of dialysate may occur at the catheter site as well as from tears in the

peritoneum within hernia sacs (134,135). Edema localized to the abdominal wall, upper thigh, or genitalia is usually evident. Most reports indicate that the incidence of dialysis leakage is somewhat more than 5% in PD patients (133,136); patients with ESKD due to cystic kidney diseases are especially prone to the development of abdominal wall defects (133). Diagnosis may be confirmed by utilizing an appropriate radiographic technique. These include intraperitoneal infusion of radiographic contrast through the catheter followed by plain roentgenogram or computed tomography (137) (**TABLES 13.8** and **13.9**; **FIGURES 13.10** and **13.11**), or intraperitoneal infusion of a radioisotope evaluated with peritoneal scintigraphy or MRI without contrast (the dialysate itself functions as contrast material) (138,139). Peritoneal membrane function is not compromised in patients with dialysate leaks. Therefore, peritoneal transport as evaluated by the PET is not changed compared with a patient's baseline study.

TABLE 13.8 Peritoneography

Take flat-plate radiogram of the abdomen.
Place 100–200 mL of nonionic contrast in dialysate (2-L bag).
Infuse 1 L of the dialysate into the supine patient.
Have the patient change positions for mixing.
Repeat flat-plate radiogram of the abdomen.

TABLE 13.9 Peritoneal Computed Tomography (CT)

Take plain CT of abdomen.
Place 100–200 mL of nonionic contrast in dialysate (2-L bag).
Infuse 1 or 2 L of the dialysate into the supine patient.
Have the patient change positions for mixing.
Repeat CT of abdomen.

Treatment of peritoneal leaks is aimed at repairing the defect in the peritoneum. Leaks associated with hernias usually require surgical repair of the hernia. Temporary transfer to HD for several weeks until adequate healing has occurred has been standard in the past, but a recent report from Shah et al. illustrates that this is not mandatory (140). Leaks that occur in the absence of a hernia usually represent a tear in the parietal peritoneum. These patients frequently have a history of multiple abdominal surgeries, pregnancies, recent corticosteroid usage, or abdominal straining (coughing, Valsalva maneuver). These patients may heal with nothing more than a period of several weeks without a daytime dwell (i.e., NIPD).

Catheter Malposition

Mechanical problems, such as a malpositioned catheter (**FIGURE 13.9**), resulted in UFF in 7% of patients in one center (8). Although this may occur because of improper initial catheter placement, it often results from the migration of catheters originally in good position due to entanglement by omentum, or it may be due to adhesions from previous surgery (141). A malpositioned catheter does not drain the peritoneal cavity effectively and leads to an increase in residual volume. A normal residual volume (R) is approximately 200 to 250 mL (40) and can be determined from information obtained during the PET using the following equation (**EQUATION 13.6**):

$$R = Vin\ (S3 - S2) / (S1 - S3) \qquad (13.6)$$

where Vin = instillation volume, S1 = solute concentration (urea or creatinine) in the pretest drain, S2 = solute concentration of the instilled fluid (0 for urea or creatinine), and S3 = solute concentration immediately following instillation (40). An increase in residual volume dilutes the glucose concentration

in the freshly instilled dialysate. This decreases the osmotic gradient and thereby reduces the rate of transcapillary UF without any significant effect on solute transport. Net UF is decreased and the D/P ratio remains essentially unchanged.

An increase in the calculated residual volume should raise the suspicion of a malpositioned catheter. However, the presence of this problem is often clinically apparent and the diagnosis is easily made with the aid of simple radiographic techniques (**FIGURE 13.9**) as PD catheters have radiopaque material embedded within them. Either open or laparoscopic repositioning of the catheter tip can be done; however, recurrence is common and may require replacing or repositioning the straight Tenckhoff catheter through a new exit site, decreasing the angle (or bend) between the exit site and tunnel. This maneuver tends to force the path of the catheter caudad into the pelvis and may prevent recurrent migration. Success with nonsurgical manipulation of catheter position through the usage of a stiff guide wire and fluoroscopy has been reported (142) but should be attempted only as a last resort. Unfortunately, despite catheter repositioning with various procedures, recurrent malpositioning may occur in up to two-thirds of patients utilizing the straight Tenckhoff catheter. If this occurs, the use of a catheter with a fixed swan neck is now recommended, as malposition recurrence with this catheter appears to be rare (143). Use of "front-loaded" catheters (that have a 5- to 12-g weight on the distal end) has also been reported to decrease migration; these catheters are not presently available in the United States (144).

Insertion of the dialysis catheter under direct laparoscopic visualization offers a number of advantages which prevent subsequent malpositioning of the catheter. The operator can ensure that the catheter tip is placed deep in pelvis, adhesions can be lysed, and redundant omentum can be tacked to the upper interior abdominal wall. Furthermore, the portion of the catheter that traverses the rectus sheath can be tunneled superoinferiorly so that the catheter has a "built-in" directionality into the pelvis, thereby decreasing the chances of its migrating into the middle or upper abdomen (145).

Decreased Transcellular Water Transport (Type II Ultrafiltration Failure)

In a group of patients with UFF, there is no associated increase in solute transport (for creatinine or glucose), residual volume, or LA rate (146,147). However, in all these patients, the normal drop in dialysate sodium concentration (**FIGURE 13.15**) is lost (i.e., no sieving is noted) due to a selective defect in peritoneal free water transport through the AQP-1 channel (ultrasmall pore). AQP-1–mediated UF is responsible for 40% to 50% of the effective transcapillary UF and is thought to decline with the duration of PD causing this selective defect in water transport. Yet, in immunohistochemical studies, no evidence was found for reduced expression of AQP-1 channels in long-term PD patients, even in those having reduced AQP-1–mediated free water transport (148). Fusshoeller et al. (113) reported a structurally modified AQP-1 form, found in the effluent of long-term PD patients, that increased in number over time on PD. Therefore, it seems that a functional alteration of AQP-1 channels, rather than a decrease of their expression, is responsible for less free water removal in long-term PD. The underlying mechanism is not clear, but a glycation- or NO-mediated process is most likely to be causative. In an animal model of acute peritonitis, the increase in nitric oxide synthase (NOS) activity correlated significantly with the decrease in AQP-1–mediated water transport, favoring an NO-related phenomenon (149). However, in a more recent human study in which AQP-1–mediated water transport was calculated more adequately, no effect of AQP-1–mediated water transport could be discerned during acute peritonitis (150). At present, a

specific treatment that enhances AQP-1–mediated water transport is not available. However, corticosteroids have been shown to upregulate the expression of AQP-1 in the peritoneal capillaries in the rats. In the same context, an increase in the sodium sieving and ultrasmall pore ultrafiltration volume was noted in PD patients shorty after living donor kidney transplantation and treatment with high-dose methylprednisone (151). More recently, an AQP-1 agonist has been developed that has been shown to improve water transport across the peritoneal membrane in an animal model (152). These two therapies open potential therapeutic avenues to treat type II UFF.

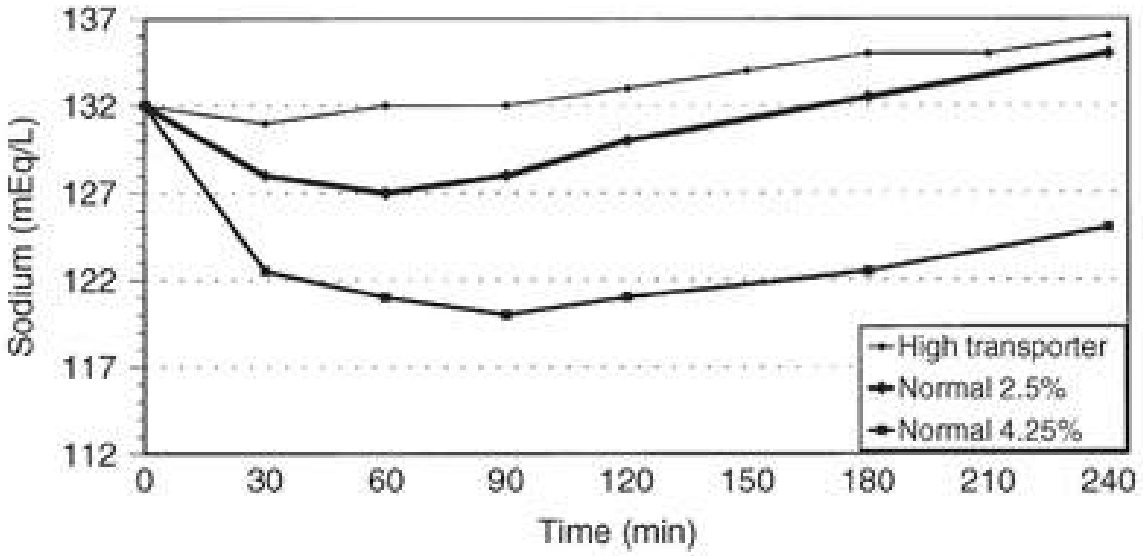

FIGURE 13.15 Dialysate sodium concentration over 4 hours using 2-L dialysate volumes in normal patients with 2.5% and 4.25% glucose concentrations and in high transporters (or patients with impaired transcellular pore transport) with ultrafiltration failure using 2 L of dialysate with 2.5% glucose concentration. The normal drop in sodium concentration is essentially lost in patients with markedly attenuated transcapillary ultrafiltration (high-transport patients or patients with impaired transcellular pore transport). [Data from Heimbürger O, Waniewski J, Werynski A, et al. Peritoneal transport in CAPD patients with permanent loss of ultrafiltration capacity. *Kidney Int* 1990;38(3):495–506; Heimbürger O, Waniewski J, Werynski A, et al. A quantitative description of solute and fluid transport during peritoneal dialysis. *Kidney Int* 1992;41(5):1320–1332; Monquil MC, Imholz AL, Struijk DG, et al. Does impaired transcellular water transport contribute to net ultrafiltration failure during CAPD? *Perit Dial Int* 1995;15(1):42–48.]

Increased Lymphatic Flow (Type IV Ultrafiltration Failure)

LA of peritoneal fluid negatively influences the overall removal of water (decreases net UF) and solute (partially negating the effect of diffusive and convective solute transport). Because the absorption of peritoneal fluid by lymphatics does not alter the concentration of solutes in the dialysate, the D/P ratio remains unchanged with increased lymphatic flow, although net UF can be significantly decreased. In a recent study, 30 of the 53 patients (57%) had UFF associated with a high LA, often in combination with other causes (153). An analysis of 20 patients on PD for more than 4 years showed that high LA was a cause of UFF in 6 of the 20, in 2 as the only cause, and in 4 in combination with other causes (16).

The mean value of the LA rate in PD patients during their first 2 years of PD treatment, as measured with intraperitoneal dextran 70, averages 1.52 mL/min (95% confidence interval of 0.30 to 2.50) when a 2-L exchange is used (153). The day-to-day intraindividual coefficient of variation averages 20%, the main part of which is due to biologic and not methodologic variation (154). The LA rate is influenced by instilled dialysate volume. Compared to 2 L, lower values are found with 1.5 L (153) and higher values with 3 L (155). It is likely that the effects of the instilled volume on LA are due to alteration in intra-

abdominal pressure. Intraperitoneal (IP) pressure is 10 to 20 cm H_2O 2 hours after a 2-L exchange utilizing a 4.25% dextrose solution but may vary from 5 to 25 cm H_2O. A correlation between IP and net UF has been reported, with each increase of 1 cm H_2O pressure associated with a decrease in net UF of 74 mL over a 2-hour dwell (156). Increased intra-abdominal pressure causes a decline in net UF primarily not only by the increase in LA rate (1.9 mL/min vs. 1.0 mL/min) but also by a slight decrease in transcapillary UF rate (1.73 mL/min vs. 2.0 mL/min) (22). This may be more of an issue in patients who require larger dwell volumes to obtain adequate solute clearance. No relationship is present between the LA rate and BSA (154,157), or the tonicity of the dialysate (158). Also, the osmotic agent used has no influence. This has been shown for amino acids (159), icodextrin (57), and glycerol (160). Contrary to prior studies (37,63), a latest study did not show any influence of patient position on LA rate, despite a higher IP pressure in the upright position compared to recumbency (154). This may be due to reduced contact area between the subdiaphragmatic lymphatics and dialysate in the upright position.

Pathogenesis

Michels et al. found significant correlations between the LA rate and MTACs of low molecular weight solutes (161). The explanation is speculative, but it may be that the presence of a large vascular peritoneal surface area, as suggested by high MTACs, is associated with a large lymphatic surface area as lymphatic vessels often accompany blood vessels. A recent study has shed light on the role of lymphangiogenesis in the UFF. It demonstrates that peritoneal tissue from patients with UFF contained more lymphatic vessels than tissue from patients without UFF. In the animal model, this enhanced lymphangiogenesis was mediated by increased VEGF-C expression induced by high TGF-β in the dialysate (162). Although, the effect of duration of PD on the LA rate has remained controversial (161,163). A deficiency in the dialysate content of surface active phospholipids (SAPLs) has also been attributed for increased LA rate. However, many trials in which peritoneal surfactant was replenished by adding exogenous SAPL to dialysate produced mixed results. The spectrum of outcomes ranged from totally negative (164,165) to increased UF (166,167). The range of compositions and their varying sources of SAPL, combined with a lack of physicochemical experience in formulation, accounted for much of the variation in the results (168). As demonstrated by Di Paolo et al. (167), a positive outcome was confirmed only in cases where UF had been previously diminished. This occurred without a change in solute transport, indicating that the increase in UF is secondary to a decrease in LA. Chen et al. (169) suggested that exogenously administered SAPL imparts semipermeability to the peritoneal mesothelium. Although able to demonstrate this in an *in vitro* model, they could not prove conclusively that addition of SAPL does the same to peritoneal mesothelium *in vivo*.

Diagnosis

Measurement of LA rate is uncommon in clinical practice because of the complexity of the procedure. Therefore, UFF secondary to increased LA becomes a diagnosis of exclusion. Icodextrin gets absorbed from the peritoneal cavity almost exclusively by lymphatics and ordinarily achieve good UF outcome even in patients with rapid transport rate. Failure to achieve UF with icodextrin over an 8- to 10-hour dwell may serve as an indirect evidence for excessive reabsorption.

The oral administration of bethanechol chloride, 0.27 mg/kg/d up to 50 mg, in four divided doses

before each exchange has been demonstrated to result in an 18% increase in net UF in patients with type III UFF. Bethanechol chloride is similar to phosphatidylcholine in having cholinergic properties. An increase in cholinergic tone appears to contract the subdiaphragmatic lymphatic stomata, thereby reducing lymph flow (170).

Experience with larger numbers of patients is necessary to confirm the benefits of these therapies. These oral preparations appear to be well tolerated and may provide an option for the management of the patient with UFF presumed to be secondary to high LA. Certainly this therapy, if successful, may obviate the need for an increased exposure to hypertonic dialysate exchanges and their potential long-term deleterious effects.

Patients with Low Solute Transport (D/P Creatinine Less Than 0.5)

A much less common cause for UFF is that associated with low solute transport (D/P creatinine less than 0.5) (**FIGURE 13.8B**), which often stems from conditions leading to a severe reduction in effective peritoneal membrane surface area and permeability (type III UFF) (4,63,146). Therefore, signs and symptoms of both fluid overload and inadequate solute removal can be present (**TABLE 13.6**). This is observed in patients who have sclerosis of the peritoneal membrane (sclerosing peritonitis) as well as in patients with extensive intra-abdominal adhesions.

Encapsulating Peritoneal Sclerosis

Encapsulating peritoneal sclerosis (EPS) is recognized as being the most serious complication of PD; it is most often associated with an extended duration of PD. An *ad hoc* committee of the ISPD defines EPS as: "A clinical syndrome with persistent, intermittent or recurrent presence of intestinal obstruction with or without the existence of inflammation parameters and the existence of peritoneal thickening, sclerosis, calcifications and encapsulation (**FIGURE 13.16**) confirmed by macroscopic inspection or radiological findings" (171). Most data on EPS comes from Japan (where, due to the unavailability of kidney transplantation, treatment with PD for more than 10 years is common) and Australia. The most recent overall EPS incidence is reported to be 2.5% in Japan (172), 0.7% in Australia (173), and 3.3% in a single-center study in United Kingdom (174).

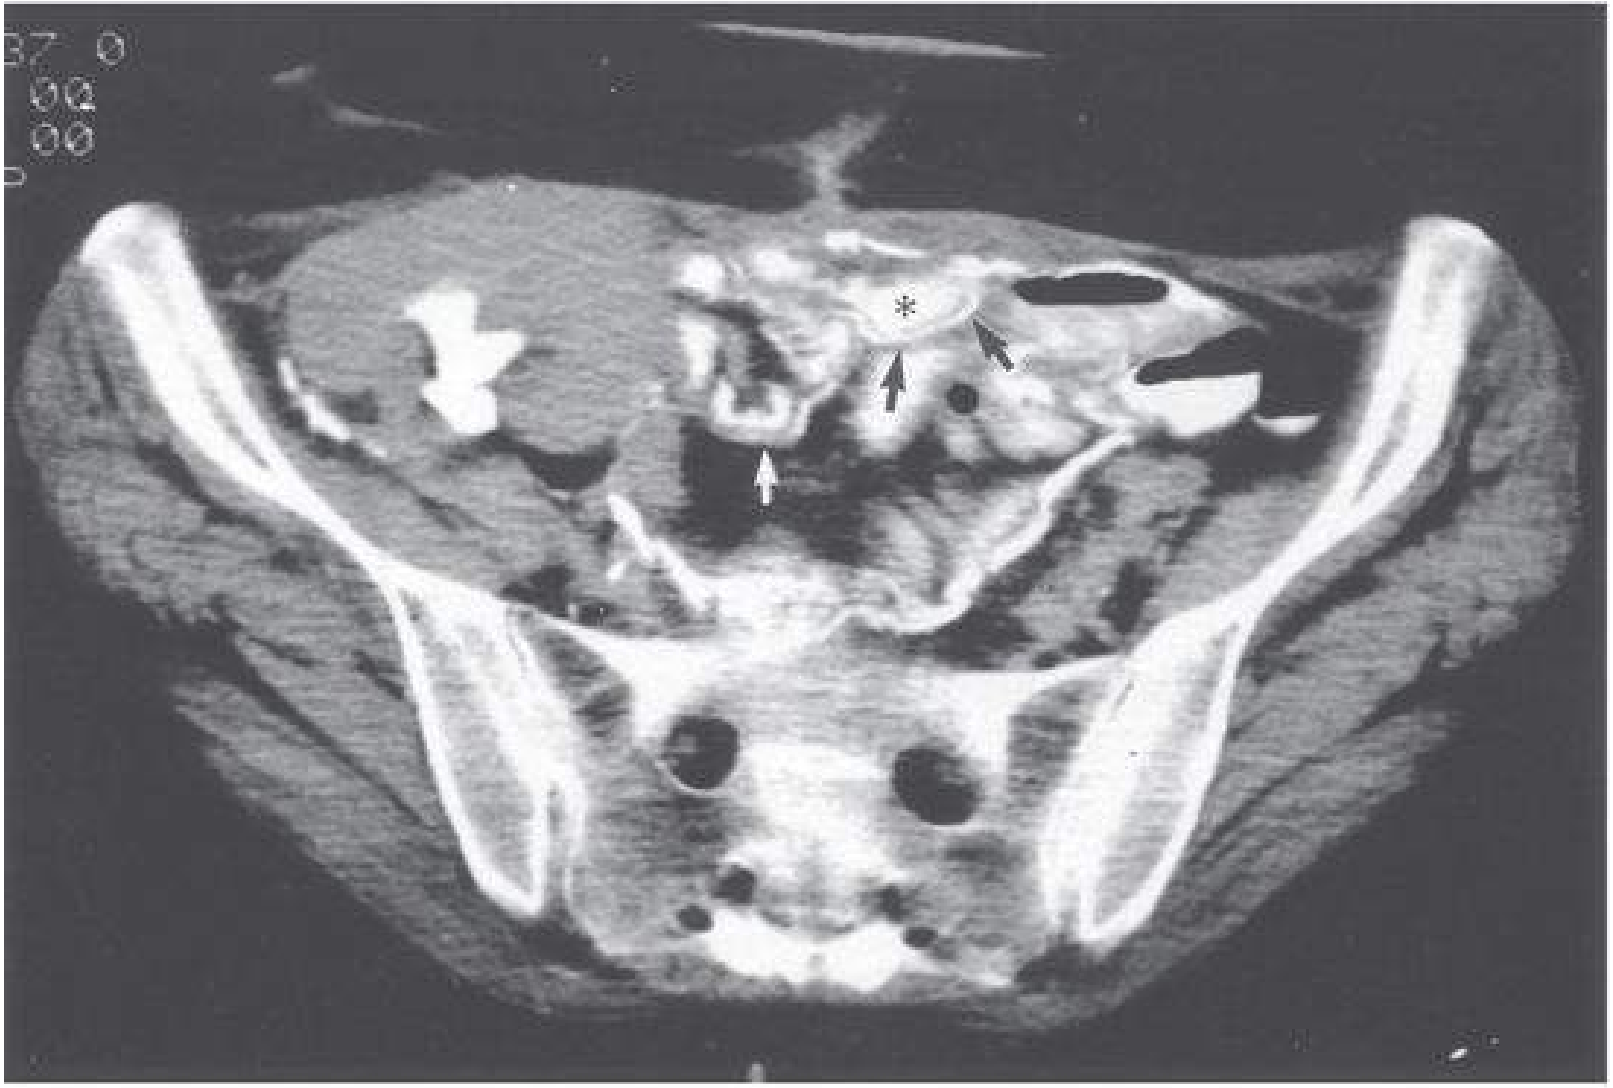

FIGURE 13.16 Computed tomographic scan of abdomen after oral contrast in a patient with sclerosing peritonitis demonstrating intestinal intraluminal coral contrast (*) and a diffusely thickened and calcified peritoneum (*arrows*).

The diagnosis of EPS is suspected clinically when PD patients with peritoneal deterioration complain of gastrointestinal symptoms of insidious nature. Progressive peritoneal sclerosis, with the formation of intra-abdominal adhesions, leads to signs and symptoms of intestinal obstruction and strangulation. The transmural extension of the sclerosing process results in encapsulation of bowel, transforming the peritoneum into a "leathery cocoon." Peritoneal biopsy is the ultimate diagnostic tool, but various imaging techniques are the key tools for early diagnosis of EPS. Computed tomography (CT) is considered a valid and reliable tool for the diagnosis of EPS. Based on CT findings, Tarzi et al. (175) have developed a scoring system including peritoneal calcification (0 to 4) and thickening (0 to 4), bowel wall thickening (0 to 4), dilatation (0 to 4) and tethering (0 to 3), and loculation of ascites (0 to 3). They report a median total score of 9 of 22 (range 2 to 16) in EPS patients with good interrater agreement (**FIGURE 13.17**). However, in this study, CT scan results neither correlated with the clinical outcome nor helped as a screening tool for EPS as the scans were frequently normal even a few months before the fulminant illness (175).

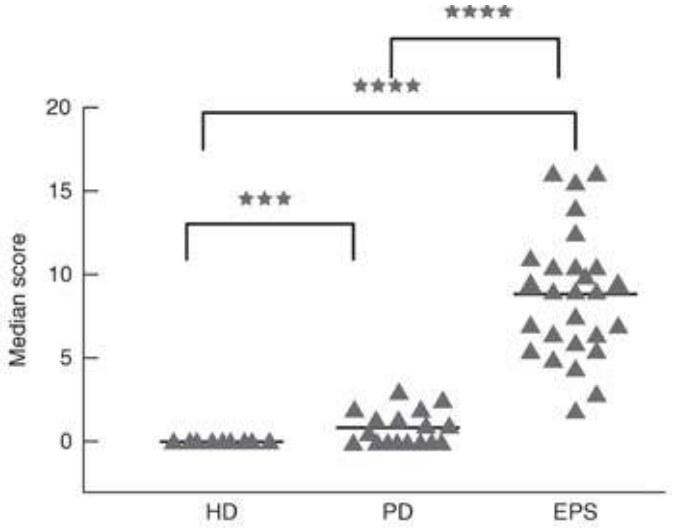

FIGURE 13.17 Ligand: computed tomographic scan scores for encapsulating peritoneal sclerosis (EPS) patients, hemodialysis (HD) and peritoneal dialysis (PD) controls (sum of scores for each parameter out of a maximum of 22). ***$p < 0.0001$, ****$p < 0.00001$. Wilcoxon rank-sum test. Horizontal lines indicates median score. Each triangle represents individual patient. [From Tarzi RM, Lim A, Moser S, et al. Assessing the validity of an abdominal CT scoring system in the diagnosis of encapsulating peritoneal sclerosis. *Clin J Am Soc Nephrol* 2008;3(6):1702–1710.]

Abdominal ultrasonographic examination may demonstrate haustration of the ileum, fixed and rigid bowel loops with ineffective peristaltic contractions, clear-cut separation between the loops involved in the sclerotic process and loops that are still free, dilated fixed loops matted together and tethered posteriorly, intraperitoneal echogenic strands, trilaminar appearance of the bowel wall, and an echogenic "sandwich" appearance of the membrane (176,177). Early diagnosis, before the development of irreversible fibrosis and encapsulation, is critical in the prevention and treatment of EPS. Unfortunately, there is as yet no reliable noninvasive method by which to screen and thereby diagnose patients during the preclinical and potentially "reversible" phase of this condition.

The causes of EPS are diverse. In one report, only 9.4% of all EPS cases occurred in PD patients (178). That is to say, non–dialysis-related causes are common and include idiopathic (primary), abdominal tuberculosis (179,180), use of the β-blocker practolol (181), ventriculoperitoneal and peritoneovenous shunts (182,183), liver transplantation (184), and recurrent peritonitis. The pathogenesis of PD-related EPS, however, still remains uncertain, although a widely accepted hypothesis is the "two-hit theory," where the first hit is chronic peritoneal membrane injury from long-standing PD followed by a second hit such as an episode of peritonitis, genetic predisposition, and/or acute cessation of PD, leading to EPS (**FIGURE 13.18**). Prolonged PD duration constitutes the single most significant risk factor for EPS. Kawanishi and Moriishi (172) reported incidences and mortality rates for EPS for patients who had undergone PD for 3, 5, 8, 10, 15, and more than 15 years, respectively (**TABLE 13.10**). As discussed earlier regarding type I UFF, chronic exposure to high concentration of glucose, GDPs, and AGEs may cause remodeling and fibrosis of the peritoneal membrane. The second factor most widely linked to an increased risk of EPS is peritonitis—especially if it is severe, recurrent, or nonresolving in nature (171). Patients with EPS have early loss of UF capacity and sodium sieving supporting the role of previously described factors in the pathogenesis of EPS (185). Preliminary studies have shown that AGE receptor (186) and eNOS gene polymorphisms (187) may play a role in the susceptibility to EPS. Increased T-cell activation has also recently been implicated in pathophysiology of excessive fibrosis as patients with EPS demonstrated increased serum-soluble CD25 (sCD25) concentration and intraperitoneal production of

sCD25 (188).

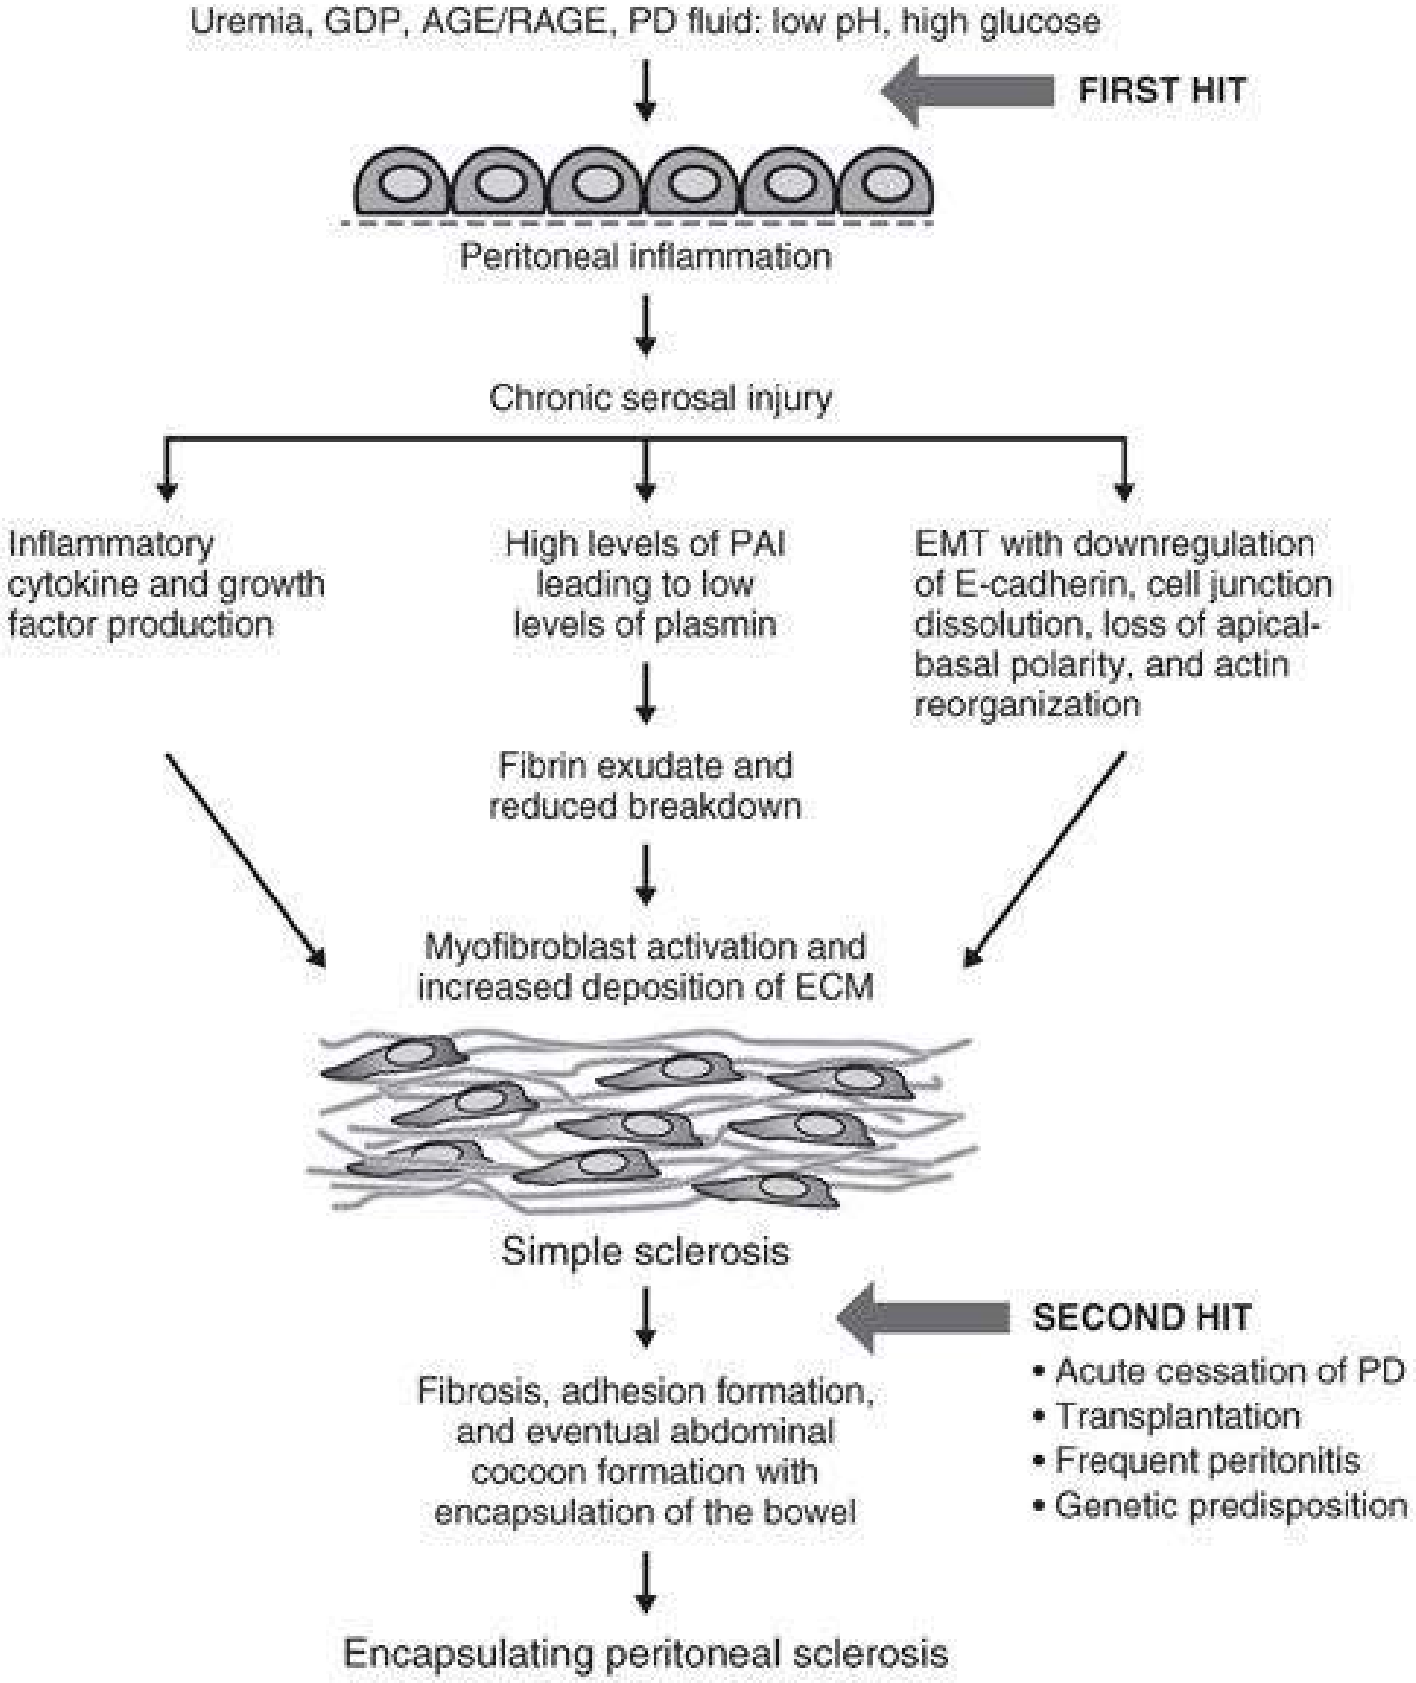

FIGURE 13.18 Proposed pathogenesis of encapsulating peritoneal sclerosis: "two-hit" theory. GDP, glucose degradation product; AGE, advanced glycation end-products; RAGE, receptors for advanced glycation end-products; PD, peritoneal dialysis; PAI, plasminogen activator inhibitor; EMT, epithelial to mesenchymal transdifferentiation; ECM, extracellular matrix. TABLE 13.10 The Incidence and Mortality Rate for Encapsulating Peritoneal Sclerosis (EPS) with Increasing Duration of Peritoneal Dialysis (PD)

PD Duration (yr)	Incidence Rate (%)	Mortality Rate (%)
3	0	0
5	0.7	0
8	2.1	8.3
10	5.9	28.6
15	5.8	61.5
>15	17.2	100

Treatment of EPS is very difficult. In patients with milder or earlier forms of sclerosis, treatment with a period of peritoneal resting with transfer to HD may be of benefit (171). With regard to pharmacologic treatment, most reports in the literature advocate the use of corticosteroids as the immunosuppressive agent (189). Azathioprine, mycophenolate, and sirolimus have been tried with some success in case reports (190). However, once this condition becomes encapsulating, improvement is unlikely to occur. The subsequent gastrointestinal manifestations of obstruction and poor motility lead to malnutrition, requiring aggressive intravenous hyperalimentation. In patients with bowel obstruction, intervention with surgical viscerolysis may be required; however, this is generally associated with a high mortality (greater than 75%), often from sepsis (135,136).

Small-scale, noncontrolled studies indicate a positive effect of tamoxifen on peritoneal sclerosis (191–194). The results of the large Dutch multicenter retrospective study supports the use of tamoxifen in patients with EPS. Survival in tamoxifen-treated patients, adjusted for calendar time, age, use of corticosteroids, presence of functioning transplantation, use of parental nutrition, and center influences, was longer in comparison to not treated patients (HR 0.39, $p = 0.056$) (**FIGURE 13.19**) (195). This antiestrogen agent acts by inhibiting protein kinase C, a mediator of cell proliferation. It has been used to treat retroperitoneal fibrosis, a condition that has some similarities to sclerosing peritonitis (144). Although data on the use of immunosuppression or tamoxifen are limited, the experience with these agents is encouraging and at least provides an option in the treatment of this highly fatal disease.

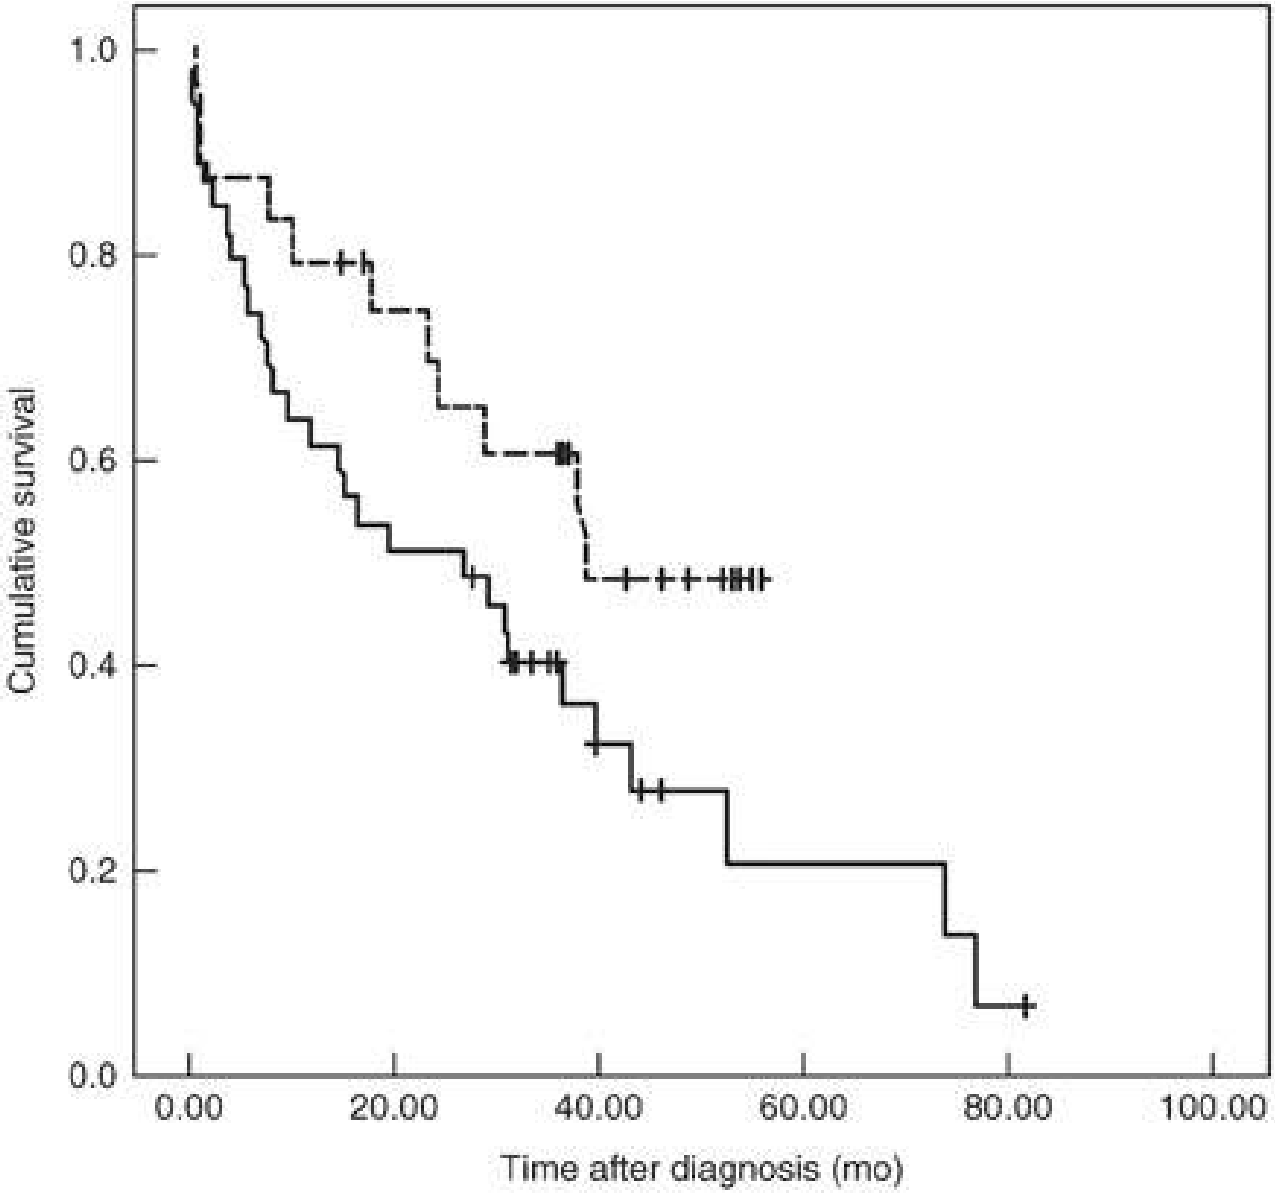

FIGURE 13.19 Survival of encapsulating peritoneal sclerosis patients with (*dashed line*, $n = 24$) and without (*solid line*, $n = 39$) treatment with tamoxifen. Time after diagnosis means times in months after EPS diagnosis. The p value was 0.077 on univariate analysis. +, censored in analysis. [Data from Korte MR, Fieren MW, Sampimon DE, et al. Tamoxifen is associated with lower mortality of encapsulating peritoneal sclerosis: results of the Dutch Multicentre EPS Study. *Nephrol Dial Transplant* 2011;26(2):691–697.]

Earlier, there were reports of improved survival after kidney transplantation (196–198). However, a recent analysis reported transplantation as a risk factor for the development of EPS because most patients with EPS underwent kidney transplantation at some point in time (199). This suggestion was strengthened by the fact that, in some patients, EPS developed shortly after kidney transplantation. It remains unclear at this point whether transplantation is beneficial or not and whether the transplantation procedure itself or the concomitant medications are responsible for the development of EPS. Cessation of peritoneal lavage after transplantation could lead to diminished clearance of fibrin and may therefore contribute to peritoneal fibrosis. Also, the known profibrotic effects of calcineurin inhibitors (CNIs) may have an effect to promote development of EPS (200,201). On the other hand, discontinuation of PD, and immunosuppression, by their inhibitory effects on lymphokine production and therefore fibroblast activity, may be responsible for the improvement in patients receiving kidney transplantation.

Abdominal Adhesions

Recurrent or severe peritonitis, catastrophic intra-abdominal events, or complicated abdominal surgery may lead to the development of extensive intra-abdominal adhesions (145). Adhesions limit dialysate flow throughout the abdominal cavity and decrease the effective surface area of the peritoneum, thereby compromising both solute transport and UF. The diagnosis can be made by radiographic techniques that utilize the intraperitoneal infusion of a radiographic contrast material through the dialysis catheter with plain roentgenographic or computed tomographic visualization, or with the intraperitoneal infusion of a radioisotope and peritoneal scintigraphy (137,202,203). If adhesions are present, peritoneal fluid will not distribute equally throughout the abdominal cavity despite changes in patient position or posture (**FIGURE 13.20**). Surgical lysis of adhesions may result in an improvement of dialysate flow and distribution; however, if adhesions are extensive, this procedure may not increase the peritoneal membrane surface area sufficiently to provide adequate solute transport for PD.

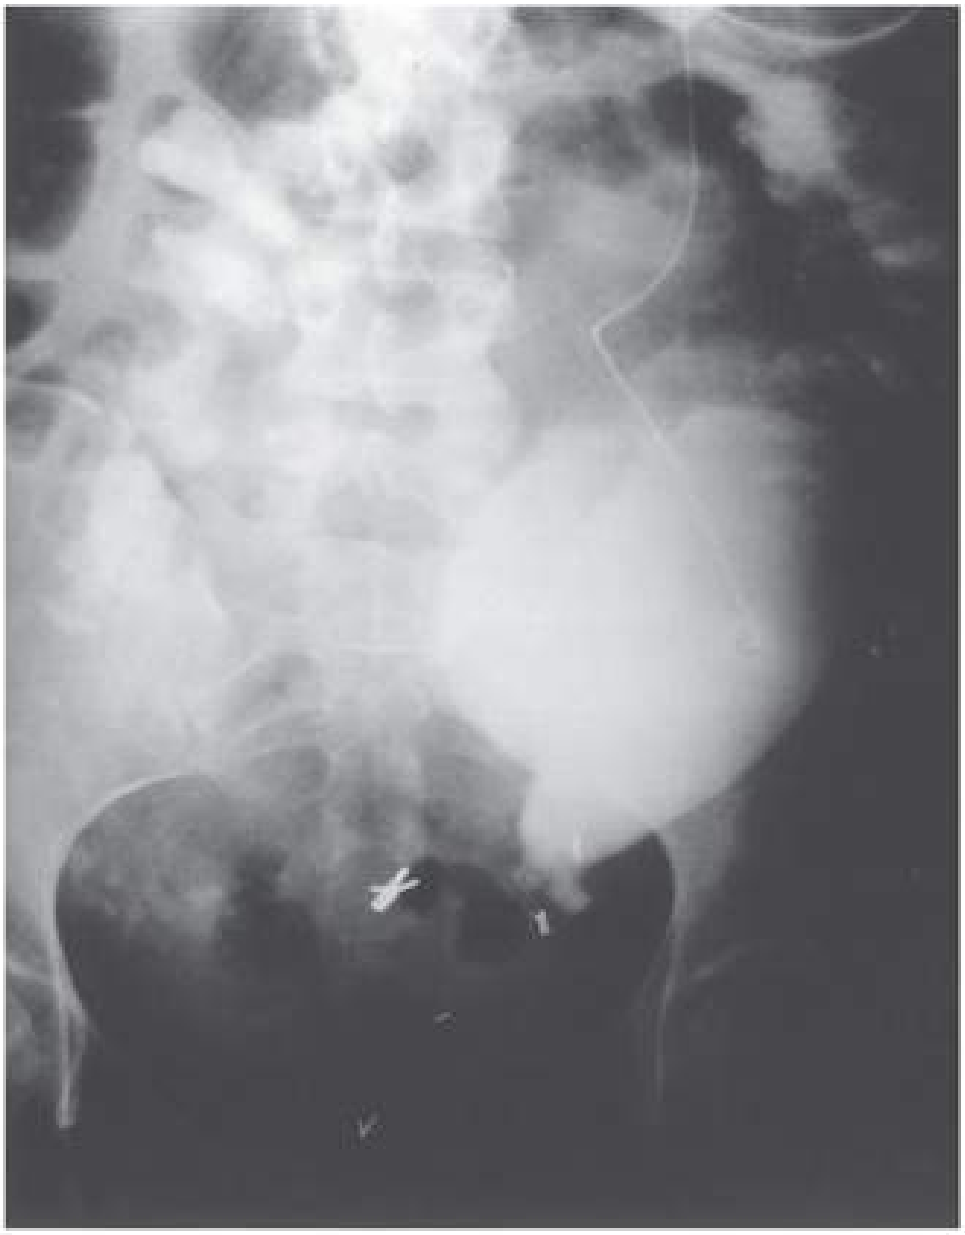

FIGURE 13.20 Plain roentgenogram (flat plate) of the abdomen in a patient with ultrafiltration failure. Before the radiographic examination, 2 L of dialysate containing 100 mL of nonionic radiocontrast were infused into the abdomen. Adhesions in the left lower quadrant of the abdomen result in a loculation of dialysate. This limits flow throughout the abdominal cavity and causes a decrease in the effective peritoneal surface area.

Compromised Peritoneal Blood Flow

Although a severe reduction in effective peritoneal blood flow or vascular permeability could theoretically compromise both fluid and solute removal, this must be an extremely rare cause of UFF as we have seen no reports to date. A significant decrease in the peritoneal clearance of urea and creatinine has been observed in a few patients with systemic vascular disease (e.g., systemic lupus erythematosus, vasculitis, scleroderma, or malignant hypertension), but this was not associated with UFF (204–206).

CONCLUSION

The potential for UFF increases as patients are successfully maintained on PD for longer periods of time. As a result, assessment of peritoneal membrane function (PET) and RRF should be done on a regular and frequent basis. UFF is usually attributed to changes in the function of the peritoneal membrane that occur with increasing frequency as time on dialysis is prolonged. However, one must recognize that a number of other factors, including loss of RRF, can significantly impact on the efficiency of this therapy and must be considered when faced with a volume-overloaded (or inadequately dialyzed) patient. Although the initial office evaluation may identify the cause of this problem in many cases, the modified PET (using a 4.25% exchange with UFF defined by a 4-hour drain volume of less than 2,400 mL) becomes an essential tool to further assist in the workup of those patients in whom the etiology of volume overload remains unexplained. With the valuable information provided by the PET and the diagnostic algorithm we provide, a logical approach to the assessment of patients with UFF can be developed. Once the appropriate diagnosis is defined, a therapeutic approach can be devised.

CHAPTER 14

Peritoneal Dialysis–Related Infections

William Salzer

Peritonitis remains the most frequent infection in patients receiving peritoneal dialysis (PD). PD has been used since the 1940s. In the early days, dialysis catheters were directly inserted into the peritoneum and were associated with very high rates of peritonitis. The Tenckhoff catheter was introduced in the late 1960s by Henry Tenckhoff. This catheter is inserted surgically and has a cuff in the subcutaneous tissue and an inner cuff where the catheter enters the peritoneum. Despite this, peritonitis rates averaged 6 episodes per patient-year. Subsequently, with improvements in equipment, techniques, and prevention strategies, peritonitis rates have decreased by 90%, such that the current International Society of Peritoneal Dialysis (ISPD) benchmark is 0.5 episodes per patient-year, or 1 episode every 2 years (1). The use of collapsible bags for peritoneal drain fluid, Y-sets for connecting, and fill-flush methods have probably contributed to reduced peritonitis rates. Also, the frequent use of automated continuous cycling peritoneal dialysis (CCPD) or automated peritoneal dialysis (APD) results in fewer connect and disconnect episodes, potentially reducing the opportunity for peritoneal fluid touch contamination which may reduce infection rates. Patient training is essential and each case of peritonitis should be investigated as to the cause and followed with patient retraining and review.

Despite best efforts, peritonitis continues to occur. PD peritonitis is fatal in about 4% but is a cofactor in mortality in about 16% of patients. Peritonitis with more virulent organisms such as *Staphylococcus aureus*, *Candida*, and *Pseudomonas* as well as repeated episodes of peritonitis results in damage to the peritoneal membrane and is the leading cause of technique failure of PD and permanent transfer to hemodialysis. Prompt diagnosis and treatment of peritonitis is the highest priority for the success of patients on PD.

PERITONEAL DIALYSIS PERITONITIS—PATHOGENESIS

Organisms that colonize the skin, *S. aureus* and coagulase-negative staphylococci (CNS), are the most frequent pathogens isolated in PD peritonitis, accounting for 50% or more of cases in most series (2,3). The most frequent cause of PD peritonitis is “touch contamination,” which occurs when organisms are

transferred from the hands of the patient or helper during connection or disconnection. Less common modes of infection are periluminal introduction of organisms from an exit-site or tunnel infection, transvisceral introduction of organisms from an intra-abdominal process, or rarely from hematogenous seeding. Once introduced into the peritoneum, the organisms encounter an environment that favors growth, with a high glucose content and few inflammatory cells initially. In the early stages of infection, the host immune response is inadequate to control the infection, with small numbers of peritoneal macrophages, very few neutrophils, and negligible quantities of host defense proteins such as immunoglobulins and complement. As the organisms proliferate, they produce toxins and other products that stimulate the resident macrophages to generate proinflammatory cytokines such as tumor necrosis factor (TNF), interleukin 1 (IL-1), interleukin 6 (IL-6), interleukin 8 (IL-8), which recruits inflammatory cells such as neutrophils, monocytes, and lymphocytes into the peritoneum. These cells and their products are responsible for the predominant symptoms of peritonitis—pain, cloudy effluent, and fever.

Factors that make the treatment of PD peritonitis more difficult are the characteristics of PD fluid and the presence of a foreign body, the catheter itself, in the peritoneum. Standard PD fluids are hyperosmolar and have a low pH, which may impair the function of neutrophils and macrophages. Although necessary to cure peritonitis, the constant exchange of PD fluid removes host phagocytic cells and host defense compounds from the peritoneum. Another factor that impairs host defense in PD peritonitis is the formation of biofilms. Biofilms are aggregates of organisms, adherent to a surface, usually embedded in an extracellular matrix composed of host compounds and products of the organism (4). Biofilms can form on infected PD catheters, particularly with infection by CNS species. Bacteria within the deeper portions of the biofilm do not divide as rapidly and therefore are far less susceptible to antibiotics and may persist despite clinical resolution of infection, providing a nidus for relapsing infection. Relapsing infection is often the result of biofilm formation and is an indication for catheter exchange.

Less common mechanisms of PD peritonitis include extraluminal spread from an exit-site or more often a tunnel infection producing a route for organisms to enter the peritoneum. These are usually clinically evident at the time of diagnosis of peritonitis. Peritonitis may arise from an intra-abdominal site, either a perforated viscus, focal intra-abdominal infection, transmural migration from the gut into the peritoneal cavity, or ascending infection from the female genital tract. The isolation of multiple enteric bacteria or the presence of particulate matter in the effluent suggests a perforated viscus and should prompt immediate imaging and surgical evaluation. Bacteremia or fungemia from an extraperitoneal site may also result in PD peritonitis.

EXIT-SITE INFECTION

Purulent drainage at the PD exit site, with or without erythema or induration, usually indicates an exit-site infection. Exit-site infection is a superficial infection that involves only the distal 2 cm or less of the catheter tunnel, which can spread proximally, resulting in a tunnel infection or frank peritonitis. The organisms that cause most exit-site infections are those that colonize the skin and exit site itself; *S. aureus*, CNS, *Candida*, and gram-negative enterics. Topical mupirocin or gentamicin cream applied to the exit site have been shown to reduce the incidence of exit-site infection overall (5,6) but increase the incidence of infection caused by antibiotic-resistant pathogens such as diphtheroids, *Candida*, and nontuberculous mycobacteria (NTM) (7).

Exit-site infection should be suspected if the patient develops purulent drainage around the catheter. Swelling, pain, and crust formation may also be present. Erythema, by itself is neither a sensitive nor a specific indicator of infection without other findings. Pericatheter drainage should be sent for Gram stain and culture. Do not culture the exit site in the absence of purulent drainage or other signs of infection because exit sites are rarely sterile and may be colonized by the same types of organisms that cause infection.

The goals of therapy are to prevent progression to a tunnel infection or peritonitis. Mild exit-site infections may be treated topically with chlorhexidine, dilute hydrogen peroxide, or gentamicin ophthalmic solution and close monitoring. In more severe infections, systemic therapy is indicated which can usually be administered orally. See **TABLE 14.1** for dosing of oral antibiotics in PD patients. Gram staining of the exudate may be helpful in directing initial antimicrobial therapy, and culture and sensitivity will direct definitive therapy. If gram-positive cocci are seen, therapy should be directed against staphylococcal species and empiric choices would be dependent on the incidence of methicillin-resistant staphylococci in your program. With a low incidence of methicillin resistance, oral therapy with dicloxacillin 500 mg po qid or cephalexin 500 mg bid to tid would be adequate. If methicillin resistance is a concern, oral therapy with trimethoprim/sulfamethoxazole (TMP/SMX) 80/400 mg po qd or clindamycin 300 mg po tid would be a better choice. Linezolid (400 to 600 mg po bid) is also an option but is much more expensive and may produce adverse effects with courses longer than 14 days (8,9). If gram-negative bacteria are seen on Gram stain, oral ciprofloxacin 250 mg po bid should be used pending culture and sensitivity results. If the Gram stain is unavailable or unrevealing, empiric therapy should cover both staphylococcal species and gram-negative bacteria including *Pseudomonas*. Use of topical antimicrobials for prevention can affect the types of organisms responsible for exit-site infection. In patients receiving topical mupirocin, gram-negative organisms are more likely, whereas topical gentamicin results in more frequent staphylococcal and fungal infection (7).

TABLE 14.1 Oral Antibiotics Used in Exit-Site and Tunnel Infection

Amoxicillin	250–500 mg b.i.d.
Cephalexin	500 mg b.i.d. to t.i.d.
Ciprofloxacin	250 mg b.i.d.
Clarithromycin	500 mg loading dose, then 250 mg b.i.d. or q.d.
Dicloxacillin	500 mg q.i.d.
Erythromycin	500 mg q.i.d.
Flucloxacillin (or cloxacillin)	500 mg q.i.d.
Fluconazole	200 mg q.d. for 2 days, then 100 mg q.d.
Flucytosine	0.5–1 g/day titrated to response and serum trough levels (25–50 μg/mL)
Isoniazid	200–300 mg q.d.
Linezolid	400–600 mg b.i.d.
Metronidazole	400 mg t.i.d.
Moxifloxacin	400 mg daily
Ofloxacin	400 mg first day, then 200 mg q.d.
Pyrazinamide	25–35 mg/kg 3 times per week
Rifampicin	450 mg q.d. for <50 kg; 600 mg q.d. for >50 kg
Trimethoprim/ sulfamethoxazole	80/400 mg q.d.

b.i.d., 2 times per day; q.d., every day; t.i.d., 3 times per day; q.i.d., 4 times daily.
Reprinted from Li PK, Szeto C-C, Piraino B, et al. Peritoneal dialysis-related infections recommendations: 2010 update. *Perit Dial Int* 2010;30(4):393–423, with permission.

Upon receipt of culture and sensitivity results, therapy should be focused. For methicillin-susceptible staphylococcal species, oral therapy with cephalexin or dicloxacillin should be used. Streptococcal species should be treated with amoxicillin 250 to 500 mg po bid or cephalexin and with enterococci oral amoxicillin. “Community-acquired” strains of methicillin-resistant *Staphylococcus aureus* (MRSA) are often susceptible to TMP/SMX, clindamycin, doxycycline 100 mg po bid or minocycline 100 mg po bid and can be treated orally with these. Hospital-acquired strains maybe susceptible only to vancomycin and can be treated with vancomycin 15 to 30 mg/kg every 5 to 7 days administered intraperitoneally or oral linezolid if susceptible. For more difficult MRSA infections, rifampin 600 mg po daily may be added (1). Infection with gram-negative enterics should be treated with oral ciprofloxacin or possibly TMP/SMX depending on drug susceptibilities. Exit-site infections caused by *Pseudomonas aeruginosa* can be more difficult to treat and may relapse (10). If the isolate is susceptible, initial therapy with oral ciprofloxacin is appropriate. In the case of ciprofloxacin resistance, a slow response to oral ciprofloxacin or a relapsing infection, treatment with intraperitoneal tobramycin 0.6 mg/kg IP daily, cefepime 1 g IP qd, or meropenem 1 g IP qd should be added. Treatment for pseudomonal exit-site infection should be continued for at least 3 weeks or until the infection has resolved clinically. Nonpseudomonal exit-site infections should be treated for at least 2 weeks or until resolution.

The goal of treating exit-site infections is to prevent progression to a tunnel infection or peritonitis. An exit-site infection that is refractory to treatment or progresses to a tunnel infection or peritonitis requires catheter removal and replacement. The one exception is CNS infection, which in some cases can be successfully treated without catheter replacement. In the absence of peritonitis, catheter removal and replacement can be performed in a one-stage procedure, with catheter placement at a different site.

TUNNEL INFECTION

Erythema, swelling, or pain along the catheter extending more than 2 cm proximal to the catheter–skin interface is indicative of a tunnel infection. These infections usually result from the spread of bacteria from the exit site along the subcutaneous portion of the catheter and pose a higher risk of peritonitis. Ultrasound of the subcutaneous track of the catheter may reveal pericatheter fluid or abscess formation. The most common pathogens causing tunnel infection are *S. aureus* and *Pseudomonas*. Gram stain and culture of material milked from the exit site should be obtained, and appropriate antibiotic therapy should be started. In most cases, antibiotic therapy alone is inadequate and catheter removal is necessary—particularly with infections caused by *S. aureus* or *Pseudomonas*.

PERITONEAL DIALYSIS PERITONITIS

Peritonitis–Diagnosis

Prompt recognition, diagnosis, and treatment of PD peritonitis is essential for patient safety and preservation of the peritoneal membrane. Peritonitis may follow an exit-site or tunnel infection or an intra-abdominal source but most often results from contamination of the external catheter connection by breaks in sterile technique, touch contamination. The earliest signs of peritonitis are cloudy dialysate effluent and/or abdominal pain, which may be accompanied by fever or nausea and vomiting. Patients using automated PD may be less likely to notice cloudy dialysate. The first drain is most likely to be cloudy. The degree of inflammation and severity of abdominal pain is dependent on the virulence of the infecting organism. *S. aureus*, gram-negative rods, and β-hemolytic streptococci generally produce more severe abdominal pain and are more likely to be associated with fever than CNS. Patients should be educated to be alert for these signs and symptoms and to notify their providers for prompt evaluation.

Diagnosis of peritonitis is made by examining the dialysis effluent. In patients with prominent systemic symptoms, blood cultures should be obtained as well (11). Effluent should be sent for cell counts, white blood cell (WBC) differential, Gram stain, and culture prior to administering antibiotics whenever possible. Dialysate WBC >100/μL and >50% polymorphonuclear cells (PMNs) from a sample of fluid that has had a dwell of >2 hours is very suggestive of peritonitis. In patients receiving APD, fluid samples with <100 WBC but >50% PMNs usually have peritonitis. In a patient with a dry abdomen, 1 L of dialysate is infused, allowed to dwell for 1 to 2 hours, and then removed for cell counts and microbiologic studies.

Fluid specimens must be obtained for microbiologic studies before administering antimicrobials whenever possible to identify the infecting organisms and their drug susceptibilities to guide effective antimicrobial therapy. Five to 10 mL of fluid should be inoculated directly into aerobic and anaerobic blood culture bottles at the bedside. Use of BACTEC/Alert culture bottles may improve yield and reduce culture-negative cases (12). In addition, 50 mL of fluid should be centrifuged at 3,000 g for 15 minutes and the sediment resuspended in 3 to 5 mL of saline. The sediment should be examined with a Gram stain and inoculated into liquid blood culture bottles and solid bacterial media plates. Cultures are usually positive in 24 to 48 hours, but if liquid media cultures are negative at 3 days, they should be subcultured on solid media and examined for an additional 3 to 5 days. ISPD guidelines suggest a benchmark for culture negative peritonitis at <20% of cases. In the patient with negative cultures who fails to respond

clinically to empiric antibiotic therapy by 3 days, repeat PD effluent sampling for cell counts and microbiologic studies should be performed. In addition to repeating routine bacteriologic studies, consideration of fastidious bacterial, mycobacterial, and fungal causes should be explored with additional microbiologic studies.

Initial Empiric Therapy for Peritonitis

Prompt initial empiric antimicrobial therapy is essential for optimal short- and long-term outcomes (**FIGURE 14.1**). A positive peritoneal fluid Gram stain can guide initial empiric therapy, focusing on gram-positive or gram-negative bacteria. If the Gram stain is negative, empiric antibiotic therapy, including coverage for both gram-positive and gram-negative bacteria should be started promptly. Antibiotics should be administered intraperitoneally, added to the dialysate. The choice of empiric therapy should be determined by the local prevalence of antimicrobial resistance in gram-positive and gram-negative bacterial causes of peritonitis. In most programs, gram-positive bacteria account for 50% or more of cases and gram-negative enterics 10% to 20%. Empiric coverage for gram positives with cefazolin 15 to 20 mg/kg IP qd or vancomycin 15 to 30 mg/kg IP every 5 to 7 days is recommended, with the choice dependent on the local incidence of methicillin-resistant staphylococcal species. Empiric coverage for gram-negative bacteria should include coverage for *P. aeruginosa*. Choices include ceftazidime 1 to 1.5 g IP qd, cefepime 1 g IP qd, gentamicin 0.6 mg/kg IP qd, or tobramycin 0.6 mg/kg IP qd, again depending on local antimicrobial resistance patterns. A recent episode of peritonitis or exit-site infection or recent antibiotic therapy may modify initial empiric antibiotic choices. Results of peritoneal fluid cultures and drug susceptibilities will direct definitive therapy for peritonitis.

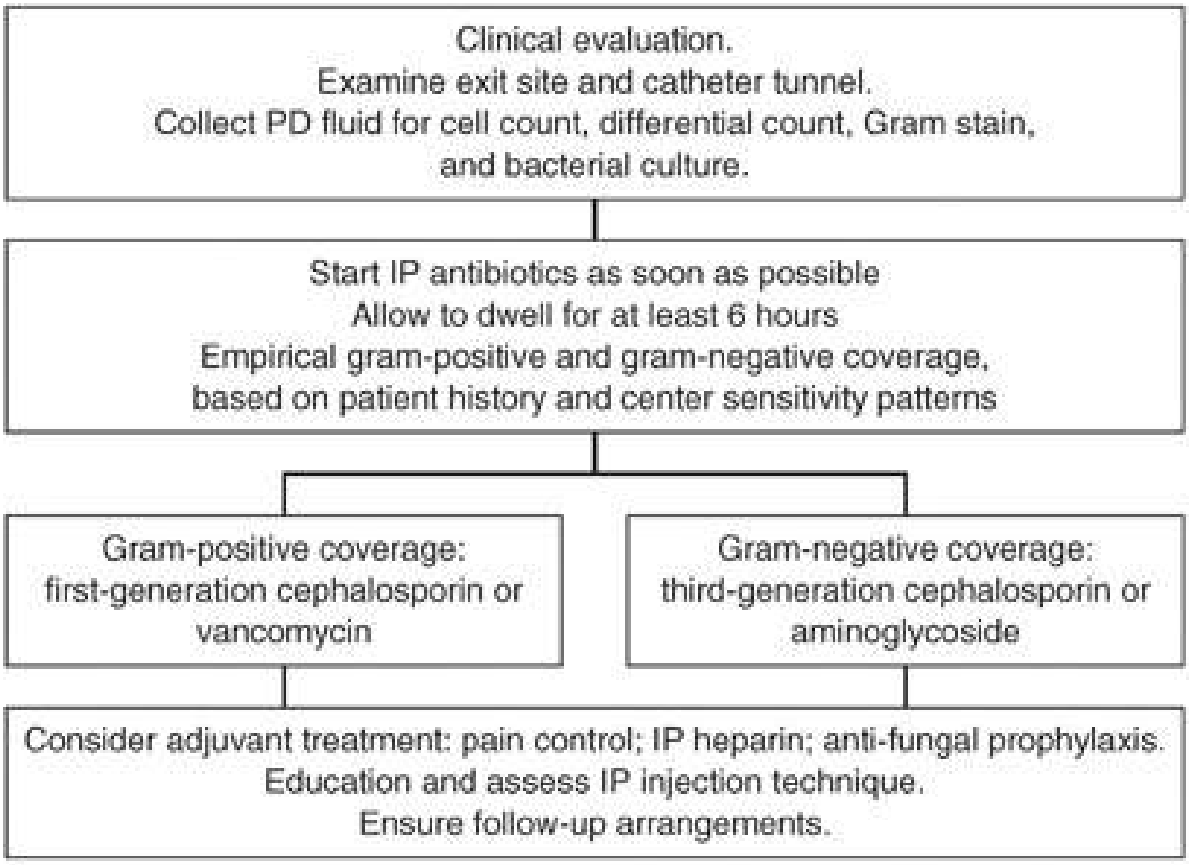

FIGURE 14.1 Initial management of peritonitis. IP, intraperitoneal. [Reprinted with permission from Li PK, Szeto C-C, Piraino B, et al. ISPD peritonitis recommendations: 2016 Update on Prevention and Treatment (published online ahead of print June 9, 2016). *Perit Dial Int.*]

Intraperitoneal Antibiotics for Peritonitis

Intraperitoneal administration of antibiotics is the recommended route of administration for the treatment of PD peritonitis for a number of reasons (13) (**TABLE 14.2**). IV access and continued IV administration is not necessary. Antibiotics added to the dialysate are delivered in high concentrations to the site of infection. The peritoneal membrane is permeable to most intraperitoneally administered antibiotics, resulting in therapeutic serum levels, which allows diffusion back into the peritoneum when the patient is not undergoing dialysis. If antibiotics are administered intermittently, the antibiotic containing fluid should dwell for at least 6 hours, usually with a daytime dwell in patients receiving APD. There is less data on the dosing and efficacy of IP antibiotics in patients receiving APD, particularly with β-lactam compounds, and some recommend converting to continuous ambulatory peritoneal dialysis (CAPD), if possible, during therapy for peritonitis. (14)

Table 14.2 Intraperitoneal Antibiotic Dosing Recommendations for Treatment of Peritonitis

	Intermittent (1 exchange daily)	Continuous (all exchanges)
Aminoglycosides		
Amikacin	2 mg/kg daily	LD 25 mg/L, MD 12 mg/L
Gentamicin	0.6 mg/kg daily	LD 8 mg/L, MD 4 mg/L
Netilmicin	0.6 mg/kg daily	MD 10 mg/L
Tobramycin	0.6 mg/kg daily	LD 3 mg/kg, MD 0.3 mg/kg
Cephalosporins		
Cefazolin	15–20 mg/kg daily	LD 500 mg/L, MD 125 mg/L
Cefepime	1,000 mg daily	LD 250–500 mg/L, MD 100–125 mg/L
Cefoperazone	no data	LD 500 mg/L, MD 62.5-125 mg/L
Cefotaxime	500–1,000 mg daily	no data
Ceftazidime	1,000–1,500 mg daily	LD 500 mg/L, MD 125 mg/L
Ceftriaxone	1,000 mg daily	no data
Penicillins		
Penicillin G	no data	LD 50,000 unit/L, MD 25,000 unit/L
Amoxicillin	no data	MD 150 mg/L
Ampicillin	no data	MD 125 mg/L
Ampicillin/Sulbactam	2 gm/1 gm every 12 hours	LD 750–100 mg/L, MD 100 mg/L
Piperacillin/Tazobactam	no data	LD 4 gm/0.5 gm, MD 1 gm/0.125 gm
Others		
Aztreonam	2 gm daily	LD 1,000 mg/L, MD 250 mg/L
Ciprofloxacin	no data	MD 50 mg/L
Clindamycin	no data	MD 600 mg/bag
Daptomycin	no data	LD 100 mg/L, MD 20 mg/L
Imipenem/Cilastatin	500 mg in alternate exchange	LD 250 mg/L, MD 50 mg/L
Ofloxacin	no data	LD 200 mg/L, MD 25 mg/L
Polymyxin B	no data	MD 300,000 unit (30 mg)/bag
Quinupristin/Dalfopristin	25 mg/L in alternate exchange[a]	no data
Meropenem	1 gm daily	no data
Teicoplanin	15 mg/kg every 5 days	LD 400 mg/bag, MD 20 mg/bag
Vancomycin	15–30 mg/kg every 5–7 days[b]	LD 30 mg/kg, MD 1.5 mg/kg/bag
Antifungals		
Fluconazole	IP 200 mg every 24 to 48 hours	no data
Voriconazole	IP 2.5 mg/kg daily	no data

LD, loading dose in mg; MD, maintenance dose in mg; IP, intraperitoneal; APD, automated peritoneal dialysis.
[a]Given in conjunction with 500 mg intravenous twice daily.
[b]Supplemental dose may be needed for APD patients.

Peritonitis Treatment Course and Outcomes

Upon receiving the results of peritoneal fluid cultures and drug susceptibilities, antibiotic therapy should be focused on the infecting pathogen using the narrowest spectrum, least toxic agent. Duration of treatment is usually 14 to 21 days depending on the pathogen. Patient symptoms should be improving, and peritoneal effluent should be clear after 2 to 4 days of definitive treatment. In one study, effluent WBC of >1,000 on day 3 of treatment predicted failure of therapy (15). If the effluent does not clear after 5 days of culture-directed therapy, ISPD guidelines define this as refractory peritonitis and recommend consideration of catheter removal. Catheter removal should also be considered for culture-negative cases if the effluent does not clear in 5 days. Failure of the effluent to clear after 5 days of appropriate empiric therapy should

also raise suspicion for infections caused by fastidious bacterial pathogens, mycobacterial, or filamentous fungal causes. This should prompt repeat cultures for bacteria, fungal, and acid-fast bacteria.

Relapsing peritonitis is defined as a second episode of peritonitis caused by the same pathogen or as a culture negative case within 4 weeks after the end of treatment for the first episode. Recurrent peritonitis is a second episode occurring within 4 weeks of completion of therapy for a prior one, caused by a different organism (16,17). Repeat peritonitis is a second episode caused by the same organism as the first, more than 4 weeks after the completion of therapy. These three forms of peritonitis are associated with subsequent cases of peritonitis. ISPD guidelines suggest that removal and replacement of the PD catheter be considered to prevent damage to the peritoneal membrane and technique failure (1).

Catheter Management in Peritoneal Dialysis Peritonitis

Appropriate management of peritonitis, tunnel, and exit-site infections is focused on resolving the current infection, preventing subsequent infection, and preserving the peritoneal membrane. Patients with refractory exit-site and tunnel infections should have their catheters removed and replaced. Catheter removal and replacement simultaneously in a one-stage procedure is feasible in patients with refractory exit-site infections and in patients with relapsing CNS infection if the effluent has cleared on appropriate therapy. Patients with refractory infections caused by *S. aureus*, *Pseudomonas*, fungi, or mycobacteria should have their catheters removed in a timely fashion and suspend PD until their infections have resolved before catheter replacement.

ORGANISM-SPECIFIC TREATMENT AND MANAGEMENT OF PERITONEAL DIALYSIS PERITONITIS

Two to 3 days after obtaining peritoneal fluid, cultures are usually growing a pathogen (**FIGURES 14.2** and **14.3**). If the peritoneal Gram stain was positive on the initial sample or when cultures become positive, your microbiology laboratory will be able to identify the organism as gram-positive, gram-negative, or yeast and whether it is cocci or bacilli. Where available, polymerase chain reaction (PCR) (BioFire) or matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) can rapidly identify the species of the infecting organism and also determine whether it contains resistance genes such as mecA for methicillin resistance, vancomycin resistance genes in enterococci, and carbapenem resistance in gram-negative bacilli. This information would allow focusing or changing antibiotic therapy.

ISPD peritonitis recommendations: 2016 update on prevention and treatment (published online ahead of print June 9, 2016). *Perit Dial Int.*]

Coagulase-Negative Staphylococcal Peritonitis

CNS are the most common cause of PD peritonitis in most series. These organisms are ubiquitous colonizers of human skin and are a group of species, one of which is *Staphylococcus epidermidis*, the commonest pathogen in PD peritonitis (18–21). Peritonitis caused by these organisms is almost always the result of touch contamination in the course of manipulating the catheter or connectors during dialysis. CNS species are not very virulent organisms and usually produce a milder form of peritonitis with less pain, peritoneal inflammation, and fewer systemic symptoms. However, these organisms have a higher propensity to produce biofilms on catheters due to their production of "slime," an extracellular matrix of bacterial and host compounds (22). Organisms in biofilms are much more resistant to antimicrobials, being embedded in slime, impairing antibiotic access, and having reduced replication in the deeper levels of the complex. Probably because of biofilm production, CNS are frequent causes of relapsing and repeat cases of peritonitis (17). Relapsing or repeat peritonitis by these organisms requires catheter removal and replacement in most cases.

Initial empiric antibiotic therapy should always include antibiotic coverage for these organisms. If

methicillin-resistant organisms are uncommon in your program, cefazolin can be used empirically; otherwise, vancomycin should be used for empiric therapy. In a series of 115 cases of CNS PD peritonitis cases from Brazil, 70% of their isolates were methicillin-resistant and initial therapy including vancomycin empirically improved outcomes (21). Upon receipt of culture and sensitivity results, methicillin-susceptible isolates can be treated with cefazolin, and methicillin-resistant strains with vancomycin. Intraperitoneal cefazolin is administered 15 to 20 mg/kg to one exchange a day, with a long dwell (>6 hours). There are some concerns about using cefazolin in patients receiving APD in that peritoneal drug levels may be inadequate during APD due to more rapid exchanges, with some authorities recommending conversion to CAPD during cefazolin therapy (1). However, the published experience suggests that these patients may receive therapy on APD, with one study showing equivalent cure rates in patients treated on APD or CAPD (22) and another study showing higher failure rates in those switched to CAPD during therapy (23). This is not a concern with vancomycin therapy, which is administered every third to fifth day intraperitoneally.

Clinical response is usually prompt, with resolution of symptoms and clearing of the effluent, with reduction in peritoneal WBC by 3 to 5 days. Patients with a good clinical response can be treated for 14 days. Failure to respond by 3 to 5 days should prompt reevaluation with repeat cultures and consideration of catheter removal, especially in the presence of an exit-site or tunnel infection. Relapsing or repeat episodes should also prompt considering catheter removal and replacement, which can be done as a one-stage procedure after treatment of peritonitis.

Staphylococcus aureus Peritonitis

In contrast to CNS species, *S. aureus* is a much more virulent organism, producing clinically more severe peritonitis with a significant risk of failure, morbidity, and mortality (24,25). The cause is often touch contamination but also may result from concurrent exit-site or tunnel infection. Initial empiric therapy should include cefazolin or vancomycin 15 to 30 mg/kg/d IP every 5 to 7 days, depending on the local prevalence of methicillin-resistant strains, followed by focused therapy based on the drug susceptibility of the infecting strain. ISPD guidelines recommend the addition of rifampin, 600 mg po qd for 7 days in addition to the primary antibiotic (1). Rifampin has synergistic activity on *S. aureus* and is active on bacteria adherent to the catheter and in biofilms. If rifampin is used, be aware of its induction of multiple drug metabolizing enzymes and its effect on concomitant medications.

S. aureus usually produces more clinically severe peritonitis, with pain, higher peritoneal effluent WBC, and systemic signs of infection such as fever and signs of sepsis. For methicillin-susceptible strains, cefazolin 15 to 20 mg/kg IP qd or continuous dosing with cefazolin, a 500 mg/L IP loading dose followed by 125 mg/L IP with oral rifampin. Methicillin-resistant strains should be treated with an initial IP loading dose of vancomycin, 15 to 30 mg/kg up to 2 g, followed by 1 g IP every 3 to 7 days, based on serum vancomycin levels. Trough serum vancomycin levels of <15 μg/mL should prompt redosing with vancomycin. Patients who are intolerant of vancomycin or have vancomycin-resistant strains can be treated with daptomycin 100 mg/L IP loading dose and then 20 mg/L IP continuously, linezolid 300 to 600 mg po bid, or perhaps ceftaroline. Ceftaroline is a third-generation cephalosporin with good MRSA activity but has not been used in PD patients at this point (26). Oral rifampin 600 mg should be given as well. Patients with a good clinical response, with decreasing pain and clearing of the effluent should be treated with 21 days of therapy. Failure to respond after 5 days of appropriate antibiotic therapy, or the

presence of an exit-site or tunnel infection, are indications for prompt catheter removal and converting to hemodialysis for 2 to 3 weeks before catheter replacement (1). MRSA peritonitis is associated with an increased risk of technique failure and permanent switching to hemodialysis (25).

Streptococcal Peritonitis

Streptococcal species are less common causes of PD peritonitis than staphylococcal species. Like staph species, the clinical presentation depends on virulence of the species, with β-hemolytic streptococci, Groups A, B, etc., resembling *S. aureus* and viridans streptococci more resembling the clinical features of CNS (27). The mode of infection is probably touch contamination in most cases, but viridans streptococci are inhabitants of the alimentary tract so a gastrointestinal (GI) source is possible. Initial empiric therapy with cefazolin 15 to 20 mg/kg/d IP or vancomycin 15 to 30 mg/kg IP every 3 to 7 days IP will cover all the β-hemolytic streptococci and most viridans streptococci, which have been shown to have increasing resistance to penicillins and cephalosporins (28). Results of cultures and sensitivities will allow focused therapy with a single agent. Continuous dosing with ampicillin 125 mg/L IP has been recommended for penicillin susceptible strains (1). Some studies have shown that ampicillin in solution begins to lose antimicrobial activity after of mixing, creating problems with patients on home therapy. A better choice may be cefazolin, which has good activity against these strains and is stable for 8 days at room temperature and 14 days refrigerated in solution (29).

β-Hemolytic streptococcal peritonitis presents like *S. aureus*, with significant abdominal pain, high peritoneal WBCs, and frequent fever and signs of sepsis. These organisms remain very susceptible to most β-lactam antibiotics and peritonitis usually responds promptly to appropriate antibiotic therapy, including cefazolin. Therapy should be continued for 14 days. Failure to respond promptly should raise questions about an exit-site or tunnel infection, or a concomitant skin and soft tissue infection or other focus.

Viridans streptococci, like CNS, include a large number of species and, like CNS, are not very virulent organisms. They are normal inhabitants of the alimentary tract, including the mouth and upper and lower GI tract and probably produce peritonitis through touch contamination, occasionally via the GI tract or hematogenously following invasive procedures involving mucosal surfaces without prophylactic antibiotics (30). Peritonitis caused by these organisms resembles CNS, with less severe abdominal pain, milder inflammatory changes on peritoneal fluid examination, and fewer systemic symptoms like fever (31). One study, however, identified an increased risk of recurrent and refractory peritonitis following an episode of viridans streptococci peritonitis (32). For penicillin-susceptible strains, continuous IP ampicillin has been recommended, but because of poor stability in solution, IP cefazolin might be a better choice. Penicillin-resistant strains with minimum inhibitory concentration (MIC) >4 μg/mL or relatively resistant strains with penicillin MICs >0.5 μg/mL should be treated with IP vancomycin. Therapy should be continued for 14 days.

The organism formerly known as *Streptococcus bovis* has been reclassified as *Streptococcus gallolyticus*. In a series of 20 patients with 23 episodes of peritonitis caused by *S. gallolyticus* reported by Yap et al. (33), some degree of penicillin resistance was common. Patients were successfully treated with cefazolin or vancomycin and an aminoglycoside for 14 days. *S. bovis*/*S. gallolyticus* bacteremia is classically associated with GI malignancies, particularly colon cancer. Ten of their 20 patients underwent diagnostic studies—colonoscopy or barium enema—and none were found to have colon cancer.

Enterococcal Peritonitis

Enterococcal species are normal inhabitants of the GI tract and are more common causes of peritonitis than streptococcal species in most series. The source of infection is usually touch contamination, but GI tract contamination also occurs and should be suspected if other enteric organisms are present. In fact, in some series, nearly half of enterococcal peritonitis cases were polymicrobial, and polymicrobial infections were associated with high rates of catheter loss and permanent transfer to hemodialysis (34,35). The clinical presentation of enterococcal peritonitis, without other organisms, is moderately severe in terms of pain and systemic symptoms. Cephalosporins have no activity against enterococci and aminoglycosides alone have very little so that empiric regimens containing cephalosporins or a cephalosporin and aminoglycoside have virtually no effect on enterococcal peritonitis. Vancomycin covers most enterococci, the exception being vancomycin-resistant enterococci (VRE).

Therapy of enterococcal peritonitis can be problematic, given that the organism is not susceptible to most commonly used antibiotics. *Enterococcus faecalis* is usually susceptible to ampicillin, penicillin, and piperacillin as well as vancomycin. Occasional strains of *E. faecalis* are resistant to vancomycin (VRE) but remain susceptible to penicillins. Ampicillin IP has been recommended as the drug of choice, but problems with stability in solution requires that it be reconstituted right before use. Piperacillin is stable in solution up to 8 days refrigerated, but there is little published experience in PD peritonitis. Vancomycin is commonly used and is recommended as the first choice in the 2016 ISPD guidelines, which also recommend the addition of IP aminoglycoside in “severe” cases of enterococcal peritonitis (1). *Enterococcus faecium* is inherently resistant to ampicillin and penicillin, making vancomycin the drug of choice. Most strains of VRE are *E. faecium*, which are resistant to all commonly used classes of antibiotics. Case reports and a few small series have reported successful treatment of VRE peritonitis with daptomycin. Daptomycin has most often been used IP with a loading dose of 100 mg/L for at least a 6-hour dwell and then 20 mg/L for APD or CAPD (36,37). Daptomycin has also been given at 7 mg/kg every 48 hours IP (38) and 5 mg/kg IV every 48 hours (39). Linezolid has also been used to treat VRE peritonitis. Because of presumed instability in dialysis fluids, linezolid has been given systemically, 600 mg IV every 12 hours (40,41). The bioavailability of linezolid given orally is 100%, so if the patient is taking po meds, po administration is certainly reasonable (42). Also be aware of the potential for hematologic and neurologic toxicities of linezolid with doses of 600 mg bid for courses exceeding 10 days (8,9). Quinupristin/dalfopristin has been used successfully treat *E. faecium* VRE peritonitis (43), but this compound has no activity on *E. faecalis*. The recommended duration of therapy for VRE peritonitis is 21 days. A suboptimal response to therapy should prompt consideration for catheter removal.

Corynebacterium Peritonitis

The genus *Corynebacterium* includes a number of species of small, gram-positive rods, often referred to as *diphtheroids*. These organisms, like CNS, are part of normal skin flora, of low pathogenicity, and usually produce infections related to implanted devices. In most case series, *Corynebacterium* account for less than 3% of peritonitis cases. This group of organisms is of low pathogenicity, and peritonitis resembles CNS clinically. Infection most likely occurs through touch contamination. Most *Corynebacterium* strains are susceptible to cefazolin. The notable exception is *Corynebacterium jeikeium*, which is resistant to β lactams and many other classes but is susceptible to vancomycin.

The optimal treatment of *Corynebacterium* peritonitis is not clear based on the two largest case series. A series of 27 patients reported from Hong Kong (44) found a better overall response and fewer recurrences after treatment with vancomycin for 2 to 3 weeks than with cephalosporins. In contrast, another series of 82 patients with *Corynebacterium* peritonitis found that 2 weeks of therapy with cefazolin was comparable to vancomycin or longer treatment courses (45). In both studies, recurrent peritonitis was frequent. One study also reported that in cases of refractory peritonitis, delaying catheter removal beyond 7 days resulted in 90% technique failure with permanent transfer to hemodialysis (45).

Gram-Negative (*Enterobacteriaceae*) Peritonitis

Gram-negative enteric bacteria, the family *Enterobacteriaceae*, are normal inhabitants of the gastrointestinal tract. The most common species causing PD peritonitis are *Escherichia coli*, *Klebsiella*, and *Enterobacter* species (46–48). The incidence of these organisms varies in different centers but usually accounts for 10% to 20% of PD peritonitis cases. Their relative percentage has increased over the past two decades, probably due to decreases in staphylococcus cases as a result of improved connective technologies and the use of mupirocin for exit-site prophylaxis. The mechanisms of infection are probably touch contamination but also exit-site and tunnel infections. Some infections may arise from an intra-abdominal source, constipation, or transmural migration of bacteria. Multiple species on Gram stains and culture suggest an intra-abdominal infection or perforated viscus. The clinical presentation is moderately severe, with fever in about one-third of cases.

Treatment of gram-negative enteric peritonitis is more complex than gram-positive bacteria, given the variety of species and differing antibiotic susceptibilities. Initial empiric therapy with a broad-spectrum cephalosporin IP, like cefepime or ceftazidime or an aminoglycoside, will cover most of these organisms. Results of culture and sensitivity will allow focused therapy. In a series of 210 patients with gram-negative enteric peritonitis, therapy with a single effective antibiotic was associated with a 39% failure rate and a high relapse and recurrence rate (46). Treatment with two effective agents improved response rates and decreased relapse. Depending on drug susceptibilities, a broad-spectrum β-lactam IP like cefepime or ceftazidime combined with either an aminoglycoside or a fluoroquinolone, ciprofloxacin or levofloxacin, would be reasonable choices.

Gram-negative enterics have a variety of potential resistance mechanisms (49). *Enterobacter*, *Serratia*, and *Citrobacter* species have a chromosomal β-lactamase enzyme, AmpC, which is derepressed when exposed to β-lactam antibiotics. Expression of AmpC results in resistance to cephalosporins and is not inhibited by β-lactamase inhibitors. The last decade has seen the emergence and spread of two novel resistance mechanisms. Extended spectrum β-lactamases (ESBLs) are plasmid mediated enzymes, first described in *Klebsiella pneumoniae*, but are present in many other gram-negative bacteria as well. Strains expressing ESBLs are resistant to all cephalosporins but remain susceptible to carbapenems and most β-lactam/β-lactamase inhibitors (50–52). Even more problematic is the emergence of carbapenem-resistant *Enterobacteriaceae* (CRE), also known as KPC—*Klebsiella pneumoniae* carbapenemase (53). These β-lactamase enzymes are carried on mobile genetic elements and induce resistance to all β-lactam antibiotics, including carbapenems. In addition, CRE strains are usually resistant to fluoroquinolones, variably resistant to aminoglycosides, and often only susceptible to polymyxin B and colistin. Colistin has been given systemically to treat PD peritonitis, 300 mg IV on day 1 and then 150 to 200 mg IV qd. There is little experience in the occurrence or treatment of CRE infections

in PD peritonitis or the use of colistin or polymyxin B intraperitoneally (54).

Nonfermenting (Aerobic) Gram-Negative Rods—*Pseudomonas*, *Acinetobacter*, and *Stenotrophomonas*

Pseudomonas

Pseudomonas species are aerobic, nonfermenting gram-negative rods that are inherently resistant to many antibiotics. *Pseudomonas*, most often *P. aeruginosa*, usually accounts for less than 5% of peritonitis cases in most programs but was the causative agent in 13% of cases in a series from Hong Kong (55). Recent antibiotic therapy appears to predispose for *Pseudomonas* peritonitis. Catheter infection, either an exit-site or a tunnel infection, is often present and is an indication for catheter removal. Clinically, compared to other bacterial pathogens, pseudomonas peritonitis results in a twofold increased risk of catheter removal and permanent transfer to hemodialysis (56).

Treatment with two effective anti-pseudomonal antibiotics, based on drug susceptibility studies, appears to improve outcomes. Oral ciprofloxacin combined with IP cefepime, ceftazidime, piperacillin, aminoglycoside, meropenem, or imipenem appear to be the most efficacious combinations. In Szeto's (55) series, outcomes were better with cephalosporin versus aminoglycoside combinations. In patients with a good primary response, antibiotics should be continued for 3 weeks. In refractory cases or in the presence of a catheter infection, prompt catheter removal improves outcomes. Following catheter removal, transfer to hemodialysis with 2 weeks of parenteral anti-pseudomonal therapy is recommended prior to catheter replacement.

Acinetobacter

Acinetobacter species are nonfermenting aerobic, gram-negative rods that are frequent agents of health care–associated infection (57). Most human infections are caused by *Acinetobacter baumannii*, which is often multidrug-resistant. *Acinetobacter*, like *Pseudomonas*, is inherently resistant to many antibiotics, frequently develops resistance during therapy, and not infrequently requires treatment with colistin or polymyxin B because of resistance to all other classes of drugs. Interestingly, most *Acinetobacter* strains are susceptible to ampicillin/sulbactam due to susceptibility to the sulbactam component. In a series of seven patients with *Acinetobacter* peritonitis reported by Zhang (58), three patients with multidrug-resistant strains failed antibiotic therapy and transferred to hemodialysis. Peritonitis caused by *Acinetobacter* should probably treated like *Pseudomonas* with two effective drugs based on drug susceptibilities, for 3 weeks, with early catheter removal for refractory cases.

Stenotrophomonas maltophilia

Stenotrophomonas maltophilia is another aerobic gram-negative bacillus that causes health care–associated infections and is multidrug-resistant. This organism is inherently resistant to all carbapenems, possessing a chromosomal carbapenemase, most fluoroquinolones, aminoglycosides, and tetracyclines (59). It is most susceptible to TMP/SMX, ticarcillin/clavulanate (no longer available in the United States), tigecycline, and colistin and polymyxin. *Stenotrophomonas* is not a common cause of PD peritonitis, but in three small case series, failure with catheter loss occurred in about half of treated patients (60,61). The most effective therapy seems to be TMP/SMX combined with an additional

effective drug for 3 to 4 weeks of therapy.

Polymicrobial Peritoneal Dialysis Peritonitis

Polymicrobial peritonitis is a case of peritonitis in which more than one organism is isolated in a single episode of peritonitis. This occurs in 10% or less of peritonitis episodes. The isolation of multiple species of organisms, particularly gram-negative enterics and anaerobic bacteria, in a patient with more severe abdominal pain and systemic signs of sepsis should raise concerns for a perforated viscus or other serious intra-abdominal infection and should prompt immediate surgical consultation. In most case series of polymicrobial peritonitis, these intra-abdominal catastrophes occur in fewer than 10% of patients with polymicrobial peritonitis (62–64).

In the majority of cases of polymicrobial peritonitis, the pathogenesis is probably similar to monomicrobial cases, the result of touch contamination or catheter-related infection. Outcomes seem to be best with mixed infection with gram-positive cocci. Isolation of gram-negative bacteria and particularly fungi is associated with higher rates of failure, catheter removal, and permanent transfer to hemodialysis.

Culture-Negative Peritonitis

Culture negative peritonitis is defined as clinical signs of peritonitis, cloudy dialysate with more than 100 WBC/μL, >50% PMNs, and with negative peritoneal fluid cultures after 3 days. PD guidelines suggest a benchmark of fewer than 20% culture-negative cases of peritonitis. A recent history of antibiotic use or initiating antibiotic therapy for peritonitis before obtaining peritoneal fluid cultures is common in these cases. It is thought that most of these cases are due to gram-positive bacteria through touch contamination based on the observation that most patients respond to standard empiric antibiotic regimens (65). If peritoneal fluid cultures remain negative after 3 days of therapy, peritoneal WBC and differential should be repeated. If the patient responds to empiric antibiotic therapy with clearing of the effluent, and persistent negative cultures, gram-negative coverage can be discontinued and cefazolin or vancomycin should be continued for 14 days.

If there is a lack of clinical response after 3 days of antibiotic therapy, peritoneal fluid WBC, differential, and cultures should be repeated. Possible causes in these patients include resistant bacteria, fastidious bacteria, mycobacterial infection, fungal infection (other than candida), or a noninfectious cause. In addition to routine bacterial cultures, peritoneal fluid should be sent for fungal and mycobacterial cultures and bacterial cultures should be held for a longer period of time and subcultured on enriched and specialized media. If there is no clinical improvement after 5 days of therapy, catheter removal should be considered.

Fungal Peritonitis

Fungal peritonitis usually accounts for less than 5% of cases in most centers, but some have higher rates (66). The clinical presentation resembles bacterial peritonitis with cloudy dialysate and abdominal pain. More than half of patients with fungal peritonitis will have a history of antibiotic therapy in the prior month, often for an episode of bacterial peritonitis (67). The presumed mechanism is that antibiotic therapy reduces the normal bacterial flora of the skin and GI tract, facilitating overgrowth or colonization by candida or other fungi. PD fluid studies are similar to bacterial infection with elevated WBC and neutrophilic predominance. Occasionally, eosinophils will be seen in PD effluent with infection by some

filamentous fungi (molds). *Candida* species are responsible for 90% or more of fungal peritonitis cases; infection with molds is less common. On Gram stain, *Candida* species are seen as gram-positive, ovoid cells, about 5 μm in diameter. Mold species do not stain with Gram stain. Calcofluor white or Gomori methenamine silver stains will detect molds and yeasts if enough organisms are present in the specimen. β-D-Glucan is an important component of most fungal cell walls and is usually measured in the serum in patients with suspected fungal infections (68). It might be a useful adjunct in the diagnosis of suspected fungal peritonitis to measure serum and peritoneal fluid β-D-glucan levels—but to my knowledge, this has not been done. *Candida* species grow well on standard bacterial culture media, usually taking a day or two longer than bacteria. In contrast, molds require specialized fungal culture media and usually take longer to grow.

In the 20th century, *Candida albicans* was the predominant species in PD peritonitis and most other sites of candida infection. In the last 15 years, *C. albicans* now accounts for fewer than 50% of cases (69–71). Of the non-*C. albicans* species that have been appearing, *Candida krusei* is always resistant to fluconazole and *Candida glabrata* is often resistant. Upon identification of Candida on Gram stain or culture of PD fluid, initial therapy is usually with fluconazole 200 mg po on day 1 and then 50 to 100 mg po qd or 200 mg IP every 24 to 48 hours (**TABLE 14.3**) (1). Upon receipt of the species ID and drug susceptibility testing results, if fluconazole resistance is present, therapy may need to be changed to a broader spectrum agent. Itraconazole, voriconazole, posaconazole, and isavuconazole are broader spectrum azole drugs that have better activity on many non-*C. albicans* species and some molds as well. Of the broader spectrum azoles, voriconazole 2.5 mg/kg IP qd (72) or 200 mg po BID (73) has the best penetration into aqueous compartments and is a potential option for fluconazole-resistant strains. Echinocandin antifungal drugs have excellent activity against *Candida* species, but there is little experience in treating PD peritonitis. A possible concern is that echinocandins are large molecules that are highly protein-bound and do not penetrate other aqueous sites such as cerebrospinal fluid (CSF) or urine well. However, caspofungin 50 mg IV qd has been used successfully in combination with amphotericin B to treat a multiresistant *C. albicans* (74) and alone IV to treat trichosporon PD peritonitis cases (75). IP administration has not been studied to my knowledge. Amphotericin B is active on most fungal species, including molds. Early attempts at using amphotericin IP failed because of severe irritant peritonitis, even at low doses. Amphotericin B given IV penetrates the peritoneal fluid poorly but has been used successfully to treat *Candida* peritonitis IV at a dose of 0.75 to 1 mg/kg/d along with po flucytosine (76). Flucytosine, 1 g po qd, is recommended to be used in combination with an azole or amphotericin B by the ISPD for the treatment of *Candida* peritonitis (1). If used, flucytosine serum levels should be measured, maintaining trough levels less than 25 to 50 μg/mL to avoid excessive levels and hematologic and GI toxicity. Most published series of *Candida* peritonitis (77) and ISPD guidelines (1) emphasize the importance of prompt catheter removal. Culture-directed antifungal therapy should be given for at least 2 weeks, followed by catheter replacement after 4 to 6 weeks (71).

Table 14.3 Systemic Antibiotic Dosing Recommendations for Treatment of Peritonitis

Drug	Dosing
Anti-bacterials	
Ciprofloxacin	oral 250 mg BD[a]
Colistin	IV 300 mg loading, then 150–200 mg daily[b]
Ertapenem	IV 500 mg daily
Levofloxacin	oral 250 mg daily
Linezolid	IV or oral 600 mg BD
Moxifloxacin	oral 400 mg daily
Rifampicin	450 mg daily for BW<50 kg; 600 mg daily for BW≥50 kg
Trimethoprim/ Sulfamethoxazole	oral 160 mg/800 mg BD
Anti-fungals	
Amphotericin	IV test dose 1 mg; starting dose 0.1 mg/kg/day over 6 hours; increased to target dose 0.75–1.0 mg/kg/day over 4 days
Caspofungin	IV 70 mg loading, then 50 mg daily
Fluconazole	oral 200 mg loading, then 50–100 mg daily
Flucytosine	oral 1 gm/day
Posaconazole	IV 400 mg every 12 hours
Voriconazole	oral 200 mg every 12 hours

BD, twice a day; IV, intravenous; BW, body weight.
[a]Ciprofloxacin 500 mg BD may be needed if residual glomerular filtration rate is above 5 mL/min.
[b]Expressed as colistin base activity (CBA).

Failure to remove the catheter in a timely fashion is reported to increase mortality and significantly increases the risk of technique failure in most series. However, Boer (78) reported eight patients with *Candida* peritonitis who were successfully treated with IP fluconazole, po flucytosine, and whose PD catheters were locked with 10 mL of 0.1 mg/mL of amphotericin B between CAPD exchanges. In a series of 13 patients reported by Wong et al. (76) who were treated with amphotericin B 0.75 to 1 mg/kg/d IV and oral flucytosine with their PD catheters in place until catheter replacement after about 4 weeks of treatment, 9 were able to continue PD.

Peritonitis caused by filamentous fungi (molds) is much less common than that caused by *Candida*. Infection caused by molds appears to be more common in tropical and subtropical climates (79). Antifungal treatment of mold infection is much more difficult. Fluconazole has no activity on molds. Itraconazole, voriconazole (72), posaconazole 400 mg IV bid (80), and more recently, isavuconazole are broader spectrum azoles that have activity on many common molds, but there is little reported clinical experience in using these agents to treat fungal peritonitis. Amphotericin B is active on many mold species (81). Treatment of mold infections is directed by the species identified and antifungal drug susceptibilities when available. Catheter removal is almost always necessary.

Mycobacterial Peritonitis

Tuberculous Peritonitis in Peritoneal Dialysis

Patients with chronic kidney disease (CKD) on dialysis have a much higher incidence of tuberculosis

(TB), with some studies reporting rates that are 7 to 50 times greater than the general population (82). In a series of 790 CAPD patients in China, 38 cases of TB were diagnosed, yielding a prevalence of 4.8% and a case rate of 800/100,000 (83). In that series, more than half of the patients had extrapulmonary TB and 37 % had TB peritonitis. Almost all cases of TB peritonitis result from reactivation of latent tuberculous infection. In developed countries, many cases of TB arise in immigrants from countries with high incidences of TB (82) and are potentially preventable by screening for latent TB and administering preventive treatment.

The clinical presentation of TB peritonitis in a patient on PD resembles bacterial peritonitis (84). Abdominal pain, fever, and cloudy dialysate are usually evident, although the onset and progression of symptoms is often more subacute than most cases of bacterial infection. Peritoneal WBCs are similar to bacterial cases, with a few hundred to a few thousand WBCs that are predominantly PMNs in most cases (85). The usual clinical course is they are treated empirically for bacterial peritonitis and meet the clinical definition of refractory, culture-negative peritonitis because they do not respond. Cases of refractory peritonitis should prompt repeat cultures and studies for mycobacteria, fungi, and fastidious organisms. In most published series, the diagnostic yield of acid-fast bacilli (AFB) smears of peritoneal fluid in TB peritonitis in PD patients is less than 20% and the yield of peritoneal fluid cultures is around 30% (86). This is because the organisms are growing in granulomas in the peritoneal membrane rather than the fluid itself. Obtaining 50 to 150 mL of peritoneal fluid, centrifuging, and processing the pellet for cultures and smears can increase the yield. Traditionally, the most reliable diagnostic method has been peritoneal biopsy with histology and AFB cultures (87). More recent series in PD patients have reported peritoneal fluid cultures positive in 50% to 100% of patients. The widespread use of the BACTEC liquid culture media systems are probably responsible for the better yield on PD fluid cultures and also reduce the time to culture positivity to 10 to 14 days in most cases rather than 3 to 6 weeks with the traditional mycobacterial culture techniques (84). Another rapid and useful test for TB diagnosis is PCR. These rapid PCR tests were initially approved for direct testing of sputum samples but have been used successfully to detect TB in extrapulmonary specimens (88). The sensitivity of PCR in detecting TB in peritoneal fluid in TB peritonitis has been reported to be 50% or more, and a result is obtained in 2 hours. In summary, the diagnosis of TB peritonitis is challenging but should be considered in the patient with refractory peritonitis with negative bacterial who fails to respond to appropriate empiric therapy.

Positive mycobacterial cultures should be sent for species identification to confirm TB versus NTM and drug susceptibility testing. Most referral laboratories can provide drug susceptibility results in about 2 weeks. Pending these results, therapy with four anti-TB drugs should be started. In patients with end-stage kidney disease (ESKD), the American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America Guidelines recommend isoniazid (INH) 300 mg po qd or 900 mg po three times weekly, pyridoxine 50 mg po qd, rifampin 600 mg po qd or 600 mg po three times weekly, pyrazinamide 25 to 35 mg/kg three times a week, and ethambutol 15 to 25 mg/kg three times weekly (89). If the organism is fully susceptible, ethambutol may be stopped and pyrazinamide discontinued after 2 months. INH and rifampin are continued for a total of 6 months. However, these guidelines were recommended for patients on hemodialysis. The 2016 ISPD guidelines for the treatment of TB peritonitis in PD patients are slightly different (1). The use of ethambutol is discouraged because of the potential risk of optic neuritis, suggesting a fluoroquinolone, ofloxacin 200 mg po qd in its place.

These guideline suggest using INH 300 mg po qd, pyridoxine 50 mg po qd, rifampin 600 mg po qd, pyrazinamide 25 to 35 mg/kg three times a week and ofloxacin. Ofloxacin and pyrazinamide are discontinued after 3 months, and INH and rifampin are continued for a total of 12 to 18 months of therapy. Lui et al. (90) reported a series of 10 CAPD patients with TB peritonitis. Two patients died during therapy, and two were converted to hemodialysis. The remaining six patients were successfully treated with INH rifampin and pyrazinamide for 9 to 12 months. In a subsequent publication, Lui et al. (83) treated 14 CAPD patients with TB peritonitis. Patients were treated for 12 to 15 months with INH, rifampin, ofloxacin, and pyrazinamide. Pyrazinamide was discontinued at 3 months, and the other drugs were continued for a total of 12 to 15 months. PD catheters were left in place during therapy. Nine patients were treated successfully, and the five deaths were not the result of TB infection itself. In summary, the optimal treatment of TB peritonitis in PD patients is not entirely clear regarding specific drugs and duration. The most prudent approach is to use standard antituberculous drugs in the regimens described earlier for about 12 months (91).

The vast majority of cases of TB peritonitis and other sites of infection are due to the reactivation of latent tuberculous infection. All dialysis programs should strongly consider screening patients for latent tuberculous infection as part of preparing for dialysis. This can be done with tuberculin skin testing or blood testing with an interferon-γ release assay (IGRA). Patients with chronic renal insufficiency have an increased risk of being anergic on skin testing and IGRA testing resulting in false-negative screening (92). Patients found to have latent tuberculous infection should be offered therapy for latent tuberculous infection and strongly encouraged to accept it. The standard regimen is INH 300 mg po qd with pyridoxine 50 mg po qd for 9 months. Identifying and treating latent TB infection will greatly reduce the risk of all forms of reactivation TB, including peritonitis.

Nontuberculous Mycobacterial Peritonitis and Exit-Site Infections in Peritoneal Dialysis Patients

NTM are a group of about 150 species, of which about half have been associated with human infections. These organisms are present in the environment, mostly in soil and water, and can cause human infections, but are not spread from person to person. In the past, NTM have been grouped according to Runyon classification, but more recently classified according to growth rates—rapid, intermediate, or slow-growing (92). Most reported cases of exit-site infections and peritonitis in PD patients have been caused by the rapid growers—*Mycobacterium abscessus*, *Mycobacterium chelonae*, and *Mycobacterium fortuitum* (93–99).

NTM have been reported to cause exit-site and tunnel infections as well as peritonitis in PD patients. Particularly with the rapid growing NTMs, exit-site infection is often present or precedes the diagnosis of peritonitis with these organisms. Recent antibiotic use, often for exit-site infection and the use of gentamicin cream for exit-site prophylaxis seem to be common predisposing factors for these infections (100,101). NTM exit-site infections are often described as culture-negative, chronic, and persistent. NTM peritonitis clinically resembles bacterial peritonitis, with fever, abdominal pain, cloudy dialysate, with a few hundred WBC that are usually >50% PMNs. Exit-site or peritoneal fluid sample Gram stains are usually negative but may show a few gram-positive rods, AFB smears are usually negative. The rapid growing NTMs will grow on most standard bacterial culture media but usually take about 5 days and are

often misidentified as “diphtheroids.” These patients are often classified as refractory bacterial peritonitis, which should prompt repeat PD fluid cultures for fastidious bacteria, AFB, and fungi.

Obtaining a positive culture is important to identify the species and obtain drug susceptibility studies, which vary according to the species and within species. The optimal treatment of NTM PD peritonitis is not well defined. Most published studies reporting the treatment of the rapid growing NTMs in PD infections have used culture and sensitivity directed therapy for 2 to 9 months for peritonitis. In most cases, the PD catheter was removed, but in some, in the absence of exit-site or tunnel infection, successful treatment was achieved with the catheter in place. Experience treating NTM PD peritonitis caused by other NTM is sparse and confined to isolated case reports.

PREVENTING PERITONITIS (102)

Reporting Monitoring Peritonitis Rates

ISPD guidelines recommend that each program monitor and report its peritonitis rates, expressed as number of episodes of peritonitis per patient year, the rates for individual organisms, and antibiotic susceptibility (1). The currently recommended benchmark rate is 0.5 episodes of peritonitis per patient-year, or 1 episode every 2 years, by 2016 ISPD guidelines. Relapsing episodes are only counted once. The rates of peritonitis for each individual pathogen should also be reported as episodes per patient-year rather than as percentage of cases.

Continuous Quality Improvement

ISPD guidelines also suggest that each program have a continuous quality improvement (CQI) committee to perform root cause analysis on each PD-related infection to determine if there were modifiable risk factors or potentially preventable causes (103,104).

Peritoneal Dialysis Catheter Placement

Several randomized controlled trials have shown that preoperative antibiotic prophylaxis with cefazolin, cefuroxime, or vancomycin prior to catheter placement reduces the incidence of early postop peritonitis (105). Several randomized controlled trials have compared postop infection rates in patients who underwent PD catheter placement peritoneoscopically, laparoscopically, or via standard laparotomy placement and found very little difference in outcomes (1). Also, placement of the catheter via a midline or lateral incision did not affect peritonitis rates. Other studies have shown no significant difference in infection rates between swan-neck and Tenckhoff catheters or an advantage to a downward facing exit site (102,106,107).

Peritoneal Dialysis—Automated Peritoneal Dialysis versus Continuous Ambulatory Peritoneal Dialysis

At this point, there is no clear definitive evidence that patients using APD have fewer episodes of peritonitis than patients using CAPD. In patients using CAPD, however, the two-bag, Y-connector flush-and-fill technique appears to reduce the rate of peritonitis compared to other methods (1,102). There is also little evidence to suggest that the choice of dialysis solution affects peritonitis rates (1,102).

Peritoneal Dialysis Patient Training

Before the initiation of home PD, patients must be trained by a qualified staff member, usually a nurse (102,108). Training should include the concepts of PD, strict adherence to aseptic technique, connecting and deconnecting procedures, care of the exit site, and recognizing complications such as possible peritonitis and taking appropriate actions. The patients and helpers should demonstrate competence in these areas before attempting home PD. A home visit by a PD nurse after initiating home PD is often useful as well. Retraining at 6-month intervals may be helpful and is indicated after an episode of peritonitis or if there is any change in the patient's PD equipment.

Exit-Site Care

The patient must also be trained in exit-site care during these training sessions, in particular, handwashing and sterile technique when cleaning and dressing the exit site. Using sterile technique, the exit site should be gently cleansed with soap and water. Cleansing with dilute sodium hypochlorite may also reduce exit-site infections (1,102). Daily application of topical antimicrobial agents to the exit site has been shown to reduce exit-site infections and peritonitis. Daily topical mupirocin has been shown to reduce the incidence of *S. aureus* exit-site infections and peritonitis (5). Gentamicin cream applied daily to the exit site can reduce the *S. aureus* and *Pseudomonas* exit-site infections (6,109). Subsequent studies of gentamicin cream revealed increases in *S. aureus*, *Pseudomonas*, and *Enterobacteriaceae* exit-site infections (7) and increases in exit-site infections and peritonitis caused by rapid growing NTM (100,101).

Miscellaneous Sources of Peritonitis and Prophylaxis

Peritonitis may follow endoscopic or other invasive procedures involving the GI or genitourinary (GU) tract. Periprocedure prophylactic antibiotics have been shown to reduce the incidence of peritonitis after colonoscopy, sigmoidoscopy, cystoscopy, and hysteroscopy (1,110). The most commonly used prophylactic regimen has been ampicillin and gentamicin. Transient bacteremia during dental procedures occasionally results in peritonitis. Some authorities recommend the administration of a single dose of amoxicillin before invasive dental procedures as in endocarditis prophylaxis (111).

Finally, most cases of *Candida* peritonitis follow a course of antibiotics for peritonitis or other indications. A number of studies have shown that administering prophylactic oral nystatin (112) or fluconazole (113) concomitant with the antibiotic course can reduce the incidence or secondary *Candida* peritonitis in programs with more frequent episodes of *Candida* peritonitis.

CHAPTER 15

Hypertension in Dialysis Patients

Arjun D. Sinha and Rajiv Agarwal

Hypertension is both a cause (1) and consequence of chronic kidney disease (CKD) across its spectrum of severity, up to and including end-stage kidney disease (ESKD). Despite steady improvement, mortality remains high in the dialysis population with a 5-year survival rate of only 40% (2), which is comparable to some advanced cancers (3). Cardiovascular events remain the leading cause of death in dialysis (4), with hypertension as an important contributor. Thus, the diagnosis and management of hypertension in dialysis is a vital topic to all dialysis patients and providers. This chapter will review the epidemiology, pathogenesis, diagnosis, prognosis, and treatment of hypertension in the dialysis population.

EPIDEMIOLOGY

The diagnosis of hypertension is complicated in the hemodialysis (HD) patient due to the episodic nature of HD and the wide fluctuations in blood pressure (BP) that result, with BP typically highest before the HD session, lowest at the end of the HD session, and slowly rising during the interdialytic period (5). Therefore, the epidemiology of hypertension in HD can vary depending not only on the BP threshold employed but also on when and where BP is measured: in the HD clinic before or after dialysis (termed peridialytic BP) versus outside the dialysis unit using ambulatory BP monitoring (ABPM) or home BP monitoring during the interdialytic period. **TABLE 15.1** summarizes the various methods of assessing BP in HD.

TABLE 15.1 Methods of Hemodialysis Blood Pressure Measurement

Method	Description	Comments
Peridialytic BP	Measured both before and after HD	Easily available but highly variable
Intradialytic BP	Median of all BP measures during one HD run	Easily available but needs more study
Ambulatory BP	Measured every 20–30 min over 44 h between HD runs	Gold standard but cumbersome
Home BP	Measured twice daily at home	Correlates well to ambulatory BP and accessible by most patients

BP, blood pressure; HD, hemodialysis.

Epidemiology Using Peridialytic Blood Pressure Measurements

Numerous observational studies have found a high prevalence of hypertension in HD ranging from 62% to 86% based on peridialytic BP measurements; notably, these studies employed varying threshold BP values ranging from 140/90 mm Hg to 160/90 mm Hg and variously included antihypertensive drug use in their definitions of hypertension (6–9).

More recent analyses of randomized trials have found similar rates of hypertension in the HD population using peridialytic BP. The Hemodialysis (HEMO) study of the late 1990s was a landmark multicenter trial of HD dose and dialyzer flux on survival (10) that recruited clinically stable HD patients (11). An analysis of the baseline characteristics of the first 1,238 subjects randomized into the HEMO study found 72% of the cohort to be hypertensive, defined as peridialytic BP ≥140/90 mm Hg during the baseline HD session (12). This high rate of hypertension was found despite 74% of the cohort receiving antihypertensive medications, with a median of 1.0 drug per subject.

A similarly high prevalence for hypertension was found when the BP data from another large randomized trial from the late 1990s was examined in detail (13). The original study was a double-blind and placebo-controlled clinical trial of sodium ferric gluconate that enrolled 2,535 clinically stable HD patients (14). With hypertension defined as pre-HD BP >150/85 mm Hg averaged over 1 week or the use of antihypertensive medications, an analysis of baseline data found a prevalence of 86% for hypertension in this cohort (13). Within the hypertensive subjects, only 30% were controlled, while 12% were not treated pharmacologically and 58% were treated but still uncontrolled (13), which is similar to previous reports (8).

Epidemiology Using Ambulatory Blood Pressure Measurements

A recent single-center study of 369 prevalent and clinically stable HD patients employed 44-hour interdialytic ABPM and found a prevalence for hypertension at 86% using a definition of hypertension as average ambulatory BP of ≥135/85 mm Hg or antihypertensive drug use (15); this prevalence is similar to prior small studies of ABPM in HD (16). In the cohort of 369 patients, hypertension was treated with medications in 89% of patients but was controlled adequately in only 38% of patients (15).

Thus, whether using peridialytic BP measurements or 44-hour ABPM, hypertension is common in the HD population with a prevalence ranging from 70% to 85%, and a majority of these affected patients have poor control of their hypertension.

Epidemiology in Peritoneal Dialysis Patients

It has been suggested that peritoneal dialysis (PD) controls hypertension better than HD; for example, a single-center study of 56 prevalent and clinically stable PD patients found that only 9% of the cohort was hypertensivew with BP >140/90 mm Hg by standardized auscultation as compared to a hypertension prevalence of 56% in the same center's HD unit (17). Similarly, control of BP was compared in the retrospective Peritoneal Dialysis Core Indicators Study in the mid-1990s that found among the 926 PD patients with BP data, only 35% were hypertensive with BP >150/90 mm Hg, and the cohort having an average BP of 139/80 mm Hg as compared to a contemporaneous cohort of HD patients whose average pre-HD BP was 151/79 mm Hg and post-HD BP 137/74 mm Hg (18). A larger study using United States Renal Data System (USRDS) data from the Dialysis Morbidity and Mortality Wave 2 study in the late 1990s found that from 1,034 PD patients, only 54% had systolic BP (SBP) of >140 mm Hg while on a mean of 1.6 antihypertensive medications (19), as compared to the 70% to 85% prevalence of hypertension in HD.

However, the reduced prevalence of hypertension among PD patients is not a universal finding. A prospective study of 504 prevalent and clinically stable PD patients found a prevalence of 88% for hypertension defined as BP >140/90 mm Hg or use of antihypertensive medications, and among the hypertensive patients, only 16% were adequately controlled (20). Additionally, 24-hour ABPM was performed, and of the 414 adequate examinations, hypertension was present in 69% based on BP load >30%, with load defined as the percentage of ambulatory BP readings >140/90 mm Hg during the day or >120/80 mm Hg at night. Another study utilized ABPM to compare 22 HD patients versus 24 PD patients that were well matched for major clinical characteristics and found no significant difference in either daytime or nighttime BP between the two groups (21). Thus, while some studies suggest that hypertension control is superior among PD patients versus HD patients, there is no conclusive evidence that this is the case.

PATHOGENESIS

As both a cause and consequence of kidney disease, the pathogenesis of hypertension in CKD not only shares commonalities with the general hypertensive population but also has complicated causes that are unique to kidney disease and its treatment. **TABLE 15.2** summarizes the major modifiable causes of hypertension in dialysis.

TABLE 15.2 Major Treatable Causes of Hypertension in Dialysis

Cause	Treatment
Obstructive sleep apnea	Continuous positive airway pressure
Volume overload	Dry-weight reduction
Renin-angiotensin-aldosterone system	ACEI, ARB, and spironolactone
Sympathetic overactivity	β-Blockers, renal nerve ablation
Erythropoietin	Reduce dose

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker.

Risk Factors in Common with the General Population

Patients with CKD often carry a burden of preexisting primary hypertension prior to the recognition of their kidney disease. Additionally, risk factors in the general hypertensive population are similarly present in the CKD population including obesity, excessive salt intake, alcohol consumption, and physical inactivity. Two additional comorbidities contributing to hypertension are important to consider, namely, arterial stiffness and obstructive sleep apnea (OSA).

Arterial stiffness, measured as pulse wave velocity, is elevated in dialysis patients (22,23), and it has long been recognized as a risk factor for cardiovascular events in both the general hypertensive population (24) and in the dialysis population (25,26). It is in this setting that a study of 125 subjects on HD found increased pulse wave velocity to be significantly associated with increased 44-hour interdialytic ambulatory BP (27), as illustrated in **FIGURE 15.1**.

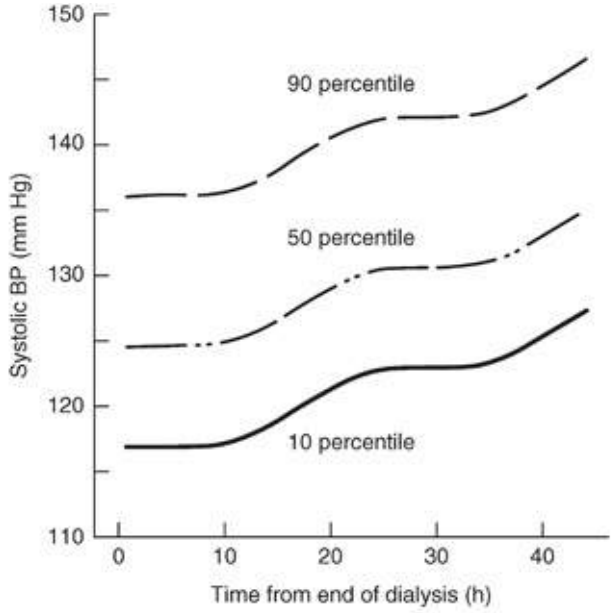

FIGURE 15.1 Impact of aortic pulse wave velocity on ambulatory blood pressure (BP) between two consecutive dialysis sessions in 125 subjects; 10th percentile of pulse wave velocity 4.1 m/s (*solid line*), 50th percentile 6.0 m/s (*dashed and dotted line*), and 90th percentile 10.6 m/s (*dashed line*). [Adapted from Agarwal R, Light RP. Arterial stiffness and interdialytic weight gain influence ambulatory blood pressure patterns in hemodialysis patients. *Am J Physiol Renal Physiol* 2008;294(2):F303–F308, with permission.]

In the general population, OSA frequently coexists with hypertension (28–30), with hypopnea leading to hypoxemia and ultimately to sympathetic activation. OSA is strongly linked with resistant hypertension as the presence of OSA is a risk factor for resistant hypertension and the severity of OSA correlates with the severity of hypertension (31–33). Given this link, it is important to note that OSA is very common in the setting of CKD with the prevalence increasing with declining kidney function (34), culminating in a prevalence over 50% for those patients on dialysis (34,35). The association between OSA and resistant hypertension is similarly strong in ESKD as a recent cohort study of subjects with advanced CKD including 75 subjects on HD and 20 on PD found a sevenfold increased risk of resistant hypertension in those dialysis patients with severe OSA (36). Interestingly, there is a growing recognition that OSA itself is caused or exacerbated by volume overload that leads to parapharyngeal edema, which worsens at bedtime in the recumbent position, both in patients without CKD (30) and in those with ESKD (37,38).

While most studies of continuous positive airway pressure (CPAP) for OSA in the non-CKD population find significant improvement in BP, this improvement is typically modest compared to medication (39), with CPAP use yielding a 1.7 mm Hg improvement in mean 24-hour ambulatory BP (40),

so similarly modest improvements would be expected with CPAP treatment in ESKD.

Classical Mechanisms of Hypertension in Dialysis: Volume Overload and the Renin-Angiotensin-Aldosterone System

The two mechanisms classically felt to be responsible for hypertension in the "renoprival" state of ESKD are volume overload and an inappropriately activated renin-angiotensin-aldosterone system (RAAS) (41). Sodium loading has long been clinically recognized as a major and essential contributor to hypertension both in those with normal kidney function (42) and in the setting of kidney disease. As the glomerular filtration rate (GFR) declines, less sodium is filtered leading to sodium retention and to an expanded extracellular fluid volume. The increased plasma volume leads to increased cardiac output and then to increased total peripheral resistance, whereby normal kidney autoregulation would lead to a pressure natriuresis and normalization of BP (43); however, this natriuresis is incomplete or absent in advanced CKD and ESKD, and the increased total peripheral resistance persists. While ultrafiltration has been recognized as an effective means of BP control in ESKD for decades since the earliest days of chronic dialysis (44), only recently has a randomized clinical trial, the Dry-Weight Reduction in Hypertensive Hemodialysis Patients (DRIP) trial, confirmed this truism (45).

The other classically recognized contributor is an inappropriately activated RAAS (46), possibly provoked by kidney ischemia in patients with renovascular disease or by regional intrarenal ischemia due to kidney fibrosis. As expected, angiotensin-converting enzyme inhibitor (ACEI) therapy has been shown to be effective at reducing BP in dialysis patients (47,48).

Novel Mechanisms of Hypertension in Dialysis

In addition to the two classically recognized causes of hypertension in dialysis patients, several additional contributors have gained widespread acceptance including increased sympathetic nervous system activity, altered vascular endothelial function, and erythropoiesis-stimulating agents.

Sympathetic Nervous System Overactivity

Among the novel mechanisms of hypertension in advanced kidney disease, sympathetic overactivity is now widely recognized as a contributor. Increased catecholamine levels (49) and increased catecholamine sensitivity (50) in CKD were both demonstrated in the 1980s, and increased catecholamine levels have been shown to predict cardiovascular events and mortality in chronic HD patients (51). Unidentified uremic toxins were originally thought to provoke this sympathetic overactivity; however, Converse et al. (52) implicated the diseased kidneys themselves via experiments where they measured muscle sympathetic nerve activity in three groups of subjects: those on chronic HD with their native kidneys, those on chronic HD status post bilateral nephrectomy, and normal controls (52). They found increased sympathetic activity and higher BP in those chronic HD patients still with their native kidneys, but those subjects who were surgically anephric had sympathetic nerve activity and BP similar to the normal controls. Uremic toxins do not appear to be the cause of the increased kidney afferent nerve signals that increase sympathetic activity, as demonstrated by studies of patients who have had kidney transplantation and still retain their native kidneys (53), but kidney ischemia is a likely contributor (54). As further evidence, a pilot study of kidney denervation by endovascular radioablation with a before-after design performed in 12 chronic HD patients with resistant hypertension showed a significant

improvement in BP (55); however, with a recent negative result from a large randomized clinical trial employing this technique in subjects without CKD, it may not be developed further (56).

Another unique contributor to sympathetic overactivity in ESKD is renalase, which was discovered only in the last 10 years (57). Renalase is a circulating monoamine oxidase enzyme that is produced primarily by the kidney that metabolizes circulating catecholamines and which is deficient in ESKD (58). As a novel mechanism contributing to hypertension in ESKD, it remains to be demonstrated via clinical trials what improvement in BP may be achieved by increasing levels of renalase in the dialysis population.

Altered Endothelial Function

Additional factors contribute to increased vasoconstriction in kidney disease, including altered endothelial cell function such that there is an imbalance in the levels of endothelial derived vasoconstrictors versus vasodilators. Nitric oxide is a potent vasodilator and is synthesized by endothelial nitric oxide synthase (eNOS) from L-arginine; however, a circulating inhibitor of eNOS has been identified in CKD patients, asymmetric dimethyl arginine (ADMA) (59). ADMA is a product of protein metabolism that is excreted into the urine by the healthy kidney, competitively inhibits eNOS, and causes local vasoconstriction on experimental infusion, and ADMA levels are elevated in ESKD (60). Elevated ADMA levels have also been shown to predict cardiovascular events and mortality in a cohort of 225 chronic HD patients (61). It remains to be demonstrated via interventional trials what improvement, if any, reductions in ADMA will make to hypertension in the dialysis population.

On the side of vasoconstriction are endothelins, which are released from the basolateral surface of endothelial cells and exert autocrine and paracrine functions that include mediating vasoconstriction via the endothelin-A receptor on vascular smooth muscle (62). Endothelin levels have been found to be elevated in various stages of CKD including ESKD (63,64). Endothelin receptor antagonists have shown efficacy for reducing BP in randomized controlled trials in primary (65) and resistant hypertension (66,67) as well as in diabetic nephropathy (68). However, some results have been mixed with divergent BP results between office and ABPM (67,68), and adverse events including edema have been frequent.

Erythropoiesis-Stimulating Agents

Conventional medications such as over-the-counter nonsteroidal anti-inflammatory drugs and decongestants can exacerbate hypertension; however, erythropoiesis-stimulating agents (ESAs) are commonly prescribed for the anemia of CKD, and resultant hypertension has been recognized since the early days of ESA use in ESKD (69). The incidence of hypertension provoked by ESA administration is associated with the ESA dose but is independent of red blood cell mass or viscosity (70,71). While the exact mechanism of how ESA use causes hypertension is unknown, the current evidence suggests that it is mediated via vasoconstrictor effects, likely through increased levels of endothelin-1 or increased vasoconstrictive response to that peptide (72–74).

Up to 30% of dialysis patients develop hypertension or require an adjustment in antihypertensive medications with ESA use (75,76), while the rise in BP with ESA use typically ranges from 5 to 8 mm Hg in SBP and 4 to 6 mm Hg in diastolic blood pressure (DBP) (77). The rise in BP with ESA administration is more likely in those with baseline hypertension (78) or a family history of hypertension (79). There is

unfortunately a dearth of evidence to guide the prevention of ESA-induced hypertension but recommended strategies include changing to subcutaneous administration, reducing the goal hemoglobin level in those who are unresponsive to ESA therapy, minimizing the ESA dose by starting low and increasing slowly, and avoiding ESA use entirely (80).

DIAGNOSIS

ABPM is the accepted gold standard for diagnosing hypertension in the general population and in the ESKD population on dialysis (81–84). The use of ABPM permits the diagnosis of nocturnal hypertension, which is common in the ESKD population (85,86), and it is also superior to peridialytic BP measurements for correlating to end organ damage manifest as left ventricular hypertrophy (LVH) (87) and for predicting the outcome of mortality (88). The proper ABPM technique includes employing a validated monitor (89) to measure BP every 20 minutes during the day from 6 AM to 10 PM and then every 30 minutes at night from 10 PM to 6 AM (90). This prolonged interval of measurement permits observation of the full change in BP during the interdialytic period, where SBP increases an average of 2.5 mm Hg every 10 hours (5,27), as depicted in **FIGURE 15.2**.

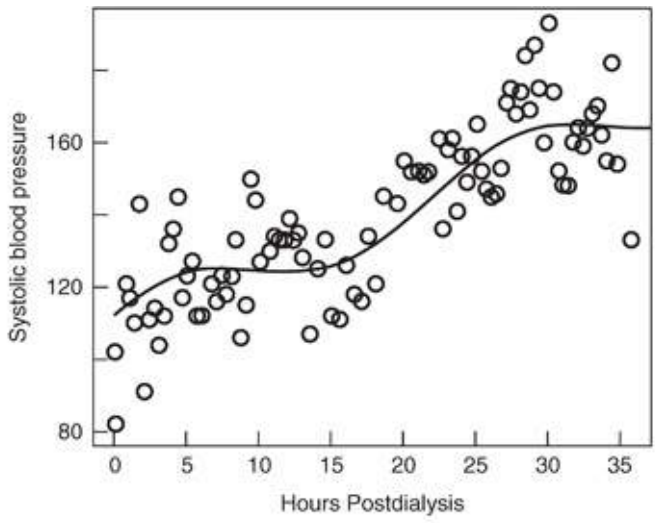

FIGURE 15.2 An example of observed interdialytic blood pressure (BP) values with fitted trended cosinar curve in an individual hemodialysis patient. [Adapted from Kelley K, Light RP, Agarwal R. Trended cosinor change model for analyzing hemodynamic rhythm patterns in hemodialysis patients. *Hypertension* 2007;50(1):143–150, with permission.]

While ABPM is the gold standard method for diagnosing hypertension, it is also cumbersome to use especially over 44 continuous hours so it remains a research technique in ESKD. More convenient methods of routinely measuring BP and diagnosing hypertension must be employed in the dialysis population. Since BP changes both during the HD session and during the interdialytic interval, there remains uncertainty about how best to diagnose and manage hypertension in the HD population, and this uncertainty contributes to both under treatment (16,91) and to over treatment of hypertension (92). Further complicating matters, HD patients have significant seasonal BP variability with lower BP during the summer and higher during the winter (93), potentially due to temperature mediated vasodilation or sweat induced volume losses.

Classically, the peridialytic BP measures taken before and after an HD session have been used to diagnose and manage hypertension, and while there are no randomized clinical trials to guide goal BP

recommendations in ESKD, long-standing professional guidelines have employed peridialytic BP values. The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF-KDOQI) guidelines recommend to target pre-HD BP <140/90 mm Hg and post-HD BP <130/80 mm Hg (94). Unfortunately, making treatment decisions based on peridialytic BP can be associated with adverse outcomes, as shown by a study of 11 HD units in London, England, that found those HD units with more patients reaching the post-HD BP goal had significantly more episodes of symptomatic hypotension requiring saline infusion (95). Peridialytic BP is highly variable such that the variability within a given patient over time is similar to the variability between patients (96), possibly due in part to these measurements often being made without attention to technique (97). While peridialytic BP does have a statistically significant relationship to gold standard interdialytic ABPM (98), a meta-analysis of 18 studies comparing peridialytic BP and interdialytic ABPM found very wide limits of agreement between the techniques such that peridialytic BP provides a very imprecise estimate of interdialytic BP (99). In the meta-analysis, the limits of agreement between pre-HD SBP and interdialytic ambulatory SBP ranged from +41.7 mm Hg to −25.2 mm Hg and the limits of agreement for post-HD SBP were similarly wide, which illustrates the reduced clinical utility of a diagnosis of hypertension or normotension based on peridialytic BP for an individual HD patient (99).

A readily available alternative to peridialytic BP is to use all the BP measurements made during a single midweek HD session to calculate a median BP, which is easier to calculate at the bedside compared to mean BP. A study of 150 chronic HD patients found that median intradialytic BP had the best reproducibility and was superior to either pre- or post-HD BP or their average for predicting 44-hour interdialytic ambulatory BP (100). In this study, median intradialytic SBP >140 mm Hg during a midweek HD session had an 80% sensitivity and specificity for diagnosing hypertension by gold standard ABPM (100). Median intradialytic BP has also been shown to change in response to interventional reduction in dry weight to reduce BP (101), adding further support for the clinical usefulness of this easily calculated measure.

After peridialytic BP and median intradialytic BP, home BP monitoring is the third alternative to the clinically inconvenient gold standard of ABPM. Home BP monitoring is the recommended method of both the American Heart Association (102) and the European Society of Hypertension (103) for the routine diagnosis and management of BP in the general hypertension population and its use is feasible and practical both in patients with CKD and ESKD (104,105). Importantly, home BP monitoring is superior to peridialytic BP measurements by *every* methodologic and clinical standard. This includes superior correlation with gold standard ABPM (106), week-to-week reproducibility (107), the ability to reflect BP changes from interventional probing of dry weight (107), correlation to the end-organ damage of LVH (87,108), and predicting outcomes including cardiovascular events (109) and mortality (109,110). **TABLE 15.3** summarizes the advantages of home BP monitoring.

TABLE 15.3 Advantages of Home Blood Pressure Monitoring over Peridialytic Blood Pressure

1. Predicts gold standard ambulatory BP
2. Reproducibility
3. Reflects changes in dry weight
4. Correlates to left ventricular hypertrophy
5. Predicts cardiovascular events
6. Predicts mortality
7. Randomized trial evidence for efficacy of BP control
8. Recommended by major professional societies

BP, blood pressure.

Two small randomized trials have found home BP monitoring to be beneficial versus usual care for management of BP in HD patients. The first randomized 34 patients to home BP monitoring plus usual care versus usual care only over 12 weeks and found that the home BP group had significantly lower BP at the end of the study (111). A subsequent trial of 65 HD patients randomized participants to usual hypertension care based on pre-HD BP versus open label monthly home BP monitoring for 6 months (112). At the end of the trial, the home BP monitoring group had a significant reduction in ambulatory SBP both from baseline and versus the usual care group, which had no change in ambulatory SBP from baseline. However, the primary endpoint of reduction in echocardiographic LVH was no different between groups, possibly due to lack of power and variability in the timing of the echocardiograms relative to the HD schedule (112).

As with ABPM, home BP increases between HD sessions, at an average rate of 4 mm Hg every 10 hours (113), so it is important to adequately sample home BP at spaced intervals between HD sessions. Randomized trials have used protocols of home BP monitoring performed twice daily over 4 to 7 days once per month (112,114), and we recommend a similar regimen for routine clinical use and decision making. Measurements performed more than once per month may be needed in more unstable patients including those recently discharged from the hospital. **TABLE 15.4** summarizes our suggested method of home BP monitoring.

TABLE 15.4 Suggested Method for Home Blood Pressure Monitoring

1. Check both morning and evening.
2. Check for 4–7 consecutive days duration.
3. Check once monthly or more often if clinically unstable.
4. Goal home blood pressure ≤140/90 mm Hg.

There are no randomized trials comparing goal BP levels in the dialysis population using any of the available BP methods including peridialytic BP, intradialytic BP, home BP, or interdialytic ambulatory BP. However, the American Heart Association defines hypertension as home BP >135/85 mm Hg on average for the general population (102), so we advocate for an interdialytic home BP target of ≤140/90 mm Hg as a reasonable goal (80), which was the target used in a recent large randomized trial of BP control in HD (114). Notably, the results of the randomized controlled Systolic Blood Pressure Intervention Trial (SPRINT) were published in November 2015 showing improved cardiovascular outcomes in over 9,000 subjects randomized to office SBP target <120 mm Hg versus a conventional target of <140 mm Hg (115). While subjects with CKD were included in the trial, those with estimated GFR <20 mL/min/1.73 m^2 or ESKD were excluded so no direct conclusions can be drawn from the trial

regarding the management of hypertension in the dialysis population.

Intradialytic Hypertension

The focus of diagnosis and treatment of hypertension in chronic HD is on interdialytic BP between HD sessions, but the case of intradialytic hypertension merits special mention. BP normally declines during the HD, but approximately 5% to 15% of chronic HD patients have a paradoxical rise in BP during the HD session (116). Intradialytic hypertension has been described variously, and there currently is no universally accepted definition. Definitions have included (a) a change in SBP or mean arterial pressure from pre-HD to post-HD greater than a given threshold ranging from >0 mm Hg to ≥10 mm Hg change (117,118), (b) a positive slope after regression of all intradialytic SBP values (119), or (c) BP increase during or immediately following HD resulting in post-HD BP >130/80 mm Hg (116).

Intradialytic hypertension has recently been recognized to be associated with worse outcomes. Inrig et al. (120) performed a secondary analysis of a randomized clinical trial including 443 prevalent HD subjects and found intradialytic hypertension to be significantly associated with greater mortality at 6 months (117). Similarly, in a subsequent observational study of a cohort of 1,748 incident HD patients, Inrig et al. (120) found 2-year survival to be significantly decreased for each 10 mm Hg increase in SBP from pre-HD to post-HD BP; however, this relationship was limited to those patients whose pre-HD SBP was <120 mm Hg. Most recently, a prospective cohort study of 115 prevalent HD patients found an average pre-HD to post-HD rise in SBP of >5 mm Hg to significantly predict both all-cause and cardiovascular mortality (121).

Intradialytic hypertension has been associated with interdialytic hypertension as measured by 44-hour ABPM (118,119), so it is not surprising that the same mechanisms implicated in causing interdialytic hypertension between HD sessions have also been implicated in causing intradialytic hypertension during the HD session (116), but the preponderance of evidence currently points to volume overload and endothelial dysfunction. Markers of volume overload such as increased cardiothoracic ratio has been associated with intradialytic hypertension (121), but most importantly, interventional trials have shown volume removal through dry-weight reduction improves intradialytic hypertension. An early study from the mid-1990s included seven patients with intradialytic hypertension and found them all to have marked cardiac dilation and to be very hypertensive with mean pre-HD BP 172/99 mm Hg despite medications (122). Dry weight was reduced in all subjects with an average weight loss of 6.7 kg that was associated with an improvement in pre-HD BP by 46/21 mm Hg despite discontinuation of all BP medications. More recently, a secondary analysis of the DRIP trial (45) regressed the intradialytic BP values for the 150 trial subjects and found that the quintile of subjects with the greatest reduction in dry weight, more than 0.94 kg reduction after the first 4 weeks of the trial, also had the most positive BP slope at baseline as they were the only quintile with intradialytic hypertension by this definition (119). Importantly, after subsequent lowering of dry weight, this same quintile had reduction in BP slopes at the finish of the trial, meaning their intradialytic hypertension had resolved such that their BP slopes were similar to the other subjects. Thus, intradialytic hypertension appears to be a marker of volume overload that is amenable to dry-weight reduction.

Endothelial dysfunction has also been identified as an important mediator as there is evidence both for a rise in endothelin-1 levels (123) and a decrease in nitric oxide during HD (124) in patients with intradialytic hypertension. The contribution of endothelial function was investigated in 25 HD patients

recruited in an 8-week pilot study with a before-after design using carvedilol (125), which has been shown to block endothelin-1 release *in vitro* (126). Subjects were given carvedilol up to a dose of 50 mg twice a day, and while endothelin-1 levels were unchanged on carvedilol, flow-mediated dilation significantly improved (125). Of clinical importance, the frequency of intradialytic hypertension was significantly reduced from 77% of HD sessions down to 28% of sessions and average 44-hour interdialytic ambulatory SBP was also reduced from 155 mm Hg to 148 mm Hg with carvedilol treatment.

Thus, based on the available evidence, a renewed focus on addressing volume overload should be a priority for those patients with a paradoxical rise in BP on HD, and specifically targeting endothelial dysfunction with agents such as carvedilol can also be considered. The features of intradialytic hypertension are summarized in **TABLE 15.5**.

PROGNOSIS

Despite a strong and direct relationship between hypertension and both cardiovascular and all-cause mortality (127) and copious evidence of benefit for treatment of hypertension in the nondialysis population (128), the relationship between BP and outcomes in dialysis patients remains a topic of controversy (129,130). A variety of studies have found an association between peridialytic hypertension and strokes (131), heart failure (132), arrhythmias (133), cardiovascular events (134), and all-cause mortality (135). However, other studies suggest that peridialytic hypertension is protective and lower BP is associated with worse mortality (6,136–138), and the risk of normotensive BP is magnified when BP is considered as a time dependent covariate (136,138). This paradoxical relationship between BP and mortality has been termed the *reverse epidemiology* of hypertension (130) and has raised concern that treatment of hypertension may be harmful (139).

When examining the prognostic value of hypertension in dialysis, it is important to additionally consider the severity of comorbid illness as well as dialysis vintage. These interactions are illustrated by a retrospective cohort study of 2,770 prevalent PD patients where a fully adjusted analysis found higher SBP, DBP, mean arterial pressure, and pulse pressure, all to be associated with decreased mortality during the first year on dialysis (140). However, higher SBP and pulse pressure were associated with increased mortality for those patients on dialysis ≥6 years. Similar findings were shown in a cohort of 16,959 HD patients where SBP <120 mm Hg was associated with increased mortality within the first 2 years of starting dialysis, but SBP >150 mm Hg was associated with increased mortality among those that survived at least 3 years (141). These findings suggest lower BP may be an indicator of more severe illness in those patients new to dialysis who are likely to have advanced chronic but unstable systemic comorbidities that recently culminated in ESKD, whereas the survivors that have been on dialysis for at least 3 to 6 years have a more normal relationship between hypertension and outcomes because they are

less acutely ill. This explanation is further bolstered by the subgroup in the PD cohort who were listed for transplant within 6 months of starting dialysis, as in this healthier subgroup higher SBP, DBP, mean arterial pressure, and pulse pressure were not associated with improved mortality during the first year of dialysis (140).

The technique of BP measurement also contributes to the controversial relationship between BP and outcomes as the reverse epidemiology of hypertension is primarily a phenomenon of peridialytic BP values. Ambulatory BP, however, has a strong relationship with mortality on HD, first demonstrated by Amar et al. (142) in a study of 57 HD patients. Alborzi et al. (110) have confirmed the relationship between ambulatory BP and mortality in a cohort of 150 HD patients, and in the same cohort, they also demonstrated home BP to have a similarly strong relationship with mortality. In an expanded cohort of 326 HD patients followed for a mean of 32 months, Agarwal (88) subsequently has shown increased mortality at the extremes of ambulatory and home BP and that mortality was best at a home SBP 120 to 130 mm Hg and ambulatory SBP 110 to 120 mm Hg, while peridialytic BP had no relationship with mortality in this cohort. Most recently, an analysis of the Chronic Renal Insufficiency Cohort (CRIC) study compared pre-HD SBP and out of HD unit SBP for prediction of mortality in the 403 subjects who started HD since the start of the study (143). There were 98 deaths over a mean follow-up of 2.7 years and pre-HD SBP showed a U-shaped relationship to mortality consistent with reverse epidemiology of hypertension. However, in the 326 subjects who had BP checked out of the HD unit in a standardized manner during a research visit, there was a significant and direct linear relationship between BP and mortality with hazard ratio 1.26 for every 10 mm Hg rise in SBP, which further emphasizes the importance of BP measurement technique when considering prognosis (143).

Thus, while there is concern for reverse epidemiology of hypertension when analyzing peridialytic BP, which would suggest that lowering BP would be harmful in HD patients, the evidence from ambulatory and home BP studies do not support those conclusions. Additionally and significantly, the evidence from two meta-analyses of randomized clinical trials of antihypertensive medication use in HD found cardiovascular benefit rather than harm with active treatment (144,145), so based on the available evidence, we strongly recommend to actively diagnose and treat hypertension in dialysis patients.

TREATMENT

Hypertension is common and poorly controlled in dialysis, and it often requires a combined approach to achieve adequate control of BP. The cornerstone of therapy is nonpharmacologic control of volume overload, but pharmacology therapy is frequently necessary, and invasive treatments have a long and recurrent history for the management of hypertension in dialysis patients.

Volume Control

The focus of nonpharmacologic treatment of hypertension on dialysis is to treat volume overload through complementary strategies, both to reduce sodium intake by dietary sodium restriction and individualization of the dialysate sodium while also augmenting sodium removal by dry-weight reduction, providing adequate time on dialysis, and considering frequent dialysis. **TABLE 15.6** summarizes the nonpharmacologic treatment of hypertension in dialysis. The archetype for this multipronged management of hypertension on dialysis is reported by Charra (146) from Tassin, France, where patients are dialyzed

for extended hours on a low-sodium dialysate, and low-sodium diet is emphasized to such a degree that low-sodium bread is provided to the patients. They report excellent control of BP despite antihypertensive medication use at only 1% to 2% (147), as well as low mortality with a 5-year survival rate reported at 87% (148), which is more than twice the current reported 5-year survival rate in the United States (2). More recently, a trial of low-sodium diet and dry-weight reduction in 19 hypertensive HD patients with a before-after design found this combined strategy reduced echocardiographic LVH (149). Similar results have been reported in PD from a single center, where all 47 of the center's hypertensive patients had their antihypertensive medications withdrawn and BP was subsequently successfully controlled in 37 patients with a combination of strict low-sodium diet and added ultrafiltration (150). A consistent feature of all these examples is the multifaceted approach to volume control requiring not only reduction in dry weight but also strict attention to reducing dietary and dialysate sodium as well as maximizing the probability of successful dry-weight reduction by providing adequate time on dialysis.

TABLE 15.6 Complementary Components of Nonpharmacologic Treatment of Hypertension on Dialysis

4. Adequate time on dialysis
5. Consideration of frequent dialysis

Dry-Weight Reduction

Malignant hypertension was common in ESKD prior to the advent of chronic HD, and since those earliest days, ultrafiltration has been recognized as an effective means of BP control in ESKD (44), including for the very first chronic HD patient in the United States, Clyde Shields, under the care of Dr. Belding Scribner (151). Only recently has the randomized controlled DRIP trial of dry-weight reduction definitively confirmed those original observations (45). The DRIP trial recruited 150 chronic and stable HD patients with hypertension confirmed by 44-hour interdialytic ABPM despite being on an average of 2.6 antihypertensive medications who were then randomized in a two-to-one ratio to intervention versus usual care for the 8-week trial. All subjects had their antihypertensive medications and their prescribed time on HD kept stable, and all were visited by a study physician on each HD session during the trial. The intervention group received progressive reduction in dry weight by at least 0.2 kg each HD session until they had symptoms of hypovolemia. Compared to the control group at 8 weeks, the intervention group had 1 kg of weight reduction and average 44-hour interdialytic ambulatory BP improved by 6.6/3.3 mm Hg (45), as illustrated in **FIGURE 15.3**. Notably, by design, those in the intervention group necessarily had to have symptoms of hypovolemia before dry-weight reduction was stopped, but despite this requirement, there was no change in any domain of the Kidney Disease Quality of Life questionnaire during the trial. Additionally, it is important to note that the DRIP trial improved BP with additional ultrafiltration without extending time on HD, which is a finding supported by older observational studies that suggest BP can be improved without extending time on HD provided volume overload is successfully reduced (152).

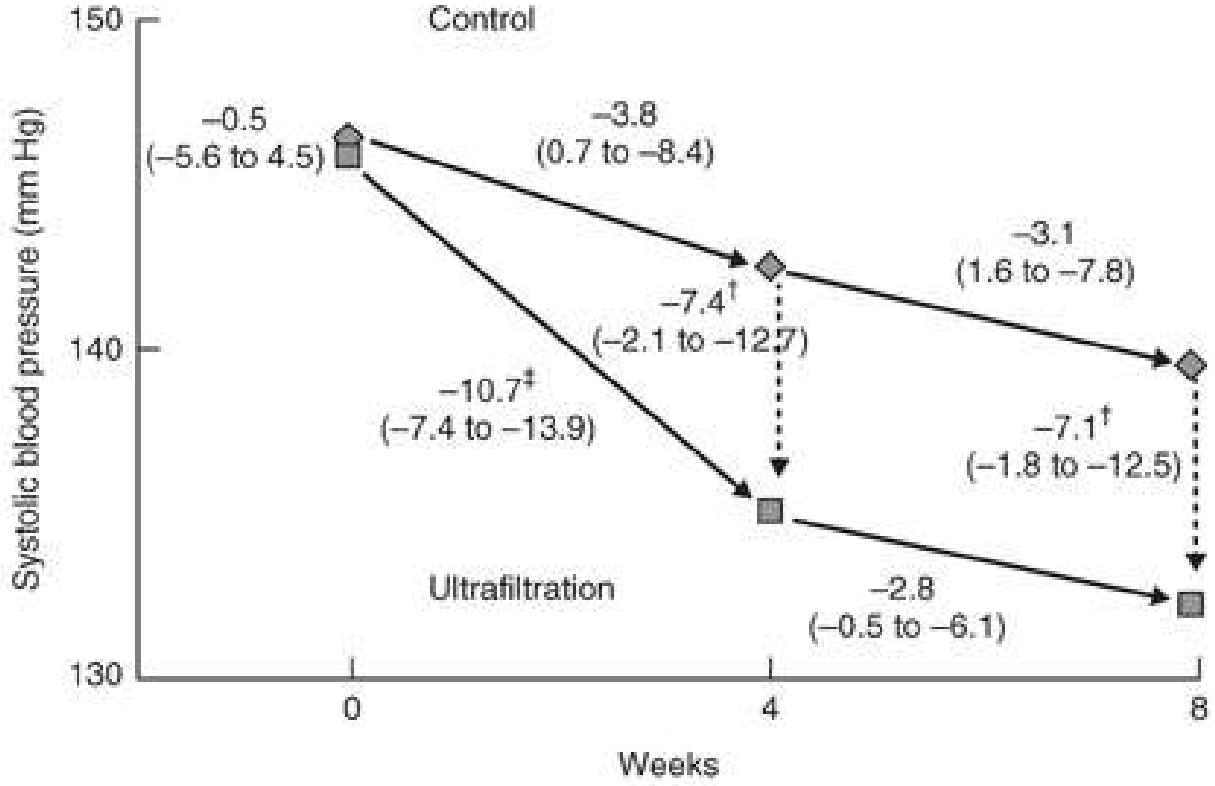

FIGURE 15.3 The effect of dry-weight reduction on interdialytic ambulatory systolic blood pressure (BP) in hypertensive hemodialysis patients. The mean systolic BPs are shown for the control and ultrafiltration groups. The mean changes in BP are shown for weeks 4 and 8 after randomization (*solid arrows*) as well as the mean differences in BPs (*dotted arrows*) between the two groups at each 4-week interval. The numbers next to the *dotted lines* connecting the data points are the mean changes in BP between groups at 4 and 8 weeks after randomization. The 95% confidence intervals are given in parentheses. †$p < 0.01$ and ‡ $p < 0.001$ indicate significant differences between groups or within groups. [Adapted from Agarwal R, Alborzi P, Satyan S, et al. Dry-weight reduction in hypertensive hemodialysis patients (DRIP): a randomized, controlled trial. *Hypertension* 2009;53(3):500–507, with permission.]

Management of Dry Weight

Unfortunately, there is no single universally accepted definition of dry weight. We suggest a reasonable definition of dry weight to be the lowest tolerated post-HD weight achieved via gradual change in post-HD weight at which there are minimal signs or symptoms of either hypovolemia or hypervolemia (153). Thus, achieving and maintaining an adequately low dry weight is a hands-on and iterative process that requires attention to details beyond only the prescribed dry weight (154), including adherence to a low-sodium diet, minimization of dialysate sodium content, providing adequate time on HD, and consideration of more frequent dialysis.

When deciding whether to adjust the dry weight prescription, the first step is the assessment for volume overload. Unfortunately, while the routine clinical exam performs well at detecting acute or massive volume overload, it performs poorly for detecting subtle and chronic volume overload (153). This is illustrated by a cross-sectional study of 150 chronic HD patients that found the presence of pedal edema to have no correlation with putative objective markers of volume overload including brain natriuretic peptide, echocardiographic inferior vena cava diameter, or relative plasma volume slope (155). As another example, it is important to consider that all the hypertensive subjects of the DRIP trial were at their clinical dry weight as determined by their primary nephrologist to start the trial, yet the subjects of the intervention group had their dry weight successfully reduced, which resulted in a clinically significant improvement in 44-hour ambulatory BP (45). This further highlights the difficulty in detecting

subtle volume overload that if ameliorated by means of dry-weight reduction will result in improved BP.

A number of experimental objective measures of volume status have been studied including natriuretic peptides, inferior vena cava diameter, relative plasma volume monitoring, and bioelectrical impedance analysis (156). The latter two have the most supporting evidence with a secondary analysis of the DRIP trial showing that baseline relative plasma volume monitoring identified the most volume overloaded subjects, who subsequently had the largest average reduction in weight at 1.5 kg and the largest improvement in ambulatory SBP at 12.6 mm Hg (157). Most recently, a randomized trial of bioelectrical impedance analysis to guide dry weight management in a cohort of largely normotensive HD subjects found a significant improvement in LVH as well as improvement in peridialytic BP despite reductions in antihypertensive drug use for the intervention group (158).

However, these objective measures of volume status remain investigational and remain to be adequately validated. Therefore, the onus is on the treating nephrologist to have a high index of suspicion for occult volume overload. Signs that should prompt consideration for reduction in dry weight include uncontrolled hypertension, especially in those patients who are on multiple medications such as in the DRIP trial where subjects were on an average of 2.6 antihypertensive drugs at baseline (45). Numerous studies have shown that greater antihypertensive drug use is associated with worse control of hypertension (15,159), which is plausibly due to inadequately addressed volume overload which could be improved with reduction in dry weight. **TABLE 15.7** summarizes the clinical signs of volume overload.

TABLE 15.7 Clinical Signs of Volume Overload on Dialysis

1. Elevated interdialytic blood pressure by home or ambulatory monitoring
2. Multiple antihypertensive medications
3. Low interdialytic weight gain
4. Constellation of symptoms and signs such as peripheral edema, cardiomegaly, elevated jugular venous pressure, pulmonary congestion, pleural effusion

Another sign to consider reduction in dry weight is a low interdialytic weight gain. This comes from the observation that interdialytic weight gain tends to rise when dry weight is reduced (160), as illustrated in **FIGURE 15.4**. Additionally, the secondary analysis of the DRIP trial that employed relative plasma volume monitoring found the flattest relative plasma volume slopes, corresponding to the most volume overload, in the group with the lowest ultrafiltration volume (157). This is not surprising considering the mechanism of relative plasma volume monitoring; however, the ultrafiltration volume generally equals the interdialytic weight gain, and, as noted in the preceding text, subsequent reduction in dry weight per the trial protocol in the group with the lowest interdialytic weight gain resulted in the greatest weight loss at 1.5 kg and in the greatest reduction in 44-hour ambulatory SBP at 12.6 mm Hg compared to any of the other groups with higher interdialytic weight gains. Thus, low interdialytic weight gain may be a sign of occult volume overload, and low interdialytic weight gain should not be considered to be synonymous with euvolemia (161). As a purely practical matter, a low interdialytic weight gain also makes it easier to challenge the dry weight.

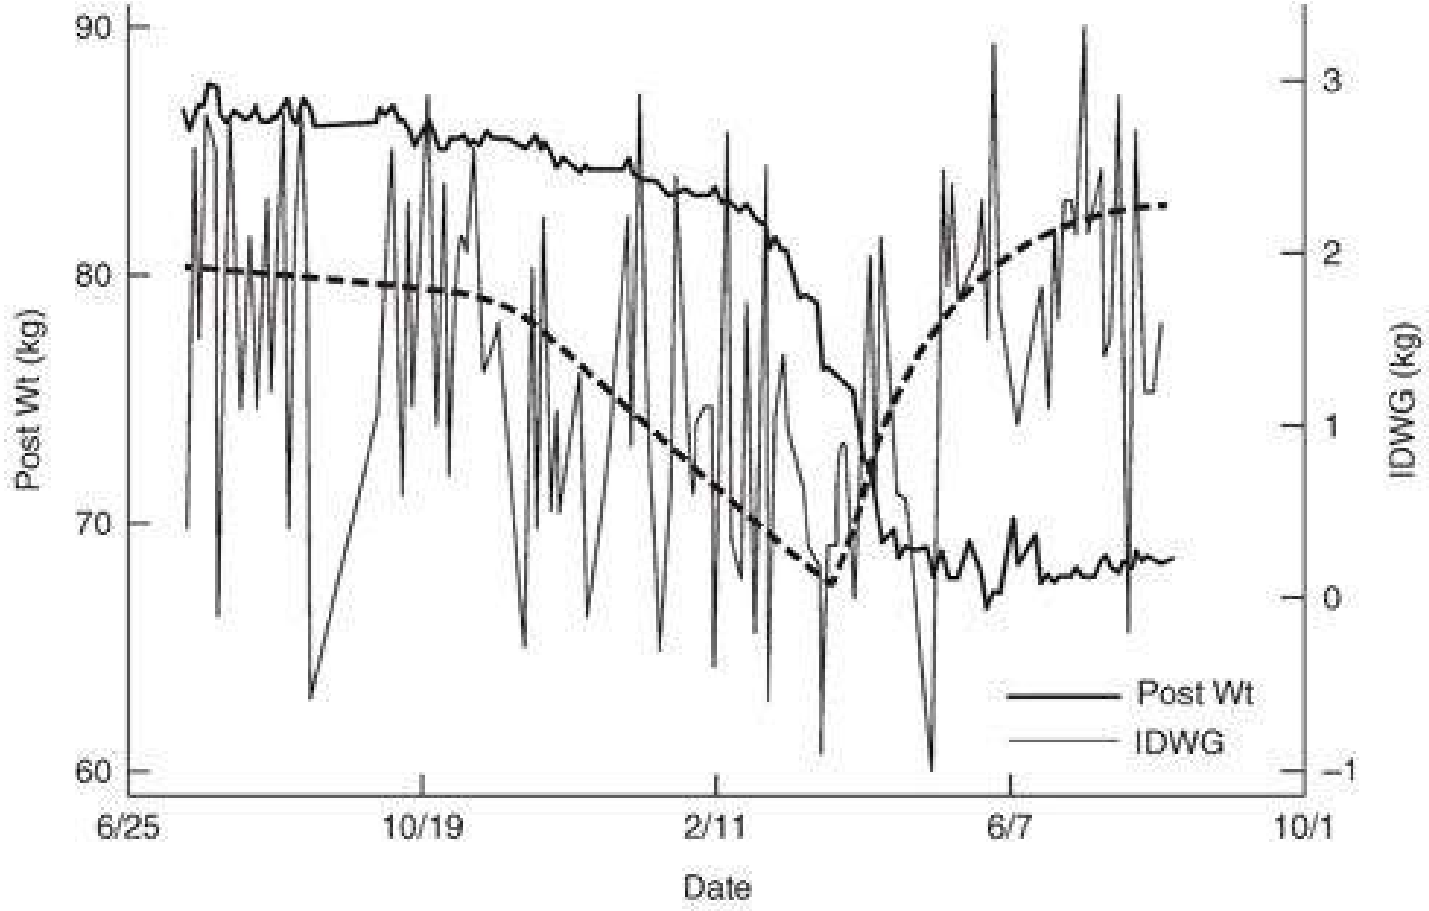

FIGURE 15.4 Relationship of dry weight to interdialytic weight gain. The subject participating in a clinical trial who previously had well-controlled BP measured at home was hospitalized for pneumonia, and on hospital discharge, home BP was poorly controlled despite increasing the number of antihypertensive medications. As shown, dry weight was reduced gradually over time. Over a few weeks, home BP was controlled to <140/90 mm Hg (not shown). The modeled *dotted line* overlying the interdialytic weight gain (IDWG) illustrates that reduction in dry weight was accompanied by increasing IDWG. [Reprinted from Sinha AD, Agarwal R. What are the causes of the ill effects of chronic hemodialysis? The fallacy of low interdialytic weight gain and low ultrafiltration rate: lower is not always better. *Semin Dial* 2014;27(1):11–13, with permission.]

It is important to note that while volume overload is a major contributor to hypertension in ESKD and volume removal is the foundation of hypertension control in ESKD, hypertension and volume overload are not equivalent. The presence or absence of hypertension does not definitively rule volume overload either in or out. This is illustrated by a study of 500 HD patients using bioelectric impedance analysis that found 33% of the cohort to be euvolemic and normotensive based on peridialytic BP, while 10% were hypervolemic yet still normotensive, and 13% were euvolemic but still hypertensive (162). The distinction is even more important when outcomes are considered. Volume overload has been shown to be independently associated with mortality both when assessed by bioelectrical impedance analysis (163) and by relative plasma volume monitoring (164), even after adjusting for BP in both studies. Therefore, while the presence or absence of hypertension is an important finding to guide the clinical assessment of volume status in dialysis, the treating nephrologist must keep an open mind and look for other confirming signs.

We recommend to reduce dry weight gradually in decrements as small as 0.2 to 0.3 kg per HD session based on the recognition that even small changes in dry weight can improve BP, as the DRIP trial had only 1-kg reduction in the dry weight of the intervention group yet found a large change in ambulatory SBP, and other trials of dry weight management have similarly found significant BP reduction with similar

changes in dry weight of only 1 kg or less (165,166). An added benefit of making small and gradual changes in dry weight is that it builds a rapport with patients who are often reluctant to permit their dry weight to be lowered for fear of provoking symptoms such as cramping.

There are risks to challenging dry weight including increased risk of clotted vascular access (110), accelerated loss of residual renal function (150), and increased frequency of intradialytic hypotension, which has itself been associated with myocardial stunning (167) and increased mortality (168). As the DRIP trial lasted only 8 weeks, long-term randomized trials are needed to examine the balance between benefits and risks of dry-weight reduction.

Dietary Sodium Restriction

Despite recent observational evidence questioning the benefits of a low-sodium diet for the general population (169), there is ample randomized trial evidence supporting the efficacy of low-sodium diet to treat resistant hypertension in those without kidney disease (170), to treat hypertension in stage 3 to 4 CKD (171), and for reduction of proteinuria and albuminuria in diabetic nephropathy (172). In the HD patient, sodium intake provokes increased interdialytic weight gain (173) which also leads to increased ultrafiltration rates, both of which are associated with cardiovascular mortality (174,175). Restricting sodium intake reduces interdialytic weight gain, which will also practically improve the ability to achieve an adequately low dry weight with dialysis (176,177). However, in the dialysis patient, reducing dietary sodium intake should be followed by probing dry weight to improve control of hypertension. In the absence of probing dry weight, the full benefit of restricting dietary sodium intake may not be realized. The American Heart Association recommends <1,500 mg (equivalent to 65 mmol) daily intake (178), which is a reasonable prescription for dialysis patients (80). Notably, except for hyponatremia treatment, there is zero rational role for fluid restriction in dialysis patients (173,179).

Dialysate Sodium Reduction

In the earliest days of chronic HD, low dialysate sodium concentrations were used and sodium removal on HD was thus in part due to diffusion in addition to convective removal with ultrafiltration. As the efficiency of dialyzers improved and dialysis times were reduced, higher dialysate sodium concentrations became the norm to reduce hemodynamic instability, cramping, and symptoms of disequilibrium (180), and initial studies suggested that hypertension was not a complication (181). However, more recently, it has been recognized that higher dialysate sodium concentrations will reduce or reverse the diffusive removal of sodium on HD, which undermines the effective management of volume control (182). As an example of the impact of dialysate sodium concentration, in a pilot study that reduced dialysate sodium from 137.8 to 135.6 mmol/L stepwise over 7 weeks, net sodium removal was significantly increased from 383 mmol to 480 mmol per HD session (183).

Numerous studies have shown interdialytic weight gain to be directly related to dialysate sodium concentration with higher dialysate sodium leading to higher intradialytic weight gain (183–185). Increased interdialytic weight gain is additionally seen with sodium profiles, also called sodium ramping, where the dialysate sodium concentration generally starts high and then is gradually lowered during the HD session (184,186,187). While higher dialysate sodium concentrations are prescribed to promote hemodynamic stability, the resulting higher interdialytic weight gain can lead to higher ultrafiltration rates which lead to the very hemodynamic instability originally to be avoided. Additionally, more recent

studies of higher dialysate sodium concentrations, whether constant or with a profile, have been associated with higher BP in some (186,187), but not all investigations (185).

An alternative to avoid the vicious cycle in the preceding text is to individualize the dialysate sodium prescription to the patient's pre-HD serum sodium. The importance of individualization is illustrated by a cross-sectional study of 1,084 HD patients that examined the difference between the individual dialysate sodium concentration and the patient's pre-HD serum sodium and found that this difference is directly related to interdialytic weight gain, with a higher dialysate sodium concentration relative to the pre-HD serum sodium being associated with greater weight gain (188). A single-blind crossover study of 27 HD patients illustrated one method of individualizing the dialysate sodium concentration by first dialyzing all patients with a standard 138 mmol/L sodium dialysate for 3 weeks and then on a dialysate sodium concentration set to 0.95 multiplied by the pre-HD serum sodium for 3 weeks (189). On the low-sodium dialysate prescription, significant reductions were seen in interdialytic weight gain by 0.6 kg, in the frequency of intradialytic hypotension, and in the pre-HD SBP in the hypertensive subjects. Based on these findings, it is reasonable to recommend that dialysate sodium be individualized to avoid being higher than the individual patient's pre-HD serum sodium and possibly as low as 0.95 multiplied by the serum sodium in hypertensive individuals or those with high interdialytic weight gain precluding the achievement of an adequately low dry weight.

A trial in 25 PD patients employed a before-after design to investigate the use of low-sodium dialysate over 2 months (190). All subjects had one exchange per day changed to a low-sodium solution, but 10 subjects had the dextrose concentration increased to compensate for reduced osmolality, while 15 subjects had no change to their dextrose concentration. The first group had significantly improved BP along with markers of improved volume overload, adding further evidence that reducing dialysate sodium is only useful if it is accompanied by adequate ultrafiltration.

Adequate Time on Dialysis

Despite reducing both dietary sodium intake and the dialysate sodium concentration to reduce interdialytic weight gain, attempts to reduce dry weight to improve BP will be unsuccessful in many patients due to intradialytic hypotension or symptoms on HD including cramping. In these patients, increasing the HD time can make ultrafiltration easier to tolerate, thus facilitating the achievement of an adequate dry weight. A secondary analysis of the DRIP trial recently showed shorter HD times to be associated both with higher BP and slower improvement in BP when dry weight is reduced (191). A randomized crossover trial of 38 HD patients evaluated time on HD by assigning subjects to 2 weeks of 4-hour versus 5-hour HD sessions and found significantly less intradialytic hypotension and post-HD orthostatic hypotension during the longer HD runs (192). An added salutary effect of longer HD time is that for a given amount of interdialytic weight gain, an increased HD time will lead to a lower ultrafiltration rate, which has been associated with mortality (175).

It is for all these reasons that the European Best Practice Guidelines recommend that HD should be delivered at least three times weekly for a total duration of at least 12 hours, unless substantial residual renal function remains (193). However, in the United States, a recent cohort study among 32,000 HD patients found that the average single HD session was only 217 minutes and that one-quarter of patients dialyzed less than 3 hours and 15 minutes per session (194). The lower average treatment times in the

United States are likely due to the practice of reducing the prescribed time to achieve a minimum goal Kt/V; however, we recommend that this practice should be avoided on account of the potential harmful effects that shorter treatment time can have on volume status and hypertension (195).

Frequent Dialysis

An additional strategy to treat patients who cannot achieve an adequately low dry weight on a conventional three times weekly HD schedule is to consider a change in modality to more frequent dialysis. Observational studies have shown frequent HD to be associated with reductions in BP despite lower antihypertensive drug use (196,197), as well as with improvements in LVH (197). More recently, randomized trials have confirmed some of these findings with a trial of 52 patients that assigned subjects to either conventional three times weekly HD versus six nights weekly nocturnal HD for 6 months and found significantly improved BP, lower antihypertensive drug use, and improved LVH in the nocturnal HD group (198). Subsequently, the Frequent Hemodialysis Network (FHN) nocturnal trial recruited 87 HD patients and randomized them to three times weekly conventional HD versus six nights weekly nocturnal HD, and weekly average pre-HD BP significantly improved in the nocturnal HD group despite a reduction in antihypertensive medication use; however, the trends toward improvement in the primary endpoints including LVH were nonsignificant, possibly due to lack of power from difficulty with subject recruitment (199). The companion FHN trial of daily HD recruited 245 patients who were randomized to three times weekly conventional HD versus 6 days weekly HD for 12 months, and this trial did find significantly reduced hazard for both coprimary composite endpoints of death or increase in left ventricular mass and death or decrease in the physical health composite score (200). Both weekly average pre-HD SBP and the number of antihypertensive medications for the intervention group were reduced significantly as well. These improvements in BP and LVH are plausibly due to better control of volume (201), especially when it is recognized that the daily HD group had significantly more ultrafiltration per week at 10.58 L on average compared to 8.99 L for the control group (200).

Pharmacologic Treatment

Patients with ESKD are routinely excluded from drug trials, limiting the evidence base from which to make recommendations for antihypertensive drug therapy. Two meta-analyses of randomized trials employing antihypertensive drugs in dialysis have found significant improvements in the cardiovascular event rates associated with treatment (144,145), which was particularly pronounced in subjects with hypertension (145). However, the trials included in these meta-analyses were highly heterogeneous; most trials were not limited to hypertensive patients, and only two trials targeted a specific BP goal.

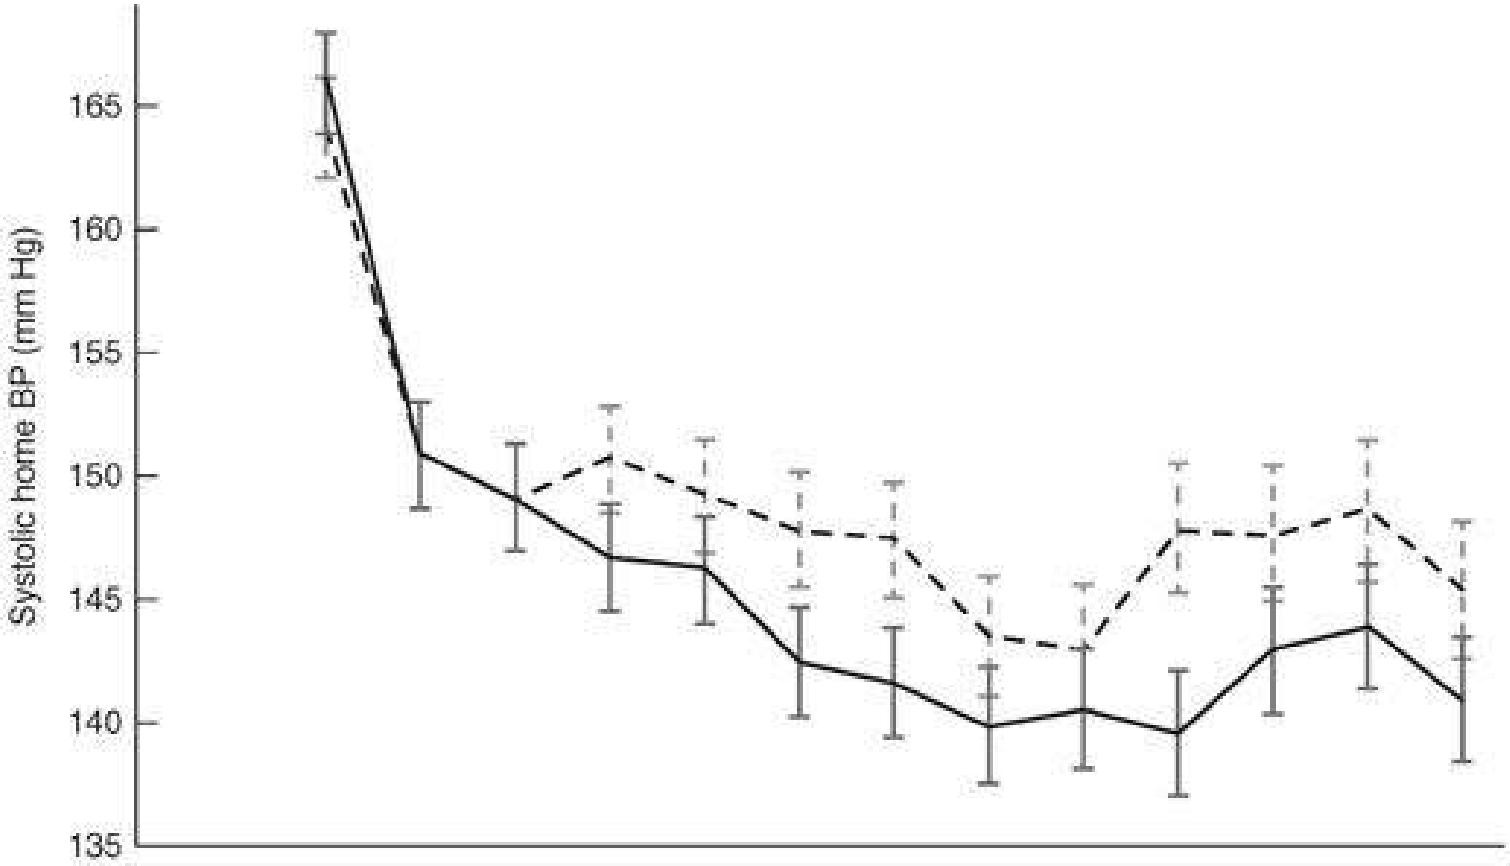
Despite the benefits from the use of antihypertensive medication in ESKD, it must be emphasized that greater use of antihypertensive medications is associated with worse control of hypertension (15,159), which is plausibly due to inadequately treated volume overload in those cases. Thus, the first step in treating hypertension in ESKD should always be to address volume overload. All classes of antihypertensive medications have roles in the treatment of hypertension in ESKD (202), as detailed in the following text.

Diuretics

While published evidence is lacking, diuretics are often used to address hypertension and volume

overload in patients with significant residual renal function, which includes those new to HD and nonoliguric patients on PD. In the setting of advanced kidney disease, higher doses of diuretics will be necessary to be effective (203). However, in anuric patients, even doses of furosemide as high as 250 mg intravenously are ineffective (204). While some investigators have suggested that thiazide diuretics exert an antihypertensive vasodilator effect (205,206), the placebo-controlled administration of thiazides to anuric dialysis patients has been shown to have no effect on BP (207). Thus, the role for diuretics in the treatment of hypertension in dialysis is at best limited to the subset of patients with significant residual renal function.

β-Blockers



β-Adrenergic blocking agents have well-established benefits in the nondialysis population including in the setting of heart failure (208) and coronary artery disease (209). As cardiovascular events are the leading cause of death in ESKD and increased sympathetic nervous system overactivity is common (52), β-blockers are an attractive therapy in this population. A retrospective cohort study of PD patients found β-blocker use to be associated with a significantly reduced risk of new-onset heart failure or the composite endpoint of new onset heart failure and cardiac mortality (210). More provocatively, Cice et al. (211) recruited 114 HD patients with reduced left ventricular ejection fraction <35% and randomized them to carvedilol versus placebo and reported significantly improved 2-year survival in the carvedilol group.

Despite these encouraging findings, enthusiasm for β-blockers as first-line pharmacologic treatment for hypertension in dialysis is tempered by the nondialysis experience where β-blockers are not recommended for initial monotherapy of hypertension (212,213); consequently, ACEI medications are often instead recommended for initial therapy of hypertension (214). While head-to-head studies of antihypertensives are few, a recent randomized controlled trial in HD comparing lisinopril to atenolol begins to address the question of which medication to prescribe first for hypertension in HD.

The Hypertension in Hemodialysis Patients Treated with Atenolol or Lisinopril (HDPAL) trial recruited 200 chronic HD patients with hypertension confirmed by 44-hour interdialytic ABPM and echocardiographic LVH and randomized them to lisinopril- or atenolol-based therapy for 12 months to determine which drug is superior for reduction of LVH (114). All patients were treated to target goal home BP ≤140/90 mm Hg checked monthly, first by maximizing the study drug and then by addition of other drugs, sodium restriction, and reduction in dry weight. The trial was terminated early by an independent data safety monitoring board for cardiovascular safety because of significantly more serious adverse cardiovascular events in the lisinopril group, which had 43 events in 28 subjects compared to only 20 events in 16 subjects in the atenolol group (incidence rate ratio 2.36, $p = 0.001$). Similarly, the combined serious adverse events of myocardial infarction, stroke, hospitalization for heart failure, or cardiovascular death occurred 23 times in 17 subjects in the lisinopril group compared to only 11 events in 10 subjects in the atenolol group (incidence rate ratio 2.29, $p = 0.002$). LVH improved in both groups, but no differences between drug groups were found.

While 44-hour ambulatory BP improved similarly in both groups measured at baseline, 3 months, 6 months, and 12 months, the monthly home BP was consistently lower in the atenolol group, as shown in **FIGURE 15.5**, despite significantly more antihypertensive medications and greater dry-weight reduction in

the lisinopril group (114). Thus, atenolol appears to be superior to lisinopril in terms of cardiovascular event rates and BP reduction in this HD population. Based on the findings of this head-to-head clinical trial of atenolol versus lisinopril in HD patients, we recommend that β-blockers should be the first-line pharmacologic therapy for hypertension. **TABLE 15.8** summarizes the recommendations for pharmacologic therapy for hypertension in dialysis. Atenolol in particular may be practically useful as it can be dosed just three times per week after HD, as was the protocol in the HDPAL trial, and this schedule has been previously shown to significantly reduce 44-hour interdialytic ambulatory BP (215). Three times weekly dosing permits the possibility of directly observed administration of atenolol in the HD unit to improve compliance with the antihypertensive regimen.

Atenolol (n)	99	90	90	89	86	76	74	69	65	61	57	54	58

FIGURE 15.5 Home systolic blood pressure (BP) profiles at baseline and over time. *Solid line* shows the atenolol group, and the *dotted line* the lisinopril group; *vertical bars* represent standard error of mean. The table at the bottom of the figure shows the number of patients in each drug [atenolol (n), lisinopril (n)]; the change from baseline (CFB) and between group comparisons of the changes (lisinopril–atenolol CFB). Home BP monitoring was performed at baseline and at every month for the entire duration of the trial; the mean reduction in BP overall was reduced more with atenolol therapy [linear rate of change for atenolol was −1.5 mm Hg systolic per month and that for lisinopril was 0.47 mm Hg flatter ($p = 0.037$)]. [Adapted from Agarwal R, Sinha AD, Pappas MK, et al. Hypertension in hemodialysis patients treated with atenolol or lisinopril: a randomized controlled trial. *Nephrol Dial Transplant* 2014;29(3):672–681, with permission.]

TABLE 15.8 Suggested Approach to Pharmacologic Therapy for Hypertension in Dialysis

Medication Class	Comments
β-Blockers	First-line therapy, superior to ACEI in a randomized trial
ACEI or ARB	Second-line therapy, superior to calcium channel blockers
Calcium channel blockers	Third-line therapy, effective even when volume overloaded
Centrally acting α agonists	Clonidine patch; guanfacine preferred since less sedation
Direct vasodilators	Minoxidil preferred to hydralazine since once daily
Mineralocorticoid receptor antagonists	Emerging evidence of efficacy and mortality benefit but definitive trials in progress.
Loop diuretics	Use limited only to those with substantial residual renal function

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

It cannot be concluded from the HDPAL trial that ACEI medications are harmful because there was no placebo-controlled group in the study (114). Indeed, ACEI and angiotensin receptor blocker (ARB) drugs are mainstays of therapy in predialysis CKD (128) and in cardiovascular disease (216,217). Both ACEI (47,48,218) and ARB medications (219) have been shown to improve BP in ESKD. As with atenolol, both lisinopril (47) and trandolapril (218) have been shown to be effective at lowering BP when dosed only three times weekly after HD.

Three randomized clinical trials have examined ACEI or ARB therapy in HD patients with cardiovascular events as the primary endpoint, and they warrant more detailed mention. The only randomized clinical trial investigating an ACEI and cardiovascular events in HD patients is the Fosinopril in Dialysis Study (FOSIDIAL) (48), which recruited 397 chronic HD patients with LVH who were followed for a 2-week run-in period on fosinopril, and those who tolerated the therapy were randomized to fosinopril or placebo and treated to goal peridialytic BP <160/90 mm Hg for 24 months (220). No benefit was found for fosinopril in decreasing cardiovascular events in this trial (48).

Two randomized controlled trials have investigated ARB use in HD and found a benefit for cardiovascular events. The first enrolled 80 HD patients who were randomized to candesartan or open label usual care for a planned 3 years (221). The trial was stopped early on account of an interim analysis that found significant and substantial benefit for candesartan for the primary endpoint of cardiovascular events as well as for mortality with zero deaths in the candesartan group and 18.9% mortality in the control group (221). The second trial included 360 HD patients randomized to open label ARB therapy with losartan, valsartan, or candesartan versus usual care with goal peridialytic SBP <150 mm Hg over 3 years (222). ARB treatment significantly reduced the primary endpoint of cardiovascular events with a 49% reduction in risk of cardiovascular events [hazard ratio (HR) = 0.51, $p = 0.002$].

In the setting of the divergent outcomes for the three randomized clinical trials using ACEI or ARB drugs in the preceding text, a recent meta-analysis examined the pooled results for cardiovascular events in the 837 total subjects in these three trials and found a trend toward benefit with a relative risk for cardiovascular events at 0.66, but this did not reach statistical significance (95% confidence interval 0.35 to 1.25, $p = 0.20$) (223). However, the intermediate endpoint of reduction of LVH did significantly favor

ACEI or ARB treatment in this meta-analysis (223). Each trial had different definitions for cardiovascular events and not surprisingly significant heterogeneity was found. Similarly, a systematic review of ACEI and ARB therapy in PD patients included three randomized clinical trials and found no improvement in cardiovascular events for the intervention groups (224).

As ACEI and ARB therapy has been shown to delay progression of predialysis CKD (225), these agents may be effective at preserving residual renal function in dialysis patients, which is emerging as an important goal for both PD and HD patients (226). Two randomized controlled open label trials in PD, one investigating ramipril in 60 subjects (227) and the other studying valsartan in 34 subjects (228), both found active treatments reduced the rate of decline in GFR, while a meta-analysis pooled the difference between the intervention groups and the control groups at 12 months and found a clinically and statistically significant benefit of 0.9 mL/min/1.73 m^2 in favor of the intervention groups (224). In HD, however, a recent randomized placebo-controlled trial of irbesartan over 1 year in 82 nonoliguric HD patients found no benefit for irbesartan in decline of GFR or development of anuria (229).

The risk of hyperkalemia with ACEI or ARB use in dialysis appears low based on the evidence from the aforementioned randomized controlled trials in both HD (48,221,222) and PD (227). We recommend ACEI or ARB agents as a reasonable second choice after β-blockers for treatment of hypertension in dialysis based on their tolerability, the evidence of benefit in the nondialysis population, and the randomized trial evidence of benefit on intermediate endpoints such as reduction in LVH (223).

Calcium Channel Blockers

Amlodipine has been shown to be effective versus placebo in improving BP in a randomized trial of 251 hypertensive HD patients where the primary endpoint of cardiovascular events showed no improvement for active treatment (230). Calcium channel blockers have the practical benefits of being well tolerated and requiring only once a day dosing; however, ACEI or ARB therapy is preferred before calcium blockers based on head-to-head trials showing calcium channel blockers to be significantly inferior for regression of LVH (231,232).

Centrally Acting α Agonists

These medications are typically reserved only for those patients whose BP is uncontrolled on the combination of β-blocker, ACEI or ARB, plus calcium channel blocker. To minimize pill burden and dosing schedule, we recommend to avoid oral clonidine and to instead use the long-acting clonidine patch, which can be administered once a week at the dialysis unit as directly observed therapy. As the clonidine patch can be expensive, a cheaper alternative is oral guanfacine, dosed only once daily at bedtime to minimize the impact of dose-related drowsiness.

Vasodilators

Direct vasodilator agents are usually reserved as last-line therapy for hypertension in ESKD. However, hydralazine use is becoming more common based on trial evidence of benefit for heart failure in the African American population in combination with isosorbide dinitrate (233), but it is important to recognize that this combination of medications has not been studied specifically in ESKD. Furthermore, the pill burden and requirement of three times daily dosing of hydralazine makes it less attractive for use in ESKD. It is for that reason that we recommend minoxidil over hydralazine on account of its

antihypertensive effectiveness with only once-daily dosing in the setting of CKD.

Mineralocorticoid Receptor Antagonists

Mineralocorticoid receptor antagonists have well-established roles in the nondialysis population for treatment of resistant hypertension (234) and heart failure (235,236). In the dialysis population, spironolactone has been shown to significantly reduce 24-hour ambulatory BP by 10.9/5.8 mm Hg in a randomized controlled double-blind trial of 76 hypertensive dialysis patients on HD or PD treated with spironolactone 25 to 50 mg daily versus placebo over 12 weeks (237). Recently, the Dialysis Outcomes Heart Failure Aldactone Study (DOHAS) clinical trial randomized 309 HD patients to spironolactone 25 mg daily versus open label usual care for 3 years and found both cardiovascular death and hospitalizations as well as all-cause mortality were significantly improved in the spironolactone group (238). Notably, spironolactone therapy was discontinued for hyperkalemia in only three patients during the trial. While the results of the DOHAS trial are very promising, they require confirmation in future blinded randomized trials to balance the risk of hyperkalemia with the potential benefits before routine use of spironolactone for hypertension in HD can be recommended.

Invasive Treatment

The history of invasive treatments for hypertension dates back at least to the 1930s when surgical sympathectomy was employed for essential hypertension (239). As efficacious oral antihypertensive agents with tolerable side effect profiles were discovered, surgery fell out of favor as a treatment for simple hypertension. However, in the early era of chronic HD in the 1960s and 1970s, it was recognized that a subset of patients with ESKD did not achieve adequate control of hypertension despite ultrafiltration on HD and the use of the antihypertensive medications available at the time (41). As high renin levels were common in these cases, bilateral nephrectomy was advocated as an effective means to reduce renin levels and BP, although it was recognized even then that other mechanisms likely were responsible for the improved BP after nephrectomy (41). With the introduction of ACEI drugs, bilateral nephrectomy too became much less common.

However, Converse et al. (52) demonstrated that sympathetic overactivity from kidney afferent nerves are a major source of hypertension in ESKD, and with the invention of a radiofrequency catheter-based approach to target the kidney nerves, there has been renewed interest in renal sympathectomy via the endovascular approach (54). A pilot study of kidney denervation by radiofrequency ablation was performed in 12 chronic HD patients with uncontrolled hypertension, and office BP was reduced in the 9 patients who had the procedure versus unchanged BP in those 3 patients whose atrophic kidney arteries precluded the endovascular denervation procedure (55). However, enthusiasm for kidney denervation must be tempered by the experience with kidney denervation in the resistant hypertension population without CKD where initial trials showed promise (240), but when a randomized, sham placebo-controlled, and blinded trial was performed, there was no BP reduction for the intervention (56). While ESKD patients are an ideal group who may benefit from this therapy, it remains to be seen whether the disappointing result from the randomized controlled trial of endovascular kidney denervation will preclude further development of this technique.

CHAPTER 16

Left Ventricular Dysfunction and Valvular Heart Disease in Dialysis Patients

Sean P. Martin, Sean W. Murphy, and Patrick S. Parfrey

Cardiovascular (CV) disease is the leading cause of mortality in patients with end-stage kidney disease (ESKD) and accounts for approximately one-half of all deaths (1–3). The prevalence of left ventricular (LV) disorders or ischemic heart disease (IHD) is extremely high in this population. Roughly 80% of patients starting maintenance dialysis therapy already have established left ventricular hypertrophy (LVH) or systolic dysfunction, disorders that are predictive of heart failure (HF), IHD, and death (4). Cohort studies have determined that the annual incidence of myocardial infarction (MI) or acute coronary syndrome requiring hospitalization among hemodialysis patients is 8%; the per annum risk of developing HF requiring hospitalization or treatment with ultrafiltration is 10% (5). United States Renal Data System (USRDS) registry data suggests that the cumulative probability of HF in incident hemodialysis patients is approximately 30% at 6 months, 56% at 2 years, and 66% by 3 years (2).

The high burden of cardiac disease associated with chronic kidney disease (CKD) is likely the end result of many etiologic factors. The prevalence of many “traditional” risk factors for heart disease, for example, diabetes and hypertension, is clearly higher among patients with kidney disease than in the general population. These same risk factors may be responsible for the development of CKD in many patients. This confounds analyses of CKD itself as an independent risk factor for CV disease, and currently, there is some debate as to whether or not this is the case. Regardless, several metabolic and hemodynamic disturbances that occur and progress in relation to declining kidney function do increase CV risk.

This chapter focuses on the pathogenesis, risk factors, and treatment of disorders of LV geometry and function in dialysis patients. The cardiomyopathy associated with uremia may manifest itself in many ways, including arrhythmia and dialysis-associated hypotension (**FIGURE 16.1**). These disorders, therefore, also are considered in this chapter. IHD is discussed in detail elsewhere in this book, but it should be recognized that myocardial dysfunction and ischemic disease are closely associated and coexist in many patients.

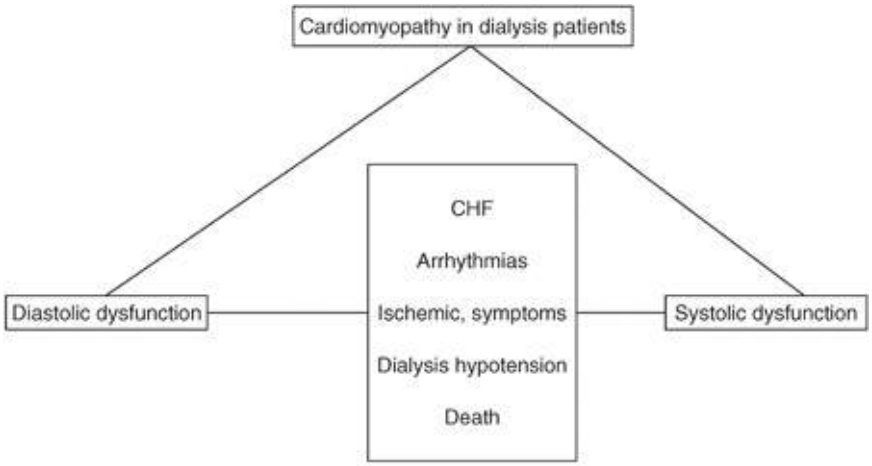

FIGURE 16.1 Manifestations of cardiomyopathy in dialysis patients. CHF, congestive heart failure.

LEFT VENTRICULAR HYPERTROPHY AND HEART FAILURE

Pathogenesis of Left Ventricular Disorders

Ventricular growth occurs in response to mechanical stresses, primarily volume or pressure overload (6). Volume overload results in addition of new sarcomeres in series, leading to increased cavity diameter (7). Larger diameter results in increased wall tension, a direct consequence of Laplace's law. This increase in wall tension stimulates the addition of new sarcomeres in parallel. Such remodeling thickens the ventricular wall, distributing the tension over a larger cross-sectional area of muscle and returning the tension in each individual fiber back toward normal. This combination of cavity enlargement and wall thickening is called *eccentric hypertrophy*. Pressure overload, on the other hand, increases wall tension by increasing intraventricular pressure, resulting directly in the parallel addition of new sarcomeres. Because sarcomeres are not added in series, isolated pressure overload leads to concentric hypertrophy, that is, wall thickening without cavity enlargement.

Both eccentric and concentric hypertrophy are initially compensatory and therefore beneficial. Dilatation permits an increase in stroke volume without an increase in the inotropic state of the myocardium and as such is an efficient adaptation to volume overload (8). It also permits the maintenance of a normal stroke volume and cardiac output in the presence of decreased contractility. Muscular hypertrophy returns the tension per unit muscle fiber back to normal, decreasing ventricular stress.

If the stimuli for ventricular remodeling persist, however, LVH eventually becomes maladaptive. Hypertrophy is associated with progressive, deleterious changes in myocardial cells. Early in the evolution of LVH, abnormalities of cellular calcium handling lead to abnormal ventricular relaxation; combined with decreased passive compliance of a thickened ventricular wall, these changes may precipitate diastolic dysfunction (9). Decreased capillary density, impaired coronary reserves, and abnormal relaxation may decrease subendocardial perfusion, promoting ischemia (10). Frequent coexistence of coronary artery disease (CAD) may exacerbate the situation. Fibrosis of the cardiac interstitium also occurs and appears to be more marked in pressure than volume overload (11). In the late phases of chronic overload, oxidative stress is prominent and contributes to cellular dysfunction and demise (12). Together, these various processes lead to progressive cellular attrition, fibrosis, HF, and death. The results of the 2013 Chronic Renal Insufficiency Cohort (CRIC) study are consistent with the

HF literature, whereby LVH is a precursor to systolic dysfunction (13). A subset of 190 patients from this longitudinal study had serial echocardiograms during advanced CKD [mean estimated glomerular filtration rate (eGFR) 16.9 mL/min/1.73 m^2] and ESKD. The majority (80%) of patients included had LVH at baseline, and the left ventricular mass index (LVMI) did not change significantly from advanced CKD to ESKD suggesting LVH is fixed by moderate to advanced stages of CKD. There was a significant decline in ejection fraction, however, from 53% to 50% ($p = 0.002$).

Many factors unique to patients with CKD appear to contribute to cardiac dysfunction. Anemia, salt and water overload, and arteriovenous (AV) fistulas in hemodialysis patients are common causes of volume overload. Hypertension is highly prevalent in patients with ESKD and is a major cause of pressure overload. These same factors promote arterial remodeling in the large and resistance arteries, characterized by diffuse arterial thickening and stiffening (arteriosclerosis), which can increase the effective load on the LV independently of mean arterial pressure (12,14).

Aside from hemodynamic factors, the uremic milieu may also lead to myocyte death. Although CAD is the major factor promoting ischemia and infarction, hyperparathyroidism increases susceptibility to ischemia through dysregulation of cellular energy metabolism (15). Poor nutrition, oxidative stress, and inadequate dialysis may all additionally promote myocyte death (6,16,17).

Diagnosis of Left Ventricular Disorders in Dialysis Patients

LV disorders can be asymptomatic or they may be manifested clinically as HF, arrhythmias, dialysis-associated hypotension, or ischemic symptoms. The diagnosis of HF is based on clinical symptoms and signs and can usually be made with an appropriate history and physical examination. HF typically presents as progressive fatigue and a decline in exercise tolerance or, alternatively, as a syndrome characterized by dyspnea, jugular venous distension, and bilateral lung crepitations and the characteristic chest x-ray appearance.

Some physicians attempt to distinguish HF from “volume overload” or circulatory congestion. This is a difficult task, as the clinical findings of both conditions are identical. The clinical context may be of some assistance, especially when fluid gains are known to be minimal based on the patient’s dry weight. Even in this situation, diastolic dysfunction may be the underlying problem. In general, HF symptoms are not likely to occur in a patient with a perfectly normal heart. Physicians are well advised to consider all episodes of symptomatic HF as evidence of some degree of myocardial dysfunction and investigate them further.

Echocardiography is an important method for the assessment of LV structure and function (18–20). Although LV mass measurement using echocardiography is highly reproducible between observers, its measurement varies over the course of a hemodialysis session by as much as 25 g/m^2 (20). This occurs because LV internal diastolic diameter decreases as the patient’s blood volume decreases, as a result of fluid withdrawal. A concomitant decrease in LV wall thickness is not observed. Consequently, the LVMI measured predialysis is higher than the postdialysis measurement, although the actual LV mass has not changed. Therefore, when possible, imaging should be carried out when the patient is close to dry weight.

Echocardiography provides relatively accurate measures of LV mass, cavity size, geometry, systolic function, and diastolic function. Systolic dysfunction is defined as an ejection fraction of less than 40%. It is often associated with LV dilatation (LV end-diastolic diameter greater than 5.6 cm), defined as LV

cavity volume index of greater than 90 mL/m^2 on echocardiogram (18). Concentric LVH is characterized by a thickened LV wall (greater than 1.2 cm during diastole) with normal cavity volume. LVMI is a calculated parameter that reflects the degree of hypertrophy. In non-CKD patients, the upper limits of normal are LVMI 130 g/m^2 for men and 102 g/m^2 for women (21). Although indexing LV mass to patient weight is the standard approach, it has been reported that LV mass indexed to patient height is more predictive of CV mortality in dialysis patients (22).

Cardiac magnetic resonance (CMR) imaging offers an alternative to echocardiography. It has been established as the most accurate noninvasive method of assessing ventricular dimensions in patients and is a useful tool in assessing cardiomyopathy in patients with ESKD (23–25). Compared to echocardiography, CMR has been shown to provide a more volume-independent measurement of the cardiac structure (26). In addition, echocardiography significantly overestimates LV mass relative to CMR in the presence of LVH and dilation, and this error is amplified in dialysis patients (27).

Other imaging techniques, such as nuclear medicine imaging of the LV using technetium-labeled red blood cells may be particularly useful in diagnosing areas of focal hypokinesis (usually resulting from ischemia). This method allows a more accurate estimate of global ejection fraction than does echocardiography alone.

Approximately half of patients presenting with a new diagnosis of HF have preserved ejection fraction (28). These patients have diastolic HF, and numerous society HF guidelines have consensus on the diagnostic criteria (28–32). The general criteria accepted by these guidelines include (a) clinical signs and symptoms typical of HF; (b) normal or only mildly reduced ejection fraction normal LV size and dimensions; (c) relevant structural heart disease including LVH, LA enlargement, and/or echo Doppler or catheterization evidence of diastolic dysfunction; and (d) a nonmyocardial cause of HF must be excluded. Overall, noninvasive measurements of diastolic function have low sensitivity, specificity, and predictive accuracy (33). The gold standard for diagnosis remains cardiac catheterization, which will directly demonstrate high LV filling pressures in the presence of normal ventricular volumes and contractility in these patients. Despite the limitations of echocardiography, however, it remains clinically useful and sufficient for diagnosis in most cases. An ejection fraction of greater than or equal to 50% is a more appropriate cutoff value to distinguish systolic from diastolic HF (34).

Because most dialysis patients have echocardiographic abnormalities at the beginning of ESKD treatment, it is a reasonable practice to perform M-mode and two-dimensional echocardiography on all patients at or before the start of ESKD therapy. This will provide baseline information for future comparisons, and the detection of LV disease at an earlier stage may allow more specific therapy to be employed in affected patients. Echocardiograms have the additional benefit of allowing detection of valve disease or a pericardial effusion, conditions that can potentially precipitate HF. Additionally, physicians may choose to give patients with significant myocardial dysfunction a somewhat different dialysis prescription than might otherwise be recommended. More frequent treatments or longer dialysis sessions may help the patient avoid symptomatic HF episodes. The Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines for the management of CV disease in patients with CKD recommend repeating the echocardiogram when there is a change in the patient's clinical status and at 3-year intervals (35).

Outcome of Left Ventricular Disorders and Heart Failure

The presence of concentric LVH, LV dilatation with normal contractility, and systolic dysfunction at baseline has been associated with progressively worse survival, independent of age, gender, diabetes, and IHD (36). All three abnormalities are also associated with increased risk for the development of HF (**FIGURES 16.2** and **16.3**). This relationship between LV mass and CV events in dialysis patients has been confirmed, as was the prognostic impact of the different types of hypertrophy (22,37).

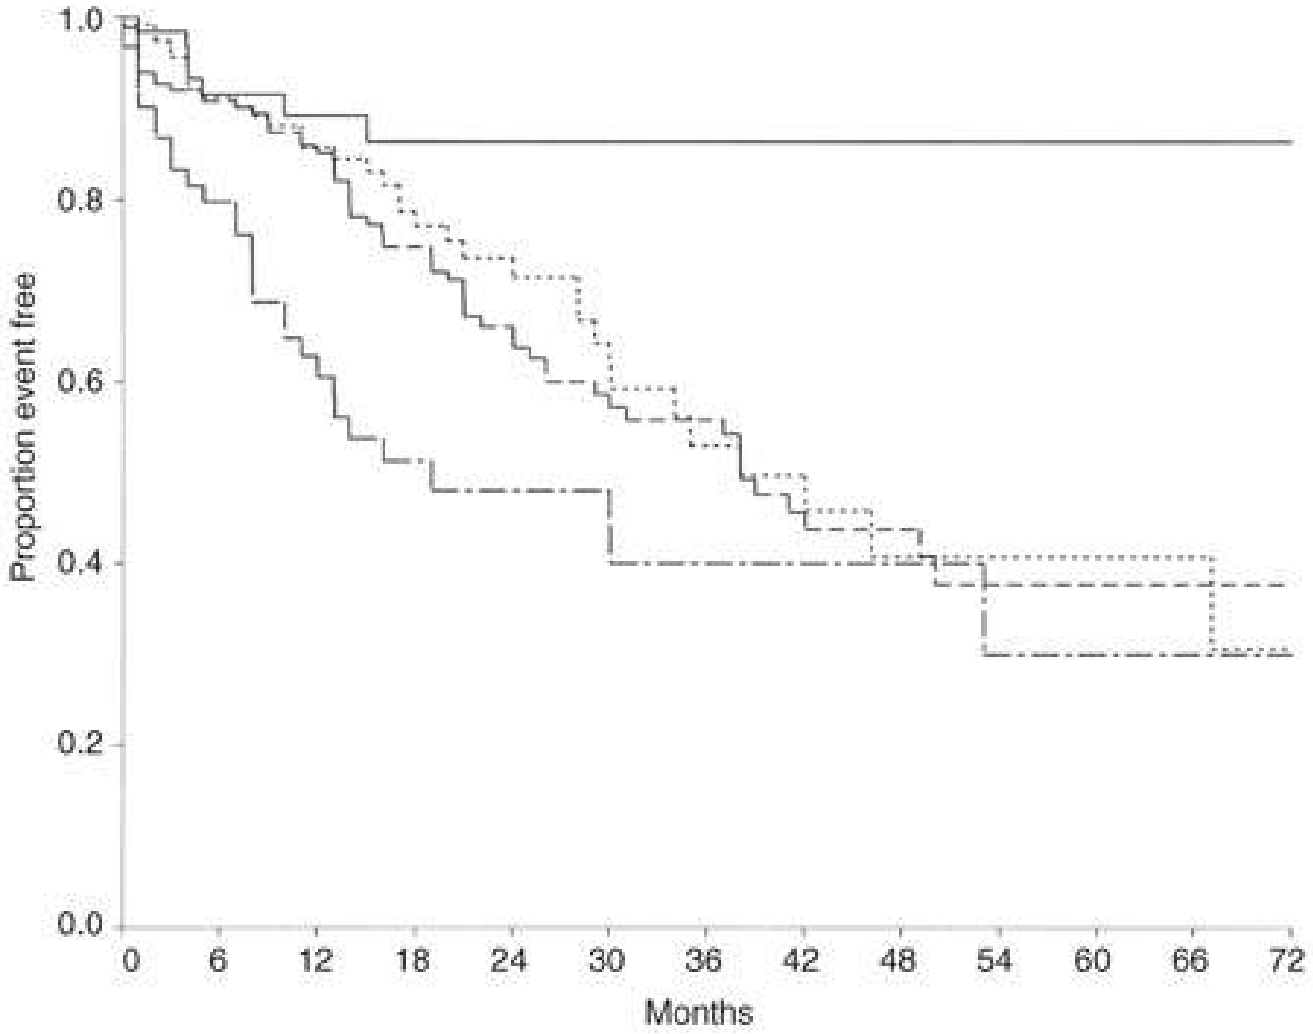

FIGURE 16.2 Time to cardiac failure for patients with normal left ventricular (LV) (—), concentric left ventricular hypertrophy (LVH) (——), LV dilation (— -), and systolic dysfunction (— - —) at inception of dialysis therapy. With permission from Oxford University Press.)

Symptomatic HF confers a poor prognosis for dialysis patients. In one cohort, the median survival of patients who had HF at or before initiation of ESKD therapy was 36 months compared with 62 months in subjects without baseline HF. This adverse prognosis was independent of age, diabetes, and IHD. Among patients who had HF at baseline, 56% developed recurrent HF and 44% remained failure-free during follow-up. Median survival in those with recurrent HF was 29 months, significantly less than in those without recurrence (45 months) (38). An analysis from the USRDS registry indicates that 1-year survival after treatment for HF is 68% for incident hemodialysis patients (2). It is interesting to note that HF has been consistently shown to be a strong independent risk factor for death, whereas the presence of IHD is not a significant risk factor for death independent of age, diabetes, and presence of HF (38). This suggests that the adverse impact of IHD exerts its effect through compromising LV pump function.

Risk Factors for Left Ventricular Disorders and Heart Failure

Independent predictors of HF at or before the time of ESKD therapy initiation include systolic dysfunction, older age, diabetes mellitus, and IHD. For patients without HF at baseline, predictors of the development of *de novo* HF include older age, systolic dysfunction, anemia, hypoalbuminemia, hypertension, and LVH (5,38). Numerous other risk factors, some unique to the dialysis patient, are known or suspected contributors to LV disorders. These include AV fistulas, disorders of divalent ion metabolism, chronic salt and water overload, altered oxidative stress, and chronic inflammation. The relative contribution of each of these risk factors in the pathogenesis of LVH has not been fully elucidated.

Nonmodifiable Risk Factor

Diabetes Mellitus

Diabetic patients without ESKD appear to be subject to a specific type of cardiomyopathy (39,40). Glycation of collagen may induce cross-linking of collagen fibers (41), and this may be a reason for large and small vessel diseases as well as myocardial dysfunction. In addition, LVH is more prevalent in hypertensive diabetic patients than in hypertensive nondiabetic patients (40,42).

In both the general and the dialysis population, diabetes is an independent risk factor for the development of HF and CAD (17,43,44). More than 50% of prevalent hemodialysis patients with a diagnosis of HF have diabetes (2). Some diabetic patients with ESKD have impairment of LV function despite normal coronary arteries, possibly resulting from the development of a diabetic cardiomyopathy as discussed earlier. Having said this, any analysis of the contribution of diabetes to the development of LV dysfunction in uremic patients is confounded by the very high prevalence of other risk factors, particularly hypertension.

The impact of diabetes was examined in a cohort study of dialysis patients who survived at least 6 months following the initiation of dialysis; 15% of these patients had insulin-dependent diabetes and 12% had non–insulin-dependent diabetes. On starting dialysis therapy, the prevalence of clinical manifestations of cardiac disease was significantly higher in diabetic patients compared with nondiabetic patients. Only 11% of diabetic patients had normal echocardiographic dimensions compared with 25% of nondiabetic patients, predominantly because of the prevalence of severe LVH (34% vs. 18%) (45). Older age, LVH, history of smoking, IHD, cardiac failure, and hypoalbuminemia were independently associated with mortality. Diabetes was a strong risk factor for the development of IHD but not for cardiac failure (45), suggesting that the excessive cardiac morbidity and mortality of diabetic patients may be mediated through ischemic disease rather than progression of cardiomyopathy while patients are on dialysis. Echocardiographic determination of LV size and function was a good predictor of survival. Diabetic patients receiving dialysis therapy with abnormal LV wall motion and abnormal LV internal diameter had the lowest mean survival (8 months), a mortality rate not matched by any subgroup defined by coronary anatomy, ventricular function, or clinical manifestation (46).

Ischemic Heart Disease

The risk factors and outcome for IHD are discussed elsewhere in this book. CAD is an important cause of systolic and diastolic dysfunction in the general population and in dialysis patients (17,47). Dialysis patients diagnosed with impaired LV systolic function should be evaluated for CAD.

Modifiable Risk Factors

Hypertension

The prevalence of hypertension is approximately 80% in hemodialysis patients, but it is closer to 50% in peritoneal dialysis patients (48). A cohort study of more than 2,500 adult hemodialysis patients reported that 86% had a systolic blood pressure (BP) greater than 150 mm Hg or a diastolic BP greater than 85 mm Hg; hypertension was controlled in only 30% of patients, and 12% were untreated (49).

The impact of hypertension was assessed in a cohort of 261 hemodialysis and 171 peritoneal dialysis patients. These patients were followed up prospectively for an average of 41 months per patient, and

echocardiographic assessments were performed annually. The mean arterial BP level during dialysis therapy was 101 ± 11 mm Hg. When adjustments were made for age, diabetes, and IHD and hemoglobin (Hb) and serum albumin levels were measured serially, each 10 mm Hg rise in mean arterial BP was independently associated with the development of concentric LVH [odds ratio (OR) 1.48, $p = 0.02$], IHD (OR 1.39, $p = 0.05$), and *de novo* HF (OR 1.44, $p = 0.007$) (50). Hypertension was also associated with progressive concentric LVH in 596 incident hemodialysis patients without symptomatic cardiac disease or dilatation in a blinded, randomized controlled trial (51). Patients had echocardiograms within 18 months of starting dialysis and subsequently at 24, 48, and 96 weeks later. LVMI rose significantly during the study period from 114.2 g/m^2 at baseline to 128.2 kg/m^2 at week 96. High systolic BP was also associated with an increase in the composite outcome of CV events and death.

In the non–kidney disease population, reductions in BP are associated with regression of LVH. Although a similar effect in patients with ESKD seems highly likely, there is considerably less direct evidence that this is the case. In an attempt to determine the effect of BP lowering on LV size, while partially correcting anemia with erythropoietin, London et al. (52) enrolled 153 hemodialysis patients in a longitudinal study and followed them up for a mean of 54 months. The first step to control BP was achievement of dry weight. If this failed to achieve the target BP, an angiotensin-converting enzyme (ACE) inhibitor, calcium channel blocker, and then α-blocker was added as required. Predialysis BP decreased from 169/90 to 147/78 mm Hg, and Hb increased from 8.7 to 10.5 g/L. LVMI decreased from 174 to 162 g/m^2. The hazard ratio associated with a 10% LV mass decrease was 0.78 for all-cause mortality and 0.72 for CV mortality. The authors concluded that alteration of hemodynamic overload favorably influenced the natural history of LVH in hemodialysis by reducing LVH, an outcome that had a beneficial effect on survival.

Current guidelines for the treatment of hypertension in the general population do not recommend different target BP for patients with and without LVH (53,54). The optimal target BP for patients requiring dialysis is not at all clear. In this group, low BP has been repeatedly associated with increased mortality (55,56). It is likely that low BP is a marker for the presence of cardiac failure (and/or other comorbidity), confounding analyses of BP and death. This hypothesis is supported by an analysis in the general population (57). In the absence of specific trial data, a conservative target is a predialysis BP of 140/90 mm Hg or less, unless the patient develops symptomatic hypotension during or after dialysis. This should be achieved primarily by maintenance of an accurate dry weight, with antihypertensive therapy added if satisfactory results are not achieved.

Anemia

There is considerable epidemiologic evidence that persistent anemia in patients with CKD is a risk factor for cardiac disease; it has been associated with LV dilatation and LVH in both CKD and ESKD patients [relative risk (RR) for LVH progression, per 10 g/L drop, is 1.74 in CKD and 1.48 in dialysis] (17,54–58). It is also a risk factor for the development of *de novo* HF and death but is not associated with *de novo* IHD (58).

Recombinant human erythropoietin is indicated for the treatment of anemia in patients with ESKD. The optimal treatment target for Hb, however, is subject to debate. Recent 2012 Kidney Disease Improving Global Outcomes (KDIGO) guidelines recommend starting erythropoietin-stimulating agents (ESAs) when the Hb is between 9 and 10 g/dL to avoid the Hb falling below 9 g/dL. ESAs should not be

used to maintain Hb concentration of Hb above 11.5 g/dL as multiple randomized controlled trials have suggested that higher Hb targets may be harmful (59). Potential harms include increased rates of mortality CV events (60,61) and cerebrovascular events (62).

Numerous uncontrolled studies in CKD and dialysis patients have assessed the treatment of anemia using ESAs with the effect on LVMI as an outcome. One hundred forty-six hemodialysis patients without symptomatic cardiac disease were randomized to normalization of Hb with erythropoietin or to partial correction of anemia. Two groups were studied, patients with preexisting LV dilatation and patients with concentric hypertrophy. In the former group, mean LV volume was high at baseline (approximately 120 mg/m^2) and a substantial minority had systolic dysfunction. Normalization of Hb failed to induce regression of LV dilatation. In the latter group, normalization of Hb failed to induce regression of LVH but it did prevent progressive LV dilatation (63).

Another randomized double blind trial involved of 596 hemodialysis patients without symptomatic cardiac disease and LV dilatation. Patients were allocated to lower (9.5 to 11.5 g/dL) and higher (13.5 to 14.5 g/dL) Hb targets using epoetin alpha. Both groups had increases in LV volume index (7.6% and 8.3%) and LVMI (16.8% vs. 14.2%). Thus, the investigators concluded that neither partial nor complete normalization of Hb has a beneficial effect on cardiac structure (62).

In contrast to these results, two studies showed favorable reductions in LVMI with correction of anemia. One study involved 230 patients and corrected Hb to 13.5 g/L for women and 14.5 g/L for men. A significant reduction in LVMI of -28 g/m^2 was observed (64). However, optimization of HF therapy during this study confounds the true effect of anemia correction alone. A lower Hb target of 10.5 g/dL was used in a study of 153 hemodialysis patients that received parallel treatment of hypertension and anemia. This study showed a regression in LVMI by 12 g/m^2 (52).

Whether treatment of anemia at an earlier stage of renal disease (e.g., in CKD) may be beneficial is still unclear. Small, uncontrolled studies have suggested that correction of anemia was associated with reductions in LVH (65,66). This has been contradicted by a trial in which 155 patients with CKD were randomized to a target Hb of 120 to 130 g/L versus 90 to 100 g/L. At the end of follow-up (2 years or the initiation of dialysis), there was no significant difference in changes in LVMI between the groups (67).

In order to further determine the impact of erythropoietin therapy on changes in the LVMI among CKD and ESKD patients, a meta-analysis of 15 studies, including those mentioned in the preceding text, involving 1,731 patients was performed. This study provided higher quality evidence that correction of severe anemia (Hb <10 g/dL) to a target of Hb ≤12 g/dL with recombinant erythropoietin resulted in significant reductions in LVMI [-32.7 g/m^2, 95% confidence interval (CI) -49.2 to 16.1, $p < 0.05$] (68). This meta-analysis was limited, however, because the studies lacked control groups and the studies involved patients with both CKD and ESKD. Furthermore, patients in many of these studies may have benefited from parallel treatment of hypertension and HF.

Although some authors have advocated individualized targets for patients with ESKD, there has yet to be any outcome-based studies to demonstrate either the safety or efficacy of this approach. Currently, it is reasonable to follow the most recent KDIGO guidelines for treatment of anemia for all patients including those with cardiac disease (59). These recommendations have been made based on studies demonstrating improvement in quality of life and exercise tolerance at Hb levels of 11.0 to 12.0 g/dL. At the same time, the current body of evidence provides no evidence of mortality benefit and a suggestion of

potential for harm when anemia is fully corrected.

Hypoalbuminemia

Low albumin is a powerful predictor of poor outcome in dialysis patients and has been associated with LV dilatation, *de novo* HF, and IHD (69). The mechanisms underlying this association are unclear. It may be a marker for malnutrition, inadequate dialysis, vitamin deficiency, or a chronic inflammatory state. To date, there is no real evidence as to the impact of the correction of any these factors on cardiac function.

Volume Overload

Sodium and water overload causes plasma volume expansion. Blood volume correlates directly with LV diameter in hemodialysis patients, as does the magnitude of weight changes between sessions (70,71). Despite these associations, it is difficult to clearly discern cause and effect. It is possible that salt and water retention is induced by preexisting systolic or diastolic dysfunction in some patients rather than predisposing to it.

Keeping the patient's dry weight optimal may minimize the degree of enlargement of the LV. It is interesting to note that LVH is more severe in long-term continuous ambulatory peritoneal dialysis (CAPD) patients than in hemodialysis patients (72). This finding is associated with evidence of more pronounced volume expansion, hypertension, and hypoalbuminemia.

In a retrospective study of 41 patients with symptomatic HF, the initiation of hemodialysis was associated with a significant decrease in LVMI by -24.3 ± 35.4 g/m^2 ($p < 0.001$) after 9 months of treatment. The authors of this study concluded the decrease in LVMI could not be explained by a decrease in BP but by better volume control and relief of venous congestion (73).

Abnormal Calcium and Phosphate Metabolism

There is considerable experimental and clinical evidence that the hyperparathyroid state associated with uremia contributes to cardiomyopathy, LVH, LV fibrosis, atherosclerosis, myocardial ischemia, and vascular and cardiac calcification (74–76). Registry data indicate that hyperphosphatemia and raised calcium × phosphate product are independent predictors of mortality (77), especially death from CAD and sudden death (78).

The appropriate use of dietary modification, vitamin D analogs, and phosphate binders are recommended to achieve target levels for serum calcium of 8.4 to 9.5 mg/dL, for serum phosphorus of 2.7 to 4.6 mg/dL, for calcium × phosphate product of 55 mg/dL, and for intact parathyroid hormone (PTH) 150 to 300 pg/mL (79). The availability of aluminum- and calcium-free phosphorus binders has significantly changed the management of ESKD patients. Sevelamer hydrochloride is an effective, although costly, phosphorus binder that is not associated with hypercalcemia. Meta-analysis suggests a survival benefit for non–calcium-based phosphate binders compared to calcium-based binders, but the evidence is weak (80). Evidence from the randomized trial of cinacalcet versus placebo in hemodialysis patients with moderate to severe hyperparathyroidism reveals a clinical benefit in the prevention of CV events in patients aged ≥65 years or in the prevention of severe unremitting hyperparathyroidism in all patients (81,82).

The recent Paricalcitol Capsule Benefits in Renal Failure-Induced Cardiac Morbidity (PRIMO) trial was a randomized, placebo-controlled trial involving 227 patients who assessed the effects of activated

vitamin D on LV mass over 48 weeks (83). Enrolled patients had stage 3 and 4 CKD along with mild to moderate LVH. Despite sufficient suppression of immunoreactive parathyroid hormone (iPTH), paricalcitol failed to reduce LVMI over a 48-week period.

Valve Disease

Acquired aortic stenosis may occur in a few patients and may induce concentric LVH (84). Calcification of the aortic valve has been observed in 28% to 55% of dialysis patients in various series, whereas hemodynamically important stenosis has been reported in 3% to 13%. Progression at times may be extremely rapid. The major factors predisposing to aortic valve calcification appear to be hyperparathyroidism, duration of dialysis, and degree of elevation of calcium × phosphate product (85).

In ESKD patients, intimal arterial disease, age, duration of dialysis, and inflammation all appear to be predictors for valve calcification. The prominent risk factor for mitral annular calcification was diabetes (86).

Mode and Quantity of End-Stage Kidney Disease Therapy

The question as to whether higher dosing targets for dialysis than those currently recommended will result in improvements in cardiac outcomes has been addressed in two randomized controlled trials, with conflicting results. The recently published Frequent Hemodialysis Network (FHN) daily trial was a multicenter, prospective, randomized parallel group trial that compared frequent, six times per week, in-center hemodialysis to conventional three times weekly dialysis (87). The two coprimary outcomes were death or change in LV mass, as assessed by CMR imaging. Two hundred forty-five patients were randomized, and frequent dialysis was associated with significant benefits in the coprimary outcome (HR 0.61, 95% CI 0.46 to 0.82). Stand-alone reduction in LV mass was assessed as a secondary outcome, and the adjusted mean LV mass decreased by 16.4 ± 2.9 g in the frequent hemodialysis group, as compared with 2.6 ± 3.2 g in the conventional group. By comparison, in the Hemodialysis (HEMO) study, 1,846 patients on thrice-weekly hemodialysis were randomized to either “standard” dose (target equilibrated $K_t/V = 1.05$) or “high” dose (target equilibrated $K_t/V = 1.45$). No difference in the primary outcome of all-cause mortality or any of the prespecified secondary outcomes was observed between the groups (88). Chertow et al. (87) note that the benefit observed in the FHN trial may have been due to an even greater between-group difference in urea clearance compared to the HEMO study.

A recent randomized, controlled, open-label, blinded endpoint study aimed to determine if cooled dialysate provided long-term cardiac protection using serial CMR imaging (89). This study group had previously demonstrated that cooled dialysate can reduce recurrent myocardial stunning during HD. Seventy-three patients were initially randomized to either a dialysate temperature of 37°C or individualized cooling at 0.5°C below body temperature for 12 months. The investigators found no difference in the primary outcome of ejection fraction. However, there was a significant reduction in LV mass in the intervention group (decreased by 15.6 g compared to control) and a significant reduction of −23.8 mL in LV-end diastolic volume in the intervention group. Furthermore, global LV systolic function was maintained in the experimental group but decreased in the control group (difference of −3.3%, 95% CI −6.5% to −0.2%). The investigators concluded that individualized cooled dialysate slowed the progression of hemodialysis-associated cardiomyopathy. The generalization of these findings is limited as only 44 participants completed the study and the experimental group had a larger baseline LV mass (157.9

± 50.5 g vs. 140.3 ± 48.7 g).

Although some patients who are unable to tolerate the intradialytic volume expansion associated with intermittent hemodialysis may be more easily managed with peritoneal dialysis, there is no good evidence that either modality is associated with improved outcomes for patients with heart disease. Nocturnal hemodialysis has been associated with an improvement in many clinical parameters, including BP and regression of LVH (90,91). Whether the observed cardiac benefits are due to amelioration of hypertension, improvement in anemia, or higher dialysis dose is not clear.

Kidney transplantation is undoubtedly the best treatment for ESKD, and a good model of what happens to cardiac function when uremia is optimally treated. Following kidney transplantation, concentric LVH and LV dilatation improves, but the most striking observation is the improvement in systolic dysfunction (92). It is not known which adverse risk factors characteristic of the uremic state have been corrected to produce the improvement in LV contractility, but hypertension and AV fistulas usually persist posttransplantation.

Management of Left Ventricular Disorders and Heart Failure

Asymptomatic LV disease is usually detected with screening echocardiography. Aggressive treatment of risk factors, particularly hypertension, anemia, and IHD, is critical to prevent further myocardial dysfunction. Periodic echocardiography to assess the efficacy of such measures is prudent, and careful observation for clinical evidence of HF is required.

The initial step in the treatment of any patient with symptoms of HF should be a careful assessment for reversible precipitating or aggravating factors. Arrhythmias, uncontrolled hypertension, and use of drugs that may adversely affect cardiac performance (e.g., most calcium channel blockers, most antiarrhythmic agents, or nonsteroidal anti-inflammatory drugs) are examples. IHD may be associated with HF. This diagnosis is not always obvious, especially in diabetic patients who may not have typical symptoms.

For some patients with CKD, the appearance of HF symptoms refractory to standard treatment heralds the need for dialysis initiation. ESKD patients with severe HF will usually require hemofiltration for relief of their acute symptoms, and those on maintenance dialysis will require careful assessment of their target weights. The maintenance of a patient’s true dry weight is of paramount importance in managing HF symptoms but may not be easily done in some cases. The occurrence of hypotension during dialysis, large interdialytic weight gains, and the possible overprescription of hemodynamically active drugs may need to be addressed. In difficult cases, ultrafiltration with simultaneous direct pressure monitoring using right heart catheterization may be helpful to define the optimal intravascular volume. HF unresponsive to changes in dry weight may be a complication of unsuspected IHD or valvular disease and should prompt further investigation.

Distinguishing systolic from diastolic dysfunction on clinical grounds is difficult, although the presence of hypertension with signs of HF is suggestive of hypertrophic disease with diastolic dysfunction. Systolic and diastolic dysfunction may coexist, and the relative contribution of each process may change with the evolution of LV disease in a given patient. Nonetheless, the clinical management of HF differs according to whether systolic or diastolic dysfunction predominates. An echocardiographic diagnosis of mainly diastolic disease could lead to changes in therapy, as discussed later. Consequently, an echocardiogram is an integral part of the evaluation of patients with HF.

A suggested approach to the treatment of LV disorders and HF is shown in **FIGURE 16.4**.

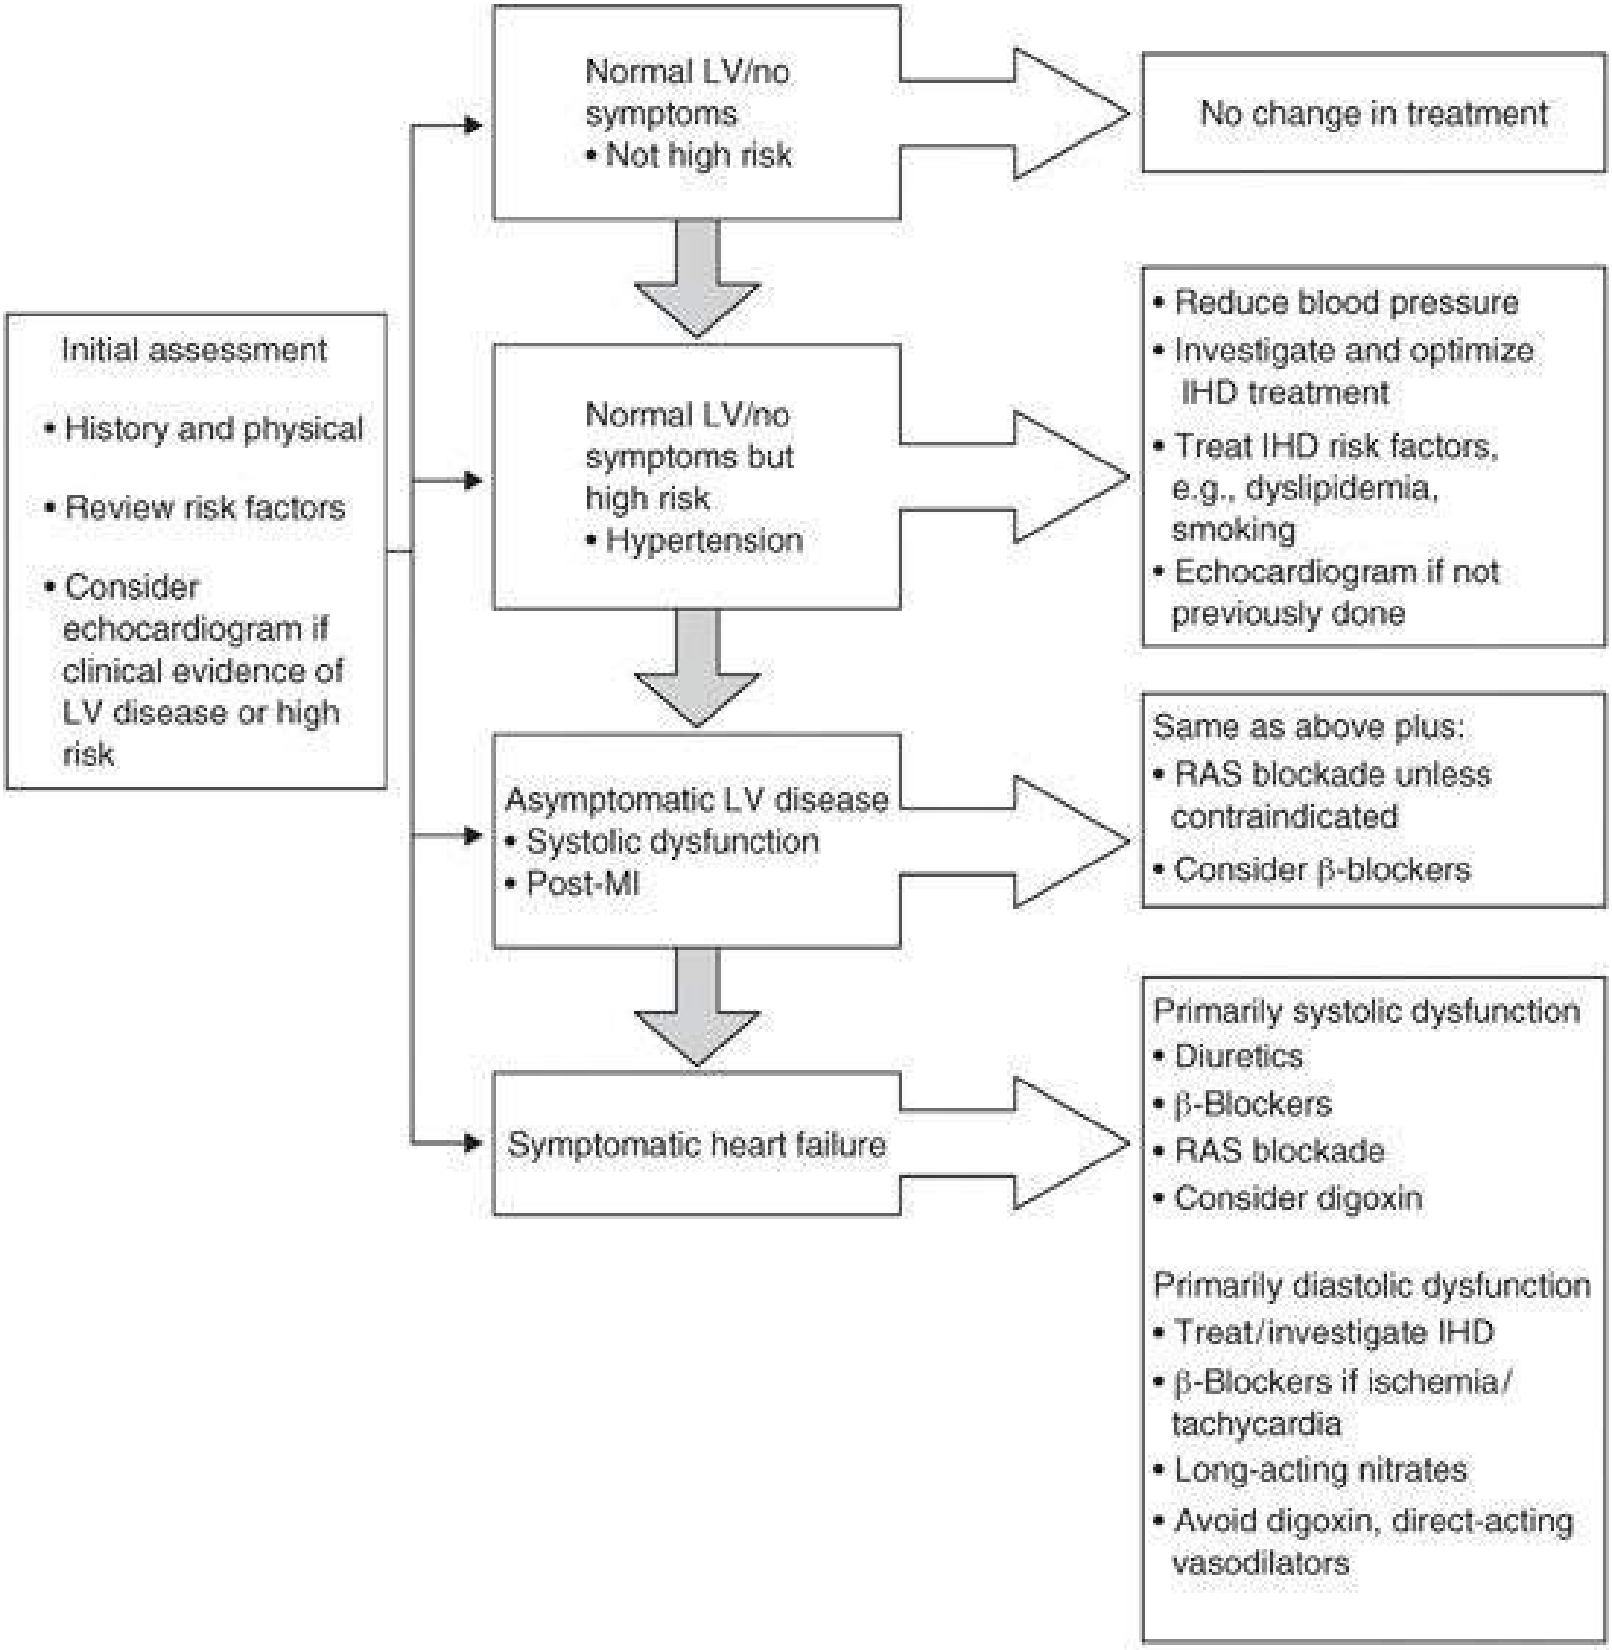

FIGURE 16.4 An approach to the treatment of left ventricular (LV) disorders and heart failure in patients with kidney disease. IHD, ischemic heart disease; MI, myocardial infarction; RAS, renin-angiotensin system.

Pharmacotherapy

Patients who have LVH without HF benefit from control of hypertension, and this should be aggressively pursued. Although many classes of drugs have been shown to improve LVH, ACE inhibitors reduce LVH beyond their BP lowering effect (93).

Non–kidney disease patients with symptomatic HF resulting from systolic dysfunction are usually managed with a combination of renin-angiotensin system (RAS) blockade, β-receptor antagonists, diuretics, and/or digoxin.

Many well-designed trials in non-CKD patients have demonstrated that ACE inhibitors consistently improve symptoms, reduce morbidity, and improve survival in patients with symptomatic HF (94). Furthermore, current trial data suggests that angiotensin receptor blockers (AT_1 blockers) may be effective for the treatment of symptomatic HF in the general population, particularly for patients who do not tolerate ACE inhibitors (95,96). In dialysis patients, the Fosinopril in Dialysis (FOSIDIAL) trial was the largest trial to date to assess ACE inhibition in the reduction of coronary vascular events (97). In this randomized, double-blind study, 397 patients with ESKD and LVH were randomized to either fosinopril (n = 196) or placebo (n = 201). Although the study lacked statistical power due to a lower than predicted event rate, patients treated with fosinopril did appear to have a lower risk for coronary vascular events in the adjusted analysis. RAS blockade was also studied in multiple small studies. A trial of 30 hemodialysis patients randomized patients to losartan, enalapril, or amlodipine (98). LVMI was measured before and after 6 months of treatment. Losartan treatment significantly reduced the LVMI by −24.7 ± 3.2% compared to enalapril (−11.4 ± 4.1%) and amlodipine (−10.5 ± 5.2%). Extrapolation of these results to the general dialysis population is obvious limited due to the very small sample size. Another small study of 33 diabetic dialysis patients were randomized patients to enalapril 10 mg, losartan 100 mg, or combination therapy (99). At 1 year, there was a reduction of LVH in all groups, but dual blockade resulted in a further 28% reduction. The clinical benefit of combination ACE inhibitor and AT_1 blocker therapy is still unclear, however. For now, such combination therapy should be employed with caution in dialysis patients as emphasized in the Veterans Affairs Nephropathy in Diabetes (VA NEPHRON-D) trial involving CKD patients (100).

Although there is insufficient trial data on RAS blockade in the dialysis population, the overwhelming benefit seen in the general population makes it likely that patients with advanced CKD will benefit as well. Although there is a risk in that these drugs may predispose dialysis patients to hyperkalemia, ACE inhibitors and AT_1 blockers are generally considered safe as long as appropriate dose titration and monitoring are instituted. Current guidelines for the general population recommend ACE inhibitors for patients who are either post-MI with an LV ejection fraction of less than 40% or who are asymptomatic with an LV ejection fraction of less than 35% (31,101). It is reasonable to apply these recommendations to dialysis patients when there is no specific contraindication.

β-Receptor antagonists are now a standard component in the management of LV systolic dysfunction. Improvements in mortality and/or hospitalization have been shown in patients with mild to moderate symptomatic congestive heart failure (CHF) treated with carvedilol, bisoprolol, or controlled-release metoprolol (102–105). Current guidelines for the general population suggest the routine use of β-receptor antagonists in clinically stable patients with LV ejection fraction less than 40% and mild to moderate HF symptoms who are on standard therapy, that is, diuretics, an ACE inhibitor, and digoxin (101). Such therapy should also be considered for asymptomatic patients with LV ejection fraction less than 40%, but the evidence supporting its use in this setting is not as strong. β-Receptor antagonists are not currently recommended for patients with severe symptomatic CHF. In one of the few randomized trials performed in dialysis patients, Cice et al. (106,107) have demonstrated that treatment of patients with dilated

cardiomyopathy with carvedilol reduced 2-year mortality [51.7% in the carvedilol group compared with 73.2% in the placebo group (p <0.01)]. Carvedilol reduced CV deaths and hospital admissions. A recent open label randomized controlled trial compared atenolol to lisinopril in 200 maintenance hemodialysis patients with hypertension and LVH (108). Both groups had an improvement in LVMI at 12 months: −21.4 ± 5.7 g/m^2 with atenolol and −15.1 ± 6.2 g/m^2 in lisinopril, and this difference was nonsignificant. However, the trial was terminated early because the lisinopril group experienced an increase in all-cause serious events, all-cause hospitalization rates, hospitalizations for CHF, hypertension, and hyperkalemia. It is difficult to ascertain the cause of this significant difference in event rates, but the withdrawal of β-blockers in the lisinopril group may have been contributory. Overall, the investigators concluded that among predominantly black hemodialysis patients with hypertension (HTN) and LVH, β-blocker therapy may be superior to ACE inhibition. These studies, along with numerous observational data, suggest that β-receptor antagonists may be safely used in dialysis populations in the same manner recommended for the general population. However, the initiation of highly dialyzable β-blockers compared to lowly dialyzable β-blockers may be associated with a higher risk of death, possibly secondary to increased ventricular arrhythmias (109). Specific contraindications to β-blockers include reactive airway disease, sinus node dysfunction, and cardiac conduction abnormalities. As in the nondialysis population, these agents should be started in low doses with careful clinical reevaluation during the titration phase. β-Blockers with intrinsic sympathomimetic activity appear to be detrimental and should not be used in patients with HF.

Loop diuretics are widely used to maintain euvolemia in most patients with HF, but their effect may be negligible in patients requiring dialysis. Thiazide diuretics usually become ineffective with a glomerular filtration rate (GFR) less than 30 mL/min and are therefore not useful in patients with severe renal impairment. Aldosterone antagonists are similarly ineffective in patients with ESKD, and hyperkalemia can result when these drugs are combined with RAS blockade and β-receptor antagonists (110). They should be avoided in such patients.

Digoxin is useful in the treatment of patients with atrial fibrillation and HF. Although digoxin does not improve survival, nonuremic patients with symptomatic LV systolic dysfunction have less morbidity and improved exercise tolerance when given digoxin in conjunction with standard therapy, that is, diuretics and ACE inhibitors (111,112). The only data from a randomized trial concerning patients with CKD is the *post hoc* analyses of data from the Digoxin Intervention Group (DIG) trial. In this case, the efficacy of digoxin did not differ by level of GFR, ranging from patients with normal kidney function to those on dialysis (113). Digoxin should therefore be considered for dialysis patients with systolic dysfunction, given a reduction in dose appropriate to their level of renal impairment. Low dialysate potassium levels should be avoided for hemodialysis patients, as hypokalemia may predispose to arrhythmias in the presence of digoxin. Peritoneal dialysis patients will frequently require potassium supplementation to maintain normal levels. Digoxin should not be given to patients with primarily diastolic dysfunction, as the increased contractility could worsen diastolic impairment.

The treatment of diastolic dysfunction is less well defined. Attempts to eliminate the cause are generally the focus of therapy. This includes aggressive control of hypertension and IHD. Long-acting nitrates may be advantageous in some patients, and β-receptor antagonists are useful for treating IHD and tachycardia. Digoxin and direct vasodilators, such as prazosin, hydralazine, or minoxidil, are generally contraindicated in this setting (101).

CARDIAC ARRHYTHMIAS AND SUDDEN CARDIAC DEATH

Sudden cardiac death (SCD) and arrhythmias occur in hemodialysis patients who encounter stressors to a vulnerable myocardium (114) (**FIGURE 16.5**). These patients develop cardiomyopathy with diastolic and systolic dysfunction, fibrosis, and vascular disease. In addition, sympathetic over activity, inflammation, abnormalities in mineral metabolism, electrolyte shifts, hypervolemia/hypovolemia, and QT prolongation together predispose to arrhythmia and SCD. In the general population, CAD and LVH appear to be associated with an increased risk of arrhythmias (115,116). In patients with CAD, for each 10 mL/min decrement in eGFR, the risk of SCD increased by 11%. CAD is present in at least 38% of the prevalent dialysis population (117), and in these patients, the intra- and postdialytic period is associated with a high frequency and lengthy persistence of ventricular arrhythmias (118). In other studies, CAD has been associated with a higher frequency of arrhythmias in some (119,120) but not all studies on patients receiving hemodialysis (121,122). While the association with LVH has not been well documented in ESKD, a 10-year cohort of 123 dialysis patients revealed that worsening of LVH is a strong predictor of sudden death (123). Furthermore, in the Deutsche Diabetes Dialyse Studie (4D) trial, the presence of LVH doubled the risk of SCD (124).

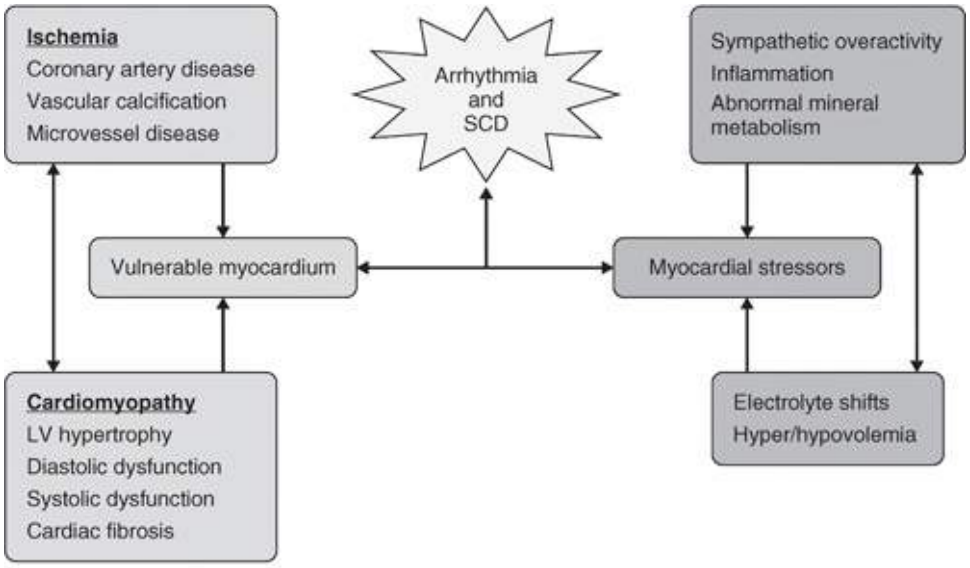

FIGURE 16.5 The etiology of sudden cardiac death (SCD) occurs in uremic kidney disease.

There are conflicting data about the effect of dialysis and various dialysis compositions and dialysis protocols on the occurrence of rhythm disturbances. Some studies show higher incidence of premature ventricular contractions (PVCs) during dialysis or immediately after dialysis (122,125,126), whereas in others, no differences could be observed (101,121). Other studies showed that a low dialysate potassium of <2 mEq/L was associated with a significantly increased risk for SCD (127,128).

In cross-sectional studies of patients with ESKD, the prevalence of atrial arrhythmias was between 68% and 88%, ventricular arrhythmias were present in 56% to 76% of patients, and PVCs were found in 14% to 21% (121,122,126). Older age, preexisting heart disease, LVH, and use of digitalis therapy were associated with higher prevalence and greater severity of cardiac arrhythmias (120).

Most PVCs observed are unifocal and below 30 per hour, but high-grade ventricular arrhythmias like multiple PVCs, ventricular couplets, and ventricular tachycardia have been found in 27% of 92 patients with 24-hour Holter monitoring (129). The finding of high-grade ventricular arrhythmias in the presence of IHD was associated with increased risk of cardiac mortality and sudden death (120,130). Whereas the

dialysis method, membrane, and buffer used do not seem to have a direct effect on the incidence of arrhythmias (131), dialysis-associated hypotension seems to be an important factor in precipitating high-grade ventricular arrhythmias, irrespective of the type of dialysis (131,132).

Holter monitoring of cardiac rhythm of 21 peritoneal dialysis patients revealed a high frequency of atrial and/or ventricular premature beats (133). There were no differences in the type and frequency of the extrasystoles between the day on peritoneal dialysis and the day on which dialysis was deliberately withheld. It seems that, in contrast with HD, peritoneal dialysis is by itself not responsible for provoking or aggravating arrhythmias. The arrhythmias are more a reflection of the patient's age, underlying IHD, or an association with LVH (134,135).

A study in which 27 peritoneal dialysis patients were compared with 27 hemodialysis patients revealed that severe cardiac arrhythmias occurred in only 4% of CAPD and in 33% of the hemodialysis group (135). Patients in both groups were matched for age, sex, duration of treatment, and cause of CKD. The lower frequency of LVH, the maintenance of a relatively stable BP, the absence of sudden hypotensive events, and the significantly lower incidence of severe hyperkalemia in patients on peritoneal dialysis may explain the lower incidence of severe arrhythmias in patients with CAPD (136).

Digoxin use in hemodialysis patients has raised concern regarding precipitation of arrhythmias, especially in the immediate postdialysis period, when both hypokalemia and relative hypercalcemia may occur (119,120,137). Keller et al. (138) studied 55 patients in a crossover study of "on-and-off" digoxin and found no increase in incidence of arrhythmias when patients were on the drug.

Given the high prevalence of dysrhythmias in the dialysis population, it is worthwhile to perform a 12-lead electrocardiogram (ECG) in all patients at the time that treatment is initiated. The treatment of arrhythmias with pharmacologic agents is controversial, regardless of the patient population. Certain antiarrhythmics may increase the likelihood of sudden death (139). In kidney disease, pharmacokinetics are altered, and hemodialysis *per se* may have a major effect on antiarrhythmic drug levels. Most agents require significant dose adjustments, and some drugs, such as procainamide and dofetilide, are to be avoided in dialysis patients altogether (35). In general, management should first be directed at the underlying cardiac disease and the amelioration of any aspects of the dialysis procedure or uremic state that may be aggravating the situation. Only then should drug therapy be considered. It is our policy to be conservative in initiating treatment with antiarrhythmic drugs in dialysis patients.

DIALYSIS-ASSOCIATED HYPOTENSION

The hemodynamic response to hemodialysis depends on the amount and rate of fluid removal and the presence and nature of any underlying ventricular dysfunction. Fluid removal during hemodialysis leads to a decrease in plasma volume and a reduction in ejection fraction and diameter. Arterial hypotension may also result. The normal defense against such hypotension is mediated by the sympathetic nervous system that causes peripheral vasoconstriction, increasing systemic vascular resistance and heart rate with a resultant rise in cardiac output. In dialysis patients, this compensatory response may be defective if autonomic dysfunction is present.

The influence of the nature of the underlying cardiac disease on the occurrence of dialysis hypotension has not been well studied. Theoretically, hypotension also may occur if LV dysfunction does not allow a compensatory rise in cardiac output (140). In patients with diastolic dysfunction, there is a

shift of the normal ejection fraction and pressure relationship (**FIGURE 16.6**). These individuals are more likely to develop decreased cardiac output and hypotension with smaller decreases in intravascular volume. Conversely, they are also more likely to develop HF with smaller increments in intravascular volume.

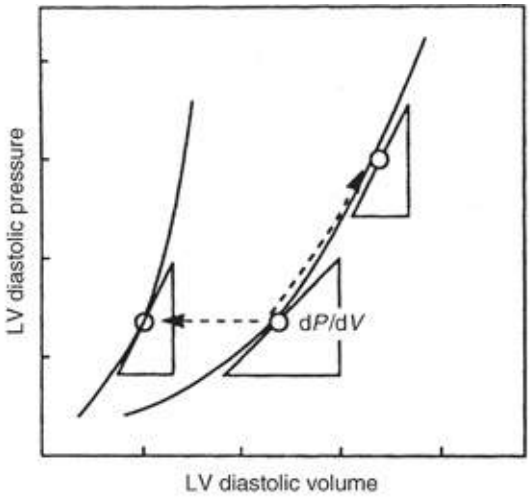

FIGURE 16.6 Compliance characteristics of the left ventricle (LV) during diastolic filling. In uremia, compliance is decreased with a leftward shift of the pressure–volume curve. (Reprinted with permission from Palmer BF, Henrich WL. The effect of dialysis on left ventricular contractility. In: Parfrey PS, Harnett JD, eds. *Cardiac Dysfunction in Chronic Uremia*. Boston, MA: Kluwer Academic Publishers, 1992.)

If the amount and rate of volume removal is too high, hypotension may result even in the presence of an intact autonomic nervous system and the absence of cardiac disease. Dialysis-associated hypotension is therefore often multifactorial. Indeed, it cannot entirely be explained by changes in volume status, because hypotension occurs more readily with conventional hemodialysis than with ultrafiltration, given identical fluid removal. The stability of plasma osmolality during ultrafiltration may be an important factor (141,142).

The most important means of preventing hypotensive episodes is the prescription of an accurate dry weight. Stepwise reduction of weight with clinical assessment at each stage is still the most common method of achieving this, but newer methods such as ultrasonic inferior vena cava measurement and bioelectric impedance determination are becoming more widely used. Cooling of the dialysate or sympathicomimetic agents such as midodrine are useful in selected patients (143). Sodium modeling during dialysis and reduction in ultrafiltration rates are also useful strategies to try (144). Overall, the prevention and treatment of hypotension are no different in patients with underlying cardiac disease than in those with normal hearts. The existence of underlying ventricular dysfunction should, however, alert the clinician that hypotension is more likely, particularly for patients with severe LVH.

CONCLUSION

LV dysfunction and HF is a common problem in patients with ESKD. Such disease may be asymptomatic and may contribute to arrhythmias or dialysis-associated hypotension. Our understanding of the optimal treatment of patients with ESKD is still evolving. In the absence of specific trial data, it is wise to consider treating this patient group in much the same way as the general population. Management is aimed at treating any reversible causes, optimizing salt and water balance, and ameliorating uremic anemia.

RAS blockade is a cornerstone of treatment, and β-receptor antagonists should be considered. Digoxin may be useful in patients with systolic dysfunction even in the absence of atrial fibrillation, but it should be avoided in those patients with predominantly diastolic dysfunction. Prevention of LV disease through early and aggressive treatment of risk factors is likely the best way to reduce morbidity and mortality.

CHAPTER 17

Coronary Artery Disease and Sudden Cardiac Death in Patients with End-Stage Kidney Disease

Wajeh Y. Qunibi, L. Richard A. Lange, and William L. Henrich

The number of patients with end-stage kidney disease (ESKD) who are receiving maintenance dialysis in the United States continues to increase and is now approaching 500,000 (1). Unfortunately, these patients are at considerably higher risk of premature death than the general population. Cardiovascular disease (CVD) is the leading cause of death in dialysis patients, accounting for 42% of deaths; a rate that is 10 to 30 times higher than in patients in the general population (2,3). This relative risk (RR) is remarkably higher in younger dialysis patients, which can be several hundredfold higher than their age-matched counterparts in the general population (**FIGURE 17.1**) (4). Simply stated, the risk of death in a 30-year-old dialysis patient is similar to that of an 80-year-old patient in the general population. Coronary artery disease (CAD) affects 30% to 60% of patients with ESKD and has been (5–8) documented by angiographic studies in >50% of patients at the initiation of renal replacement therapy (9). Indeed, by the time they begin hemodialysis (HD), 73% of patients with angina and 54% of asymptomatic patients will have CAD (7). Of great concern is the high mortality rate of dialysis patients after a cardiovascular event. Approximately 20% of deaths from CVD have been attributed to acute myocardial infarction (MI) (10). Interestingly, dialysis patients who develop an acute MI are less likely to have ST-segment elevations and are more likely to suffer in-hospital cardiac arrest (11). In-hospital mortality after acute MI among patients on dialysis is approximately 30%; at 1 year, the mortality rate is 60% and at 5 years, the mortality rate increases to 90% (10) (**FIGURE 17.2**). Moreover, dialysis patients have more than a 10-fold increased risk for CAD-related death per 1,000 person-years than a patient with five Framingham risk factors (12). The large burden of CAD among patients with ESKD prompted the American Heart Association and the National Kidney Foundation to state that individuals with chronic kidney disease (CKD) are members of the “highest risk group” for subsequent cardiovascular events (13,14).Thus, understanding both the risk factors for CAD as well as the most effective therapeutic modalities are critically important in reducing the burden and consequences of CAD in dialysis patients.

Some of the factors that contribute to the high prevalence of CAD in patients with ESKD include

advancing age and diabetes. The average age of dialysis patients has increased steadily over the past two decades, such that currently their median age is 65 years (1). This older age group has the highest rate of cardiovascular-related deaths in the ESKD population (15). At the same time, even young HD patients have a high prevalence of CVD death: Among ESKD subjects aged 20 to 44 years, the incidence of CVD death is roughly 40 per 1,000 patient-years (15,16). Interestingly, the percentage of deaths that are cardiovascular in cause is similar in all age groups with ESKD (16), leading some investigators to suggest that atherosclerosis may be accelerated in this patient population (17). Also, diabetes mellitus is the leading cause of ESKD in the United States (1). CVD accounts for almost 75% of deaths of patients with diabetes, almost entirely as a result of CAD (18). In a recent study of new diabetic dialysis patients without cardiac symptoms or a known cardiac history, significant CAD was present in 83% (9). In many patients with diabetes mellitus and resultant ESKD, atherosclerosis is well established by the time dialysis is initiated so that many of them manifest ischemic heart disease (IHD), peripheral vascular disease, ischemic bowel disease, or cerebrovascular events shortly after dialysis is begun (19). Not surprisingly, therefore, diabetic patients with ESKD have an extremely high risk for cardiac death.

PATHOGENESIS OF ATHEROSCLEROSIS IN PATIENTS WITH END-STAGE KIDNEY DISEASE

The hypothesis that ESKD, in some way, might cause accelerated atherosclerosis was proposed more than 30 years ago by Lindner et al. (17) who reported a high incidence of MI in the Seattle dialysis population. Of their 39 subjects undergoing HD for an average of 6.5 years, 23 (59%) died, 14 of which were attributed to complications of atherosclerosis (MI in 8, cerebrovascular accident in 3, and refractory congestive heart failure in 3). The incidence of these complications was several times higher than that noted in normal and hypertensive patients of similar age without ESKD. Subsequent postmortem (20) and angiographic (21,22) studies confirmed that the prevalence of atherosclerotic CAD is increased in dialysis patients when compared with age-matched individuals with normal renal function. For example, in a postmortem examination of dialysis patients, Ansari et al. (20) found >50% luminal diameter narrowing of at least one epicardial coronary artery in 60% and at least some degree of atherosclerotic CAD in 86%.

Subsequent studies have shown that the high prevalence of atherosclerosis among patients on maintenance dialysis is the result of the high prevalence of both “traditional” and uremia-related risk factors (**TABLE 17.1**). Whether maintenance HD in itself promotes progression of atherosclerosis (due, e.g., to exposure to bioincompatible dialysis membranes and/or contaminated dialysis fluids) remains unclear. Long-term studies have shown no correlation between the duration of dialysis and the occurrence of cardiac events, a relation that might be expected if, in fact, dialysis itself promotes atherogenesis (23,24). Dialysis patients have a high prevalence of many of the Framingham risk factors for CAD. A cross-sectional comparison of 1,041 dialysis patients with the general population (via the National Health and Nutrition Examination Survey database) found a high prevalence of hypertension (96%), limited physical activity (80%), diabetes mellitus (54%), hypertriglyceridemia (36%), and electrocardiographic evidence of left ventricular hypertrophy (LVH) (22%) in those with ESKD (25). Even after adjusting for race, gender, and atherosclerotic vascular disease, these factors remained more common in ESKD

patients (25). Apart from the increased prevalence of these "traditional" risk factors in patients with CKD (26,27), several uremia-related risk factors are thought to contribute to CAD in these patients (**TABLE 17.1**), including hyperphosphatemia, oxidative stress, inflammation, and hyperhomocysteinemia. Finally, newly discovered risk factors for atherosclerosis in patients with ESKD may contribute, such as the accumulation of the endogenous inhibitor of nitric oxide (NO) synthase, asymmetric dimethylarginine (ADMA), which results in reduced NO synthesis (28,29).

TABLE 17.1 Risk Factors for Cardiovascular Disease in Patients with End-Stage Renal Dysfunction

Traditional CAD Risk Factors	Uremia-Related Risk Factors
• Older age	• Uremic serum
• Male gender	• Hyperphosphatemia
• Hypertension	• Calcium load
• Diabetes	• Elevated serum PTH levels
• Smoking	• Dialysis vintage
• High serum LDL cholesterol	• Hyperhomocysteinemia
• Low serum HDL cholesterol	• Anemia
• Physical inactivity	• Malnutrition
• Family history of premature coronary artery disease	• Chronic inflammation
	• Oxidative stress
	• Sympathetic overactivity
	• Increased asymmetric dimethylarginine (ADMA)

CAD, coronary artery disease; LDL, low-density lipoprotein; HDL, high-density lipoprotein; PTH, parathyroid hormone.

An increased prevalence of atherosclerotic CAD is progressive over a range of reduced glomerular filtration rates (GFRs) even before the initiation of dialysis (30–33). In a landmark study of >1 million subjects, Go et al. (30) showed that the age-adjusted rate of cardiovascular events (i.e., MI, stroke, heart failure, and peripheral arterial disease) increased markedly below an estimated GFR of 60 mL/min/1.73 m^2. After adjustment for a variety of potentially confounding variables, a lower estimated GFR persisted as a graded, independent predictor of adverse outcomes, and this association was robust in those with or without diabetes. CKD patients with known CAD are at the highest risk for subsequent cardiovascular complications and death, with nearly 46% of subjects with an estimated GFR <45 mL/min/1.73 m^2 dead within 3 years of follow-up (31). In angiographic studies, patients with CKD were more likely to have severe three-vessel disease and left main disease as estimated GFR decreases (34,35). These findings may explain the high early risk of acute MI after the initiation of dialysis; in one study, 29% of infarctions occur within 1 year and 52% within 2 years of dialysis initiation (10).

RISK FACTORS FOR ATHEROSCLEROSIS IN PATIENTS WITH END-STAGE KIDNEY DISEASE

The Role of Traditional Risk Factors for Coronary Artery Disease

The Choices for Healthy Outcomes in Caring for ESRD (CHOICE) study reported a prevalence of traditional risk factors for atherosclerotic CVD in incident dialysis patients (25). This population, which was more likely to be older, African American, and male than the general United States adult population, had a high prevalence of hypertension (96%), low physical activity (80%), diabetes (54%),

hypertriglyceridemia (36%), low high-density lipoprotein (HDL) cholesterol (33%), and LVH by electrocardiogram (ECG) criteria (22%). A high proportion of dialysis patients have multiple traditional risk factors such as older age, hypertension, and diabetes (36). Also, smoking seems to be more prevalent in dialysis patients with CAD than those without CAD (37,38).

Hypertension

Hypertension, defined as 1-week average predialysis systolic blood pressure (BP) measurements >150 mm Hg or diastolic BP >85 mm Hg or the use of antihypertensive medications, was documented in 86% of clinically stable adult HD patients (39). Among HD patients who were hypertensive, 58% were treated but had uncontrolled BP and only 30% had controlled BP (40,41). The independent determinants of poor control of BP were the use of antihypertensive drugs and an expanded extracellular volume state (42). It has been suggested that hypertension may be better controlled in peritoneal dialysis patients than in those on HD (43–45). However, 44-hour ambulatory BP monitoring showed no differences in daytime and nighttime BP (46). Hypertension is believed to be the predominant risk factor for atherosclerosis in this patient population (47–50). Hypertension in most dialysis patients is systolic (due to arterial stiffness), although an increased pulse pressure (also a reflection of arterial stiffness) is common in these subjects as well. Systolic pressure is more strongly associated with an increased risk of cardiovascular death than either pulse or diastolic pressures in this patient population (51). Interestingly, a U-shaped relation between systolic pressure and mortality is present in dialysis subjects, in that both lower and higher levels are associated with an increased mortality (**FIGURE 17.3**) (3,52).

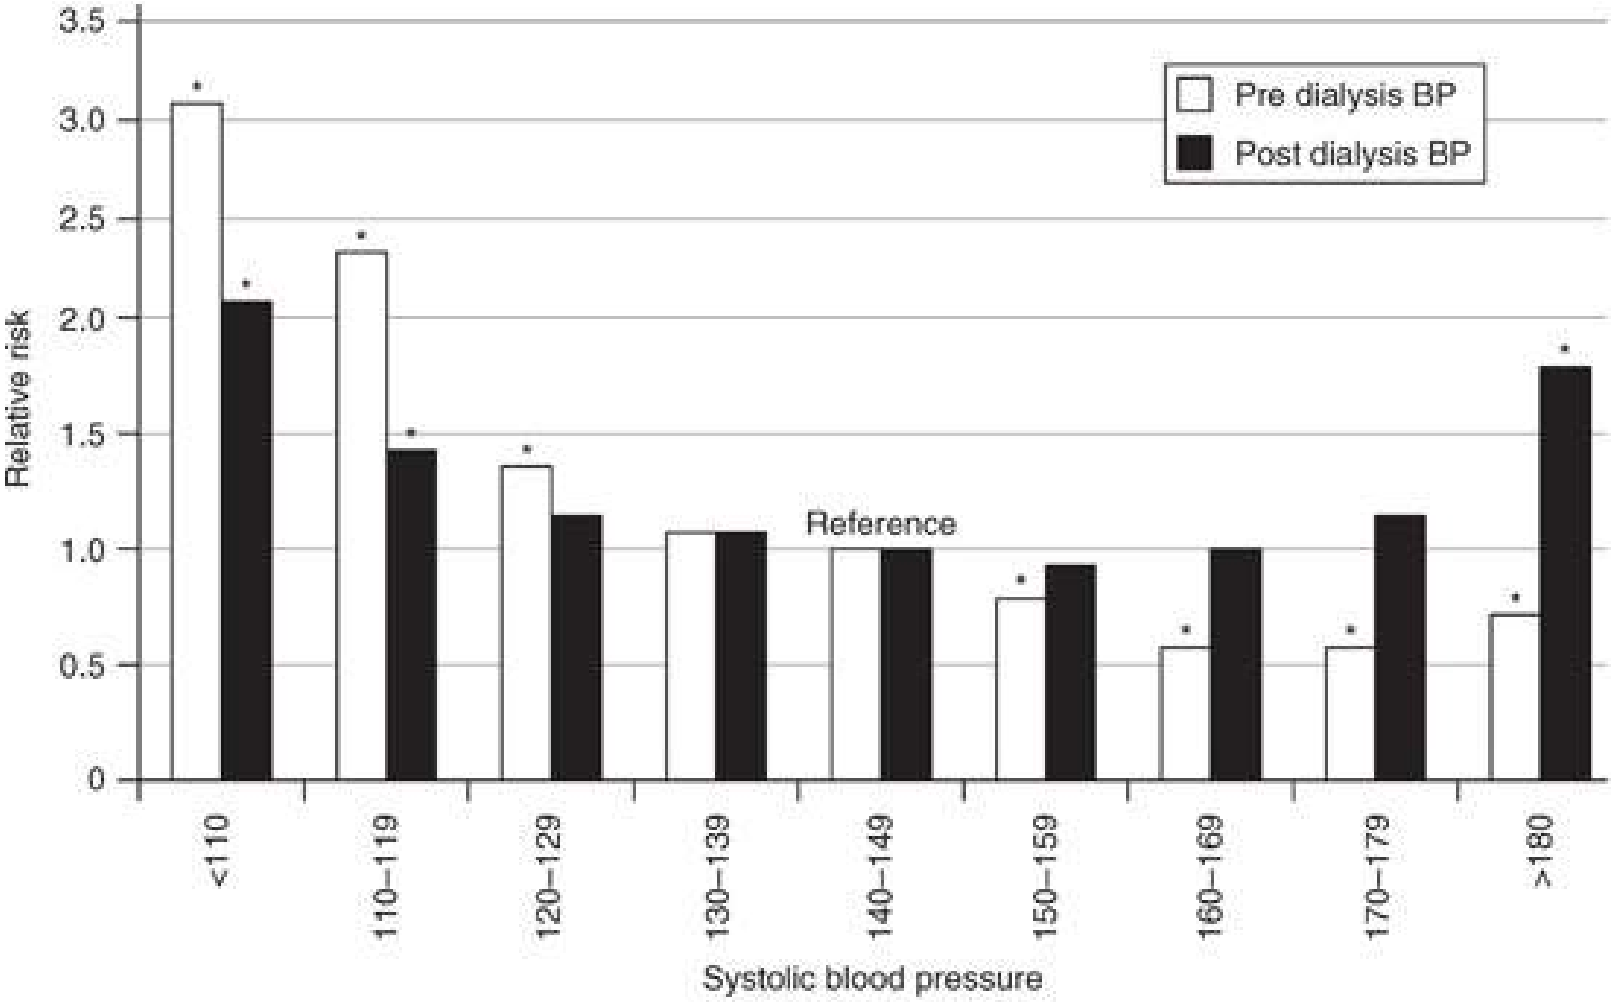

FIGURE 17.3 Mortality risk versus systolic blood pressure (BP) in hemodialysis patients. Asterisk (*) denotes significance. (Adapted with permission from Sarnak MJ, Levey AS, Schoolwerth AC, et al. Kidney disease as a risk factor for development of cardiovascular disease: a statement from the American Heart Association Councils on Kidney in Cardiovascular Disease, High Blood Pressure Research, Clinical Cardiology, and epidemiology and Prevention. *Circulation* 2003;108;2154–2169; and Zager PG, Nikolic J, Brown RH, et al. "U" curve association of blood pressure and mortality in hemodialysis patients. Medical Directors of Dialysis Clinic, Inc. *Kidney Int* 1998;54:561–569.)

Hypertension is usually present for years during the course of CKD before dialysis is initiated. Despite aggressive dialysis and antihypertensive therapy, BP is poorly controlled in about half of ESKD patients. The long duration of poorly controlled hypertension is an important contributor to the increased risk of CAD (53). The increased tensile and sheer stresses caused by hypertension induce endothelial cell injury and activation. This, in turn, is followed by secretion of vasoactive and growth-regulating factors which can elicit a series of cellular interactions that culminate in the appearance and progression of atherosclerosis (54). Aside from its role as a major risk factor for atherosclerosis, poorly controlled hypertension is associated with an increased likelihood of complex ventricular arrhythmias (55–57), and the hypertension-induced increase in left ventricular mass increases the morbidity and mortality of these arrhythmias, should they occur (57–59). Not surprisingly, a reduction of left ventricular mass (e.g., accomplished through an increase in hematocrit, effective antihypertensive therapy, sympathetic nervous system blockade, or improved control of intravascular volume) is associated with a reduced morbidity and mortality in ESKD patients (60–62). Interestingly, conversion from conventional to nocturnal daily dialysis has been reported to induce regression of LVH (63).

Diabetes Mellitus

Diabetes mellitus affects >11% of the adult population in the United States, and its prevalence continues to increase (64). Moreover, diabetes is associated with increased risk of CVD morbidity and mortality in the general population (65,66). Diabetes mellitus is also the leading cause of ESKD in the United States, accounting for nearly 40% of cases (1). In dialysis patients, the presence of diabetes is an independent risk factor for IHD, heart failure, and all-cause mortality (1,26). The incidence of CAD in diabetic patients with nephropathy is 8 to 15 times higher than in diabetics without nephropathy (49,67). Furthermore, diabetic patients with ESKD have a cardiovascular mortality twice that of age-matched nondiabetic patients. In patients with diabetes mellitus in whom coronary angiography is performed routinely as a prelude to renal transplantation, significant CAD is noted in 25% to 50% (21,22,68). The prevalence of CAD in diabetic patients awaiting renal transplantation is particularly high in those older than 45 years (69). Moreover, these patients have worse long-term outcomes after coronary interventions than nondiabetic patients (70,71).

Although virtually all studies of CAD have defined “significant” coronary atherosclerosis as a luminal diameter narrowing >50% to 70%, the extent of luminal diameter narrowing and the occurrence of acute coronary events (unstable angina pectoris, MI, or sudden cardiac death) are not tightly coupled. Ambrose et al. (72) and Little et al. (73) showed that the extent of atherosclerotic coronary arterial narrowing often does not predict the risk of total or subtotal thrombotic coronary arterial occlusion, in that many acute ischemic events are caused by thrombotic occlusion of a coronary artery without a significant stenosis.

Glycemic control improves survival in diabetic patients on HD (74,75). Two studies in Japanese diabetic dialysis patients reported a higher risk of death in those with worse glycemic control (76,77). Furthermore, even mild degrees of hyperglycemia in nondiabetic dialysis populations are associated with reduced survival (78). In short, effective glycemic control in dialysis patients is an important determinant of survival. The hemoglobin A1c assay (HbA1c) is the gold standard test for monitoring glycemic control in patients with diabetes mellitus. Unfortunately, its measurements may not be as reliable in ESKD subjects as in the general population. HbA1c levels may be falsely elevated or decreased in patients with ESKD. This may be due to a number of factors that contribute to shortened red blood cell survival such as uremia, recent transfusion, iron deficiency, erythropoietin-induced accelerated erythropoiesis, and metabolic acidosis. Moreover, the decreased time for glucose and erythrocytes to interact in patients with ESKD leads to lower HbA1c levels for any given level of glycemia compared to those with normal kidney function (79). In some assays such as agar gel electrophoresis, analytical interference from carbamylated hemoglobin formed in the presence of elevated concentrations of urea may lead to false elevations in the HbA1c level. By contrast, the Boronate-agarose affinity chromatography (80–82) and the thiobarbituric acid method (82,83) are more reliable in measuring HbA1c in patients with ESKD. However, other studies have reported that HbA1c significantly underestimates glycemic control in diabetic dialysis patients, whereas those of glycated albumin more accurately reflect this control (84). As a result, glycated albumin may be a more robust indicator of long-term glycemia than HbA1c in HD patients (84). Recent studies have shown that glycated albumin levels more accurately predict hospitalizations and patient survival in ESKD than HbA1c (85,86).

Hyperlipidemia

Dyslipidemia, defined as increased levels of serum cholesterol and triglycerides, is a well-established traditional risk factor for CAD in the general population and in patients with mild to moderate CKD particularly those with nephrotic-range proteinuria (87). The pathogenic role of serum cholesterol as a risk factor in atherosclerotic CVD was confirmed by several randomized clinical trials which demonstrated that reductions in total and low-density lipoprotein (LDL) cholesterol levels, primarily with statins, is effective in reducing coronary artery events and mortality (88–91). Clinical trials have also shown that lipid-lowering therapy is effective in reducing the risk of atherosclerotic cardiovascular events in the nondialyzed CKD population (92,93). Serum lipid abnormalities are frequent in dialysis patients and are considered a major risk for CAD (87,94). These are characterized most often by elevated serum triglycerides and triglyceride-rich lipoproteins—such as very low-density lipoprotein (VLDL)—as well as low HDL cholesterol (**TABLE 17.2**) (87,95–99). The prevalence of dyslipidemia (defined as the presence of at least one abnormal lipid variable) in ESKD patients is approximately 67% (96). Peritoneal dialysis appears to be associated with a somewhat more atherogenic lipid profile than HD (96). The cause of kidney disease does not appear to influence the specific lipid abnormalities that are seen. The most common pattern, seen in 50% to 75% of patients on HD, is an elevated serum triglyceride concentration in conjunction with a normal LDL cholesterol concentration (87,95–99). This pattern is caused by diminished removal of triglyceride from the serum due to an acquired deficiency of lipoprotein lipase and hepatic triglyceride lipase. Apoprotein (apo) CII, an activator of lipoprotein lipase, is reduced in ESKD patients, whereas apo CIII, an inhibitor of lipoprotein lipase, is increased (24,97). The serum concentration of HDL is reduced substantially in many subjects with ESKD, probably because of a reduction in its synthesis and turnover (**TABLE 17.2**) (87,95,98,99). Rapoport et al. (98), for example, reported that dialysis patients had an average serum HDL cholesterol concentration of only 26 mg/dL, substantially lower than the average of 52 mg/dL in normal individuals.

TABLE 17.2 Lists the Various Lipid Abnormalities in Nondialyzed Chronic Kidney Disease Patients and Dialysis Patients

	CKD Stages 1–4	Hemodialysis Patients	Peritoneal Dialysis Patients
Triglycerides	Normal or high	High	Very high
Total cholesterol	High, normal, or low	Normal, low, or rarely high	Commonly high
LDL-cholesterol	High, normal or low	Normal, low or rarely high	Commonly high
HDL-cholesterol	Normal or low	Low	Low
VLDL	High	High	High
Small dense LDL-cholesterol	High	High	High
IDL cholesterol	High	High	High
Lp(a)	High	High	High

CKD, chronic kidney disease; LDL, low-density lipoprotein; HDL, high-density lipoprotein; VLDL, very low-density lipoprotein; IDL, intermediate dense lipoprotein; Lp(a), lipoprotein(a).

Because hypertriglyceridemia is only weakly associated with CAD in patients with ESKD, it is likely that other more complex lipid abnormalities are important in promoting atherogenesis in these patients (87,97,100–102). Deficiencies of lipoprotein lipase and hepatic triglyceride lipase delay hydrolysis of triglycerides, allowing intestinal and hepatic triglyceride remnants to accumulate, thereby enriching the triglyceride content of VLDL, intermediate-density lipoprotein (IDL), and LDL cholesterol (**TABLE 17.2**) (102). Apo A-IV and apo B-48, absent in the serum of normal individuals during fasting,

are present in patients with ESKD (102), and prolonged exposure of vascular endothelium to these remnant lipoproteins may promote atherogenesis (101,102). The cholesterol content of VLDL is increased and that of HDL is decreased in patients with ESKD (95,97). This cholesterol-enriched form of VLDL, termed β-VLDL (because of its electrophoretic properties), may be more atherogenic than VLDL (**TABLE 17.2**). In addition, the apo E content of VLDL is increased in patients with ESKD, and this may allow VLDL to interact with LDL at apo B and apo E receptors (97). Finally, lipoprotein (a) [Lp(a)] concentrations are increased in patients with ESKD, independent of the cause of kidney disease (103). All these factors, combined with the decreased antiatherogenic defense mechanisms that accompany a decreased HDL, likely contribute to the development of atherosclerosis.

In patients with early stages of CKD, dyslipidemia contributes significantly to the pathogenesis of atherosclerotic CAD (14,94). This process was thought to be accelerated in HD patients as was initially described by Lindner et al. (17) in 1974. Subsequently, Lowrie and Lew (104) reported a U-shaped relationship between serum total cholesterol level and the risk for all-cause mortality in dialysis patients. Other large observational studies have confirmed the negative relationship between low serum total or LDL cholesterol and CVD in dialysis (105) and nondialyzed CKD patients (106). In one study, serum LDL cholesterol <70 mg/dL was strongly associated with all-cause mortality risk, but black patients displayed a more conventional association between high LDL cholesterol and increased death risk (105). The high risk associated with low cholesterol level was attributed to malnutrition-inflammation complex. To clarify this relationship further, Liu et al. (107) reported that hypercholesterolemia is an independent risk factor for all-cause and CVD mortality in a subgroup of ESKD patients without serologic evidence of inflammation or malnutrition. Given that statins reduce inflammation in addition to cholesterol level, these authors stated that their findings support the use of statins in preventing CVD in dialysis patients.

Oxidative Stress

The association between oxidative stress and atherosclerosis was recognized by Glavind et al. (108) in 1952. Since then, increased production of reactive oxygen species (ROS) in the vascular wall has been recognized as a characteristic feature of atherosclerosis (109). This entity results from an imbalance between reactive oxygen and nitrogen species production and antioxidant defense mechanisms. Oxidative stress with or without endothelial dysfunction occurs commonly in dialysis patients and is thought to contribute to the pathogenesis of CVD (110–112). There has been mounting evidence that ESKD is associated with increased oxidation and impaired antioxidation systems (111–117). Oxidative stress may contribute to atherogenesis by multiple mechanisms that may or may not be linked to LDL oxidation (118) since ROS may mediate pathologic processes in the endothelium, smooth muscle cells, and inflammatory cells. Free oxygen radicals can rapidly react with and inactivate NO and enhance proatherogenic factors, such as leukocyte adherence to the endothelium, impaired vasorelaxation, and platelet aggregation (118).

Exogenous factors may contribute to the increased oxidant activity noted in ESKD patients. The use of incompatible dialysis membranes (cellulosic) may dramatically increase H_2O_2 release from activated granulocytes (119). This increase in ROS and activated neutrophils in close proximity to endothelial cells may contribute to endothelial cell injury. The chronic, cumulative exposure to cellulosic membranes may augment lipid peroxidation, thereby contributing to the generation of oxidized LDL (117,120). The use of cellulosic membranes may lead to an increased production of ROS by complement-dependent and

complement-independent processes (119,121). In addition to the role of exogenous factors, a reduced concentration of endogenous antioxidants, such as vitamins C and E, has been reported in HD patients (122,123).

On the other hand, the antioxidant activity is significantly improved with HD to a level comparable to that of healthy controls, as shown by Nagasi et al. (121). In short, ESKD patients manifest diminished oxygen-scavenging activity, which is improved with dialysis. Some studies have shown a decrease in fatal cardiac events in nonkidney disease patients who consume large amounts of β-carotene or vitamin E (124,125). However, prospective, randomized trials in patients with ESKD have not observed a reduction in the incidence of fatal cardiac events with antioxidant dietary supplementation (126). Nonetheless, vitamin E may slow the progression of atherosclerosis in ESKD patients (127), and endothelium-dependent vasoreactivity may be improved by the combination of antioxidant and lipid-lowering therapy (128,129). In this regard, two randomized trials of antioxidants (*N*-acetylcysteine and vitamin E) in HD patients reported a decreased risk of cardiovascular events in patients randomized to the antioxidant arm (130,131). Given the small sample size of these studies, further trials are clearly required to confirm their results.

Advanced Glycosylation End Products

Advanced glycosylation end products (AGEs) are formed by a series of complex nonenzymatic reactions between glucose and the amino groups of proteins, peptides, and amino acids. Their serum concentrations are increased up to 10-fold in ESKD patients when compared to healthy subjects. They are not removed by dialysis (132–134). The levels of AGEs in nondiabetic patients undergoing dialysis may be even higher than diabetic nonuremic patients not requiring dialysis. This increase in AGEs levels is due to both an increase in AGE synthesis by oxidative or carbonyl stress and a decrease in AGE excretion by the kidney and the dialyzer (133). Strong evidence exists to suggest a role for AGE compounds in most diabetic vascular complications (134). In this regard, high levels of AGEs can inhibit the production of NO, thereby diminishing vasodilation (134,135). This may result in an increase in BP as well as an increased risk of stroke and ischemic cardiac events.

Advanced glycation end product moieties may also modify lipid biomolecules, particularly LDL cholesterol, which contributes to the development of atherosclerosis (136). On the basis of data from experimental animals, Palinski et al. (137) suggested that AGEs are present in atherosclerotic lesions. Through all these mechanisms, it seems plausible that AGEs may potentiate atherosclerosis in ESKD patients (138). By contributing to the increased oxidative stress that exists in patients with ESKD, AGEs may contribute to the excessive CVD seen in this patient population. In this regard, tissue accumulation of AGEs, as estimated by skin autofluorescence, has been implicated as a risk predictor for cardiovascular mortality in patients with ESKD (139,140). In contrast, the relationship between serum AGEs and mortality in HD patients remains controversial with some studies reporting a strong relationship between serum AGEs levels and survival (141,142), whereas others did not (139,143,144).

Oxidized Low-Density Lipoproteins

As stated previously, dialysis patients are exposed to enhanced oxidative stress initiated by the generation of oxygen free radicals. Oxidation of LDL occurs *in vivo* and contributes to the development of atherosclerosis by causing endothelial cell injury and apoptosis (145). Cellular lipoxygenase and ROS

are believed to induce LDL oxidation (146,147), which leads to a chemical rearrangement of fatty acid structure and subsequent fragmentation, resulting in aldehyde and ketone formation. These alterations favor the recognition of oxidized LDL by monocytes, which act as scavengers in the subendothelial space. Scavenger cells that take up oxidized LDL gradually become cholesterol enriched and form foam cells, the initial "building blocks" of atherosclerosis (148). Leukocyte–endothelial cell interaction further promotes the process of atherosclerosis by potentiating monocyte chemotaxis. In addition, oxidized LDL directly damages endothelial cells (137,149). One intriguing observation is that LDL oxidation can occur *in vivo* and generate antigenic epitopes (149), leading Salonen et al. (150) to propose that autoantibody formation against oxidized LDL may contribute to the progression of atherosclerosis. Other reactions, such as the carbamylation of LDL, may contribute to altered LDL clearance and influence the scavenger pathway in ESKD patients. An elevated urea nitrogen concentration can trigger condensation of cyanate with lipoprotein lysine residues, leading to reduced clearance and increased pathogenicity (151).

Oxidized LDL is present in chronic dialysis patients, and ESKD patients have an increase in plasma lipid peroxidation products (152–154). In fact, oxidized LDL is more than eightfold higher in chronic dialysis patients when compared with controls (155). In short, ESKD patients on dialysis have increased concentrations of oxidized LDL, which play an important role in accelerated atherogenesis.

Lipoprotein(a)

In CKD, there is accumulation of highly atherogenic lipoproteins such as chylomicron remnants, IDLs, oxidized LDL, small dense-LDL (sd-LDL), and Lp(a) (95). Lp(a) is an LDL-like lipoprotein consisting of apolipoprotein (a) that is covalently bound to an LDL particle. Lp(a) has been linked to atherogenesis in the general population and in ESKD patients (156). In patients with CKD, plasma Lp(a) levels are significantly influenced by the GFR. In patients with large (but not small) apo(a) isoforms, plasma Lp(a) levels begin to rise early in the course of kidney disease (157). This isoform-specific increase in plasma Lp(a) levels has also been observed in HD patients (158). Concomitant malnutrition and inflammation have been associated with high plasma Lp(a) levels in HD patients (159). Its atherogenicity may be related to its binding of apolipoprotein B and subsequent uptake by macrophages, forming foam cells. Lp(a) accumulates in atherosclerotic plaque, after which it undergoes further alterations, including oxidation, which may contribute to its atherogenicity (156). In addition, Lp(a) inhibits plasminogen activation and may stimulate vascular smooth muscle proliferation, each of which may further enhance atherosclerotic plaque formation (160). Lp(a) serum concentrations are typically two to three times higher in ESKD patients than in healthy controls (157,158), resulting largely from a decreased renal catabolism of Lp(a). Certain Lp(a) phenotypes may be particularly atherogenic, for example, the low molecular weight phenotype of Lp(a) may increase the risk of atherosclerosis in ESKD patients. Following successful renal transplantation, the plasma Lp(a) concentration decreases in HD patients with large apo(a) isoforms (161).

Malnutrition–Inflammation Complex Syndrome

Protein-energy malnutrition and inflammation, known as *malnutrition–inflammation complex syndrome* (MICS), have been implicated as a powerful predictor of death in dialysis patients (162,163). Hypoalbuminemia, a reliable indicator of the presence of MICS, is common in dialysis patients and correlates strongly with a poor outcome, including cardiovascular death (163). In one study, an increase

in serum albumin above 3.8 g/dL was associated with improved survival, whereas a falling serum albumin over time correlated with increased cardiovascular death independent of demographic, clinical, or other laboratory variables (164). Malnutrition may contribute to atherosclerosis, in that an inverse relation between low serum albumin and elevated Lp(a) concentrations is present in chronic dialysis patients (159). Whether vascular reactivity is altered by poor nutrition is unknown, but Ritz et al. (165) suggested that malnourished patients have diminished NO production. Although the mechanisms underlying the increased CVD risk of hypoalbuminemia are unclear, it is possible that albumin may act as an oxidative product scavenger so that hypoalbuminemia renders the patient more vulnerable to atherogenesis. In diabetic subjects with ESKD, Koch et al. (166) demonstrated an association between lower skin fold thickness and mortality. Moreover, a low baseline body fat percentage and fat loss over time are independently associated with a higher mortality in dialysis patients even after adjustment for demographics and surrogates of muscle mass and inflammation (167). Also, inflammation is associated with an enhanced cardiovascular risk profile and an increased cardiovascular mortality in HD patients. Inflammation plays a key role in CAD and other manifestations of atherosclerosis (168). A number of plasma markers of inflammation such as high-sensitivity C-reactive protein (hs-CRP), serum amyloid A, and cytokines such as interleukin-6 (IL-6) and soluble intercellular adhesion molecule type 1 have been advocated as potential tools for predicting the risk of CAD events (169). Approximately half of HD patients exhibit an activated acute phase response characterized by increased concentrations of CRP and serum amyloid A (167). In addition, several changes in the atherogenic risk profile in HD patients, such as elevated Lp(a) and fibrinogen levels as well as decreased HDL cholesterol and apo A-I concentrations, are due, at least in part, to an activated acute phase response (170). Finally, the plasma IL-6 concentration, the major mediator of the acute phase response, is elevated in ESKD patients and is considered to be a strong predictor of clinical outcome. Although hypertension, adiposity, insulin resistance, fluid overload, and persistent infections can be associated with elevated IL-6 levels, factors related to the dialysis procedure, such as bioincompatibility of dialyzer membranes and dialysis solutions, also may stimulate its production (171).

Role of Nontraditional Risk Factors for Coronary Artery Disease

Evidence from recent studies suggests that the underlying pathophysiology of CAD is different in patients with CKD when compared to the general population (172). A recent postmortem analysis of CAD showed that the ESKD group had significantly increased coronary arterial medial thickness, higher degree of plaque calcification, and reduced vessel lumen compared with CAD patients and normal renal function (173). Of interest, this study also reported that the frequency of both advanced atherosclerotic lesions and calcified lesions increased as the estimated glomerular filtration rate (eGFR) decreased. In another study that used intravascular ultrasound, which can detect coronary plaque composition, the eGFR was significantly associated with an increase in the percentage of lipid volume and a decrease in the percentage of fibrous volume in coronary lesions with mild to moderate stenosis: a change in composition that may contribute to coronary plaque vulnerability (174). Even after adjustment for coronary risk factors, a low eGFR was independently associated with this shift in coronary plaque composition. Thus, it appears that CKD may independently exacerbate the effects of other conventional CVD risk factors such as hypertension or anemia (175).

Cardiovascular Calcification

The Work Group of the Kidney Disease: Improving Global Outcomes (KDIGO) included cardiovascular calcification in the newly described systemic disorder "chronic kidney disease-mineral and bone disorder (CKD-MBD)" that occurs as a result of CKD (176). The kidney plays a central role in regulating mineral metabolism. Disturbances in mineral metabolism may occur in the course of CKD because of the inability of the failing kidneys to maintain the levels of serum phosphorus and calcium in the normal range. Vascular calcification develops early, and its prevalence increases as the GFR declines such that approximately 80% of incident dialysis patients have evidence of coronary artery calcification (CAC) (177–181) (see Chapter 24 on CKD-MBD).

Vascular calcification results from abnormal deposition of calcium phosphate salts into the vascular wall. This process, which affects coronary arteries and peripheral vessels, may also affect other cardiac structures including the cardiac valves and aorta. Vessels from healthy subjects do not usually calcify even after long-term exposure to supraphysiologic levels of phosphate and/or calcium *in vitro*, whereas vessels from subjects with CKD and dialysis calcify (182). However, calcification starts as early as CKD stage 2, as shown in an animal model of CKD (183) and accelerates with progressive loss of GFR particularly in patients with ESKD who are receiving dialysis. Vascular calcification in patients with CKD can be atherosclerotic, affecting the intima or medial with calcium phosphate deposition in the media of the vessel wall. It has been argued that medial calcification is a manifestation of accelerated atherosclerosis in patients with CKD (184). However, others argue that atherosclerotic and medial calcification are two distinct entities, with the latter developing more commonly in patients with CKD particularly those with diabetes mellitus (185). Clearly, both forms of calcification can occur concomitantly in patients with CKD.

Vascular calcification in patients with CKD was initially believed to be a passive, physicochemical process in which serum phosphate and calcium are deposited in the arterial wall. However, we now know that vascular calcification is an active, cell-mediated, and highly regulated process similar to bone formation with vascular smooth muscle cells (VSMC) playing a critical role. Just as in bone formation, vascular calcification results from either an imbalance between factors that promote calcification and those that act to inhibit calcification (177,179,186). Incubation of human aortic smooth muscle cells in high phosphate or calcium medium directly induces transformation of VSMC to an osteoblast-like cell (182). It is likely that calcium and phosphate have synergistic procalcification effects (187). Transformed VSMCs lose their contractile function and behave like bone-forming cells that lay down a collagen-1 rich extracellular matrix and form matrix vesicles rich in calcium and phosphate that pinch off from the plasma membrane and interact with the extracellular matrix. These vesicles are capable of initiating mineralization of the vascular wall just as they do so in bone (186). Increased calcium levels promote calcification further by inducing apoptosis of VSMC (182,188,189). Both matrix vesicles and apoptotic bodies serve as nucleation sites for hydroxyapatite, particularly in the presence of low calcification inhibitors such as matrix-Gla protein (MGP) and fetuin-A. Thus, unlike vessels from healthy individuals, vessels from predialysis and, to a much greater extent, dialysis patients have been primed to calcify (182). Susceptibility to calcification in CKD may be related both to a decrease in matrix vesicle calcification inhibitors such as fetuin-A and MGP and to degradation of the extracellular matrix by matrix metalloproteases (MMP), such as MMP-2 and MMP-9, which are upregulated in the arterial wall in CKD

patients (186). The latter leads to overexpression of transforming growth factor (TGF)-β, which is thought to be involved in osteoblast differentiation and in enhancing VSMC calcification and arterial stiffness (186).

The cause of accelerated calcification in patients with ESKD is multifactorial and includes both the traditional CVD risk factors and uremia-related risk factors (177) (**TABLE 17.1**). High serum phosphate, even within the normal range, is associated with a greater risk of coronary calcification and cardiovascular mortality in patients with CKD (190,191). However, recent *in vitro* studies found calcium to be a stronger procalcification factor than phosphate. In one study in which arterial rings obtained during abdominal surgery from children with normal renal function, those with impaired renal function, and from those on dialysis were exposed to high phosphate or calcium media, calcium-induced calcification more potently than phosphate, but only in rings from patients with CKD or those on dialysis (182). This suggests that VSMC from healthy vessels have effective inhibitory mechanisms that prevent calcification, while those from subjects with CKD, particularly dialysis patients, become susceptible to calcification. Also, both high and low parathyroid hormone levels may increase the risk of vascular calcification (192). Some studies reported an independent association between circulating fibroblast growth factor (FGF)-23 levels with the progression of coronary calcifications (193,194), but more recent data indicate that FGF-23 is not involved in vascular calcification (195). On the other hand, klotho deficiency is a well-recognized factor in this process (196).

One of the factors that was suspected of enhancing vascular calcification in general, and CAC in particular, in dialysis and CKD patients is the calcium load provided from use of calcium-based phosphate binders (CBPBs). While a number of clinical trials (197–199), epidemiologic studies (200,201), and meta-analysis (202) have shown increased risk of all-cause mortality or progression of cardiovascular calcification in CKD patients treated with CBPB, other clinical trials (203,204), epidemiologic studies (205), and meta-analysis (206) did not show a difference between calcium-based and non-CBPBs. In fact, a recent randomized, placebo-controlled pilot clinical trial by Block et al. (207) showed that therapy with both noncalcium and CBPBs resulted in progression of vascular calcification, albeit to a lesser degree in noncalcium phosphate binders. Thus, the effect of calcium load from use of CBPB on progression of cardiovascular calcification, while plausible, remains controversial (208). An important issue that needs to be investigated is whether slowing vascular calcification by any means, including phosphate binders, will translate into improvements in clinical outcomes. Two epidemiologic studies have in fact reported that use of any type of phosphate binder, possibly with the exception of aluminum-based binders, is independently associated with improved survival in dialysis patients compared with no use of binder at all (209,210). A third study in an incident United States Renal Data System (USRDS) cohort that started dialysis in 1996 to 1997, when only CBPBs were used in the United States, found no association between the use of these agents and mortality (211). The KDIGO work group stated that there were inconclusive data to indicate that any one binder has beneficial effects on mortality or other patient-centered outcomes when compared with any other binder (176). However, in patients with CKD stages 3 to 5D, the work group recommends restricting the dose of CBPBs and/or the dose of calcitriol or vitamin D analog in the presence of persistent or recurrent hypercalcemia, arterial calcification, or adynamic bone disease.

The clinical consequences of vascular calcification in patients with CKD are serious.

Cardiovascular calcification increases the risk of cardiovascular events including MI, fatal arrhythmia, congestive heart failure, and valvular heart disease (212,213). Measurement of CAC by electron beam computed tomography (EBCT) can help in the evaluation of asymptomatic ESKD patients. Using this technique, several studies have shown a high prevalence of CAC and cardiac valve calcification in HD patients, even those who are young (172,197,198,203,214–218). In the Calcium Acetate Renagel Evaluation (CARE-2) study, we found mitral valve calcification in 55%, aortic valve calcification in 40%, and both in 27% (203). Unfortunately, there is no proven effective treatment for cardiovascular calcification in HD patients. In the ADVANCE (A Randomized Study to Evaluate the Effects of Cinacalcet plus Low-Dose Vitamin D on Vascular Calcification in Subjects with Chronic Kidney Disease Receiving Hemodialysis) Study, subjects with CAC scores ≥30 were randomized to cinacalcet (30 to 180 mg/d) plus low-dose calcitriol, or vitamin D analog (≤2 μg paricalcitol equivalent/dialysis), or flexible vitamin D therapy for 52 weeks (219). The cinacalcet-treated patients had a trend toward lesser progression of calcification of four cardiac structures (coronaries, aorta, mitral, and aortic valves) despite the fact that all subjects received CBPBs. However, the effect was modest and statistically insignificant except for the aortic valve. The clinical significance of these findings is currently unclear but probably at best is likely to be minimal (219). Indeed, the Evaluation of Cinacalcet Hydrochloride Therapy to Lower Cardiovascular Events (EVOLVE) trial tested the hypothesis that cinacalcet, as compared with placebo, would reduce the risk of death and cardiovascular events in dialysis patients with secondary hyperparathyroidism (220). The trial enrolled 3,883 participants from many countries and followed them for up to 5 years. Patients in the cinacalcet group experienced a nonsignificant relative reduction in the primary outcome of only 7% compared to placebo (220). Thus, the trial does not provide clear evidence that treatment of HD patients with cinacalcet provides protection against cardiovascular events.

CLINICAL PRESENTATION OF CORONARY ARTERY DISEASE IN PATIENTS WITH END-STAGE KIDNEY DISEASE

Myocardial ischemia is caused by a relative imbalance of myocardial oxygen supply and demand. Most often, it occurs during transient increases in oxygen demand in the presence of atherosclerotic narrowing of one or more coronary arteries. Less often, it may be caused by (a) a transient primary fall in myocardial oxygen supply, such as that caused by coronary arterial vasospasm, or (b) an excessive augmentation of myocardial oxygen demand without any decrease in supply, such as that which may occur with severe aortic stenosis, a sustained supraventricular or ventricular tachyarrhythmia, or severe sustained systemic arterial hypertension. Myocardial ischemia is usually diagnosed when typical angina pectoris occurs during exertion, emotional excitement, or HD. Physical exertion or emotional excitement cause an increase in the three major determinants of myocardial oxygen demand (heart rate, left ventricular wall tension, and cardiac contractility). HD may induce myocardial ischemia by precipitating hypotension, thereby diminishing coronary arterial blood flow and myocardial oxygen supply, or by provoking tachycardia and/or increased cardiac contractility, thereby increasing myocardial oxygen demand. It is not surprising, therefore, that angina pectoris sometimes occurs during HD.

Chest pain, abnormal findings on physical examination, and electrocardiographic changes, the

cardinal features of myocardial ischemia in the general population, may occur in patients with ESKD, but these patients are likely to manifest myocardial ischemia in an atypical fashion. For example, many subjects with ESKD have baseline electrocardiographic ST-T wave abnormalities (221), making the electrocardiographic diagnosis of ischemia difficult or impossible. Not uncommonly, dialysis patients with acute coronary events may be asymptomatic. Such "silent" (painless) ischemia is considered to be present when, in the absence of chest pain, (a) ST segment alterations of ischemia are noted during provocative testing or ambulatory electrocardiographic monitoring, (b) reversible myocardial perfusion defects appear with thallium imaging, or (c) reversible segmental wall motion abnormalities are noted by echocardiography. Although the pathogenesis of such silent ischemia is uncertain, three mechanisms have been proposed. *First*, some patients may have altered neural pathways, such that they cannot sense the pain of myocardial ischemia. Cardiac transplant recipients, in whom the heart is surgically denervated, and diabetic patients with generalized neuropathy are particularly likely to have such episodes. *Second*, patients with silent myocardial ischemia may have unusually high thresholds for pain and, therefore, do not sense painful stimuli as other individuals do. *Third*, differences in the duration and severity of ischemic episodes may explain why some of them occur without pain. Because chest pain is a relatively late manifestation of myocardial ischemia, short-lived episodes may interfere with myocardial relaxation and contraction, induce electrocardiographic and perfusion abnormalities, but resolve before chest pain appears.

The presence of silent myocardial ischemia provides helpful prognostic information. In asymptomatic patients without a cardiac history, silent ischemia identifies those at increased risk of a subsequent cardiac event, such as angina pectoris, MI, or sudden cardiac death. Patients with silent as well as painful ischemia or a previous MI are more likely to have an adverse outcome (i.e., MI, the need for coronary revascularization, or cardiac death) in comparison to those without silent ischemia. Although agents that are useful in treating painful ischemia are also effective in treating silent ischemia, the overall impact of therapy (medical or nonmedical) on prognosis is unknown.

DIAGNOSIS OF CORONARY ARTERY DISEASE IN END-STAGE KIDNEY DISEASE PATIENTS

In stable patients with ESKD, the occurrence of angina pectoris, pulmonary edema without major changes in intravascular volume, unexplained hypotension, or a marked change in exercise capacity may trigger an investigation of the presence of CAD. Because most deaths in dialysis patients are caused by CVD, two important assumptions have been used in order to justify screening these patients for CAD. *First*, dialysis patients have a high frequency of obstructive CAD, even in the absence of angina. In a recently reported cohort of stable asymptomatic HD patients, 41% had obstructive CAD, and almost 30% had stenosis in the proximal segments of at least one coronary artery (222). *Second*, it is hypothesized that early and aggressive intervention in subjects with asymptomatic CAD could prevent MI and cardiac death.

Despite the high prevalence of CAD in CKD patients, routine screening tests are not currently recommended for most patients in the absence of suggestive clinical symptoms and signs of CAD. Clinical practice guidelines have recommended that coronary angiography or noninvasive testing be performed based on the individual's estimated risk of CAD (223). Routine coronary angiography in new

dialysis patients was proposed as a means of improving the detection and treatment of high-risk patients (222). Among diabetic patients with ESKD who are awaiting transplantation, CAD, symptomatic or asymptomatic, is associated with an increased incidence of allograft failure and mortality (22,47,224,225). Philipson et al. (224) performed coronary angiography in 53 diabetic transplant candidates, detecting significant CAD in 20 (38%). During an average follow-up of 1 year, mortality was 44% in those with and only 5% in those without CAD. Based on data such as these, transplant candidates with angina or evidence of previous MI typically undergo coronary angiography as a part of the pretransplant evaluation, and subsequent transplantation may be denied if CAD is extensive and not amenable to revascularization (224,225).

Patients with ESKD without angina or with atypical symptoms of CAD pose a difficult management problem because many of them, particularly if they are diabetic, have CAD (11). For example, Weinrauch et al. (22) reported that 41% of asymptomatic diabetic patients with ESKD awaiting transplantation had significant CAD, and their 2-year survival was only 22%, compared to 88% in those without CAD. Similar findings were reported by Braun et al. (47), who also noted that depressed left ventricular systolic performance was associated with a particularly guarded cardiovascular outcome (47,68,226). ESKD patients with diabetes, peripheral vascular disease, or previous MI are clearly at higher risk of CAD, major adverse coronary events, or both; as a result, they usually are referred for coronary angiography (222). Such an approach may not be justified in other patients with ESKD. Hence, noninvasive cardiac risk stratification is thought to offer a more appropriate alternative to routine diagnostic catheterization.

Levels of cardiac biomarkers may be chronically elevated in 80% to 90% of asymptomatic patients with ESKD who are receiving maintenance dialysis in the absence of myocardial ischemia, possibly because of myocardial apoptosis or silent microinfarction due to small vessel disease (227). However, serial serum cardiac troponin level elevation indicates acute myocardial damage. Serum concentration of troponin T (cTnT) was consistently found to be associated with all-cause mortality and cardiovascular events in patients with ESKD (228). Thus, elevated serum concentrations of troponin T may offer diagnostic and prognostic information in ESKD patients (228). The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (K/DOQI) Clinical Practice Guidelines for Cardiovascular Disease in Dialysis endorse the use of the serum troponin concentration for risk stratification in dialysis patients (229).

Serum concentrations of troponin T and troponin I (cTnI) often are elevated in dialysis patients; increased concentrations of these biomarkers are predictive of subsequent death in these individuals (230–232). Measurement of cTnT may have a greater potential for its diagnostics and prognostic capabilities. However, cTnI remains more specific than cTnT in the diagnosis of acute MI (228). Of importance, troponin levels should be obtained just before dialysis, as the dialysis procedure can affect levels (233). Data from Zoccali et al. (234) and deFilippi et al. (35) suggest that ESKD patients with a cTnT >0.07 ng/mL are at a particularly high risk for underlying CAD and its associated adverse events. Other studies have found that cTnT is useful in predicting short-term prognosis in patients with a wide range of renal function (235–237). In addition to the relationship between cTnT and CAD, elevated cTnT levels have been linked to increased left ventricular mass in dialysis patients (238–240).

The increased risk of CAD in patients with ESKD may be mediated, at least in part, through chronic

inflammation (241–247). Serum markers of inflammation, such as CRP, brain natriuretic peptide (BNP), and the endogenous inhibitor of NO synthase, ADMA, are elevated in patients with ESKD, and they identify those with a high cardiovascular risk (241). In addition, plasma IL-6 may be useful in predicting cardiovascular mortality in HD patients (244). A study from Pisa, Italy, of 757 HD patients prospectively followed for 30 months found that those with combined high levels of CRP and proinflammatory cytokines had an increased risk of cardiovascular and all-cause mortality (245). In addition, elevated serum concentrations of BNP and its inactive N-terminal fragment, Nt-proBNP, both surrogates of myocardial vulnerability, appear to predict cardiovascular events in this patient population (246,247). Finally, Zoccali et al. (248) suggested that raised plasma concentrations of ADMA in ESKD patients are associated with a 52% increased risk of death and a 34% increased risk of cardiovascular events in dialysis patients.

Screening for Coronary Artery Disease in Candidates for Renal Transplantation

Based on Medicare billing claims, it has been estimated that the cumulative incidence of MI is in the range of 8.7% to 16.7% by 3 years after kidney transplant listing and from 4.7% to 11.1% after kidney transplantation (249,250). Observational studies have also found a high frequency of cardiovascular events in the first months after kidney transplantation (249,251,252). Since most ischemic cardiac events in renal transplant recipients are related to preexisting CAD and occur during the first few months after transplantation (253–256), screening for the presence of CAD is an important component of the pretransplant evaluation. A recent study from Spain that screened 356 patients for CVD before inclusion in the renal transplant waiting list found significant CAD in 38% of patients. Among these, 82% had no cardiac symptoms (257). In asymptomatic patients, screening for CAD should be done if the results are expected to lead to changes in management that improve patients' outcomes. Moreover, screening should also be cost-effective, and its results may be used to deny transplantation to high-risk patients if they have short life expectancy. However, one study found that in selected high-risk patients, the overall 5-year survival after renal transplantation was superior to the expected 5-year survival with continued dialysis (258).

Evaluation should start with a thorough history and physical examination to identify active cardiac conditions before renal transplantation. In asymptomatic patients who are undergoing pretransplant evaluation, guidelines by the American College of Cardiology/American Heart Association (ACC/AHA) and NKF/KDOQI differ (259). While the NKF/KDOQI recommends noninvasive cardiac stress imaging in patients with diabetes mellitus out of concern for silent (asymptomatic) ischemia, the AHA/ACCF stated that "based on available data, routine noninvasive screening of patients with diabetes mellitus either for peritransplantation cardiac evaluation or for long-term care is not justified by existing evidence." However, the statement added that noninvasive stress testing may be considered in kidney transplantation candidates with no active cardiac conditions based on the presence of multiple CAD risk factors regardless of functional status (260). Relevant risk factors include diabetes mellitus, prior CVD, over 1 year on dialysis, left ventricle hypertrophy, age >60 years, smoking, hypertension, and dyslipidemia; the specific number of risk factors that should be used to prompt testing remains to be determined, but the committee considers >3 to be reasonable (260). The AHA/ACCF Scientific Statement emphasized the high variability in the sensitivity and specificity of radionuclide stress testing and dobutamine stress echocardiography (DSE) for the detection of significant CAD in patients with ESKD

(260). In general, CKD patients may not able to undergo full exercise testing and their ST-segment response may not be specific for myocardial ischemia. Moreover, the sensitivity and specificity of noninvasive cardiac tests in CKD patients is lower than that in the general population (261). Radionuclide perfusion imaging is more sensitive but less specific than stress echocardiography for diagnosis of significant CAD in patients on renal replacement therapy (262).

Given that coronary angiography is expensive, invasive, and not risk-free, it is not an ideal screening procedure for all patients with ESKD who are being considered for transplantation. Among its potential deleterious effects, contrast-induced nephrotoxicity may cause further deterioration in patients with some degree of residual renal function. As a result, coronary angiography should be reserved for those who are likely to have significant CAD and may benefit from revascularization (263,264). The reader is directed to **FIGURE 17.4** for a suggested approach to the management of patients with ESKD and possible CAD (265). According to the American Society of Transplantation (223), patients with diabetes mellitus, a history of IHD, an abnormal ECG, or age >50 years are at high risk for CAD and should undergo noninvasive stress testing and, if abnormal, then one should proceed to coronary angiography (266). Also, patients with typical angina, previous MI (by history or ECG), or congestive heart failure should be considered high risk, and they should undergo cardiac catheterization to assess left ventricular systolic function and the presence and severity of CAD (267). Other noninvasive studies for the diagnosis of CAD are provided in **TABLE 17.3** (268). Patients with congestive heart failure are considered to be high risk because those with CAD and concomitant left ventricular systolic dysfunction have a particularly guarded prognosis and may derive a survival benefit with revascularization (268,269). Even after successful renal transplantation, left ventricular systolic dysfunction is a persistent risk factor for cardiac morbidity and mortality (270).

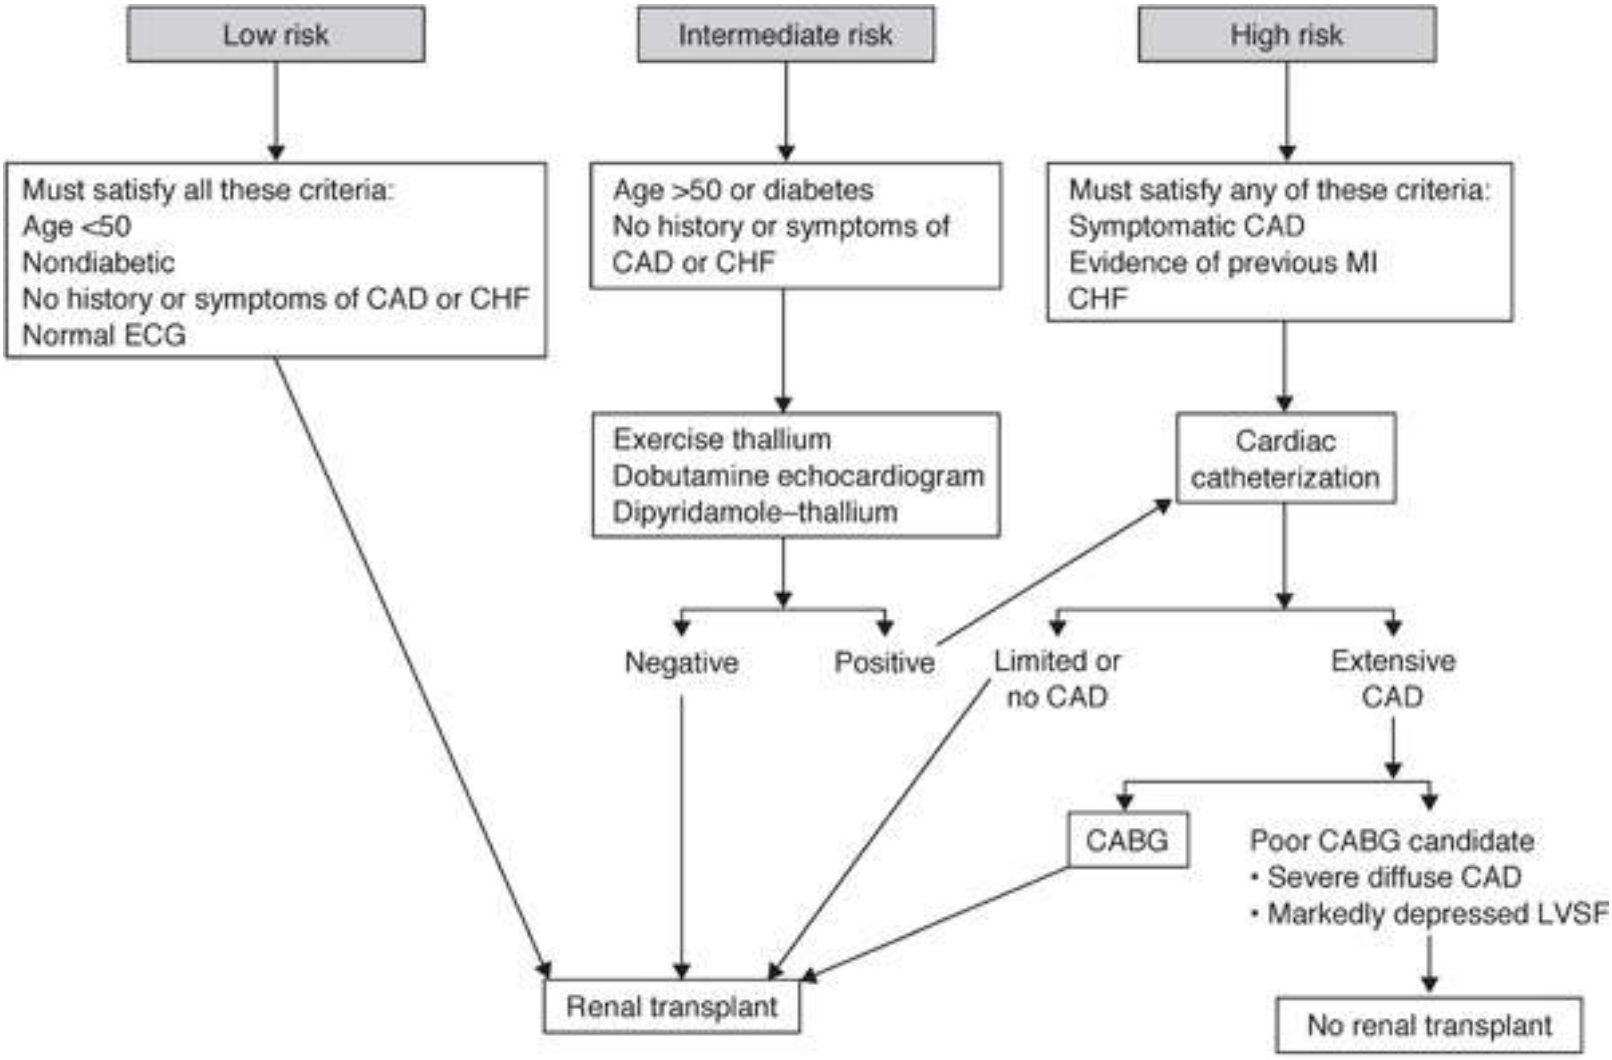

FIGURE 17.4 Proposed management strategy for end-stage kidney disease (ESKD) patients who are candidates for renal transplantation. CABG, coronary artery bypass grafting; CAD, coronary artery disease; CHF, congestive heart failure; ECG, electrocardiogram; LVSF, left ventricular systolic function; MI, myocardial infarction. Several investigators have attempted to devise a strategy whereby low-risk patients, who can safely undergo renal transplantation without a preoperative cardiovascular evaluation, can be identified expeditiously, inexpensively, and noninvasively. Le et al. (264) prospectively enrolled 189 consecutive candidates for renal transplantation in a risk stratification program based on the presence of five risk

variables: insulin-dependent diabetes mellitus, age >50 years, a history of angina, a history of congestive heart failure, and an abnormal ECG. Patients were considered to be low risk if they had none of these variables and high risk if any was present. Of the 189 subjects, 94 were considered low risk and 95 high risk. Over a follow-up period averaging almost 4 years, cardiac mortality was 17% in the high-risk subjects and only 1% in the low-risk individuals (264).

Other investigators have used a similar approach in diabetic patients with ESKD. In a retrospective study, analysis of the cardiac catheterization data of 97 asymptomatic type 1 and 2 diabetes mellitus kidney and kidney-pancreas transplant candidates revealed that 33% of type 1 and 48% of type 2 diabetic patients had significant CAD (271). By multivariate logistic regression analysis, a body mass index greater than 25, older age, and cigarette smoking were associated with CAD. African American patients, who comprised 30% of the sample, had a 71% lower risk of CAD compared with whites ($p = 0.03$) (271). Manske et al. (272) retrospectively identified several clinical variables that were associated with CAD in diabetic transplant candidates: age older than 45 years, more than 5 pack-year history of cigarette smoking, more than 25 years of diabetes mellitus, and nonspecific ST-T wave abnormalities on a resting ECG. In a small group of subjects studied prospectively, they showed that these variables provided a sensitivity of 97% and a negative predictive value of 96% for detecting angiographically significant CAD. Furthermore, they concluded that diabetic patients younger than 45 years with none of these variables could safely undergo renal transplantation without a preoperative cardiovascular assessment.

Most renal transplant candidates are at intermediate risk for CAD. This group includes older patients without symptoms of CAD, previous MI, or congestive heart failure, as well as most diabetic patients with no symptoms or atypical symptoms of CAD. In these subjects, noninvasive testing may be particularly useful in the pretransplant cardiac evaluation (273–275). Many patients with ESKD have electrocardiographic abnormalities at rest that make the ECG difficult or impossible to interpret during provocation (often because of LVH). Moreover, other patients, particularly those who are diabetic, fail to attain a sufficient heart rate during exercise to provide a reasonable predictive accuracy (22,134,276). As a result, provocative pharmacologic testing with concomitant cardiac imaging (using nuclear scintigraphy or echocardiography) has been used in an attempt to identify patients with underlying CAD.

Conflicting reports have appeared concerning the utility of thallium imaging with dipyridamole to identify CAD in patients with ESKD awaiting transplantation. On the one hand, Marwick et al. (277) and Boudreau et al. (278) concluded that such imaging was of little use in identifying angiographically significant CAD or in predicting cardiac prognosis in this patient population. Of Marwick and colleagues' (277) transplant candidates, thallium imaging with dipyridamole offered only fair specificity and poor sensitivity in identifying CAD. Importantly, five of the six individuals who died of cardiac causes over a mean follow-up of 2 years had normal thallium imaging studies. Of the 80 patients reported by Boudreau et al. (278), 36 had negative dipyridamole thallium studies, 6 (17%) of whom had significant angiographic CAD, giving a negative predictive value of only 83% (**TABLE 17.3**). In contrast, several reports have concluded that thallium imaging with dipyridamole provides an effective noninvasive means of identifying transplant candidates with no chest pain or atypical chest pain who are at increased risk of having a subsequent cardiac event. Camp et al. (274) showed that 6 of 9 patients with dipyridamole-induced reversible perfusion abnormalities had a subsequent cardiovascular event, whereas none of 31 patients without reversible defects had a subsequent event. Other studies (226,279) have supported the

contention that thallium imaging with dipyridamole can identify those at increased risk of an adverse cardiovascular outcome. In addition, a normal thallium imaging study appears to predict a very low likelihood of a subsequent cardiovascular event (226,264,274). The reasons that these dipyridamole-thallium data are disparate are not clear but may include differences in study design, definition of end points, interpretation of "positive" thallium images, and patient selection. In addition, most of these studies included only patients referred for noninvasive evaluation, and the differences in referral patterns between centers may explain some of the variability in results.

Two-dimensional echocardiography during the intravenous infusion of dobutamine (so-called dobutamine stress echocardiography) was evaluated in 97 patients (some diabetic, others not) with ESKD awaiting renal transplantation (275). In these patients, this technique had a sensitivity of 95% and a specificity of 86% for predicting cardiovascular complications or death during the subsequent year. Although the positive predictive value was poor (only 14%), the negative predictive value was excellent (97%) (**TABLE 17.3**). In a more recent study, renal transplant candidates had coronary angiography, DSE, and resting and exercise electrocardiography. Of the 125 patients, 36 (29%) had severe CAD, 55% were on dialysis, and 39% were diabetic. Stepwise logistic regression analysis identified an abnormal resting ECG and a positive stress echocardiogram result as independent predictors of severe CAD (280). Finally, a meta-analysis of 12 observational studies involving 913 patients was performed to determine the prognostic significance of myocardial perfusion studies on future MI and cardiac death in patients with ESKD assessed for kidney or kidney-pancreas transplantation (281). In comparison to patients with normal tests, those with evidence of inducible ischemia (reversible perfusion defects or new wall motion abnormalities) had a sixfold increased risk of MI and an almost fourfold increased risk of cardiac death. In addition, those with noninducible ischemia (fixed perfusion defects or wall motion abnormalities at rest) had a significantly higher risk of cardiac death (RR 4.7). Diabetic patients had a similar pattern of risk, with reversible perfusion defects alone strongly associated with MI (RR 9.3) and both fixed and reversible perfusion defects associated with cardiac death (RR 4.0 to 4.7). In an assessment of symptoms, electrocardiographic findings, thallium dipyridamole scintigraphic results, and resting echocardiographic results in 42 ESKD patients and 42 patients after renal transplantation, the presence of angina offered the best prognostic information (282), whereas the other variables lacked sensitivity and/or specificity in the identification of those with CAD.

In summary, all high-risk transplant candidates (those with symptoms of CAD, previous MI, or congestive heart failure) should undergo coronary angiography before renal transplantation. At the opposite extreme, young, nondiabetic patients without symptoms of CAD or previous MI comprise a low-risk group, and they do not require cardiac evaluation before transplantation. In addition, young diabetic patients, particularly nonsmokers who have had diabetes for less than 25 years and whose ECGs are normal, may not require cardiac evaluation before renal transplantation. Subjects in the intermediate risk group include older patients without symptomatic CAD. In preparation for transplantation, these individuals should undergo noninvasive evaluation (DSE or dipyridamole-thallium imaging), recognizing that neither procedure is perfect. Because most insulin-dependent diabetic patients older than 45 years have underlying CAD, we recommend that these individuals routinely undergo coronary angiography, even in the absence of angina or evidence of previous MI (**FIGURE 17.4**) (265,269,283).

MANAGEMENT OF CORONARY ARTERY DISEASE IN PATIENTS WITH END-STAGE RENAL DISEASE

Medical Management

Evidence-based recommendations for the medical management of CAD in patients with ESKD are hampered by the lack of data from randomized controlled trials because the studies which demonstrated that aspirin, β-blockers, angiotensin-converting enzyme (ACE) inhibitors, and lipid-lowering agents are efficacious in patients with CAD excluded patients with ESKD (284). Because of concern that these agents have limited efficacy and/or enhanced toxicity in subjects with ESKD, they often are underused in this patient population (12). Given that the etiology of CVD in ESKD is complex and may be different from that in the general population, randomized trials that evaluate the efficacy and safety of these drugs in patients with ESKD are still needed. Until such studies are performed, the medications noted previously should be used in patients with ESKD. In addition, correction of the hemoglobin concentration to 10 to 11 g/dL to improve oxygen-carrying capacity should be pursued with erythropoietin therapy and intravenous iron supplementation (285). Such an improvement in hemoglobin may allow the patient to participate in exercise training, which offers additional benefits (286,287). Adequate BP control is critically important in reducing the magnitude of LVH and myocardial oxygen demand, resulting in reduced angina frequency, ventricular irritability, and perhaps even mortality (287–289). Several studies have shown an independent association between measures of glycemic control and mortality in patients with or without diabetes (290). The role of glycemic control in diabetic ESKD was examined by Shurraw et al. (291) in 1,484 incident HD patients during a follow-up of up to 8 years. The authors found that increased serum glucose and HbA1c levels were not independently and directly associated with mortality and strict glycemic control may not benefit dialysis patients with or without diabetes mellitus (291). Other interventions such as smoking cessation, exercise, dietary salt reduction, weight loss, and control of hypertension should be tried, although clear evidence for these measures in ESKD patients is limited.

Several antianginal medications may be useful in dialysis patients with stable angina. Long-acting nitrates are effective orally or cutaneously in reducing angina frequency and severity, but their influence on survival is unknown. Twice-daily dosing with a nitrate-free period is recommended so that nitrate tolerance is minimized. The use of sublingual nitroglycerin may induce hypotension, particularly if the patient uses it during dialysis. Other drugs that are often prescribed in patients with ESKD and angina include β-blockers, which reduce heart rate, contractility, and left ventricular wall tension, and calcium channel blockers, which induce coronary arterial vasodilation and simultaneously reduce the determinants of myocardial oxygen demand. These agents reduce angina frequency and the frequency of cardiovascular events in patients with painless myocardial ischemia (292). Some of these agents should be given with caution to patients with ESKD because they are excreted unchanged by the kidney. However, since the calcium channel blockers diltiazem, verapamil, and the dihydropyridines are metabolized by the liver, dosing adjustments are unnecessary in patients with ESKD.

For patients with known CAD with or without ESKD, low-dose aspirin is recommended. Unfortunately, the frequency of aspirin use in dialysis and CKD patients who have survived an MI is low in comparison to those without CKD: In one study, the rate of aspirin use was only 61% in dialysis patients compared to 89% in subjects with normal renal function (293). This reduced frequency of aspirin

use is due, at least in part, to safety concerns because aspirin prolongs the bleeding time. Subgroup analyses of randomized trials have demonstrated convincing cardiovascular risk reduction from daily aspirin in individuals with estimated GFR <45 mL/min/1.73m^2, including dialysis patients, although the risk of bleeding is higher in these patients (294,295). In survivors of MI, aspirin reduces mortality irrespective of renal function. The efficacy of aspirin after MI was examined in 1,025 patients with ESKD and 145,740 controls (296). The benefit of aspirin treatment on 30-day mortality was similar in the two groups (**FIGURE 17.5**). In short, the routine use of aspirin after MI in all CKD patients could save one life for every five patients treated (296). To minimize bleeding risks, low-dose aspirin, 81 mg/d, is recommended.

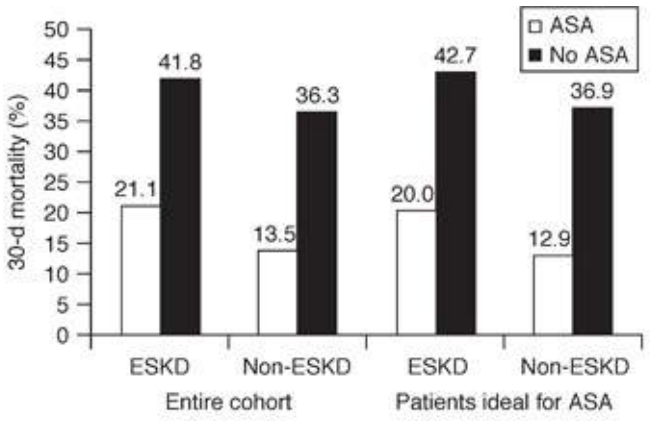

FIGURE 17.5 Thirty-day mortality following myocardial infarction in end-stage kidney disease (ESKD) patients. ASA, aspirin. (Reproduced with permission from Berger AK, Duval S, Krumholz HM. Aspirin, β-blocker, and angiotensin-converting enzyme inhibitor therapy in patients with end-stage renal disease and an acute myocardial infarction. *J Am Coll Cardiol* 2003;42:201–208.)

Similarly, β-blockers are underutilized in survivors of MI with ESKD when compared to those without ESKD. In the above-mentioned study, β-blockers were prescribed in only 43% of dialysis patients (296), despite the fact that survivors of MI receiving dialysis had a 22% reduction in mortality with their use [RR 0.78, 95% confidence interval (CI) 0.60 to 0.99] (compared to a 30% reduction in those without ESKD). Apart from the beneficial effects of β-blockers on mortality following MI, they also reduced the incidence of new-onset heart failure (297,298). It should be recognized that some β-blockers are removed by HD ("high dialyzability"), while others are not ("low dialyzability") (299). The high-dialyzability group includes atenolol, acebutolol, and metoprolol; these β-blockers should be administered after dialysis. The low-dialyzability group includes bisoprolol and propranolol.

Dyslipidemia is very common in patients with ESKD (87). Although statins are very effective in lowering total and LDL cholesterol concentrations in ESKD patients, their efficacy in reducing cardiovascular events and mortality in this patient population is uncertain. Some retrospective and small prospective studies showed that statins reduced cardiovascular and all-cause mortality (87), but the recently published Die Deutsche Diabetes-Dialyze (4D) study, a randomized comparison of placebo and atorvastatin in 1,255 diabetic patients on HD, showed no mortality benefit with statin therapy (300). Also, the Study to Evaluate the Use of Rosuvastatin in Subjects on Regular Hemodialysis: An Assessment of Survival and Cardiovascular Events (AURORA) trial which randomly assigned 2,776 patients on maintenance HD to either rosuvastatin or placebo found no effect of statin therapy on the combined primary end point of death from cardiovascular causes, nonfatal MI, and nonfatal stroke [hazard ratio (HR) 0.96, 95% CI 0.84 to 1.11] or on its individual components despite a 43% reduction in LDL

cholesterol levels, and an 12% reduction in median hs-CRP levels (301). However, the Study of Heart and Renal Protection (SHARP) trial showed that reduction of LDL cholesterol with simvastatin plus ezetimibe reduced major atherosclerotic events by 17% but did not appear to reduce overall mortality (302). A review of the medical literature by an expert panel concluded that statin therapy is safe in patients with CKD, although the risk of myopathy may be increased when statins are used in combination with fibrates (303–305). A proposed schema for treatment of dyslipidemia in HD patients is shown in **FIGURE 17.6** (87). The KDIGO Work Group does not recommend a specific on-treatment LDL-C target and thus does not recommend adjusting the dose of statins based on LDL-C levels (306).

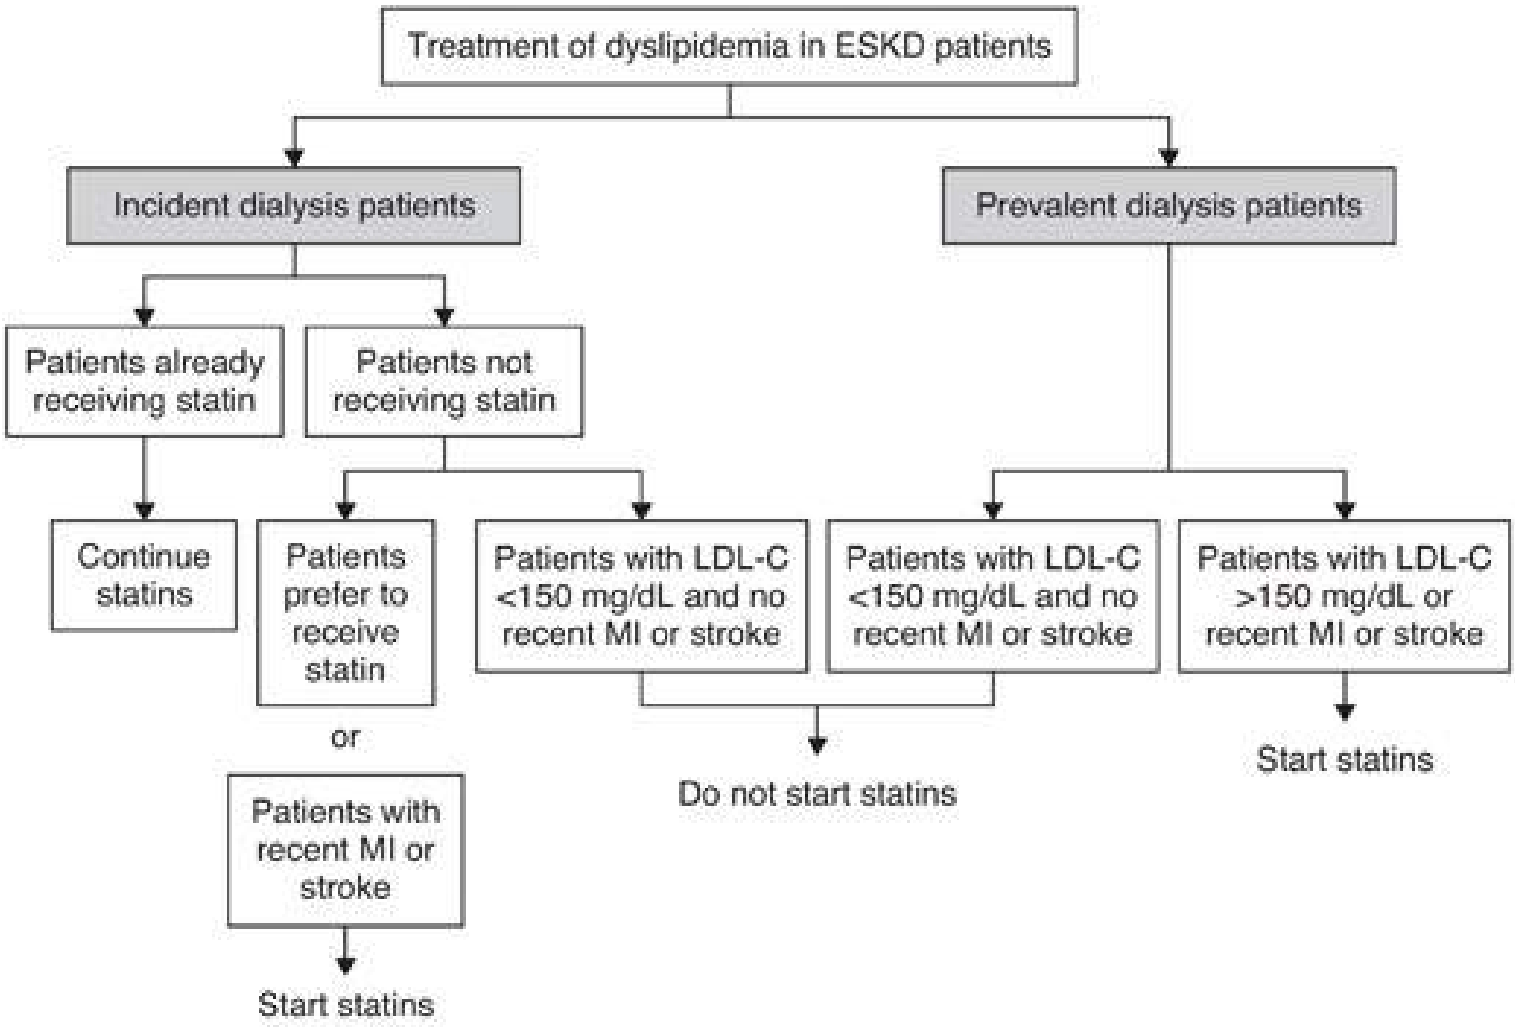

FIGURE 17.6 Schema for treatment of dyslipidemia in end-stage kidney disease (ESKD) patients. MI, myocardial infarction; LDL-C, low-density lipoprotein cholesterol. (Reproduced with permission from Qunibi WY. Dyslipidemia in dialysis patients. *Semin Dial* 2015;28:345–353.)

Finally, the beneficial effect of ACE inhibitors and/or angiotensin receptor blockers (ARBs) on reducing the risk of cardiovascular events and death in dialysis patients has not been well studied. ACE inhibitor therapy exerts a short-term survival benefit among patients with ESKD similar to that observed in patients not receiving dialysis. Berger et al. (296) reported that ACE inhibitor use was associated with a 16% absolute reduction in 30-day mortality in dialysis patients age 65 years and older presenting with clinical evidence of MI. In a small study, HD patients treated with an ACE inhibitor had a 52% RR reduction in 5-year mortality (307). Over an 8-year period, McCullough et al. (308) identified ESKD patients admitted to a coronary care unit. Of the 368 patients, 37% were given an ACE inhibitor during the hospital stay, and 63% were not; patient assignment was not random. The incidence of hypotension

and arrhythmias was similar in the two groups. Those receiving an ACE inhibitor manifested a 37% reduction in mortality ($p = 0.0145$). In contrast, a prospective comparison of placebo and fosinopril in 400 HD patients with documented LVH demonstrated no mortality difference in the two groups (309).

Acute MI in patients with ESKD is associated with increased risk of morbidity and mortality. Among these patients, the overall proportion of ST-elevation MI (STEMI) was approximately 18% as compare to 40% in the general population with acute MI (11,310). Herzog et al. (11) hypothesized that the lower proportion of STEMI in patients with ESKD may be due to a greater prevalence of preexisting obstructive CAD and the resultant increase in coronary collateralization and myocardial ischemic preconditioning, thus reducing the likelihood of transmural ischemia in the setting of acute coronary occlusion.

Management and outcomes of STEMI in these patients has recently been examined. Gupta et al. (310) analyzed the 2003 to 2011 Nationwide Inpatient Sample databases to examine the temporal trends in STEMI, use of mechanical revascularization for STEMI, and in-hospital outcomes in patients with ESKD aged >18 years in the United States. From 2003 to 2011, the number of patients with ESKD admitted with the primary diagnosis of acute MI increased from 13,322 to 20,552, there was a decrease in the number of STEMI hospitalizations from 3,169 to 2,558 ($p_{trend}<0.001$). The overall incidence rate of cardiogenic shock in patients with ESKD and STEMI increased from 6.6% to 18.3% ($p_{trend}<0.001$). The use of percutaneous coronary intervention (PCI) for STEMI increased from 18.6% to 37.8% ($p_{trend}<0.001$), but there was no significant change in the use of coronary artery bypass grafting ($p = 0.32$). During the study period, in-hospital mortality increased from 22.3% to 25.3% [adjusted odds ratio (OR) (per year) 1.09, 95% CI 1.08 to 1.11; $p_{trend}<0.001$] (310).

Coronary Artery Revascularization

Percutaneous Coronary Intervention

In patients with CKD, particularly those with ESKD, atherosclerotic coronary artery lesions are more frequently proximal and longer in length and substantially more calcified than their counterparts with normal renal function. Thus, revascularization procedures in these patients may be more complicated than those with normal renal function. Unfortunately, there are limited data on outcomes of coronary artery revascularization in CKD patients. Moreover, dialysis patients are less likely than those with normal renal function to be referred for coronary revascularization (**FIGURE 17.7**) (311). However, the number of PCI in these patients has increased by almost 50% over the past decade (312). Earlier studies reported unfavorable outcomes with balloon angioplasty in patients with ESKD (313,314). However, recent experience with the use of coronary arterial stenting in dialysis patients has been shown to be associated with good outcomes. Le Feuvre et al. (315) reported comparable rates of procedural success (90% vs. 93%), in-hospital mortality (1% vs. 0%), stent thrombosis (0% vs. 0%), and STEMI (0% vs. 1%) in dialysis patients compared with those with normal renal function, respectively. In addition, the incidence of symptomatic restenosis within 1 year of the procedure (31% vs. 28%) and MI during that same time period (6% vs. 2%) was similar in the two groups. However, cardiac death occurred more commonly in the dialysis patients (11% vs. 2%, $p<0.03$).

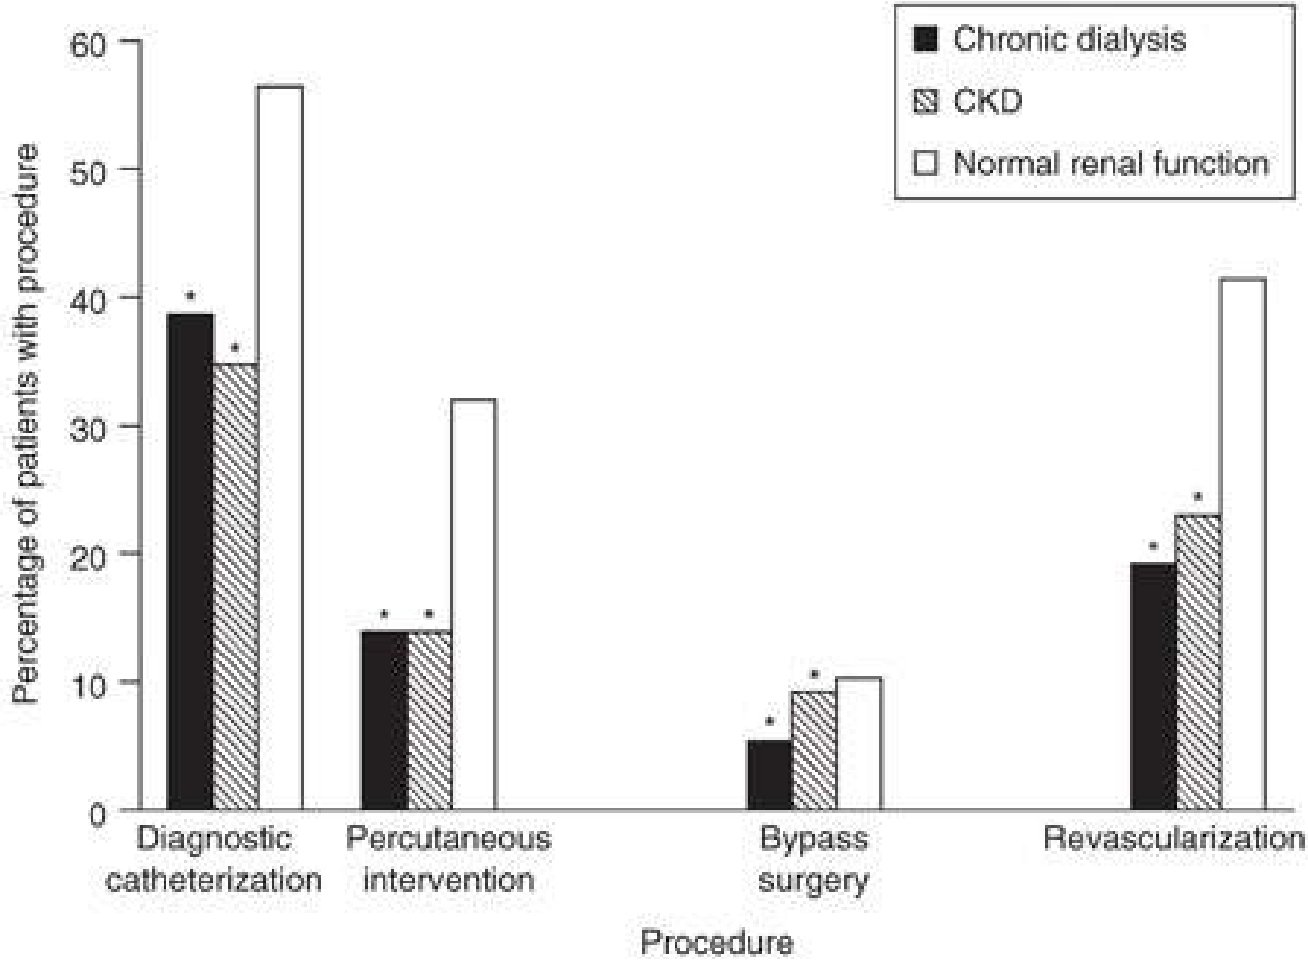

FIGURE 17.7 Rates of interventional procedures and revascularization in chronic kidney disease (CKD) and dialysis patients compared with individuals with normal renal function. *p <0.001. (Reproduced with permission from Charytan D, Mauri L, Agarwal A, et al. The use of invasive cardiac procedures after acute myocardial infarction in long-term dialysis patients. *Am Heart J* 2006;152:558–564.)

In subjects with normal renal function, the likelihood of symptomatic restenosis following balloon angioplasty is about 35%; it is approximately 20% to 25% following implantation of a bare metal stent and <10% after deployment of a drug eluting stent. In patients with ESKD, the incidence of restenosis after balloon angioplasty is considerably higher (roughly 65% to 80%) (316,317). Although few data are available concerning the incidence of restenosis following insertion of a bare metal stent in subjects with ESKD, some reports have suggested that its incidence in these individuals is similar to that of those with normal renal function (318). The incidence of symptomatic restenosis in ESKD patients following implantation of a drug eluting stent is uncertain. A small nonrandomized study of 89 consecutive ESKD patients receiving drug eluting or bare metal stents and then followed for at least 9 months showed that target vessel revascularization was required in 1 (4%) of the former group and 17 (26%) of the latter group (p = 0.036) (319). During the period of observation, death, MI, or target vessel revascularization occurred in 8 (33%) of those receiving a drug eluting stent and in 39 (60%) of those in whom a bare metal stent was implanted (p = 0.005). In contradistinction, a small nonrandomized study from Japan compared the results of drug eluting stenting in 88 consecutive HD patients with bare metal stenting in 78 HD patients in whom stent implantation was accomplished in the preceding year (320). The primary end point of the comparison was angiographic restenosis (defined as 50% or greater diameter stenosis at the site of stenting 6 to 8 months after the procedure). The rate of angiographic restenosis was 22% in those receiving a drug eluting stent and 24% in those in whom a bare metal stent was implanted (320). Given

that 80% of dialysis patients have calcified coronary arteries, a recent study from Japan found a higher risk of death and target lesion revascularization beyond 1 year of drug eluting stent placement for HD patients with calcified lesions versus those with noncalcified lesions (321). More research is needed concerning the relative efficacies of bare metal versus drug eluting stent use in subjects with ESKD.

Subjects with CKD, particularly ESKD patients on maintenance dialysis, have an increased risk of periprocedural and postprocedural morbidity and mortality during and after PCI when compared to those with normal renal function. In fact, the likelihood of adverse periprocedural and postprocedural events is related to the magnitude of preprocedural renal dysfunction. Best et al. (322) reviewed all adverse events that occurred in-hospital and within 1 year of PCI in 5,327 subjects undergoing balloon angioplasty (in 25% to 30%) or coronary stenting (in 65% to 70%) at the Mayo Clinic, after which they related these events to the estimated preprocedural creatinine clearance. Periprocedural in-hospital death occurred in 0.5% of those with a creatinine clearance greater than 70 mL/min, 0.7% of those with a clearance of 50 to 69 mL/min, 2.3% of those with a clearance of 30 to 49 mL/min, 7.1% of those with a clearance less than 30 mL/min, and 6.0% of those on dialysis. Similarly, death within 1 year of hospital discharge occurred in 1.5% of those with a creatinine clearance greater than 70 mL/min, 3.6% of those with a clearance of 50 to 69 mL/min, 7.8% of those with a clearance of 30 to 49 mL/min, 18.3% of those with a clearance less than 30 mL/min, and 19.9% of those on dialysis (322). Rubenstein et al. (323) reviewed the Massachusetts General Hospital experience in 3,334 patients undergoing PCI. Of these, 362 had a preprocedural serum creatinine greater than 1.5 mg/dL, whereas the other 2,972 had a creatinine less than 1.5 mg/dL. In comparison to those with a serum creatinine less than 1.5 mg/dL, those with a serum creatinine greater than 1.5 mg/dL had a lower rate of procedural success (90% vs. 93%, $p = 0.007$) and a markedly increased periprocedural mortality (10.8% vs. 1.1%, $p < 0.0001$). Similar data recently were reported by Gruberg et al. (324).

In summary, PCIs of all types (balloon angioplasty or coronary stenting) in patients with CKD are associated with substantial periprocedural and short-term postprocedural morbidity and mortality, particularly in subjects with ESKD. Mortality in this patient population remains high after successful PCI, probably due to a multiplicity of comorbid diseases. However, patients presenting with STEMI should undergo primary PCI with stenting, with the goal of performing the procedure within 90 minutes of presentation (door-to-balloon time) (325).

Coronary Artery Bypass Grafting

Data from several registries have consistently shown better long-term outcomes with coronary artery bypass grafting (CABG) compared to PCI in patients with ESKD, even though CABG in this patient population is associated with a high incidence of periprocedural complications. A retrospective study compared the outcomes of 279 dialysis patients with those of 15,271 patients with normal renal function who underwent a first CABG (326). After adjusting for age and comorbidities, the dialysis patients were 3.1 times more likely to die after CABG (9.6% vs. 3.1%), and they had an increased risk of postoperative mediastinitis (3.6% vs. 1.2%) and stroke (4.3% vs. 1.7%) (**FIGURE 17.8**). A follow-up study from the same database reported an 84% 5-year postoperative survival for patients with normal renal function and a 56% 5-year survival in those with ESKD (327). The survivals of dialysis patients after coronary angioplasty, coronary arterial stenting, and CABG were reported from the USRDS database (71): 4,836

dialysis patients were treated with balloon angioplasty, 4,280 with stenting, and 6,668 with CABG. Those undergoing balloon angioplasty were more likely to require a repeat revascularization procedure than those in whom stenting was performed. Those who had CABG had the lowest rate of repeat revascularization procedures. Although the in-hospital mortality was higher (8.6%) in the CABG-treated patients than in those undergoing balloon angioplasty (6.4%) or stenting (4.1%), the 2-year survival was better in the CABG patients (56.4%) when compared with balloon angioplasty (48.2%) and coronary arterial stenting (48.4%) (p <0.0001) (**FIGURE 17.9**). After adjustment for comorbidities, the RR for CABG [vs. percutaneous transluminal coronary angioplasty (PTCA)] was 0.80 (95% CI 0.76 to 0.84, p<0.0001) for all-cause death and 0.72 (95% CI 0.67 to 0.77, p<0.0001) for cardiac death.

Comparative survival of dialysis patients in the United States after coronary angioplasty, coronary artery stenting, and coronary artery bypass surgery and impact of diabetes. *Circulation* 2002;106:2207–2211.)

The optimal revascularization strategy in patients with ESKD and CAD remains unknown. However, recent studies have highlighted the more favorable long-term survival benefit with CABG compared with PCI. In the Alberta Provincial Project for Outcomes Assessment in Coronary Heart Disease (APPROACH) study which captures information on all patients undergoing cardiac catheterization in Alberta, Canada, Hemmnelgarn et al. (328) compared survival in 662 dialysis patients and 750 nondialysis-dependent CKD patients with 40,374 non-CKD patients. In the nondialysis-dependent CKD group, they reported adjusted 8-year survival rates of 46% for CABG, 33% for PCI, and 30% with no revascularization (p <0.001 for CABG vs. NR; p = 0.48 for PCI vs. NR). In the dialysis group, adjusted 8-year survival rates were 45% for CABG, 41% for PCI, and 30% with no revascularization (p = 0.003 for CABG vs. NR; p = 0.03 for PCI vs. NR). They concluded that CABG was associated with better survival than no revascularization in all categories of kidney function and that PCI was associated with a lower risk of death than no revascularization in the non-CKD patients and dialysis-dependent kidney disease patients but not in patients with nondialysis-dependent CKD. Accordingly, the presence of kidney disease or dependence on dialysis should not be a deterrent to revascularization, particularly with CABG (328). A recent meta-analysis of retrospective observational trials comparing CABG with PCI in ESKD patients with CAD showed that CABG was associated with a lower risk for late mortality (RR 0.90, 95% CI 0.87 to 0.93), MI (RR 0.64, 95% CI 0.61 to 0.68), repeat revascularization (RR 0.22, 95% CI 0.16 to 0.31), and cumulative events (RR 0.69, 95% CI 0.65 to 0.73), despite having a higher risk for early

mortality (RR 1.98, 95% CI 1.51 to 2.60) (329). In another meta-analysis comparing CABG with PCI using 17 trials (N = 33,584) in the ESKD arm and 6 studies (N = 15,493) in the CKD arm, the authors found significantly reduced early mortality with PCI with the OR of 2.08 (1.90 to 2.26, p <0.00001) and 2.55 (1.45 to 4.51, p = 0.001), respectively (330). However, they found decreased late mortality with the CABG when compared with PCI [OR 0.86 (0.83 to 0.89, p <0.000001) and 0.82 (0.76 to 0.88, p <0.00001)] in the ESKD and CKD arms, respectively. There was also a strong trend for decreased risk of stroke with PCI when compared with CABG in the ESKD and CKD populations (330). In summary, dialysis patients that require coronary revascularization appear to have a better long-term survival with CABG than after PCI.

Given that there are no randomized controlled trials comparing various interventions for coronary artery revascularization in patients with ESKD, it is difficult to make evidence-based decisions for the management of these patients. A summary of our recommendations for CABG in patients with ESKD is displayed in **TABLE 17.4**, which was adapted from the work of Fellner et al. (331). In general, the indications for CABG in ESKD patients are similar to those in subjects with normal renal function. *First*, individuals with limiting angina despite adequate medical therapy should be considered for bypass grafting to eliminate or to improve symptoms. *Second*, certain patient subgroups should be considered for bypass grafting to improve long-term survival, including those with (a) more than 50% luminal diameter narrowing of the left main coronary artery; (b) more than 70% luminal diameter narrowing of two or three major epicardial coronary arteries, in whom the proximal portion of the left anterior descending coronary artery is significantly narrowed; and (c) more than 70% luminal diameter narrowing of all three major epicardial coronary arteries in association with left ventricular systolic dysfunction (ejection fraction less than 0.50) (331). No data from prospectively performed, randomized trials have shown that CABG is superior to medical therapy in improving survival in subjects with ESKD and any of the three aforementioned arterial anatomic patterns. Subjects with no or mild symptoms obviously do not require bypass grafting for symptom relief. Those with less extensive CAD (involving one, two, or all three coronary arteries without involvement of the proximal portion of the left anterior descending coronary artery) do not manifest a better survival with CABG than with medical therapy.

TABLE 17.4 General Recommendations for Coronary Bypass Surgery in Patients with End-Stage Kidney Disease

Generally indicated	Intermediate interactions	Not indicated
Limiting angina despite adequate medical therapy	Severe three-vessel disease	Asymptomatic and one- or two-vessel disease
Left main disease of >50%	Symptomatic two-vessel disease with LV dysfunction	Stable angina with one-vessel disease
Severe three-vessel disease (>70% narrowing) with LV dysfunction (ejection fraction <50%)	Symptomatic two-vessel disease with a normal LV function	Angina with no significant CAD
Severe two- or three-vessel disease including a proximal left anterior descending artery	Symptomatic one-vessel disease	

Symptomatic can refer to clinical symptoms or an abnormal exercise stress test result. Asymptomatic refers to no symptoms or a negative stress test result.
LV, left ventricular; CAD, coronary artery disease.

Numerous reports have noted the high perioperative morbidity and mortality in patients with ESKD undergoing CABG (332–339). In all these reports, the perioperative mortality of ESKD subjects is 5% to

10% (in contrast to the 1% to 2% in patients with normal renal function). In addition, perioperative morbidity, such as stroke, mediastinitis, and excessive bleeding, occurs in as many as 20% of ESKD patients (326). Recently developed "off-pump" bypass grafting, with which surgical revascularization is accomplished on the beating heart without cardiopulmonary bypass, may be associated with less morbidity and mortality than the classic "on-pump" procedure (340), but adequately sized, randomized comparisons of on-pump and off-pump bypass grafting in patients with CKD have not yet been reported. Beckermann et al. (341) reviewed the experience in almost 4,000 subjects in the USRDS who underwent bypass graft surgery. Of these, on-pump surgery was performed in 3,382 and off-pump surgery in 540. Significantly less postoperative atrial fibrillation was noted in those undergoing off-pump CABG (37.5% on-pump vs. 4.8% off-pump, $p = 0.028$), and off-pump bypass grafting was associated with a 16% reduction in all-cause mortality ($p = 0.032$). Off-pump bypass grafting is still performed uncommonly in dialysis patients in the United States even though it may provide a lower risk of morbidity. The 5-year survival of ESKD patients undergoing bypass grafting (regardless of how it is performed) is only 50% (340–342).

SUDDEN CARDIAC DEATH

Definition and Incidence of Sudden Cardiac Death in Patients with End-Stage Kidney Disease

In 2006, the American College of Cardiology/American Heart Association/Heart Rhythm Society (ACC/AHA/HRS) proposed the following definition of sudden cardiac death (SCD): "Sudden cardiac arrest is the sudden cessation of cardiac activity so that the victim becomes unresponsive, with no normal breathing and no signs of circulation. If corrective measures are not taken rapidly, this condition progresses to sudden death. Cardiac arrest should be used to signify an event as described above, that is reversed, usually by CPR and/or defibrillation or cardioversion, or cardiac pacing. Sudden cardiac death should not be used to describe events that are not fatal" (343). SCD in dialysis patients has been defined as unexpected death from a cardiac cause within 1 to 24 hours after the last dialysis and/or onset of symptoms in a patient not known to have a potentially fatal condition (344,345).

SCD is now considered the leading cause of death in HD patients, accounting for up to 70% of deaths from CVD and 27% of all causes of mortality in this population (1,344,346). This represents about 20-fold higher risk that dialysis patients may experience SCD compared with the general population (1,347). Recent estimates from the USRDS suggest that the annual SCD rate among prevalent dialysis patients is 5.5% (348). Data from the Dialysis Outcomes and Practice Patterns Study (DOPPS) registry suggest that sudden death accounts for the highest proportion of HD deaths in the United States (33%) compared with other countries (349).

Pathophysiology of Sudden Cardiac Death in Patients with End-Stage Kidney Disease

Sudden Cardiac Death in Chronic Kidney Disease Patients versus the General Population

The biologic mechanisms and pathogenesis of SCD among the dialysis and CKD population have not been established but are clearly different from those in the general population. In the general population, up to

80% of SCD cases have post mortem evidence of CAD. By contrast, CAD is not as prevalent in dialysis patients who are victims of SCD (344). In one postmortem study of 93 dialysis patients who had sudden death, only 12% of cardiac sudden deaths that occurred within 24 hours of onset of symptoms were due to CAD (350). Similarly, LVH or poor left ventricular systolic function are strong predictors of SCD in the general population but may not be so in dialysis patients. In a multivariate analysis, Genovesi et al. (351) found LVH not to be associated with sudden death and also found no significant difference in the incidence of sudden death between patients with left ventricular ejection fraction <40% or >40%. However, a subgroup analysis of the 4D study showed that electrocardiographic evidence of LVH was associated with a higher rate of sudden death in diabetic HD patients (352). Two other studies in HD patients who experienced SCD found LVH in more than 70% of cases (353,354). Moreover, an increase in left ventricular mass index over time was found to be the most potent predictor of SCD in 10-year observational study of HD patients (355).

Thus, although patients with CKD share some of these risk factors, including atherosclerosis, with the general population, the presence of renal dysfunction *per se* increases the risk of SCD to an extent that cannot be simply explained by the severity of atherosclerotic CAD or known risk factors. Studies have shown that decreased renal function is an independent risk factor for SCD, and this risk is present from the early stages of CKD, increases as renal function declines, and reaches its peak in the dialysis population (**FIGURE 17.10**). In a retrospective longitudinal study encompassing 19,440 consecutive patients who underwent cardiac catheterization at a single academic institution, Pun et al. (356) reported 3.8 SCD events in 14,652 patients with estimated GFR ≥60 (stage 2 CKD or better) and 7.9 events in 4,788 patients with GFR <60 (stages 3 to 5 CKD). In an adjusted multivariate Cox proportional hazards model, the eGFR was independently associated with SCD (HR = 1.11 per 10 mL/min decline in the eGFR).

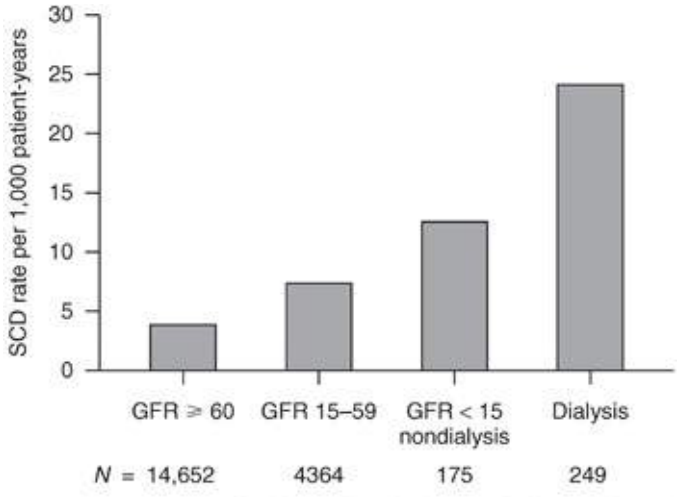

FIGURE 17.10 Rates of sudden cardiac death (SCD) by the baseline estimated glomerular filtration rate (eGFR) category. (Reproduced with permission from Pun PH, Smarz TR, Honeycutt EF, et al. Chronic kidney disease is associated with increased risk of sudden cardiac death among patients with coronary artery disease. *Kidney Int* 2009;6:652–658.)

Triggers for Sudden Cardiac Death Unique To Chronic Kidney Disease Patients

What could explain this unique predisposition of CKD patients to SCD since CAD does not seem to be the major culprit? A plausible explanation is that the myocardium is vulnerable to various arrhythmic triggers that are prevalent in CKD and dialysis patients, in part due to diffuse myocardial fibrosis. Studies

of HD patients using magnetic resonance imaging (MRI) describe a diffuse pattern of myocardial fibrosis underlying LVH, and this pattern occurs in the absence of significant CAD (357–359). This myocardial fibrosis may result from various factors that are commonly encountered in CKD patients such as microvessel disease with capillary deficit (the so-called capillary/myocyte mismatch) (359), abnormal mineral metabolism (360), and recurrent myocardial ischemia from reduced myocardial perfusion during dialysis (**TABLE 17.5**) (361). In one study, 64% of patients had significant myocardial stunning during HD. Age, ultrafiltration volumes, intradialytic hypotension, and cTnT levels were independent determinants associated with myocardial stunning (361).

TABLE 17.5 Potential Risk Factors for Sudden Cardiac Death in Patients with End-Stage Kidney Disease

Systemic diseases:
- Diabetes mellitus
- Systemic inflammation/malnutrition

Underlying cardiac disease
- Coronary artery disease
- Diastolic dysfunction
- Left ventricular hypertrophy
- Congestive heart failure
- Myocardial fibrosis

Lack of cardioprotective drugs
- β-Blockers

Electrolyte abnormalities
- Hypokalemia
- Hyperkalemia
- Hypocalcemia
- Hypomagnesemia
- Metabolic alkalosis

Dialysis-related risk factors
- Long interdialytic interval
- Low dialysate potassium concentration
- Low dialysate calcium concentration
- Rapid ultrafiltration
- High bicarbonate dialysate concentration leading to metabolic alkalosis
- Prolongation of the QTc interval during dialysis
- Air embolism

It is likely that many of the dialysis-associated factors may trigger serious cardiac arrhythmias, such as sustained ventricular tachycardia or ventricular fibrillation, similar to terminal events in the general population. For example, intermittent fluctuations of BP, fluid, and electrolytes during the dialysis cycle may pose a significant risk for SCD which seems to be more frequent in HD patients particularly following a long interdialytic interval. Bleyer et al. (353) reported a bimodal distribution of SCD in HD patients, with a 1.7-fold increased death risk occurring in the 12-hour period starting with the dialysis procedure and a threefold increased risk of death in the 12 hours before HD at the end of the weekend interval ($p = 0.011$) (**FIGURE 17.11**). They also reported that patients with SCD had a high prevalence of congestive heart failure and CAD. Only 40% of patients experiencing SCD were receiving β-blockers, and the prior monthly serum potassium value was less than 4 mEq/L in 25%. They suggested that every other day, HD could be beneficial in preventing SCD (353). Genovesi et al. (351) found that a serum potassium level >6.0 mEq/L was associated with a significant increase in risk of SCD in dialysis patients (HR 2.74, $p = 0.009$), while Paoletti et al. (355) could not reproduce this finding in their study of 123 patients followed up for 10 years. In a large observational study of 81,013 dialysis patients, Kovesdy et al. (362) reported that a predialysis serum potassium level of 4.6 to 5.3 mEq/L was associated with the

lowest all-cause mortality. Thus, both hypokalemia and hyperkalemia may increase the risk of SCD in HD patients (363). Moreover, dialysis conducted with low potassium and/or calcium dialysate may increase the risk of SCD in these patients (363,364). Also, aggressive ultrafiltration may be associated with dialysis-associated hypotension and dialysis-induced myocardial "stunning" (361,365–367). In addition, higher dialysate bicarbonate concentrations and metabolic alkalosis have been associated with hypokalemia, hemodynamic instability, QTc interval prolongation, and increased mortality risk (368,369).

(Reproduced with permission from Bleyer AJ, Hartman J, Brannon PC, et al. Characteristics of sudden death in hemodialysis patients. *Kidney Int* 2006;69:2268–2273.)

Other potential risk factors for SCD in dialysis patients have been the subject of recent investigations (**TABLE 17.5**). Diabetes mellitus is known to be associated with an independent risk of SCD likely due to arrhythmias caused by nocturnal hypoglycemia and QT interval prolongation. The presence of diabetes in dialysis patients is also associated with an increased risk of SCD (370). In the 4D, patients with an HbA1c level ≥8% had a twofold increased risk for SCD compared with those with an HbA1c level <6% (371). The role of inflammation and malnutrition in SCD was examined in the CHOICE cohort of 1,041 incident dialysis patients (372). In this study, SCD was responsible for 22% of all mortality over a median 2.5 years of follow-up. Using Cox proportional hazards, they found that the highest tertiles of serum levels of hs-CRP and IL-6 were each associated with twice the adjusted risk of SCD compared to their lowest tertiles. Decreased serum albumin was associated with a 1.35 times increased risk for SCD in the lowest compared to the highest tertiles independent of traditional cardiovascular risk factors (372). Interestingly, a recent study identified 5,117 pairs of patients who came from the same family from a sample of 647,457 dialysis patients and matched each to a control subject from the same population and found that genetically related family members who did not cohabitate had an OR of 1.88 (95% CI 1.25 to 2.84) for cardiac arrest compared with their phenotypically matched unrelated controls (373). Genetically related family members who lived together in the same environment had an OR of 1.66 (95% CI 1.20 to 2.28). Spouses, who were genetically unrelated but lived together in the same environment, had an OR of 0.95 (95% CI 0.60 to 1.59) for cardiac arrest. The authors suggested that the risk of cardiac arrest in patients on dialysis may be attributable to inherited factors (373).

Nature of Terminal Arrhythmia in Sudden Cardiac Death of Chronic Kidney Disease Patients

The terminal arrhythmias associated with SCD in CKD and dialysis patients are not well defined. Some

studies suggested that ventricular tachyarrhythmia is the common final pathway for SCD (374), while other studies found bradycardia, asystole, and pulseless electrical activity more common (375). Wan et al. (374) described the characteristics of sudden cardiac arrest (SCA) and post-SCA survival in 75 HD patients who experienced at least one SCA event using a wearable cardioverter defibrillator (WCD) between 2004 and 2011. Sixty-six (79%) SCA events were due to ventricular tachycardia or ventricular fibrillation, and 18 (21%) were due to asystole. Most SCA episodes occurred during the daytime. Of these, 70% occurred during dialysis sessions. Acute 24-hour survival was 71% for all SCA events; 30-day and 1-year survival were 51% and 31%, respectively. Monday was the day where most arrhythmias occurred (n = 31), followed by Tuesday, Thursday, and Saturday with 19 each; Wednesday had the least number of SCA events (n = 6) (**FIGURE 17.12**). The distribution was statistically significant (p = 0.001). Women had a better post-SCA survival than men (HR = 2.41, 95% CI 1.09 to 5.36, p = 0.03). In an animal model of CKD, Hsueh et al. (376) found that cardiac ion channel and calcium handling are abnormal, leading to increased vulnerability to early after-depolarization, triggered activity, and ventricular arrhythmias.

Prevention of Sudden Cardiac Death in Dialysis Patients

There are no randomized clinical trials of interventions to reduce SCD in dialysis patients, and thus, current recommendations are based on existing evidence from observational studies as well as on demographic, comorbid, clinical, and behavioral risk factors (377). In order to prevent or minimize the occurrence of SCD, an understanding of its pathogenesis among dialysis patients is required. An important observation is that the first month after initiation of HD appears to be a period of increased risk of SCD (378,379). However, the risk seems to increase with longer dialysis vintage for both HD and peritoneal dialysis patients alike (380). This is particularly true for dialysis patients who have large interdialytic weight gains, extremes of serum potassium level, or abnormal mineral metabolism and nutrition (363,381). For all CKD patients, victims of SCD are commonly diabetic and have a history of arrhythmias and preexisting heart disease (356,382).

Some risk factors for SCD may be modifiable. Shastri et al. (383) used baseline clinical characteristics to identify predictors associated with various causes of death in the Hemodialysis (HEMO) Study and to develop a prediction model for SCD using a competing risk approach. During a median follow-up of 2.5 years, SCD was recorded in 22% of patients. They found age, diabetes, peripheral vascular disease, IHD, serum creatinine, and alkaline phosphatase to be independent

predictors of SCD. However, the primary predictors for SCD in their study were diabetes and IHD. Traditional risk factors such as smoking, hypertension, cholesterol level, and obesity were not associated with SCD. Unfortunately, no data on dialysis prescription, dialysis bath, or arrhythmias, factors that increase risk for SCD, were readily available. It is not clear yet whether identifying predictors for SCD may lead to different interventions in a particular patient. As an example, it is unclear whether tighter glycemic control will reduce the risk for SCD in this population. On the other hand, IHD may trigger arrhythmias and its treatment may decrease the risk of SCD, although this has not been clearly shown in dialysis patients. The use of β-blockers has been shown to reduce SCD after MI in the general population but not in dialysis patients. However, their use in HD patients has been shown in some studies to reduce overall mortality and mortality after cardiac arrest, with a nonsignificant reduction in SCD (384,385). Medications that are known to lower cardiovascular risk in the general population such as lipid-lowering agents and the renin-angiotensin-aldosterone blockers have not been shown to reduce cardiovascular risk in CKD or dialysis patients or at best to have minimal effect (386).

Given that the dialysis prescription may have adverse effects in HD patients, it is imperative that large fluctuation in fluid and electrolytes be avoided in order to reduce the risk of SCD. Thus, dialysate potassium level <2.0 mEq/L and/or dialysate calcium <2.0 mEq/L should be avoided (387). In one study, the use of a dialysate potassium modeling to maintain a constant serum-to-dialysate potassium gradient during the procedure was shown to reduce the incidence of premature ventricular contractions during dialysis (388). Also, the use of lower dialysate sodium concentration may help reduce interdialytic weight gain and large ultrafiltration targets (389). Other maneuvers that may be beneficial include the use of dialysate cooling as well as more frequent or long slow dialysis. In a small randomized crossover study of 11 patients comparing left ventricular regional wall motion abnormalities, reducing dialysate temperature by 2°C below body temperature was associated with reduced dialysis-induced myocardial wall motion abnormalities which are known risks for cardiac death (390).

The Role of Implantable Cardiac Defibrillators

The benefits of implantable cardiac defibrillators (ICDs) for prevention of SCD in patients with ESKD remain unclear. This is because CKD and dialysis patients have been excluded from major clinical trials which showed reduction in SCD with ICDs in the general population. As of now, no clinical trials have been published assessing the efficacy and safety of ICDs for prevention of SCD in dialysis patients. A recent meta-analysis of three randomized trials of primary prevention in patients with symptomatic heart failure and left ventricular ejection fraction <35% used data from the Multicenter Automatic Defibrillator Implantation Trial I (MADIT-I), MADIT-II, and the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) (391). The investigators found that the mortality reduction associated with the ICD is significantly impacted by the baseline renal function, with decreasing benefit as eGFR declines. The study documented no survival benefit for ICDs in patients with eGFR <60 mL/min/1.73 m^2 (adjusted HR 0.8, 95% CI 0.4 to 1.5) compared to usual care. In contradistinction, a significant survival benefit was observed for patients with eGFR >60 mL/min/1.73 m^2 (adjusted HR 0.49, CI 0.24 to 0.95) (391) (**FIGURE 17.13**). In fact, several studies have reported increased complication rates and mortality in CKD patients treated with ICDs (392–395). These complications include bacteremia, central venous stenosis, access malfunction, and others. A recent retrospective cohort study of 9,528 HD patients who received ICDs from 1994 to

2006 found a high annual mortality rate of 45%, and that most deaths were attributed to arrhythmias (396). The rate of infection was also high with annual rates of bacteremia of 52% and device infection in 4%. In that study, the authors noted that almost all ICDs used in the 1990s was for secondary prevention, while half the patients received ICDs for apparent primary prevention in 2006. Patients receiving ICDs for secondary prevention had an overall 14% (95% CI 9% to 19%) lower mortality risk compared with propensity-matched controls, but these benefits seemed to be restricted to the early postimplantation time (396). Based on the above discussion, ICDs have not been shown to afford a significant benefit among U.S. dialysis patients who received an implantable defibrillator, even after a MI. However, the ICD2 trial, a prospective randomized controlled study designed to evaluate the efficacy and safety of prophylactic ICD therapy in reducing SCD in 200 dialysis patients aged 55 to 80 years over a 4-year period, is currently underway (397). Given that the initiation of HD is characterized by a marked increase in the rate of SCD, particularly in the first 3 months after HD initiation, a new trial entitled "WED-HED" (Wearable External Defibrillator in Hemodialysis patients), has been initiated to test the efficacy of wearable external defibrillators in preventing SCD in incident HD patients (398). Until further studies become available, a rational approach to identify HD patients at high risk for SCD and to target these patients for focused attention on their dialysis-related risk factors. Timely changes in the dialysis prescription and/or medications may help in attenuating or preventing SCD in this vulnerable population.

CHAPTER 18

Hemodynamic Stability and Autonomic Dysfunction in End-Stage Kidney Disease

Biff F. Palmer and William L. Henrich

The usual manifestation of hemodynamic instability during ultrafiltration dialysis (in which fluid removal is the primary goal) is hypotension. The incidence of a symptomatic reduction in blood pressure during or immediately following dialysis ranges from 15% to 50% of dialysis sessions (1). In some patients, the development of hypotension necessitates intravenous fluid replacement before the patient leaves the dialysis unit, which results in volume overload. Symptomatic hypotension may necessitate a premature discontinuation of the treatment, which if repetitive can lead to inadequate clearance. Intradialytic hypotension (IDH) and orthostatic hypotension after the procedure have been found to be independent risk factors affecting the morbidity and mortality of dialysis patients (**TABLE 18.1**) (2).

TABLE 18.1 Complications of Intradialytic Hypotension

Myocardial ischemia
Stroke
Mesenteric ischemia
Clotted access
Ischemic atrophy of the optic nerve with loss of vision
Inadequate clearance secondary to shortened treatment time
Persistent posttreatment volume overload

A second type of dialysis-related hypotension is a chronic, persistent form of hypotension that occurs in approximately 5% of dialysis patients (1). This second form of hypotension is usually observed in patients who have been on hemodialysis (HD) for at least 5 years. Such patients often come to the dialysis unit with a systolic blood pressure of less than 90 mm Hg. This form of hypotension is associated with an increased mortality and is often a manifestation of malnutrition and/or cardiovascular disease in the chronic HD patient (3–5). In one recent review of a group of such patients, chronically hypotensive patients had a lower peripheral resistance than normotensive patients (6). Of interest is that in this study, cardiac output was not significantly elevated in the hypotensive group, perhaps suggesting some decrease in cardiac reserve. This chapter focuses on the problem of episodic hypotension, which is the most

frequent form of HD-related hemodynamic instability.

OVERVIEW OF THE PROBLEM

Dialysis hypotension is the result of an inadequate cardiovascular response to the reduction in blood volume that occurs when a large volume of water is removed over a short period of time. In a typical dialysis procedure, an ultrafiltrate volume that is equal to or greater that the entire plasma volume is often removed. Despite the large ultrafiltrate volume, plasma volume typically decreases by only approximately 10% to 20% (7). This ability to maintain plasma volume during ultrafiltration requires mobilization of fluid from the interstitial into the intravascular space. Adequate tone and normal compliance characteristics of the venous system is required to redistribute this fluid into the central circulation where it becomes available for cardiac refilling. Once delivered to the central circulation, normal systolic and diastolic function of the heart ensures maintenance of cardiac output. Should cardiac output begin to decline, blood pressure is stabilized by sympathetic nervous system–induced increases in peripheral vascular resistance.

Disturbances in either one or several of these steps will render the patient prone to develop hypotension in the setting of fluid removal (**FIGURE 18.1**). These disturbances can be the result of the chronic uremic state as well as accompanying comorbid conditions. The following sections review the various abnormalities in the autonomic and cardiovascular systems that contribute to the development of episodic dialysis hypotension. The chapter concludes with a discussion of the prevention and management of dialysis-related hypotension.

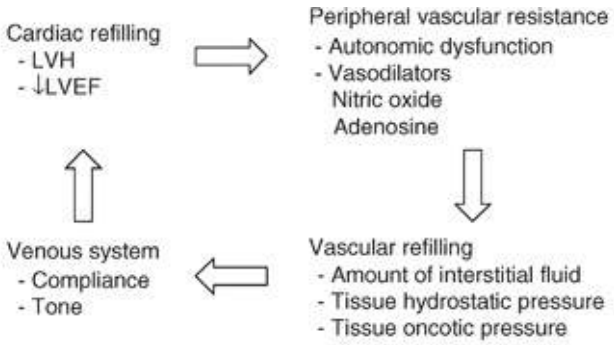

FIGURE 18.1 Overview of factors that influence vascular refilling and preservation of plasma volume in the setting of ultrafiltration. LVEF, left ventricular ejection fraction; LVH, left ventricular hypertrophy.

VASCULAR REFILLING

The ability to maintain plasma volume during ultrafiltration requires mobilization of fluid from the extravascular into intravascular space. The success of vascular refilling is influenced by the stability of plasma osmolality, the rate of fluid removal, and other patient characteristics that dictate the distribution of fluid between the body fluid compartments.

Stable Plasma Osmolality

The importance of a stable plasma osmolality as a key element in preventing dialysis hypotension is discussed in detail concerning dialysate composition. The main mechanism by which a stable plasma osmolality contributes to hemodynamic stability appears to be through the maintenance of a more stable

extracellular fluid volume and plasma volume (**FIGURE 18.2**) (8). The rapid fall in plasma osmolality that results from solute removal leads to the movement of water to intracellular loci. This movement of water will decrease the amount of fluid accessible for vascular refilling. The use of a higher dialysate sodium concentration (greater than 140 mEq/L) is an effective means to assure adequate vascular refilling and has proved to be among the most effective and best-tolerated therapies for episodic hypotension. A high-dialysate sodium concentration limits the decline in plasma osmolality and therefore leads to the removal of volume during ultrafiltration from both intracellular and extracellular compartments. This effect limits the compromise in the plasma volume that normally occurs during rapid falls in plasma osmolality coupled with a very large ultrafiltration rate. Another potential mechanism by which a decline in plasma osmolality may contribute to dialysis hypotensive episodes is by impairing peripheral vasoconstriction during volume removal (9,10). A decline in plasma osmolality may also adversely affect baroreceptor function by blunting afferent sensing mechanisms, thereby contributing to autonomic dysfunction (9).

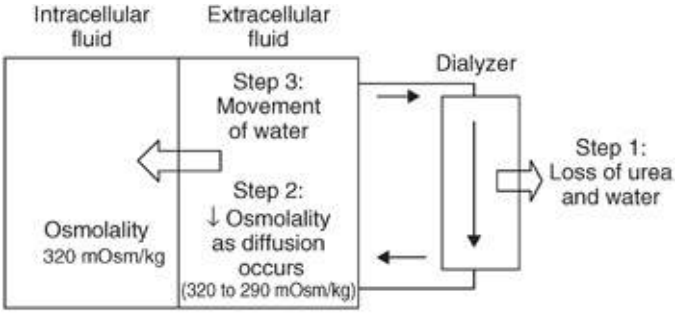

FIGURE 18.2 A decline in extracellular osmolality can contribute to hemodynamic instability. The first step is a reduction in osmolality as urea and other solutes are removed from the body across the dialyzer. This solute removal results in a decline in extracellular osmolality relative to the intracellular space. The third step is the osmotic movement of water from the extracellular to intracellular space.

Local Starling Forces

Several patient characteristics that affect Starling forces operating at the capillary level influence the process of vascular refilling. One such characteristic is the amount of interstitial fluid present, a parameter clinically reflected by the dry weight of the patient. When the volume of interstitial fluid is small, any ultrafiltrate volume will more likely be associated with hemodynamic instability. This explains the development of hypotension when patients are dialyzed below their true dry weight. By contrast, increased amounts of interstitial fluid will expand the volume of fluid accessible for refilling of the intravascular space and, therefore, decrease the likelihood of hypotension. In most patients, a dry weight is selected that minimizes the amount of interstitial fluid present because chronic volume overload has long-term deleterious effects on the cardiovascular system. However, in patients with recurrent IDH or chronic persistent hypotension that is not amenable to other interventions, it may be necessary to purposely maintain the patient in a hypervolemic state so that the dialysis procedure can be employed with a lower likelihood of hemodynamic instability.

Determinants of the oncotic and hydrostatic pressure at the tissue level will also affect vascular refilling. For example, a well-nourished patient with a normal serum albumin concentration is more likely to have better preserved vascular refilling as compared to a patient with hypoalbuminemia. On the other hand, administration of a vasodilator has the potential to impair vascular refilling by allowing excessive transmission of arterial pressure into the capillary bed resulting in increased hydrostatic pressure.

CARDIAC REFILLING AND VENOUS DYSFUNCTION

When vascular refilling and plasma volume are normal, IDH can still occur if there is a failure to properly redistribute intravascular volume into the central circulation (11). In some patients, this failure can be traced to functional and structural abnormalities on the venous side of the circulation.

Because most plasma volume is located on the venous side of the circulation, even a small decrease in tone of the venous system can potentially limit cardiac filling because of a decrease in central blood volume. Abrupt splanchnic vasodilation can be the cause of IDH. Such vasodilation may result from ingestion of food during the dialysis procedure or withdrawal of sympathetic tone resulting from an increase in core body temperature. Increased production of vasodilators such as adenosine or nitric oxide may also play a role in this complication.

Decreased venous compliance has also been demonstrated in hypertensive HD patients (12,13). Such a disturbance in venous compliance can lead to hemodynamic instability in at least two ways. First, decreased venous compliance leads to a steep volume-to-pressure relationship such that a major drop in cardiac filling pressure can occur with only a small decrease in plasma volume. In this regard, an inverse relationship has been observed between venous compliance and the fall in central venous pressure in dialysis patients during isolated ultrafiltration (12). Second, impaired venous compliance can lead to higher hydrostatic pressures in the upstream capillary bed resulting in reduced vascular refilling from the interstitium. Patients with evidence of decreased venous compliance exhibit a greater decrease in plasma volume during ultrafiltration as compared to those subjects with normal venous compliance characteristics (12,13). The basis for altered venous function in chronic uremia may relate to structural abnormalities of the venous wall. Morphologic studies of the iliac and inferior caval veins of hypertensive patients with end-stage kidney disease (ESKD) have shown increased thickness of the media in the venous wall (14). Such structural abnormalities may also impair the ability to mobilize erythrocytes from the splanchnic or splenic circulation into the systemic circulation during ultrafiltration (15). This mechanism may be particularly important in patients who also exhibit impaired autonomic function.

SYSTOLIC AND DIASTOLIC FUNCTION OF THE HEART

As the central circulation is filled, hemodynamic stability then becomes dependent on normal systolic and diastolic function of the heart to generate an adequate cardiac output in the face of volume removal. Myocardial dysfunction is commonly present in patients with ESKD and can be an important cofactor in dialysis-induced hypotension (16).

Diastolic Dysfunction

The frequent occurrence of hypertension and on occasion aortic stenosis contributes to pressure overload of the left ventricle and accounts for the frequent occurrence of concentric left ventricular hypertrophy (LVH). Other contributing factors include the presence of an arteriovenous fistula, anemia, and intermittent bouts of volume overload.

Left ventricular (LV) dilatation and hypertrophy lead to changes in ventricular performance that differ strikingly from that seen in the healthy heart. A high incidence of LVH and abnormal diastolic function leads to diminished diastolic distensibility, such that the volume–pressure relationship during diastolic

filling is steeper and shifted to the left (**FIGURE 18.3**). When LV compliance is diminished, a small rise in left ventricular end-diastolic volume (LVEDV) may cause a disproportionately large increase in left ventricular end-diastolic pressure (LVEDP) with consequent pulmonary venous congestion but little or no increase in stroke volume. Even in the presence of well-preserved systolic function, the preload reserve of the left ventricle can be exceeded by abrupt or large increases in plasma volume or because decreased ventricular compliance leads to inappropriately high filling pressure and pulmonary congestion. Furthermore, decreases in plasma volume, as during ultrafiltration in the setting of a steep volume–pressure relationship, can critically decrease the filling pressure of the heart and result in hypotension. In short, many patients with ESKD operate within a narrow LV volume–pressure relationship such that changes in plasma volume are often not well tolerated.

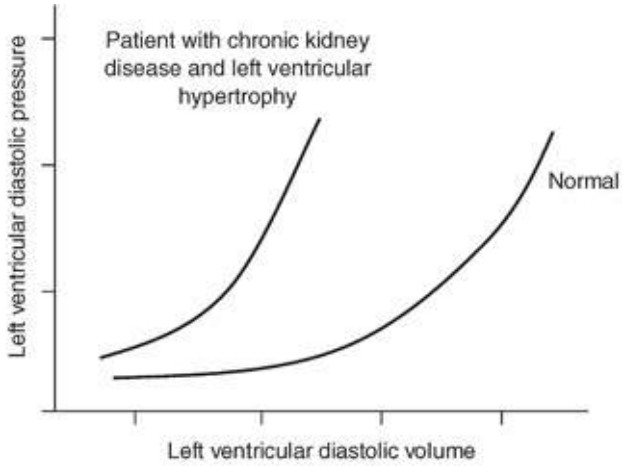

FIGURE 18.3 Compliance characteristics (left ventricular ejection fraction/left ventricular end-diastolic pressure) of the left ventricle during diastolic filling. Patients with end-stage renal disease often have the pressure–volume relationship of the left ventricle shifted to the left such that myocardial compliance is decreased.

The contribution of LVH to hemodynamic instability during dialysis is highlighted by a number of studies that have shown LVH to be more common in dialysis patients who experience episodic dialysis hypotension (17). Ritz et al. (18) observed that the LV mass-to-volume ratio was 37% greater in 27 patients with recurrent IDH than in 27 patients without this complication. Similarly, Wizemann et al. (19) noted that the incidence of dialysis hypotension was several times greater in patients with echocardiographic LVH than in those with normal ventricular mass. Another study found patients with recurrent IDH had a lower predialysis blood pressure, more severe concentric LVH, and lower LV compliance (20).

Patients with diastolic dysfunction are particularly difficult to treat. In the setting of impaired ventricular relaxation, a small amount of volume replacement can potentially trigger pulmonary edema. Therapy with inotropic agents can exacerbate the problem by further impairing ventricular relaxation. Calcium channel blockers such as verapamil or diltiazem may have some utility in this setting because these agents exert a negative inotropic effect on the heart and have the potential to improve LV relaxation. In a small series of patients, use of these drugs produced a functional improvement in cardiac performance and a reduction in the frequency of hypotension (21). However, it must be emphasized that the use of vasodilator calcium channel blockers has the potential disadvantage of lowering blood pressure. Hence, the trade-off of improving LV relaxation may not be tolerated in all patients because of the effect of the drugs to lower blood pressure.

On a more chronic basis, therapy can be instituted with the goal of reducing LV mass toward normal and presumably improve ventricular diastolic function. Partial or complete regression can be achieved by control of hypertension and by correction of anemia with erythropoietin (22). Studies in nonuremic hypertensive subjects suggest that, at equivalent blood pressure control, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and calcium channel blockers reduce LV mass more rapidly and perhaps more effectively than most other antihypertensive drugs. It is not clear if these observations apply to the patient with renal failure. Correction of anemia with erythropoietin presumably acts by improving tissue oxygen delivery, thereby allowing the cardiac output (which is increased in anemia) and, therefore, cardiac work to fall toward normal. These changes have been associated with a 10% to 30% reduction in LV mass index (22). However, attention must also be paid to the frequent elevation in blood pressure following erythropoietin, an effect that may partially counteract the benefit associated with the elevation in hematocrit. In addition, one needs to be cautious not to increase the hemoglobin concentration to values in excess of 12 g/L because higher values have been associated with an increase in cardiovascular events (23,24).

Systolic Dysfunction

Impaired systolic function of the heart is common in dialysis patients. Depressed systolic function may be the result of a prior myocardial infarction, ischemic or hypertensive cardiomyopathy, or ischemic injury resulting from microvascular disease as in diabetes mellitus. Some patients with this disorder manifest the chronic persistent form of hypotension. More commonly impaired systolic function contributes to an increased frequency of dialysis-associated hemodynamic instability. Decreased myocardial contractility leads to poor LV performance and, importantly, a diminished cardiac reserve in the context of a hemodynamic challenge. Patients prone to hypotension during dialysis exhibit a blunted increase in cardiac index in response to a dobutamine infusion as compared to those subjects without hemodynamic instability (25). An inability to generate a sufficient cardiac output despite adequate cardiac filling can contribute to IDH and pulmonary edema.

ARTERIAL DYSFUNCTION

An increase in vascular resistance on the arterial side of the circulation is an important defense against the development of hypotension when cardiac output begins to fall. Disturbances in this response can contribute to hemodynamic instability through several mechanisms. Impaired autonomic function or increases in core body temperature can lead to decreased arterial tone and result in more direct transmission of systemic pressure into the venous circulation. A sudden increase in venous pressure will increase the holding capacity of the venous compartment potentially leading to the sequestration of fluid thereby limiting cardiac refilling (7).

Disturbances in arterial function can also be the result of structural abnormalities in the arterial circulation. Vascular lesions in arteries of patients with uremia are characterized by intimal fibrosis and medial calcifications with little to no deposition of lipid droplets (26). These changes tend to be more reminiscent of accelerated aging or diabetic macroangiopathy rather than typical atherosclerosis. The causes of these pathologic changes are presumably related to age, effects of hypertension, and abnormalities of calcium and phosphorus metabolism. Such changes lead to increased wall stiffness and

importantly contribute to the development of LVH.

Adenosine

Arteriolar vasoconstriction mediated by increased sympathetic nerve activity maintains blood pressure by increasing peripheral vascular resistance. In some patients, this response is inadequate due to production of vasodilators. In the setting of hypotension, no matter what the cause, tissue ischemia will result in net negative balance between the synthesis and degradation of adenosine triphosphate (ATP). As a consequence, ATP metabolites will begin to accumulate and will be released into the extracellular fluid. One such metabolite of ATP is adenosine (**FIGURE 18.4**) (27). Adenosine is an endogenous vasodilator released by endothelial cells and vascular myocytes and has been implicated in the sudden onset of decreased blood pressure during dialysis. In an attempt to demonstrate that accumulation of adenosine during dialysis-induced hypotension is more than just a marker of the ischemic event, Shinzato et al. (27) measured the metabolites of ATP before, during, and after dialysis-induced hypotension in a group of hypotensive-prone chronic dialysis patients. In this study, plasma levels of inosine, hypoxanthine, and xanthine rose sharply with the development of sudden IDH and quickly decreased as the blood pressure was restored. By contrast, there was no significant variation in the plasma levels of the metabolites when hypotension developed more gradually during the course of the procedure. Adenosine levels were not measured because of the short half-life of the metabolite. These patients were then treated with caffeine, a nonselective A_1 and A_2 adenosine-receptor blocker, and the frequency of hypotensive episodes was examined. A 250-mg capsule of caffeine administered 2 hours into the procedure resulted in a significant decrease in the development of hypotensive episodes.

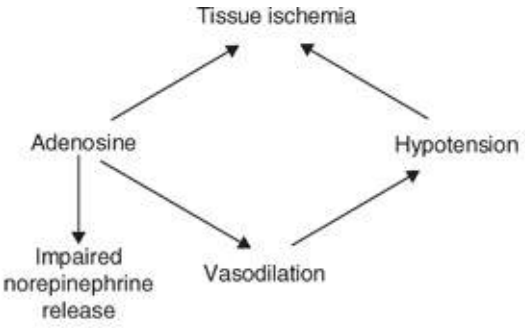

FIGURE 18.4 A cycle in which tissue ischemia can lead to intradialytic hypotension through the generation of adenosine. Adenosine can potentially exacerbate hypotension by its direct vasodilatory effects and secondarily by inhibiting norepinephrine.

In a prospective double-blind placebo-controlled trial in patients with frequent IDH, injection of a selective A_1 receptor blocker provided a significant but modest benefit in reducing the incidence of hypotension (28). Expression of the A_{2A} receptor is increased to a greater extent on peripheral blood mononuclear cells in dialysis patients with frequent hypotension compared to hemodynamically stable patients; suggesting A_{2A} receptors antagonism might also be of benefit (29).

Nitric Oxide

Another intriguing and as yet ill-defined contributor to the development of HD hypotension is that of nitric oxide (30). It has been proposed that blood bioincompatibility with dialysis membranes leads to the activation of monocytes in the peripheral circulation. This is thought to produce a variety of cytokines

including interleukin 1 (IL-1) and tumor necrosis factor (TNF). These cytokines in turn induce the synthesis of nitric oxide by endothelial cells. The support for this hypothesis is derived from several sources. First, plasma levels of IL-1 and TNF are elevated in patients with ESKD on dialysis (31). Furthermore, IL-1 and TNF induce hypotension when administered *in vivo*, predominantly as a result of a decline in systemic vascular resistance (32). *In vitro* studies have also shown that IL-1 and TNF promote nitric oxide synthesis in endothelial cells. Nitric oxide has a direct effect as a smooth muscle vasodilator, working through intracellular cyclic guanylyl monophosphate (GMP) as a second messenger. In addition, IL-1 is also capable of inducing the synthesis of vasodilator prostaglandins (PGs), including PGE_2 and PGI_2 in human vascular smooth muscle cells and endothelial cells (33). These arachidonic acid metabolites are direct smooth muscle vasodilators as well and could thereby contribute to a decline in peripheral vascular resistance.

The concentration of the stable end products of endogenously released nitric oxide, nitrite and nitrate, is increased in chronic kidney disease patients undergoing HD as compared with healthy controls (34,35). Normally, these levels decrease significantly during a dialysis treatment in otherwise hemodynamically stable patients. By contrast, studies show these metabolites actually increase in patients who develop IDH (34,35). A higher predialysis fractional exhaled nitric oxide concentration has also been found in patients with IDH as compared with those with stable hemodynamics (35). These findings suggest that increased synthesis of nitric oxide may be contributing to hemodynamic instability in hypotensive-prone subjects. The basis for increased nitric oxide activity is unknown but may be related to the dialytic removal of the nitric oxide inhibitor, asymmetric dimethylarginine (ADMA) (36). If further studies confirm an important role for increased synthesis of nitric oxide in dialysis-associated hemodynamic instability, administration of an antagonist to nitric oxide production such as N(G)-monomethyl-arginine acetate (l-NMMA) may ultimately prove useful in the treatment of hypotensive-prone patients.

AUTONOMIC NEUROPATHY

Autonomic Dysfunction in Uremia

The importance of autonomic dysfunction as a contributing factor to dialysis hypotension has been the subject of vigorous investigation for the last 15 years. One of the first clinical associations between impaired autonomic nervous system control and hypotension was described by Bradbury and Eggelston (37) in 1925. They observed that the autonomic nervous system was essential in the orthostatic regulation of arterial pressure through baroreflex mechanisms. Subsequently, the central and peripheral neuronal pathways that control vasomotor tone, heart rate, myocardial contractility, and venous capacitance have been described in greater detail.

An autonomic reflex arc is composed of an afferent limb that consists of sensory nerve fibers originating from the vascular tree, visceral organs, and the skin. These afferent fibers travel to the central nervous system mainly through the spinal cord and vagus nerves. Arterial baroreceptors are located in the aortic arch and carotid sinus and sense changes in blood pressure; cardiopulmonary baroreceptors are located in the atrium, ventricles, great veins, and pulmonary vessels and sense changes in cardiac filling pressures. Information about these pressure changes is integrated in the central nervous system at several different levels including the brainstem, cerebellum, hypothalamus, and cerebral hemispheres. The

efferent limb of the system consists of both sympathetic and parasympathetic pathways that exit the brainstem to the spinal cord and travel to the heart and circulation.

Abnormalities in autonomic function are commonly present in patients with chronic kidney disease (38,39). The presence of these abnormalities can potentially impair the patient's ability to maintain systemic blood pressure following a large degree of fluid removal by ultrafiltration. One such abnormality is an inadequate sympathetic response to volume removal in patients with recurrent IDH. The postdialysis plasma concentration of chromogranin A (a protein coreleased with catecholamines) increases to a lesser extent in patients with IDH compared to those with stable blood pressure consistent with a blunted response of sympathetic nerve activity to hypotension (40).

Under normal conditions, sympathetic neural outflow is under tonic restraint by baroreceptors in the aortic arch and carotid sinus and by baroreceptors in the cardiopulmonary region. With the volume removal that accompanies HD, reductions in central venous pressure and arterial blood pressure would be expected to unload these baroreceptors and thereby reduce their tonic restraint on the vasomotor center, resulting in reflex increases in sympathetic outflow to the heart and peripheral circulation to help maintain blood pressure. Defects in this homeostatic response may play an important role in the development of hypotension during the dialytic procedure.

Numerous tests have been employed to assess the autonomic nervous system in patients with chronic kidney disease. These tests may be used to try to localize the defect in the autonomic nervous system. For example, the Valsalva test probes the integrity of the entire autonomic nervous system: low-pressure and high-pressure baroreceptors in the cardiopulmonary circulation, the afferent and efferent limbs of these pathways, and both sympathetic and parasympathetic function. This test is, therefore, useful in detecting a defect but not in identifying the site of the abnormality. The amyl nitrite inhalation test may be used to test low-pressure baroreceptors and the resultant efferent sympathetic outflow expected when blood pressure declines. The cold pressor test (performed by placing a cold cloth on the patient's forehead or by submerging a hand in ice slush) predominantly reflects efferent sympathetic function activated by cold-induced peripheral vasoconstriction. The precise role of the autonomic nervous system in dialysis patients has been difficult to assess in part because tests of autonomic function have not been routinely included in large surveys of dialysis subjects. For this reason, the natural history of changes in the autonomic nervous system in subjects with ESKD is not presently clear.

The initial study that suggested that a defect in the autonomic nervous system could be related to HD hypotension was published in 1976 by Lilley et al. (41). These investigators performed a variety of autonomic tests and concluded that the defect in the autonomic nervous system in patients with ESKD was on the afferent side of the autonomic loop. More specifically, they concluded that the defect resided in the baroreceptors. The finding of autonomic dysfunction at the levels of the afferent branch of the baroreflex arc is consistent with numerous other studies published in the literature in which selective testing of the vasomotor center and the efferent sympathetic tract (cold pressor test, handgrip test, mental stress) showed normal function (41,42), whereas tests of the complete baroreflex arc showed a diminished response (41–44).

The precise mechanism of the autonomic dysfunction remains unclear but, because efferent sympathetic function appears to be normal, the most likely sites of primary damage are the baroreceptors or their afferent fibers or central nervous system connections. Chronic fluid overload leading to persistent

overstretching has been suggested as one cause of baroreceptor dysfunction (45). In addition, there has been some sentiment that uremic “poisoning” of baroreceptors is involved in dialysis hypotension (46,47). Chronic exposure to uremic toxins has been thought to poison the baroreceptors, leading to almost complete removal of their tonic inhibitory effects on sympathetic vasomotor outflow in some patients (41,46). According to this hypothesis, uremia-induced sinoaortic baroreceptor deafferentation would cause central sympathetic outflow to be nearly maximal under basal conditions so that it could not possibly increase much further during the hypotensive stress of HD. However, the experimental support for this hypothesis is indirect, relying mainly on plasma catecholamines and semiquantitative bedside tests to assess sympathetic neural function, and a definitive relation between impaired baroreflexes and dialysis-induced hypotension has not been established. Chronic hyperkalemic depolarization of nerves has also been suggested as playing a contributory role (48).

Paradoxical Withdrawal of Sympathetic Tone in Dialysis-Induced Hypotension

To better characterize the role of autonomic dysfunction in the genesis of IDH, Converse et al. (49) examined baroreflex control of heart rate, efferent sympathetic nerve activity, and vascular resistance in 16 hypotension-resistant and 7 hypotension-prone HD patients. Hypotension-prone patients were defined as those in whom a sudden, symptomatic decrease in mean arterial pressure of greater than 30 mm Hg occurred during at least one-third of maintenance HD sessions. Patients with diabetes were excluded from the study because autonomic neuropathy is a well-known complication of diabetes mellitus. Direct measurements of sympathetic nerve activity and several quantifiable reflex maneuvers were employed to test the effects of chronic uremia on a number of specific reflexes, including arterial baroreflex control of heart rate and cardiopulmonary baroreflex control of vascular resistance. By studying the same patients both during the interdialytic period and during actual sessions of maintenance HD, these investigators were able to separate the autonomic effects of chronic uremia from the acute autonomic effects of the HD procedure.

To assess whether a chronic abnormality was present in either arterial or cardiopulmonary baroreceptors, both groups of patients were first studied during the interdialytic period. Measurement of heart rate and sympathetic nerve activity during the intravenous infusion of nitroprusside and measurement of forearm vascular resistance during the application of negative pressure to the lower body disclosed no abnormalities in either group of patients. These results suggested that there was no baseline autonomic defect chronically present to account for dialysis-induced hypotension in this select group of nondiabetic patients. It should be pointed out that in other groups of dialysis patients, such as those with diabetic autonomic neuropathy, impaired baroreflexes indeed may contribute more to hypotension during HD.

Studies were then undertaken to examine autonomic function during the dialytic procedure. In a subgroup of patients who developed severe hypotension on dialysis, baroreceptor function was again normal, that is, a small initial decrease in blood pressure was accompanied by the appropriate reflex increases in sympathetic nerve activity, heart rate, and peripheral vascular resistance. As the hypotensive episode became severe, however, normal baroreflex function was replaced by the sudden appearance of an inappropriate vasodepressor reaction. With the additional fall in blood pressure, sympathetic activity, heart rate, and vascular resistance did not increase further but rather fell paradoxically back to or below baseline levels. Shortly after the onset of the hypotension and loss of sympathetic activation, classic signs and symptoms of vasovagal syncope developed in the patients, including nausea, abdominal discomfort,

diaphoresis, and giddiness.

To further examine the mechanism triggering this vasodepressor reaction, additional experiments were performed in which the normal HD procedure was separated into its component parts, ultrafiltration alone and dialysis alone. Using measurements of calf vascular resistance, it was found that ultrafiltration reproduced both the increases and decreases in vascular resistance (including vasodilation and hypotension), whereas dialysis alone had no effect on calf vascular resistance in either group of patients. These results suggested that withdrawal of volume appears to be the key stimulus triggering this vasodepressor reaction, which in turn exacerbates the volume-dependent fall in blood pressure.

An inhibitory reflex arising in the heart is the most likely mechanism causing this paradoxical bradycardia and vasodilation during hypovolemic hypotension (50–52). In addition to being a pump, the heart is also a sensory organ, being richly innervated with sensory (or afferent) nerves. Many of these sensory nerves function as mechanoreceptors and therefore signal the brain of changes in loading conditions and contractility of the ventricles. Their function is to inhibit sympathetic outflow. During euvolemia, these sensory nerves normally exert a tonic inhibitory influence on sympathetic vasomotor outflow. During mild hypovolemia, this inhibitory influence is reduced. During severe hypovolemia, however, this inhibitory influence is not reduced further but instead increases paradoxically. The theory is that the receptive fields of these endings are deformed as the adrenergically stimulated heart contracts forcefully around an almost empty ventricular chamber.

It was hypothesized that mild hypovolemia might simulate nonhypotensive HD: unloading of inhibitory ventricular afferents causing reflex sympathetic activation. In contrast, severe hypovolemia might simulate HD-induced hypotension: paradoxical activation of inhibitory ventricular afferents causing reflex inhibition of sympathetic outflow resulting in bradycardia and peripheral vasodilation. Echocardiographic measurements of LV volumes before the onset of severe hypotension showed near-obliteration of the LV cavity possibly accounting for the paradoxical activation of inhibitory LV afferents.

Therefore, in a subset of hypotensive-prone dialysis patients, a form of acute autonomic neuropathy plays an etiologic role. For this paradoxical sympathetic failure to occur, severe volume depletion must occur. To determine the prevalence of this type of hypotension (bradycardic hypotension) in the dialysis population, Zoccali et al. (53) identified 20 patients out of a total population of 106 who suffered from IDH. In 60 hypotensive episodes recorded in the 20 patients, heart rate increased in 35 episodes, remained unchanged in 19 episodes, and decreased in 6 episodes. The five patients who developed bradycardic hypotension were characterized by high ultrafiltration rates and smaller LV end-diastolic diameters as compared with those with tachycardic or fixed heart rate.

Autonomic Dysfunction and Chronic Hypotension

As mentioned previously, a small fraction of HD patients have difficulty maintaining a normal blood pressure and are chronically hypotensive between dialysis treatments. The role of autonomic dysfunction in this condition was examined in one study that compared numerous measures of autonomic function among hypotensive HD patients, normotensive HD patients, and control patients (all groups consisted of 17 individuals) (54). Chronically hypotensive individuals exhibited a significant downregulation of α- and β-adrenergic receptors, suggesting an inability to produce an adequate sympathetic response.

Autonomic Dysfunction and Arrhythmias

The development of cardiac arrhythmias in ESKD can be traced to several factors that are operative alone or in combination and include the presence of myocardial dysfunction, fluid and electrolyte shifts, and poor oxygen saturation. A previously unrecognized predisposing factor may be autonomic dysfunction. One study of 41 dialysis patients evaluated the correlation between arrhythmia (as determined by 24-hour Holter examination) and autonomic dysfunction (as determined by blood pressure and heart rate responses) (55). Compared with patients with normal autonomic function, a significantly increased incidence of atrial and/or ventricular arrhythmia was found among those with one or more autonomic abnormalities (41 abnormal rhythms in 26 patients with autonomic dysfunction vs. 1 in 15 with normal autonomic responses).

Sympathetic Nervous System and Hypertension in the Uremic State

Despite the frequent presence of autonomic dysfunction, baseline plasma catecholamine levels are often elevated in chronic kidney disease (56). Increased sympathetic tone, decreased degradation, and diminished neuronal reuptake all may contribute to this finding. The physiologic significance of this finding is uncertain, but sympathetic overactivity could contribute to the common development of hypertension in ESKD. The signal for this increased sympathetic tone may in part originate with stimulation of renal afferent nerves.

Chemosensitive renal afferent nerves have been implicated in the pathogenesis of hypertension by causing reflex activation of sympathetic outflow to the heart and peripheral circulation (57–59). Stimulation of these afferent nerves by either ischemic metabolites, such as adenosine, or by uremic toxins, such as urea, evokes reflex increases in sympathetic nerve activity and blood pressure in experimental animals (60). Reduced sympathetic activity may be one important mechanism by which bilateral nephrectomy lowers blood pressure in some HD patients (61).

In recent years, additional tests of autonomic dysfunction have been assessed. Principle among these is heart rate variability, a noninvasive measure of the autonomic system (62,63). In the most extensive of these studies, a lower heart rate variability was associated with progression to ESKD and poorer outcome. Of interest is the fact that at least one study (64) demonstrated improvement in heart rate variability after successful renal transplantation, suggesting that, to some degree, autonomic dysfunction in ESKD patients is reversible.

THERAPY FOR HEMODYNAMIC INSTABILITY DURING HEMODIALYSIS

In patients in whom dialysis hypotension has not been a problem but in whom it develops suddenly, the differential diagnoses must be expanded to include occult septicemia and unrecognized cardiac or pericardial disease. In this regard, the exclusion of a pericardial effusion and tamponade and/or a significant segmental wall motion abnormality are important in the assessment in any patient with hypotensive episodes occurring frequently. Other serious underlying conditions that can give rise to new-onset hypotension include intestinal ischemia with impending bowel infarction and occult hemorrhage. Hypotension during the early part of the procedure should make one consider exaggerated cytokine release resulting from a reaction with the dialysis membrane. After excluding these processes, there are

several options available for the treatment and prevention of episodic dialysis hypotension (**TABLE 18.2**).

TABLE 18.2 Treatment of Hemodynamic Instability

- Exclude nondialysis related cause (cardiac ischemia, pericardial effusion, infection)
- Individualize the dialysis prescription
  - Accurate setting of the dry weight
  - Optimize dialysate composition
    - Fixed Na^+ concentration >140 mEq/L or Na^+ modeling
    - HCO_3 buffer
    - Avoid low Mg^{2+} dialysate
    - Avoid low Ca^{2+} dialysate
  - Optimize method of ultrafiltration (Uf)
    - Ultrafiltration modeling alone or with Na^+ modeling
    - Sequential Uf and isovolemic dialysis
  - Cool temperature dialysate
- Maximize cardiac performance
  - Inflatable abdominal band to enhance venous return to heart
- Avoidance of food
- Avoid antihypertensive medicines on dialysis day
- Pharmacologic interventions
  - Midodrine
  - Vasopressin
  - Adenosine antagonists
  - Others: sertraline, ephedrine, phenylephrine, carnitine

Before discussing therapies for IDH, it is important to note that there have been recent insights into the definition of IDH. Most notably, Flythe et al. (65) analyzed data from 1,409 patients in the Hemodialysis (HEMO) study and concluded that a nadir-based definition of IDH was most helpful because it was associated with adverse outcomes more reliably. Thus, a systolic blood pressure <90 mm Hg was identified as a level compatible with untoward symptoms or poorer prognosis (65,66).

There are several reasons to be concerned about IDH, but among these, the recognition that IDH is associated with poor cardiovascular outcomes is particularly compelling. One longitudinal study linked IDH to major adverse cardiac events (67), while another found a greater hospitalization rate in patients with IDH (68). Perhaps even more worrisome is the association of IDH with cardiac remodeling abnormalities, a process by which a vicious cycle is established as repetitive IDH occurs (69). In any case, the recognition of the adverse consequences of IDH are recognized more frequently as new therapies to present its occurrence are evaluated (70–73).

INDIVIDUALIZING THE DIALYSIS PRESCRIPTION

Accurate Setting of the "Dry Weight"

At present, the determination of dry weight is largely assessed empirically by trial and error. The dry weight is set at the weight below which unacceptable symptoms, such as cramping, nausea and vomiting, or hypotension occur. The dry weight is highly variable in many patients and can fluctuate with intercurrent illnesses (such as diarrhea or infection) and with changes in hematocrit (as with erythropoietin). A number of methods have been proposed to more objectively define the dry weight of the patient (**TABLE 18.3**). Comparative studies have generally favored methods based on bioimpedance measurements, which provide an assessment of extracellular and intracellular volume and total body water (74–76). A variant of this technique in which continuous intradialytic measurements are confined to the calf shows particular promise because the relative volume of excess extracellular fluid is greatest in

the lower extremities (77). During dialysis, plasma refilling is more dynamic from the leg in comparison to the trunk or arms suggesting the calf could be used as a window to monitor intradialytic changes in whole body extracellular fluid volume (78).

TABLE 18.3 Objective Tools to Determine Dry Weight in Hemodialysis Patients

- Blood volume monitoring
  - Relative change during treatment
    - Blood volume with ultrafiltration pulse (to assess increment of vascular refill)
- Ultrasonographic assessment of inferior vena cava (IVC)
  - IVC diameter
  - IVC collapsibility index (fractional ↓ of diameter during breathing cycle)
- Brain natriuretic peptide (BNP), N-terminal pro-BNP, atrial natriuretic peptide levels
- Bioimpedance methodology
  - Whole body (wrist-to-ankle)
  - Segmental
  - Continuous intradialytic calf measurements
- Extravascular lung water index (invasive)

Of interest is the fact that a recent study emphasized the superiority of the absolute change in weight over a percentage weight gain in predicting IDH in dialysis patients (79). This observation was particularly true in heavier patients (79). The importance of overhydration on overall cardiovascular morbidity/mortality has also been recently emphasized (80). New insights into the complex relationship between ultrafiltration on dialysis and blood pressure suggest that in some hypertensive patients, rapid vascular refilling may inhibit an expected fall in blood pressure, thereby sustaining a higher than desired pressure (81–83). The many positive benefits of strict volume control on many cardiovascular parameters are emphasized in the literature frequently. Recently, one such paper reported an improvement in vascular function with meticulous volume management (84).

Dialysate Composition

A detailed discussion is provided elsewhere on how the composition of the dialysate can be adjusted to maximize hemodynamic stability. Summary statements regarding these components are provided in the following sections.

Dialysate Sodium Concentration and Sodium Modeling

The use of a higher dialysate Na concentration (greater than 140 mEq/L) has been among the most efficacious and best-tolerated therapies for episodic hypotension. The high Na concentration prevents a marked decline in the plasma osmolality during dialysis, thereby protecting the extracellular volume by minimizing osmotic fluid loss into the cells. Na modeling is a technique in which the dialysate Na concentration is varied during the course of the procedure. Most commonly, a high dialysate Na concentration is used initially with a progressive reduction toward isotonic or even hypotonic levels by the end of the procedure. This method of Na control allows for a diffusive Na influx early in the session to prevent the rapid decline in plasma osmolality resulting from the efflux of urea and other small molecular weight solutes. During the remainder of the procedure, when the reduction in osmolality accompanying urea removal is less abrupt, the dialysate Na level is set at a lower level, thereby minimizing the development of hypertonicity and any resultant excessive thirst, fluid gain, and

hypertension in the interdialytic period. The precise role of Na modeling has not been fully defined as yet; studies with positive and negative findings have been performed. It is a procedure associated with low morbidity and is, therefore, worthy of a trial in individual problem dialysis patients.

Dialysate Buffer

In prior years, the use of acetate as a dialysis buffer had been a potential cofactor in causing dialysis hypotension by leading to peripheral vasodilatation. The current use of high-efficiency and high-flux dialysis procedures prohibits the use of acetate as a dialysis buffer. Bicarbonate is now widely available and adaptable to all new dialysis machines. In general, blood pressure is generally better maintained with bicarbonate. The cost differential between bicarbonate dialysate and acetate dialysate has decreased sufficiently to make this issue of dialysate buffer moot.

Dialysate Magnesium Concentration

Low magnesium in the dialysate may also contribute to IDH. One study, for example, randomized 78 clinically stable patients on HD to treatment with dialysate containing low (0.38 mmol/L) or high (0.75 mmol/L) concentrations of magnesium in combination with either bicarbonate or acetate buffer (85). For both bicarbonate and acetate solutions, patients dialyzed with the low magnesium concentration solution experienced a significant increase in the number of episodes of hypotension and a lower absolute decrease in mean arterial pressure compared with those dialyzed with the higher concentration.

Dialysate Calcium Concentration

Cardiac contractility can be enhanced in many dialysis patients by increasing the dialysate calcium concentration. A limitation of this approach is the development of hypercalcemia particularly in patients being treated with calcium-containing phosphate binders and vitamin D. In patients prone to IDH who are at risk for hypercalcemia, dialysate calcium profiling can be used as a strategy to improve hemodynamic stability and yet minimize the potential for hypercalcemia (86). In one study of patients dialyzed for 4 hours, the dialysate calcium concentration was set low (1.25 mmol/L) for the first 2 hours and then increased to 1.75 mmol/L for the last 2 hours. Use of the varying dialysate calcium concentration was associated with greater hemodynamic stability as compared with a fixed dialysate calcium concentration of either 1.25 or 1.5 mmol/L. This hemodynamic benefit was accomplished by an increase in cardiac output. At the end of 3 weeks, there was no difference in the predialysis ionized calcium concentration between the three groups.

Optimized Method of Ultrafiltration

Volumetrically Controlled Ultrafiltration

Modern dialysis machines have helped in the avoidance of dialysis hypotension by allowing clinicians to program the volume removal pattern from patients during dialysis. These machines use an accurate volumetric device to evenly program ultrafiltration. Hence, a steady and even ultrafiltration rate throughout the course of dialysis is achievable. In the absence of an ultrafiltration control device, the rate of ultrafiltration can fluctuate considerably as the pressure across the membrane tends to vary. In addition, high venous pressures can lead to exaggerated rates of fluid removal. To minimize the risk for excessive fluid removal when such a device is not available, membranes with a low water permeability (K_{Uf})

should be used.

Ultrafiltration Modeling

Clinicians may desire to ultrafilter more volume at the beginning of the procedure and less toward the conclusion of the procedure. In this manner, dialysis ultrafiltration may be tailored to the individual dialysis subject. Recent studies suggest that this approach is particularly effective when combined with sodium modeling (56,87).

Sequential Ultrafiltration and Isovolemic Dialysis

A similar goal of maintenance of the plasma osmolality can be attained by initial ultrafiltration alone (without dialysis) followed by isovolemic dialysis in which little or no further fluid removal occurs because of reduced transmembrane pressures. This sequential procedure often allows a large volume of fluid to be removed without inducing hemodynamic instability. The downside to this approach is that adequacy can be impaired unless the period of dialysis is prolonged.

Blood Volume Monitoring

Devises to monitor intradialytic changes in blood volume have been advocated as a tool to minimize IDH based on the concept that the likelihood of developing hypotension will always occur at roughly the same reduction of blood volume. Unfortunately, most studies have not found a close relationship between individual changes in blood volume and occurrence of hypotension (88). In a prospective randomized trial, use of an intradialytic blood volume monitoring devise was associated with greater nonvascular and vascular access–related hospitalizations and mortality as compared to standard monitoring (89).

The lack of benefit noted with blood volume monitoring as typically employed may in part be explained by its tendency to underestimate the actual amount of volume removed. The technique is based on measuring the degree of hemoconcentration that occurs with ultrafiltration and assumes uniform mixing of plasma and red blood cells throughout the circulation. Recent observations suggest this assumption is incorrect (90). Whole body hematocrit is lower than arterial or venous blood due to a dynamic reduction in hematocrit in the capillary beds, a phenomenon known as the *Fahraeus effect*. During ultrafiltration, there is presumably a compensatory mobilization of hematocrit-poor blood from the microvasculature into the central circulation. This dilution effect minimizes the degree of hemoconcentration leading to a potential underestimation of the total ultrafiltrate volume.

Blood volume monitoring has been shown to be an effective tool when incorporated into a biofeedback system in which dialysate conductivity and ultrafiltration rate are constantly adjusted through the procedure based on input from the measured change in blood volume. The system is designed to guide the reduction in blood volume along a preset individual trajectory to avoid the acute and sudden reductions that can precipitate hypotension. This technique has been found to reduce the frequency of hypotensive episodes and provide greater stability of blood pressure both during and after the procedure (91,92). In hypertensive dialysis patients, this technique can lead to better blood pressure control through optimization of volume status and at the same time reduce the frequency of hypotensive episodes when compared to standard treatment (93).

The frequency of IDH has also been reduced using a biofeedback system in which the ultrafiltration rate is adjusted according to changes in blood pressure measured every 5 minutes during the dialysis

procedure (94). This method utilizes a fuzzy logic control system that adjusts ultrafiltration according to instantaneous changes in blood pressure in the context of historical data concerning the individual's blood pressure behavior during prior treatments. One recent review of carefully conducted biofeedback dialysis technique concluded that these systems continue to hold promise in reducing IDH (81).

Cool Temperature Dialysate

In response to ultrafiltration, increased activity of the sympathetic nervous system leads to vasoconstriction of the dermal circulation. As a result, heat dissipation is impaired and core body temperature tends to increase. Indirect evidence suggests that the increase in body temperature is directly related to the amount of ultrafiltration (95). In addition to impaired heat dissipation, there is also increased central heat production that accompanies the dialysis procedure. At some point, the increase in core body temperature can overcome peripheral vasoconstriction and precipitate acute hypotension (**FIGURE 18.5**).

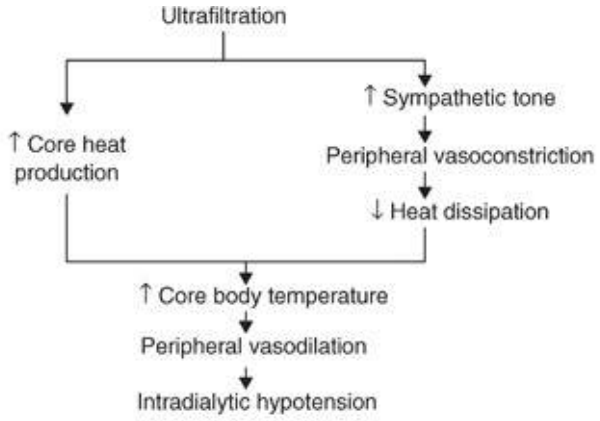

FIGURE 18.5 There is an increase in core body temperature that typically occurs during the dialysis procedure. The degree to which core body temperature rises is related to the amount of ultrafiltration. At some point, the increased body temperature overcomes peripheral vasoconstriction and leads to the sudden onset of hypotension.

Recently, the simple maneuver of lowering the dialysis temperature 2°C from 37°C to 35°C has been associated with improvement in both symptoms and blood pressure. Cooling the dialysate reduces the rate of IDH by 7.1 times when compared to conventional therapy (96). Use of cooler temperature dialysate results in increased myocardial contractility in stable dialysis patients (97). In patients selected for frequent episodic hypotension or predialysis hypotension, use of the 35°C dialysate has also been shown to increase peripheral vasoconstriction (98). The peripheral vasoconstrictive response was measured directly by venous occlusion plethysmography in these studies. The increase in peripheral vasoconstriction resulted in an improvement in both supine and standing blood pressure following ultrafiltration HD in both groups of hypotensive-prone patients. No episodes of hypotension were recorded during the 35°C procedure, whereas many were noted when the patients were on the 37°C procedures. Also, the 35°C procedure was associated with an increase in plasma norepinephrine levels. In addition to increased myocardial contractility and peripheral vasoconstriction, lowering the dialysate temperature is also associated with better preservation of central blood volume through enhanced mobilization of pooled venous blood (99). Taken together, these findings suggest that the combination of an improvement in myocardial contractility, increased peripheral vasoconstriction, and less venous pooling add to providing improved support for blood pressure in patients undergoing ultrafiltration

dialysis.

This hemodynamic protection is present even in those patients with the highest proclivity to develop dialysis hypotension. When applied to a more general dialysis population, those patients with subnormal predialysis temperatures (present in up to 23% of patients) may derive the greatest hemodynamic benefit from this procedure (100). The mechanism of the protection would appear to be an increase in efferent autonomic outflow, as deduced from the increase in plasma norepinephrine levels seen on exposure to 35°C dialysis. The improved hemodynamic stability observed with convective dialysis treatments such as hemofiltration may, in part, be related to the lower extracorporeal blood temperature typical of this procedure.

Despite the potential for cool temperature dialysis to increase the degree of urea compartmentalization as a result of peripheral vasoconstriction, the procedure has been shown to have no significant effect on dialysis efficiency (101). Although tolerated well in most patients, it should be noted that 35°C dialysis may not be tolerated in all patients. This may be particularly true of patients who are sensitive to temperature changes and in patients who develop excessive vasoconstriction and symptoms and signs of either coronary insufficiency or peripheral vascular insufficiency. The mechanism of action for vasoconstriction during cooler temperature dialysis does not appear to be a change in cytokine concentration (82).

A recent refinement in the implementation of cool temperature dialysate is the use of what has been termed *isothermic dialysis*. This technique employs a blood temperature monitor that senses temperature changes in the arterial and venous catheters of the extracorporeal circuit. This information is used to then adjust the dialysate temperature on an ongoing basis such that the body temperature remains unchanged. Use of isothermic dialysis allows for dialysate temperature to be individualized and adjusted throughout the procedure rather than subjecting every patient to the same cold stress. The procedure takes into account patient-to-patient variability in predialysis body temperature and the increase in body temperature as ultrafiltration volume varies. The effectiveness of this technique was recently verified in a large group of patients selected because of the frequent occurrence of IDH (102).

Maximize Cardiac Performance

A reduction of plasma volume will not necessarily result in symptomatic hypotension as long as the circulatory system is able to respond by compensatory vasoconstriction. Venoconstriction leads to a shift of blood into the central circulation helping to maintain cardiac output. Impaired sympathetic nerve activity or abnormalities in venous compliance can limit this response. In a study of 25 patients with intractable postdialytic orthostatic hypotension, application of an inflatable abdominal band was found to be an effective means to attenuate the fall in blood pressure immediately after the treatment (103). This device improved venous return to the heart as evidenced by an increase in ejective fraction and fall in atrial natriuretic peptide concentration.

The frequency of dialysis-associated hemodynamic instability is greatly increased in patients with a prior history of congestive heart failure, cardiomegaly, or ischemic heart disease. These conditions lead to poor LV performance and, importantly, a diminished cardiac reserve in the context of a hemodynamic challenge. As discussed previously, cardiac contractility can be enhanced in many dialysis patients by increasing the dialysate calcium concentration, using cool temperature HD, and correcting anemia with erythropoietin.

Avoidance of Food

Food ingestion during dialysis leads to a significant decline in systemic vascular resistance that can contribute to a fall in blood pressure (104). In addition, increased splanchnic pooling of blood will impair maintenance of central blood volume and thereby limit cardiac refilling. This effect is not corrected by the concurrent intake of caffeine.

Pharmacologic Prevention of Hypotension

Erythropoietin Therapy

Correction of anemia can potentially improve hemodynamic stability in several ways. An increase in the hematocrit is associated with an exponential rise in blood viscosity that in turn is an important component of peripheral vascular resistance (105,106). Correction of the hematocrit has been shown to be beneficial in causing regression of LVH (107). An increased hematocrit may result in less tissue ischemia, thereby minimizing the release of the vasodilatory metabolite, adenosine. As mentioned previously, hemoglobin values should be maintained between 11 and 12 g/L because higher values have been associated with an increase in cardiovascular event rates (23,24).

Caffeine

Adenosine is an endogenous vasodilator that has been related to hypotensive episodes in a subset of patients on HD. This response can be blunted in some patients by the administration of caffeine, which may act as an adenosine receptor antagonist in this setting. This therapy may be limited by the fact that caffeine is rapidly removed by dialysis and chronic use may be associated with considerable tolerance to the hemodynamic effects.

Midodrine

Midodrine is a selective α_1 adrenergic pressor agent that has been used to treat patients with frequent IDH. In addition to increasing peripheral vascular resistance, midodrine has been shown to limit venous pooling and effectively restore central blood volume and maximize cardiac refilling (99). This drug may also have the additional benefit of better preserving cerebral blood flow in patients with orthostatic hypotension after HD (108).

A pilot study examining 21 patients with severe hypotension during dialysis reported a significant beneficial effect on hemodynamic stability (109). The dose was initiated at 2.5 mg given before the procedure and then titrated in 2.5-mg increments to maintain the systolic pressure above 100 mm Hg. The mean dose was 8 mg, and the drug was well tolerated. Studies examining the chronic efficacy of the drug also demonstrate a significant hemodynamic benefit in patients suffering from IDH (110). In a systematic review of the literature, 2.5 to 10 mg of the selective α_1 adrenergic agonist midodrine has proved to be an effective treatment in some patients with frequent IDH (111). It is noteworthy that many of the patients enrolled in these studies are elderly and had several comorbid conditions including diabetes mellitus, coronary artery disease, and peripheral vascular disease. Despite the high-risk nature of the patients studied, the drug is well tolerated and safe to use. The dose should be individually titrated according to blood pressure and symptoms; most patients require 10 to 20 mg administered 30 minutes before dialysis.

Sertraline

Preliminary evidence suggests that sertraline, a central nervous system serotonin reuptake inhibitor, may also be beneficial in dialysis-induced hypotension (112). A retrospective study of nine patients placed on sertraline (50 to 100 mg/d) for depression compared the blood pressure response during dialysis for the 6-week period before drug initiation to the response during an equivalent period immediately after the drug was begun. Sertraline was associated with an increase in the lowest mean blood pressure measured during dialysis (68 vs. 55 mm Hg), a lower frequency of hypotensive episodes (0.6 vs. 1.4 episodes per session), and fewer required therapeutic interventions for hypotension during the study period (1.7 vs. 11.0). This benefit may be due to an attenuation of sympathetic withdrawal. Although more data are needed, sertraline is considered a safe drug and, therefore, should be considered as a reasonable agent to administer in hypotension-prone patients.

Other Drugs

In a multicenter study of otherwise stable chronic dialysis patients, intravenous infusion of carnitine was found to significantly decrease the incidence of IDH and cramps as compared with a control group (113). Other drugs that have been used to treat patients with IDH include ephedrine (114) and phenylephrine (115). In a study of six patients with refractory HD-induced hypotension, intranasal lysine vasopressin administered 1 hour before a dialysis treatment and again 12 hours later resulted in a significant decline in the number of hypotensive episodes and in the volume of intravenous fluids used in the treatment of hypotension (116). A more recent study (117) corroborated these larger, positive results with vasopressin administration intranasally. Previous observations have found plasma vasopressin levels do not significantly increase during ultrafiltration dialysis despite an anticipated unloading of baroreceptors. In a randomized double-blind placebo-controlled trial, the continuous administration of subpressor doses of vasopressin provided for greater hemodynamic stability even in the setting where target fluid loss was set to be increased by 0.5 kg over the baseline prescription (118). Another recent study reported a similar finding: high baseline AVP levels at baseline but no increase following ultrafiltration (119).

Comparative Studies

All of the measures delineated previously provide some degree of prophylactic benefit. However, their relative efficacy in the same patient is unclear and comparative studies are limited. In one study, the efficacy and tolerability of midodrine, cool temperature dialysate, or the combination were compared in a study of 11 patients with IDH (57). All three therapies were found to be equally effective in improving hemodynamic stability. There was a trend for the combined group to have superior improvement in hemodynamic stability; however, this did not reach statistical significance.

A second study compared five different procedures in a single-blinded crossover study of 10 patients with a history of IDH (58). After 1 week of standard dialysis, all patients underwent 1 week of each of the following four strategies: high Na dialysate, Na modeling, sequential ultrafiltration and isovolemic dialysis, and cool temperature dialysis. The following results were reported: High Na dialysate, Na modeling, and cool temperature dialysis resulted in significantly fewer hypotensive events than that observed with standard dialysis. Compared with the other test strategies, sequential ultrafiltration and isovolemic dialysis had a significantly greater number of hypotensive episodes. Postdialysis upright

blood pressure was best with Na modeling and cool temperature dialysis compared with that measured with standard and isolated ultrafiltration dialysis. Weight loss was virtually identical with all protocols. In general, the best-tolerated and most effective strategy was Na modeling. High Na and cool temperature dialysis were also effective, whereas sequential ultrafiltration and isovolemic dialysis was significantly less useful.

ACUTE TREATMENT OF HYPOTENSION

Although occasionally asymptomatic, patients with hypotension may suffer from light-headedness, muscle cramps, nausea, vomiting, and dyspnea. The acute management of low blood pressure associated with HD includes stopping or slowing the rate of ultrafiltration, placing the patient in the Trendelenburg position, decreasing the blood-flow rate, and restoring intravascular volume (**TABLE 18.4**).

TABLE 18.4 Acute Treatment of Intradialytic Hypotension

Stop or slow rate of ultrafiltration
Place patient in Trendelenburg position
Decrease blood-flow rate
Restore intravascular volume (hypertonic saline)
Assess for ischemic injury
Check patency of vascular access

The use of hypertonic saline solutions appears to be particularly effective; it allows Na to be administered in a small volume of water, and the rapid rise in plasma osmolality may have a positive effect on cardiac inotropy (59). One study found that three different regimen safely and effectively raised the blood pressure: 10 mL of 23% saturated hypertonic saline; 30 mL of 7.5% hypertonic saline; and the latter solution with 6% dextran-70 (59). The addition of dextran appeared to prolong the duration of the blood pressure response.

Further treatment is based on the cause of the hypotension; the prompt recognition of life-threatening causes of low blood pressure is essential. Particular concerns should include occult sepsis, previously unrecognized cardiac and/or pericardial disease, and gastrointestinal bleeding.

CHAPTER 19

Oxidant Stress in End-Stage Kidney Disease

Ravinder K. Wali

DEFINITION OF OXIDANT STRESS

Oxidative stress is a pathologic state in which reactive oxygen intermediates (ROI) or reactive oxygen species (ROS) can cause oxidation of cellular and matrix macromolecules including sugars, proteins, deoxyribonucleic acid (DNA) bases, and lipids (1). ROS are generated in mitochondria from the use of molecular oxygen for the efficient cellular energy production for routine aerobic metabolic activity. ROS are the detrimental by-products resulting in oxidative damage to cellular organelles and have been associated with several disease states, including cancer, diabetes, Alzheimer's disease, Parkinson's disease, aging, inflammation, and atherosclerosis (2,3). Oxidative stress is an imbalance between the quantities of oxidants produced during normal metabolism of our cells and the quantities of antioxidant gene products [superoxide dismutase (SOD), catalases (CATs), glutathione (GSH) peroxidases, etc.], required to maintain the equipoise to prevent accumulation of oxidant molecules.

Increasing evidence suggests that oxidative stress may have a significant role in the development of complications in patients with chronic kidney disease (CKD). Understanding the role of oxidant stress in the pathogenesis of multisystem involvement in patients with CKD or dialysis-associated pathology will ultimately help to develop the strategies for the prevention and treatment of increased oxidative stress in CKD and its associated complications.

GENERATION OF REACTIVE OXYGEN SPECIES IN THE BIOLOGIC SYSTEM

In biologic systems, cells generate energy aerobically to produce adenosine triphosphate (ATP) by reducing molecular oxygen (O_2) to water. The cytochrome-C oxidase-catalyzed reactions involve transfer of four electrons (e^-) to oxygen; the consumption of oxygen at the mitochondrial level is associated with production of oxygen intermediates. One percent to 2% of total oxygen consumption may, in fact, be

converted to superoxide anion radical ($O2^-$). Formation of $O2^-$ anion radical leads to a cascade of other ROS production (4) (**FIGURE 19.1**). The biologic toxicity of superoxide is due to its capacity to inactivate iron-sulfur containing enzymes (these enzymes are critical for different metabolic pathways) and liberate free iron in the cell, which can undergo Fenton chemical reaction and generate highly reactive hydroxyl radicals (OH^-). Hydroxyl radical immediately develops into HO_2 (hydroperoxyl radical), HO_2 in combination with superoxide anion can initiate lipid peroxidation of polyunsaturated fatty acids, react with carbonyl compounds and halogenated carbons to create toxic peroxy radicals. Superoxide reacts avidly with nitric oxide (NO) to form peroxynitrite ($ONOO^-$). As such, superoxide in combination with HO_2, and $ONOO^-$ are the main causes of oxidative stress.

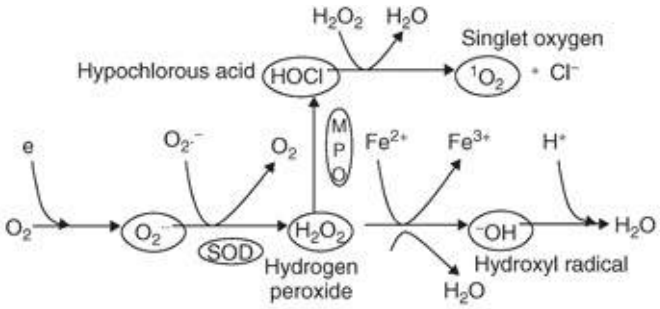

FIGURE 19.1 Generation of reactive oxygen species. The biologically active oxygen free radicals are the radical ion superoxide O_2^-, hydroxide ion OH^-, and peroxide ion O_2^{2-}. These radicals are intermediates in the respiratory process at the mitochondrial level, in which peroxide ion (O_2^{2-}) is reduced to water in a stepwise six-electron process in the presence of glutathione(s) and catalases. H_2O_2 rapidly diffuses across the lipid membranes and is converted into strong oxidants. H_2O_2 in the presence of cytoplasmic MPO produces HOCl, a free radical ion with toxic effects. MPO, myeloperoxidase; SOD, superoxide dismutase.

Superoxide dismutase (SOD) rapidly converts $O2^-$ to hydrogen peroxide (H_2O_2) and oxygen. Because $O2^-$ is more toxic than H_2O_2, its rapid removal is of paramount importance for the proper function of the microenvironment (5). H_2O_2 is a versatile ROS because it can cross plasma membranes, increase intracellular hydroxyl radicals, trigger peroxidation of cell membrane lipids (CMLs), promote protein aggregation, and damage and/or cleave DNA (5,6). H_2O_2 converts carboxylic acid (RCOOH) into peroxy acids (PRCOOH), which are used as oxidizing agents. H_2O_2 reacts with acetone to form acetone peroxide, and it interacts with ozone to form hydrogen trioxide. Its reaction with urea produces carbamide peroxide. In aqueous solution, hydrogen peroxide can oxidize or reduce a variety of inorganic ions. When H_2O_2 acts as a reducing agent, oxygen gas is also produced. In acid solution, Fe^{2+} is oxidized to Fe^{3+} (**EQUATION 19.1**).

$$2Fe^{2+}(aq) + H_2O_2 + 2H^+(aq) \rightarrow 2Fe^{3+}(aq) + 2H_2O \quad (19.1)$$

Also, through catalysis, H_2O_2 can be converted into hydroxyl radicals (.OH), the most powerful ROS in the biologic system. H_2O_2 is removed by several different pathways *in vivo*.

1. Catalase (CAT) and the reduced form (GSH) of glutathione peroxidase (GPx) catalyze H_2O_2 to H_2O + O_2. This is presumably a detoxification mechanism.
2. H_2O_2 is converted by the abundant myeloperoxidase (MPO) enzyme in neutrophils to hypochlorous acid (HOCl) (6). HOCl is a strong oxidant that acts as a bactericidal agent in phagocytic cells.

Reaction of HOCl with H_2O_2 yields singlet oxygen ($^1O_2$) and H_2O.

3. H_2O_2 also reacts spontaneously with intracellular iron to form highly reactive hydroxy radical (OH^-) (7) by the Haber-Weiss cycle or Fenton reaction (8). The hydroxyl radical reacts instantaneously with the hydrogen moiety of other biologic molecule to produce long-lived ROS called *reactive amines* (RH) (9).
4. Superoxide ($O2^-$) anion regulates the bioavailability of NO. Superoxide anion can react with NO and result in the formation of peroxynitrite ($ONOO^-$) (9). $ONOO^-$ is a strong oxidant with vasoconstrictor activities as compared with the vasodilator potential of NO (10). In addition, $ONOO^-$ reacts nonenzymatically with arachidonic acid components of phospholipids resulting in the formation of isoprostanes (8-iso-PGF2α), a potent vasoconstrictor with a long half-life.

ROS have a very short life, and excessive production and prolonged exposure of cell constituents to these evanescent radicals can result in oxidative modification of cellular macromolecules. *In vivo* measurements of ROS-modified cellular macromolecules serve as indirect markers of prevailing oxidative stress. These include products of carbohydrate and protein oxidation (11), lipid peroxidation (12), and nucleic acid oxidation with DNA fragmentation leading to DNA instability and mutation (13).

PHYSIOLOGIC ANTIOXIDANT SYSTEM

An imbalance due to increased production of ROS and the available antioxidants results in the excessive exposure of the tissue macromolecules to ROS, resulting in the production of biomarkers of oxidant stress. Under physiologic conditions, protection against oxidant stress is offered by the presence of different types of antioxidants—enzymatic and nonenzymatic antioxidants (1).

Enzymatic antioxidants include glutathione dismutase (GPx), glutathione reductase (GR) and glutathione transferase (GT), SOD, and CAT. GPx is a selenium-dependent enzyme present in the plasma and red blood cell (RBC) and is mainly produced in the kidneys. GPx exists in three different forms [GST, oxidized glutathione (GSSG), and GSH]. GR uses nicotinamide adenine dinucleotide phosphate (NADPH) to convert GSSG to its reduced form (GSH).

Recent discovery of the crystal structure of nicotinamide nucleotide transhydrogenase (TH) that facilitates the disposal of ROS and prevents the development of oxidative stress at the cellular level has further advanced the basic mechanisms of how ROS are disposed (14). The mitochondrial ROS defense system transforms reactive superoxide anions ($O2^-$) formed by electrons leaking to molecular oxygen during aerobic respiration to hydrogen peroxide (H_2O_2). H_2O_2 is detoxified to water by peroxidases that use reduced GSH as a substrate. Cellular levels of GSH are maintained by reduced NADPH-dependent GR (**FIGURE 19.2** and **EQUATION 19.2**).

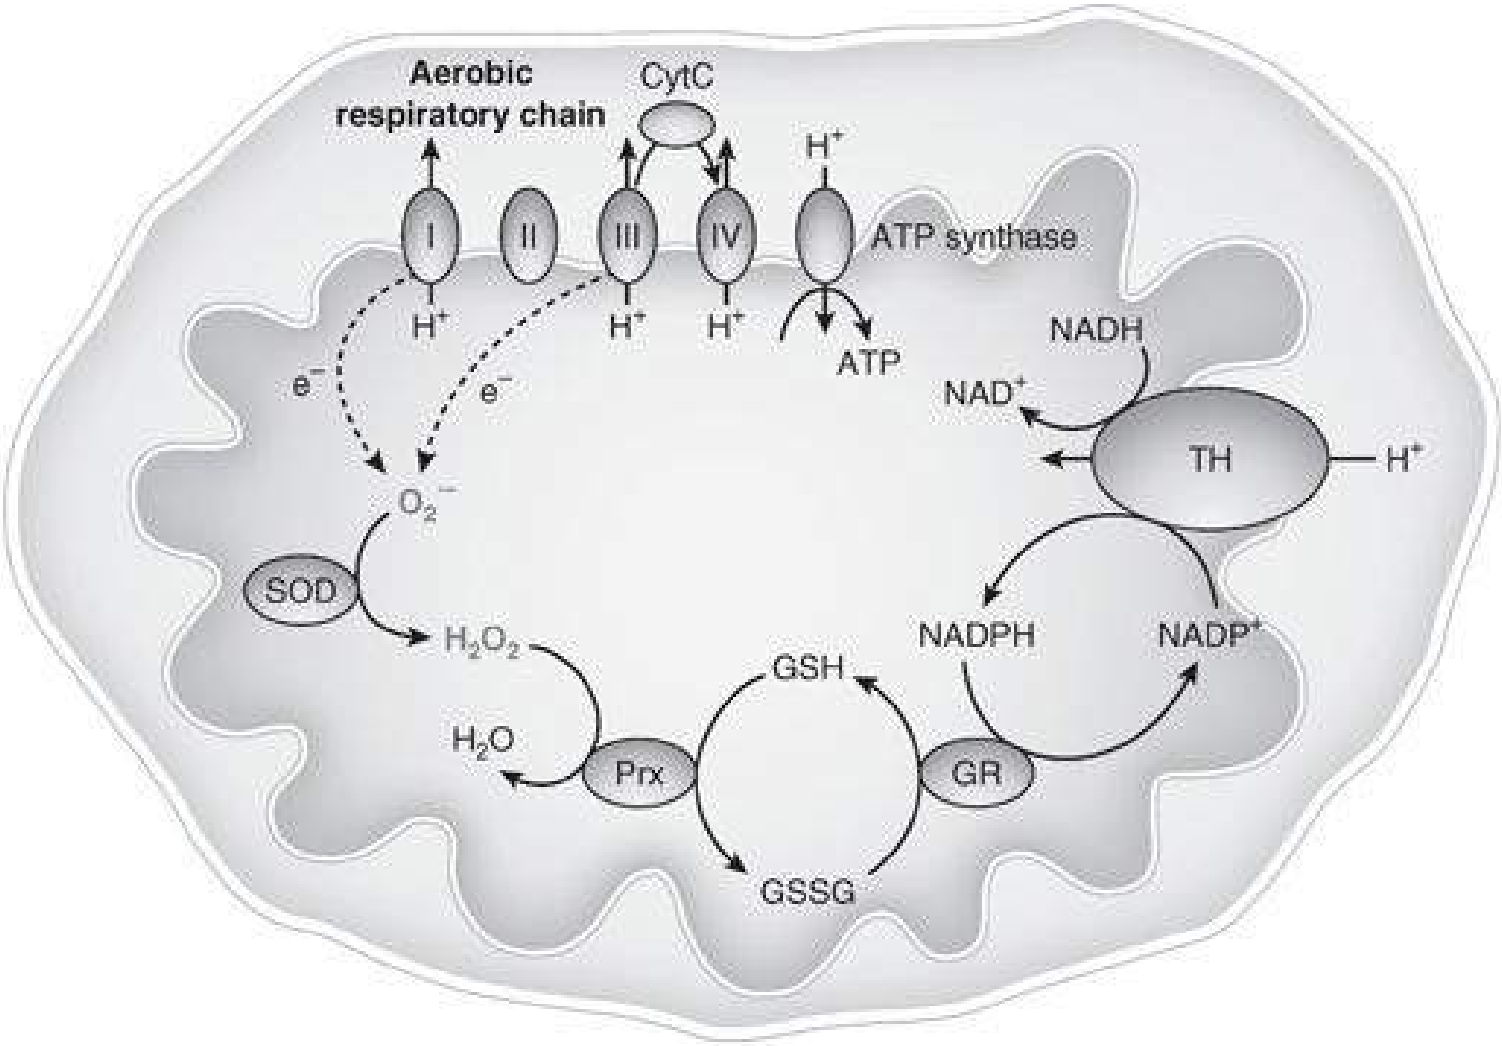

FIGURE 19.2 Mitochondrial reactive oxygen species (ROS) defense. Transhydrogenase (TH) contributes to mitochondrial ROS defense by producing NADPH. During aerobic respiration, electrons leak to molecular oxygen, primarily from complexes I and III. This results in "superoxide anions" $O_2^{\cdot-}$, which is converted to H_2O_2 by mitochondrial superoxide dismutase (SOD) and finally to water by peroxidases (Prx), using reduced glutathione (GSH). GSH levels are maintained by glutathione reductase (GR), which uses NADPH formed by TH to reduce glutathione (GSSG). CytC, cytochrome C; ATP, adenosine triphosphate. (Modified and reproduced from Krengel U, Törnroth-Horsefield S. Coping with oxidative stress. *Science* 2015;347:125–126.)

$$NADH = NADP^+ + H^+out \leftrightarrow NAD^+ + NADP^+ + H^+in \quad (19.2)$$

The resultant NADPH is used for amino acid biosynthesis and by GR and GPx to remove ROS (15).

Nonenzymatic antioxidants: Majority of nonenzymatic antioxidants have a thiol as a functional group —SH (reduced) and can be oxidized via disulphide bond formation (oxidized). Thiols have the ability to react with almost all the tissue oxidants and maintain the tissue redox (reduction/oxidation) state. The major biologic thiol/disulphide couples include GSH, thioredoxin, and other cysteine-containing proteins. GSH is particularly unique as it is able to detoxify H_2O_2, OH^-, and chlorinated oxidants. Extracellular thiols present in the plasma and interstitial fluid are important antioxidants to promote redox state. When these protective thiols are decreased as in acute as well as CKD patients, oxidized thiols lead to endothelial injury, and increased vascular morbidity (16).

Other nonenzymatic antioxidants: Important ones include α-tocopherol (vitamin E); vitamin C (ascorbic acid); albumin; and other proteins such as transferrin, ceruloplasmin, and microamounts of extracellular superoxide dismutases (ecSOD) (17). α-Tocopherol (vitamin E) is perhaps the major lipid-soluble chain-breaking antioxidant (reacting with chain-propagating radicals such as peroxyl radicals)

(18). This antioxidant is particularly important because it prevents lipid peroxidation. Ascorbic acid, on the other hand, has mostly scavenging properties and other minor antioxidant properties. It scavenges the singlet oxygen ($^1O_2$), $O2^-$, and H_2O_2 at a constant rate at optimal pH (7.4). It is a powerful scavenger of HOCl and also can be a substrate for the enzyme MPO to prevent the generation of HOCl (19). Vitamin C deficiency in CKD and dialysis patients is perhaps more common than thought given that such patients often avoid the consumption of fresh fruits, vegetables, and also loss of water-soluble vitamins with dialysis therapy. However, ascorbic acid in high doses can also be a pro-oxidant (20).

Acute-phase reactive proteins such as ferritin, transferrin, ceruloplasmin, haptoglobin, and others also function as effective antioxidants by binding to transitional metals such as iron, copper, and bromide to prevent the formation of halides, hemes, and chloramines (21).

PATHOPHYSIOLOGY OF OXIDATIVE STRESS IN DIALYSIS PATIENTS

CKD is associated with qualitative and quantitative changes in the physiologic antioxidants. This is further complicated by the increased production or decreased removal of ROS and its related oxidation products. These sequences of events culminate in excessive tissue damage from the ROS and its end products.

Increased Generation of Oxidant Radicals (Reactive Oxygen Species) in Dialysis Patients

Advanced kidney disease is associated with increased production of ROS, and this oxidant stress is further aggravated with the initiation of dialysis therapy. There are several pathways involved in the excessive generation of ROS in CKD and dialysis population.

Activation of neutrophil-macrophage system

1. The increased oxidative stress in CKD as well as in dialysis patients could be due to activation of monocyte-macrophage cells by the uremic milieu and further aggravated by exposure of blood to extracorporeal circulation (see Chapter 20).

   Activation of phagocytes results in respiratory burst activity with the production of ROS, necessary for host defenses, cell activation, and cell signaling (22). The respiratory burst activity is associated with activation of mitochondrial NADPH-oxidases that catalyzes the single electron transfer and generates superoxide anion (O_2^-) at the electron transfer chain level (23). The NADPH-oxidases are highly regulated group of homologous proteins comprising of cytoplasmic (p47, p67, p40) and membrane-bound proteins (gp91 and p22) domains (24). Deficiency or dysfunction of NADPH-oxidases is associated with increased risk of bacterial infections and results in the development of chronic granulomatous disease (CGD). Similar deficiency can lead to unbalanced effects of O_2^-.

   In addition, phagocytic cells have abundant MPO in the azurophilic granules, which is released on stimulation of mononuclear cells. The MPO enzyme system in phagocytic cells catalyzes the oxidation of halides like chloride, bromide, and iodide. MPO in the presence of chloride (Cl^-) ions converts H_2O_2 to HOCl. In addition to its primary function of bactericidal killing, HOCl is a potent oxidant as it can oxidate the thiol groups of membrane proteins and intracellular enzymes, and it also inhibits the

mitochondrial cytochrome system, perpetuating the production of ROS. HOCl can react with endogenous amines (R-NHI) to result in the production of long-lasting oxidants called *chloramines* (RNH-Cl) (6).

Himmelfarb et al. (25) studied phagocytic function in patients on hemodialysis (HD) and peritoneal dialysis (PD) and demonstrated an exaggerated respiratory burst activity of phagocytes after *in vitro* stimulation. This respiratory burst production of ROS coincides with the peak of complement activation during dialysis treatment (26). Furthermore, Tepel et al. (27) showed that increased ROS production from peripheral blood cells either spontaneously or after phorbol-myristate-acetate (PMA)-induced stimulation in patients on maintenance dialysis, remained unchanged before and after dialysis using biocompatible membranes.

In summary, during the last 10 years, despite the advances in dialysis therapy and introduction of high-performance dialysis membranes and improvements in the quality of dialysates and water purification methods, the rate of progression of chronic inflammation and vascular disease in dialysis-dependent patients has remained unchanged due to inability of conventional dialysis membranes to remove unconventional uremic toxins such as the products of glycation and oxidation (28,29). Therefore, the burden of proinflammatory and pro-oxidant state associated with chronic dialysis therapy has not changed (**FIGURE 19.3**). On the other hand, evidence supports that the levels of proinflammatory and pro-oxidant levels decrease significantly following kidney transplantation (30).

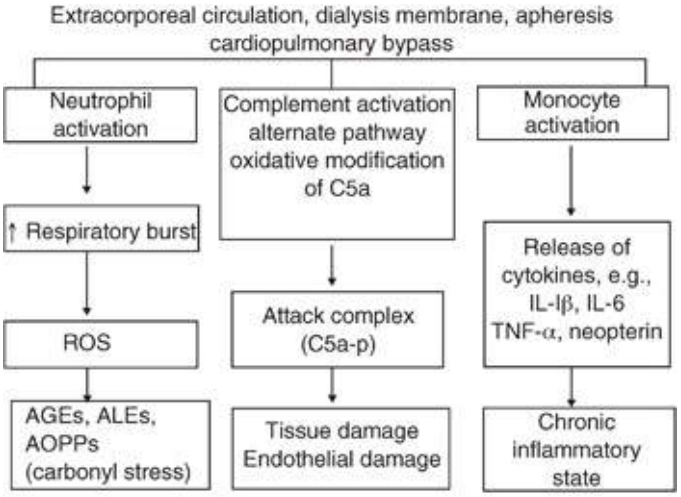

FIGURE 19.3 Different pathways of reactive oxygen species (ROS) production on exposure to extracorporeal circulation. IL, interleukin; TNF, tumor necrosis factor; AGEs, advanced glycation end products; ALEs, atomic layer epitaxies; AOPPs, advanced oxidized protein products.

During maintenance dialysis, exposure of monocyte-macrophage system to the uremic solutes along with exposure to extracorporeal circulation, the two in combination, changes the phenotype of these cells to the state of proinflammatory phenotype with unbalanced production of both pro- and anti-inflammatory cytokines. These phenotypic changes result in increased production of adhesion molecules and chemotactic factors such as vascular cell adhesion molecules (VCAM), leukocyte adhesion molecules [intercellular adhesion molecule (ICAM-1) and P-selectins], monocyte chemoattractant protein-1 (MCP-1), and others (31). These changes increase leukocyte activation with migration and adhesion to subendothelial space and to atherosclerotic plaques (32), particularly in the presence of already activated platelets and endothelial cells (33). Cumulatively, these dynamic interactions at the molecular level may contribute to the pathogenesis of accelerated atherosclerosis in

dialysis patients (34).

2. **Qualitative or quantitative changes in physiologic antioxidants** The effects of increased production of ROS in dialysis patients are further aggravated by decreased levels or impaired function of both enzymatic and nonenzymatic antioxidants. Therefore, imbalance between the increased ROS production and reduced availability of antioxidants aggravates the prevailing oxidative stress.

   GPx converts H_2O_2 to $2H_2O$. GPx is mainly produced in the kidney, and its levels in both serum and RBC decreases in proportion to the decreasing glomerular filtration rate (GFR). All three forms of glutathione (GST, GSSG, and GSH) decrease in patients with advanced kidney disease and in patients on kidney replacement therapy (HD or PD). Ross et al. (35) and Mimić-Oka et al. (36) demonstrated that whole blood and RBC glutathione and CAT levels (CATs also convert H_2O_2 to H_2O and O_2) were significantly decreased in patients with kidney disease (CKD) as well as in dialysis-dependent patients.

   The levels of nonenzymatic antioxidants like vitamin C and vitamin E have been demonstrated to be low normal in dialysis patients as compared with healthy controls. The reasons for decreased levels of antioxidants in patients with kidney disease are multifactorial: increased consumption resulting from increased burden of ROS, relative deficiency of vitamin C and vitamin E (possibly related to a decreased intake and dietary restriction of fresh fruits and vegetables to avoid hyperkalemia), and the excessive losses of nutrients of different molecular weights with dialysis (37,38). It is also possible that uremic toxins that persist despite an adequate dialysis dose may cause functional deficiency of these physiologic antioxidants. Hypoalbuminemia is often present in dialysis-dependent patients and results in decreased antioxidant stores in blood (37,39).

BIOMARKERS OF OXIDATIVE STRESS

Because ROS have a very short half-life, their *in vivo* presence is extremely transient. Therefore, to understand the consequences of the presence of excessive amounts of ROS, one has to study the downstream effects of excessive ROS, called *footprints of increased oxidative stress*. Wolff and Dean (1987) introduced the concept of the Maillard reaction to describe the role of reducing sugars as catalysts in the oxidative modification and cross-linking of proteins, defined as reactive carbonyls (RCO): autoxidative glycosylation leading to production of reactive dicarbonyls such as methylglyoxal, 3-deoxyglucosone, and glyoxal. These Schiff bases undergo spontaneous rearrangements (Amadori products) resulting in the formation of advanced glycation end products (AGEs) (40).

ADVANCED GLYCATION END PRODUCTS

Aging and hyperglycemia are associated with increased production of ROS resulting in the modification of long-lived extracellular proteins such as collagen, elastin, laminin, and myelin sheath proteins. Similar phenomenon has been demonstrated in patients with CKD (41,42).

Three different carbohydrate-derived oxidation products are identified as N^{ε}-(carboxymethyl)lysine (CML), N^{ε}-(carboxymethyl)hydroxylysine (CMhL), and pentosidine (41). Intravenous administration of experimentally prepared AGE-modified albumin or enzymatically prepared AGE-peptides results in

widespread vascular leakage, increased macrophage chemotactic activity, impaired NO-induced vasodilatation, and glomerulosclerosis (42).

Sell and Monnier (43) reported increased tissue levels of the AGE-specific moiety pentosidine in collagen tissues of patients with end-stage kidney disease (ESKD) and aging patients. Makita et al. (44), with the use of radioreceptor assays, demonstrated significantly higher levels of AGEs in medium-sized arteries of diabetic patients and nondiabetic subjects. Diabetic patients with ESKD had twice the levels of tissue AGEs as compared with diabetic patients without kidney disease. Dialysis-dependent diabetic patients had mean AGE levels five times higher than those diabetic patients without kidney disease. Although serum creatinine decreases by 75% with each dialysis session, AGE levels decreases by less than 25%. Successful kidney transplantation, however, is associated with a decrease in the plasma levels of AGEs commensurate with the decrease in creatinine, but levels of AGEs continue to remain higher than in healthy controls.

Different sizes of AGEs have been noted in the blood of patients with diabetes and uremia: those with AGEs less than 10 kDa versus greater than 10 kDa. Makita et al. (44) measured peptide-linked degradation products of AGEs, labeled as low molecular weight AGE-modified molecules (LMW-AGEs), with a molecular weight of 2,000 to 6,000. Serum levels of LMW-AGE remain five- to sixfold higher in patients undergoing dialysis therapy with cuprophane or high-flux membranes as well as in PD patients than in healthy controls (45).

The use of high-flux membranes was associated with at least a 50% decrease in LMW-AGE in both diabetic and nondiabetic dialysis patients. However, these levels returned to baseline values within first 4 hours after dialysis. *In vitro* experiments demonstrated that LMW-AGEs retain strong chemical activity against tissue collagen and vascular endothelium; this interaction was abrogated with the use of inhibitors of AGE-cross-linking, such as aminoguanidine (AGN). These results suggest that LMW-AGEs are refractory to removal by current modes of dialysis therapy and may be a component of the “middle molecule” uremic toxin (46).

ADVANCED LIPID PEROXIDATION PRODUCTS

Nonenzymatic oxidation of polyunsaturated fatty acids either in the plasma or cell membranes by H_2O_2, and HOCl results in the formation of lipid hydroperoxides and reactive aldehydes (47,48). These lipid hydroperoxides and reactive aldehydes are unstable and undergo spontaneous rearrangements or break down into different smaller and stable compounds such as malondialdehyde (MDA), 4-hydroxynonenal, glyoxal, and acrolein (49). Boaz et al. (50) found that patients with highest levels of post-HD MDA were almost four times more likely to have accelerated atherosclerosis.

Isoprostanes (8-iso-PGF2a) are generated by peroxidation of arachidonic acid of CMLs. The peroxidation occurs *in situ* in membrane phospholipids; these are then cleaved by endogenous phospholipases and circulate as isoprostanes. These new classes of oxidative stress by-products are strong vasoconstrictors (51). Elevated levels of urinary isoprostanes decrease with antioxidant treatment in healthy volunteers (52).

ADVANCED OXIDIZED PROTEIN PRODUCTS

ROS can alter the primary, secondary, or tertiary structure of proteins resulting initially in denaturation and fragmentation and finally cross-linking of protein moieties (11). Such cross-linked proteins are less susceptible to proteolytic digestion, resulting in long-term accumulation. Witko-Sarsat et al. (53) developed a novel spectrophotometric assay for the detection of oxidatively modified proteins called *advanced oxidized protein product* (AOPP). The plasma levels of AOPP were significantly increased in patients on dialysis (HD or PD) and in patients with advanced kidney disease but not on dialysis when compared with healthy controls.

The plasma levels of AOPP in dialysis patients correlated well with increased levels of methylguanidine (a marker of oxidant-induced protein cross-linking and aggregation), thiobarbituric acid reactive substances (TBARS), and pentosidine as markers of advanced lipid oxidation product (ALE) and AGE, respectively. Similarly, the levels of AOPP were closely related to soluble markers of monocyte activation such as neopterin and tumor necrosis factor alpha (TNF-α) (54).

In vitro exposure of control plasma samples and human serum albumin (HSA) to HOCl (a strong oxidizing agent) results in the dose-dependent formation of AOPP. *In vitro* exposure of HSA-AOPP aggregate is capable of triggering the respiratory burst of isolated neutrophils in a dose-dependent manner. In view of these findings, it is postulated that neutrophils generate HOCl leading to the formation of AOPP, and these molecules will in turn stimulate phagocytes and release more HOCl (53). The molecular mechanisms that allow AOPP to stimulate monocytes may be dependent on ligand–receptor type interaction. These *in vitro* experiments demonstrate that AOPPs *per se* can perpetuate oxidative stress (54).

THE EUROPEAN UREMIC TOXIN WORK GROUP

Owing to recent advances in proteomics and metabolomics and a reanalysis of uremic solutes, “The European Uremic Toxin (EUTox) Work Group” defined more than 90 compounds that were classified as uremic toxins. These toxins have different molecular weights and have been distributed in three different groups based on their molecular weights; of these 96 toxins, 68 are smaller than 500 Da (*small molecules*), another 10 toxins are between 500 and 12,000 Da (*middle molecules*), and the remaining exceed 12,000 Da (*large molecules*). More than 25% of these toxins are protein-bound (46). This definition was later revised to classify uremic molecules into two categories: protein-bound solutes and middle molecules. For the latter group, the Work Group proposed that middle molecules comprise a group of proteins with a molecular weight (500 to 60,000 Da), which incorporates many toxins identified since the original middle molecule hypothesis, for which the upper molecular weight limit was approximately 2,000 Da. The low molecular weight peptides and proteins (LMWPs) comprise nearly the entire middle molecule category in the new scheme (55,56). Most of the toxins generated under the influence of increased oxidative stress fall in the category of middle molecules and are not amenable to removal by the routinely available dialysis techniques. In addition, the EUTox group demonstrated that kinetics of urea removal do not correlate with clearance of the middle and the large molecules, hence leading to the accumulation of these molecules that could potentially perpetuate the oxidative stress (46,57).

As middle molecules are modified by the ROS and reactive nitrogen species (RNS), such modifications affect their mass transfer (filterability), molecular weight, and net charge. These physiochemical changes impede their removal by the conventional dialysis methods (55–57). This

concept is important to understand so that effective strategies for the removal of these factors can be developed in the future to prevent the progression in atherosclerosis and inflammation in dialysis patients.

ADVANCED NUCLEIC ACID PEROXIDATION PRODUCTS

The interaction of OH^- with nucleobases of DNA strand, such as guanine, leads to the formation of C8-hydroxyguainine or its nucleoside form named 8-hydroxy 28-deoxyguanosine (8-OH-dG). 8-OH-dG undergoes keto-reaction and results in the formation of oxidized product leading to the formation of 8-oxo-dG. Both 8-OH-dG and 8-oxo-dG are important biomarkers of free radical–induced oxidative DNA damage. Increased levels of these compounds have been demonstrated in HD as well as continuous ambulatory peritoneal dialysis (CAPD) patients (58,59). Electron spin resonance spectroscopy can be used to measure plasma oxidant activity. Roselaar et al. (60) used this technique to measure 8-OH-dG in CKD patients, and these levels did not change with dialysis therapy. Similarly, increased levels of 8-OH-dG levels in peripheral mononuclear cells have been demonstrated in dialysis patients compared to healthy controls (59).

CONSEQUENCES OF INCREASED OXIDATIVE STRESS

Increased markers of oxidant stress (especially in patients with diabetes mellitus) correlate with the severity of diabetic complications. In patients with kidney disease, oxidant stress-related processes are more diverse and intense, with an attendant alteration of a variety of cellular components irrespective of the level of blood glucose. These oxidized products play a prominent role in a variety of complications and may contribute a significant degree of morbidity and mortality in dialysis patients (**FIGURES 19.4** and **19.5**).

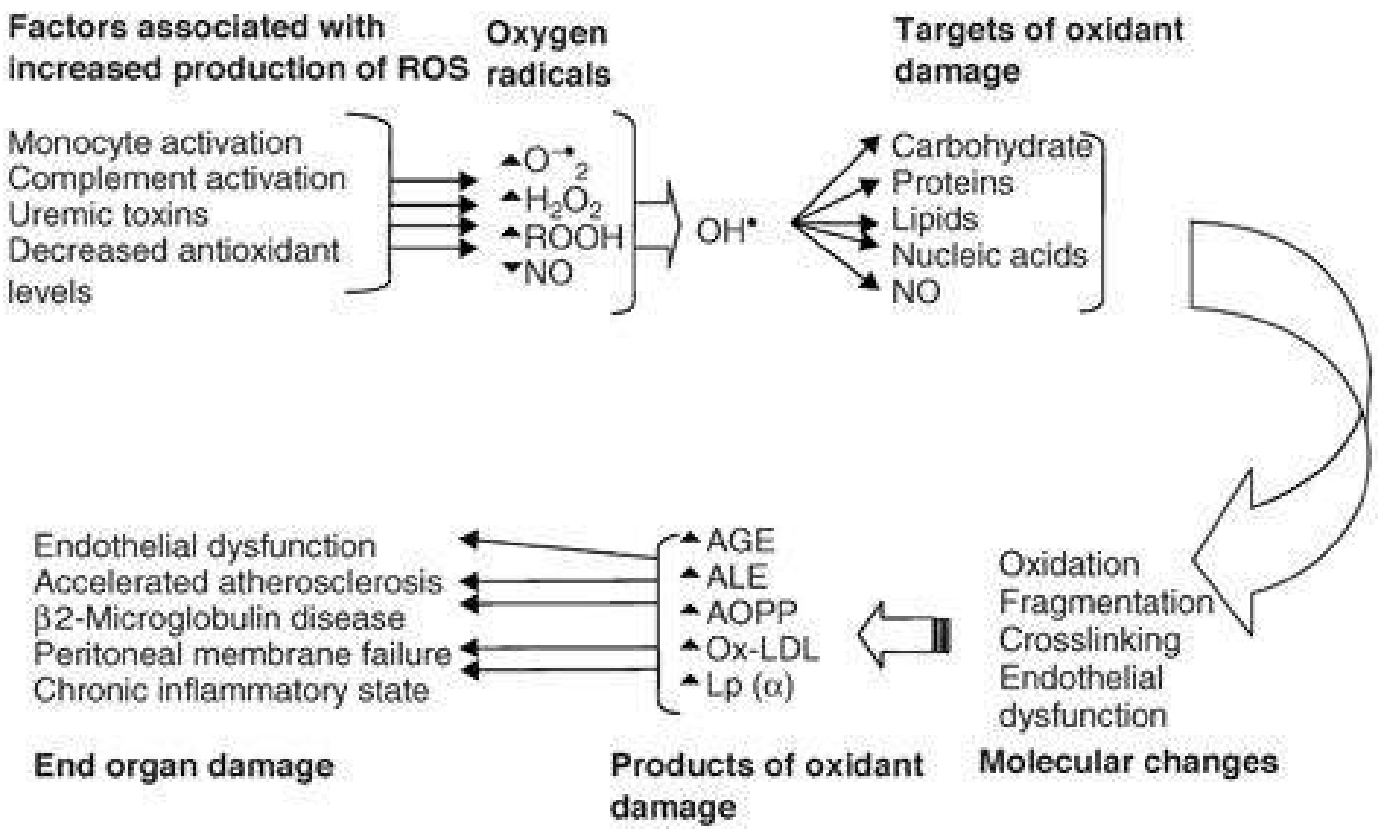

FIGURE 19.4 General pathway by which increased production of reactive oxygen species may contribute to the development of complications in patients with end-stage kidney disease. Intermediate oxygen radicals such as ($O^{-\bullet}_2$) superoxide, (H_2O_2) hydrogen peroxide, and lipid hydroperoxide (ROOH) lipid peroxides are precursors of toxic reactive species, such as (OH•) hydroxyl radicals. These radicals can cause chemical modifications of biologic molecules. These include advanced glycation end products (AGEs), advanced lipid oxidation products (ALEs), advanced oxidized protein products (AOPPs), oxidized low-density lipoprotein (ox-LDL), and increased lipoprotein (a) with decreased availability of nitric oxide.

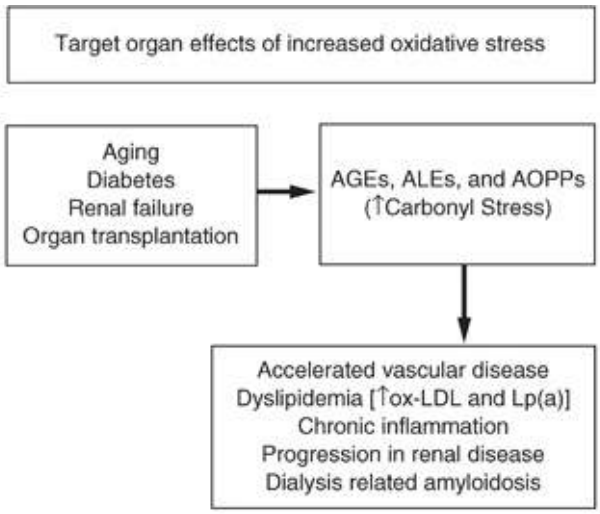

FIGURE 19.5 Target organ effects of increased oxidative stress. AGEs, advanced glycation end products; ALEs, atomic layer epitaxies; AOPPs, advanced oxidized protein products; ox-LDL, oxidized low-density lipoprotein.

Role of Low-Density Lipoprotein Oxidation

Perhaps the most common modification is the oxidation of LDL, resulting in the formation of ox-LDL. As LDL becomes oxidized, the lipoprotein loses its ability to be recognized by the LDL receptor, and it becomes easily available to be phagocytosed by other scavenger cells such as macrophages. The macrophages become lipid loaded with decreased degradation and decreased mobility, and these changes result in the conversion of such macrophages into foam cells. The accumulation of foam cells in the intima

of blood vessels is an initial step in the development of the fatty streak of the atherosclerotic lesion. Steinberg and others demonstrated the role of the early fatty streak (the precursor lesion) that subsequently leads to the development of an intermediate lesion and finally the complicated lesion of atherosclerotic plaques leading to the development of plaque rupture and acute cardiovascular event (61,62).

Increased levels of autoantibodies against the epitopes of ox-LDL and MDA-LDL have been demonstrated in the atherosclerotic plaques of coronary arteries and in the blood of dialysis patients with and without coronary artery disease. Several longitudinal studies in subjects with normal renal function have shown that the titers of circulating antibodies against ox-LDL are independent cardiovascular risk factors for progression in atherosclerosis (63). Maggi et al. (64) showed that LDL from patients with uremia and those dependent on dialysis is easily susceptible to *in vitro* oxidation. Increased ratio of plasma antioxidized LDL antibodies to anti-native LDL was present in patients with advanced uremia and in patients on maintenance dialysis compared with healthy controls (**FIGURE 19.5**).

Ox-LDL is generated by a number of pathways, including the MPO–hydrogen peroxide–nitrite (MPO–H_2O_2–NO_2–) system (65). MPO is activated during each dialysis session due to the exposure of blood with extracorporeal circulation and other dialysis-related factors. This pathway is particularly relevant in dialysis patients (**FIGURE 19.6**). During the oxidation process of LDL, there is a concomitant generation of atherogenic oxidized choline glycerophospholipids (oxPCCD36) which reacts with its ligand called *CD36* and had been demonstrated *in vivo* at sites of increased oxidative stress (66). CD36 is expressed on macrophages and endothelial cells. It functions as a signaling molecule and stimulates macrophage foam cell formation by uptake of ox-LDL. Recent evidence has shown that CD36 is also expressed on platelets. Interaction of oxPCCD36 with platelet CD36 increases platelet reactivity and facilitates prothrombotic phenotype (66). Therefore, it establishes a strong link between oxidant stress, dyslipidemia, and prothrombotic events in the vascular system.

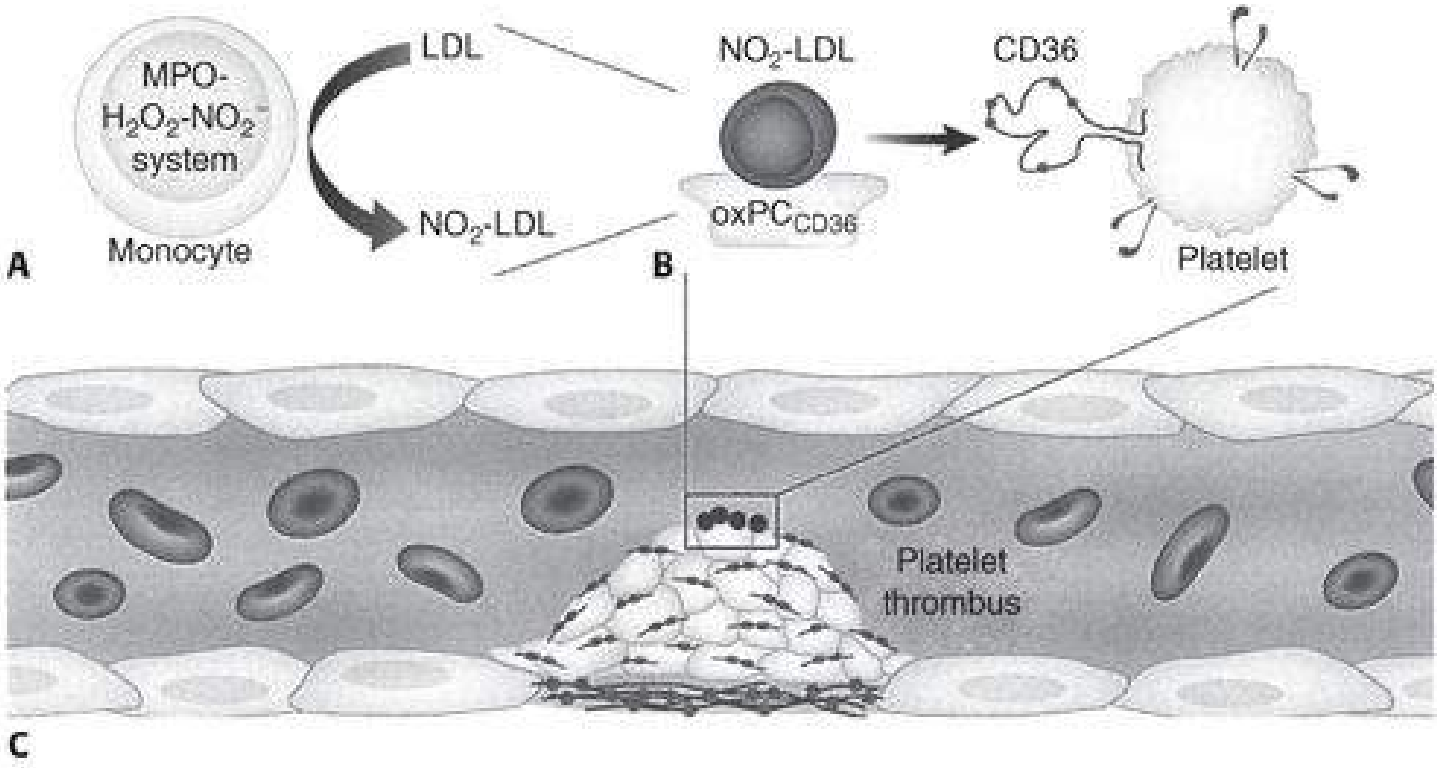

FIGURE 19.6 Role of oxidized products of low-density lipoprotein (LDL) in promoting platelet activation and thrombus formation in vivo. **A:** LDL cholesterol can be modified by monocytes through the myeloperoxidase (MPO)-H_2O_2-NO_2^- system to form ligands that have a high affinity for CD36 (oxPCCD36). **B,C:** oxPCCD36 interaction with platelet CD36 results in increased platelet activation **(B)** and enhanced thrombus formation **(C)** at sites of vascular injury *in vivo*. (Modified and reproduced with permission from Jackson SP, Calkin AC. The clot thickens—oxidized lipids and thrombosis. *Nat Med* 2007;13:1015–1016.)

Role of Urea Oxidation

Carbamylation of amino acids and proteins can develop in dialysis patients due to spontaneous generation of cyanate from urea (67). The active form of cyanate (OCN^-) is isocyanic acid that carbamylates amino acids, proteins, and other molecules. The carbamylation process changes their structure, charge, as well as function. In addition, carbamylated molecules can inhibit or potentiate other noncarbamylated proteins, producing various metabolic derangements including the production of reactive oxidant molecule, ε-N-C-lysine (homocitrulline) (67) (**FIGURE 19.7**). Using monoclonal antibodies, ε-N-C-lysine (homocitrulline) was demonstrated in neutrophils, monocytes, and more importantly, conjugated with low-density lipoprotein (called *carbamylated-LDL*); this transformation enhances the atherogenicity of LDL (68) (**FIGURE 19.8**).

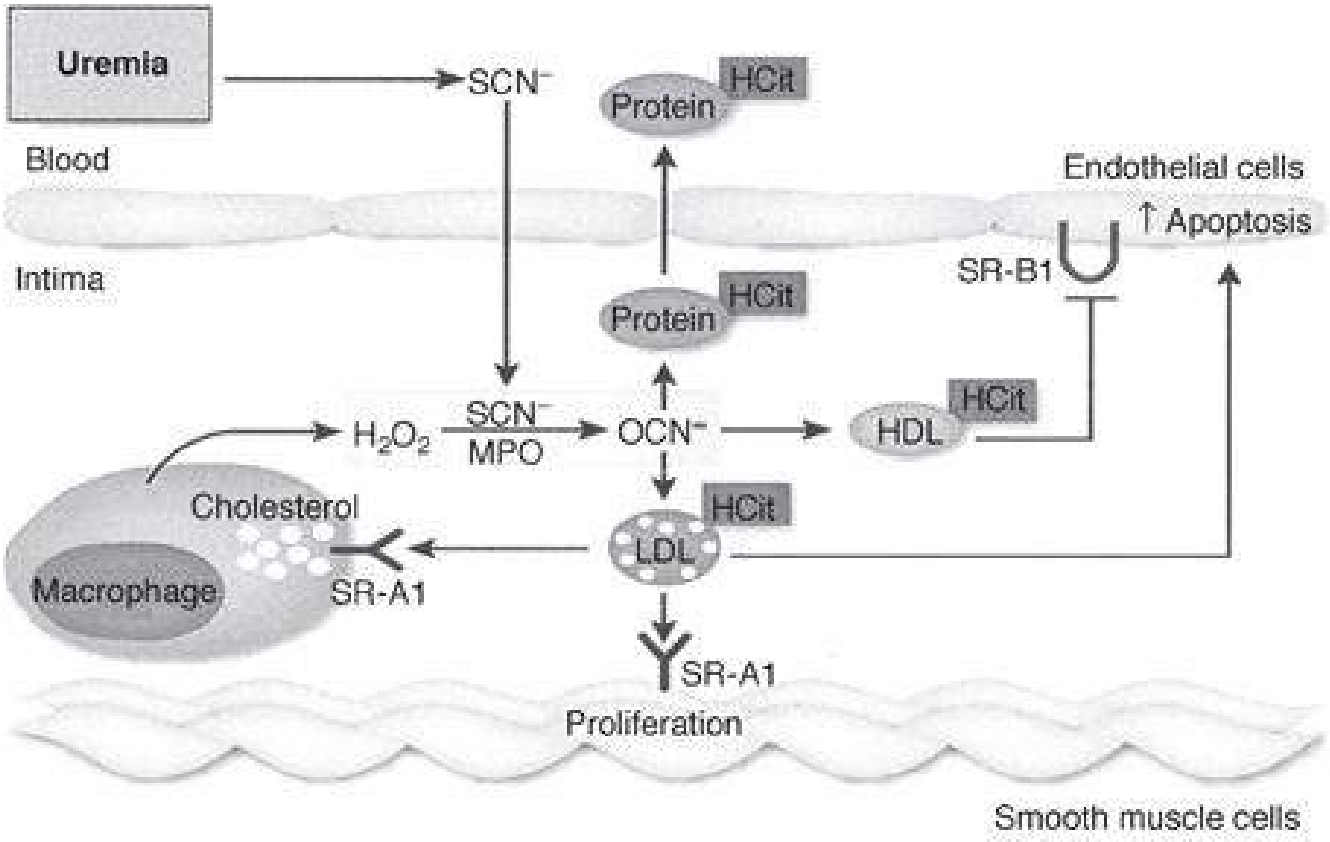

FIGURE 19.7 Role of myeloperoxidase (MPO) in the generation of cyanates in uremia. The chemical reaction catalyzed by MPO that generates cyanate (OCN^-). The substrate for this reaction is thiocyanate (SCN^-), which can accumulate in the body either from urea, cigarette smoking, or other dietary sources. Cyanate (OCN^-) modifies lysine residues to form homocitrulline (HCit) on proteins and lipoproteins, in a process called *carbamylation*. The carbamylation of proatherogenic low-density lipoproteins (LDLs) promotes their binding by the scavenger receptor (SR)-A1, leading to increased macrophage LDL uptake and proliferation of smooth muscle cells, as well as increased endothelial cell apoptosis. The antiatherosclerotic high-density lipoproteins (HDLs) are also modified by this reaction, and HDL loses antiatherogenic potential. (Modified and reproduced with permission from Rader DJ, Ischiropoulos H. 'Multipurpose oxidase' in atherogenesis. *Nat Med* 2007;13:1146–1147.)

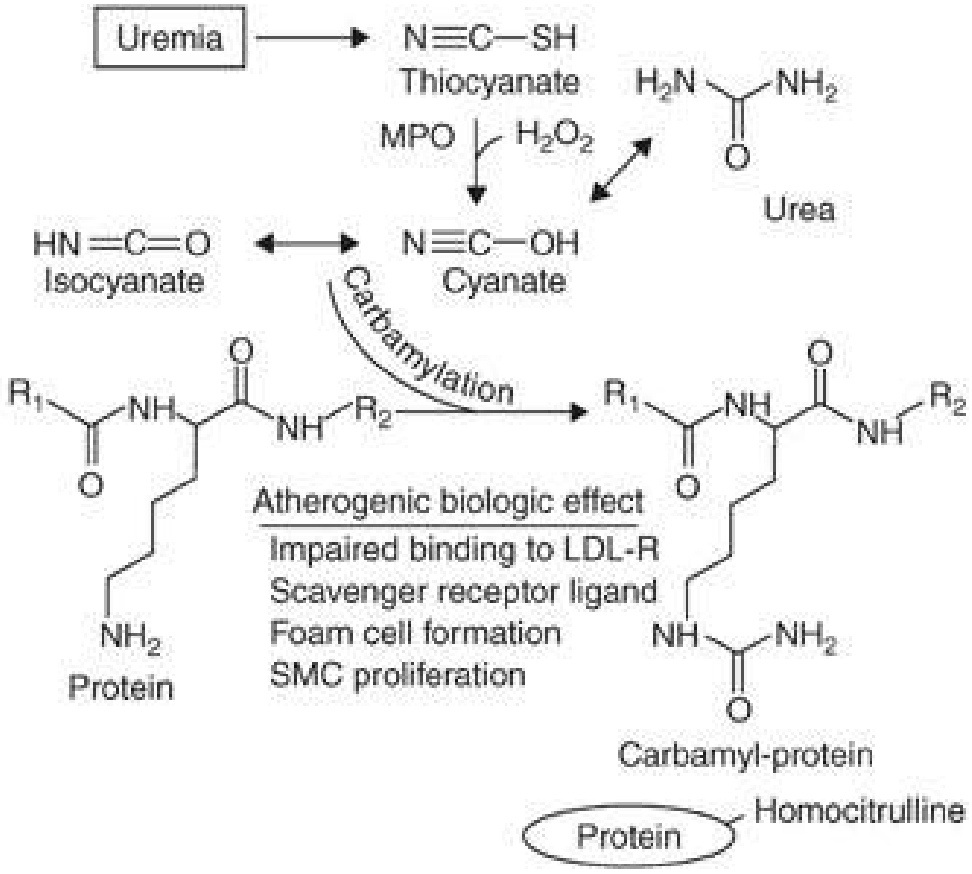

FIGURE 19.8 Schematic illustration of different pathways for protein carbamylation in uremia. Leukocyte myeloperoxidase (MPO) uses H_2O_2 and SCN^- as cosubstrates to generate OCN^- and promote protein carbamylation at sites of inflammation such as atherosclerotic plaque. Protein carbamylation is also increased in patients with chronic kidney disease as well as uremia as urea is a rich source of OCN^-. (Modified and reproduced with permission from Wang Z, Nicholls SJ, Rodriguez ER, et al. Protein carbamylation links inflammation, smoking, uremia and atherogenesis. *Nat Med* 2007;13:1176–1184.)

Treatment with an antioxidant drug such as probucol without lipid-lowering potential has been reported to reduce the extent and the progression of atherosclerotic lesions in Watanabe heritable hyperlipidemic rabbits (WHHL) (69). On the basis of these data, it is reasonable to speculate that, in addition to the usual lipid abnormalities, enhanced *in vivo* LDL oxidation plays an important role in the process of accelerated atherosclerosis. Therefore, pharmacologic interventions that can decrease LDL oxidation should provide an important tool to ameliorate the accelerated progression in atherosclerosis in dialysis-dependent patients.

Recent introduction of vitamin E–bonded dialysis membranes may have the potential to reduce the overall oxidant stress, decrease lipid peroxidation, and LDL oxidation by providing site-specific high-dose vitamin E to prevent the release of ROS in the extracorporeal circulation (70).

ROLE OF REACTIVE OXYGEN SPECIES IN THE PATHOGENESIS OF β_2-MICROGLOBULIN DISEASE

Progression in kidney disease and subsequently the need for dialysis is associated with accumulation of middle molecular weight proteins (11.8 kDa) called β_2-*microglobulin* (β_2-M) (levels in dialysis patients are usually 30-fold higher than normal healthy controls) (71,72).

Gejyo et al. (72) described increased serum levels of β_2-M in patients on maintenance HD that did

not correlate with the joint or bone disease as seen in dialysis-related amyloidosis (DRA). This questioned the concept of simple deposition disease of dialysis amyloidosis. It is postulated that unknown amyloid-enhancing factors result in the qualitative or conformational changes in the β_2-molecule that plays an important role in the pathogenesis of amyloid disease. Subsequently, Miyata et al. (73,74) demonstrated that β_2-M produces tissue injury after it is modified by products of oxidant stress such as AGE, ALE, or AOPP.

AGE-modified β_2-M stimulates monocyte-macrophage cells, releases cytokines TNF-α and IL-1β, and induces collagenase gene expression in rabbit synovial cells (73). In addition, β_2-M increases the expression of IL-8 and profibrogenic cytokine TGF-β (75) with increased recruitment of polymorphonuclear neutrophils (PMNs) (76) and increased expression of fibroblasts in the synovial membranes of DRA-affected joints. These markers of neutrophil activation and tissue damage were absent in the presence of β_2-M deposition but without accompanying joint damage.

Further insights about the AGE and ALE modification of β_2-M were demonstrated by the use of anti-AGE monoclonal antibodies for the epitopes of imidazoline and Nε-carboxymethyllysine adducts of β_2-M in the synovial tissues of patients with dialysis-related arthropathy along with increased serum levels of both imidazolone and CML-modified β_2-M (74).

These studies support the evidence that excessive generation of ROS in dialysis patients results in β_2-M modification by AGEs, AOPPs, and ALEs; such a modification could be an important factor in the pathogenesis of tissue injury at the site of deposition of β_2-M and subsequent development of DRA (73). The combined use of hemoperfusion and HD increases the rate of removal of β_2-M and prevents the development of DRA (77).

REACTIVE OXYGEN SPECIES AND THEIR ROLE IN PERITONEAL MEMBRANE FAILURE IN PERITONEAL DIALYSIS PATIENTS

Progressive loss of ultrafiltration is the most common cause of PD failure. The morphologic changes associated with ultrafiltration failure include mesothelial denudation, interstitial fibrosis, and increase in extracellular matrix proteins; the end result is peritoneal membrane thickening (78). Electron microscopy reveals a characteristic replication of the basement membrane of the peritoneal capillaries and hyalinization of vascular media. These structural changes are well described in diabetic nephropathy (79). AGEs and pentosidine have been demonstrated in the peritoneal tissues and peritoneal blood vessel walls. Increased levels of AGEs and pentosidine have been correlated with the degree of peritoneal fibrosis and have been linked to the cumulative peritoneal glucose load (78,79). Whether the use of low glucose or nonglucose dialysate solutions will prevent the production of local AGEs remains to be studied and could provide new therapeutic strategies for the preservation of peritoneal function in long-term CAPD patients.

It is clear that CKD patients treated with different modes of dialysis invariably demonstrated increased levels of ROS and decreased levels of almost all the biologic antioxidants.

A recent comparative study demonstrated increased levels of different products of oxidation in three different groups (CKD, HD, and PD) of patients along with decreased levels of different antioxidants (**TABLE 19.1**) (80).

TABLE 19.1 Effect of Hemodialysis and Peritoneal Dialysis on Redox Status: A Comparative Study

Products of ROS	CKD	HD	CAPD
TBARS (μmol/L)	0.21 ± 0.01	0.23 ± 0.02	0.18 ± 0.01
Carbonyl (μmol/L)	0.3 ± 0.16	0.92 ± 0.15	1.90 ± 0.10
Nitric oxide (μmol/L)	22.53 ± 7.24	30.57 ± 8.7	20.52 ± 1.58

OXIDANT STRESS–RELATED INFLAMMATION, ACCELERATED ATHEROSCLEROSIS, AND CARDIOVASCULAR DISEASE

Patients with CKD as well as patients on long-term dialysis are characterized by a vasculopathic state as 50% patients with CKD or ESKD die of cardiovascular disease (see Chapter 17). This vasculopathic state is not completely explained by the presence of traditional risk factors known to be associated with the development of atherosclerosis (81,82).

Neutrophil–Macrophage Interactions Facilitate Inflammation and Atherosclerosis

Neutrophil extracellular traps (NETs) play a critical role to prime macrophages for inflammatory responses, these mechanisms of communication has been shown to play a critical role in the inflammation-atherosclerosis pathology (83). For example, recent study by Warnatsch et al. (84) demonstrated how NETs set the stage for inflammatory atherosclerosis. In this case, extracellular cholesterol crystals interact with neutrophils to trigger NET formation (NETosis), triggering burst of ROS, and neutrophil elastase translocation to the nucleus; an important determinant for NETosis. ROS plays a critical role in NETosis since inhibitors of reduced NADPH oxidase as well as inhibitors of neutrophil-specific proteases (NE) and proteinase 3 (PR3) were able to prevent NETosis. In-addition, NETs, which in turn primes the macrophages to produce a precursor of interleukin-1B (pro-IL-1B). Furthermore, cholesterol crystals bind to the cell surface protein CD36 on macrophages (66), which are internalized by endocytosis, activate the signaling complex called inflammasome. Activation of

inflammasome results in activation of pro-IL-1b to IL-IB with its plethoric cytokine and paracrine effects on other tissue inflammatory processes (84) (**FIGURE 19.9**).

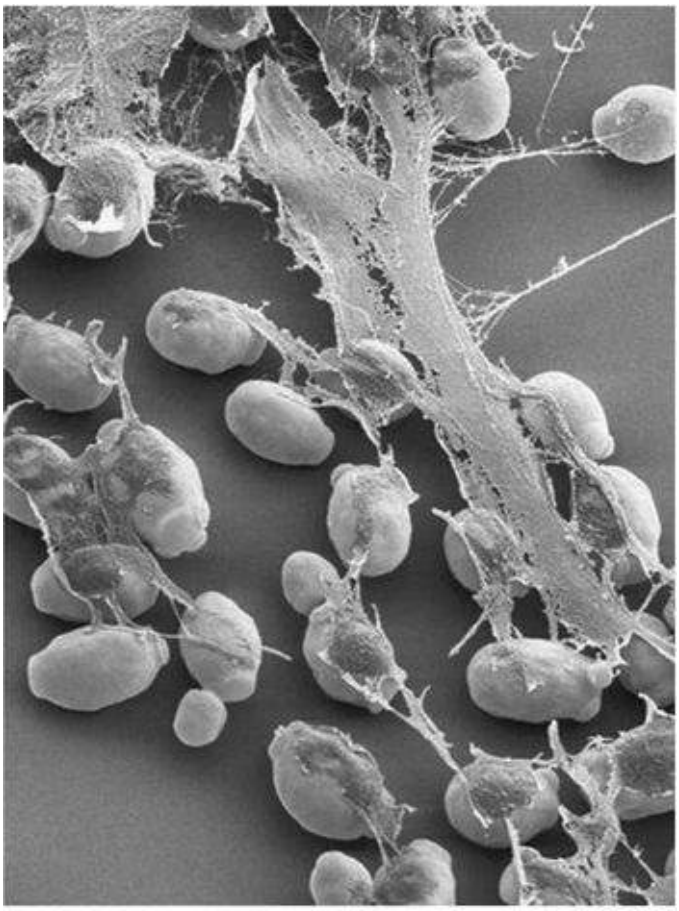

FIGURE 19.9 Deploying NETs. Colored scanning electron micrograph of neutrophil extracellular traps (NETs, brown) capturing spores from the yeast *Candida albicans* (*yellow*). [Modified and reproduced from Nahrendorf M, Swirski FK. Immunology. Neutrophil-macrophage communication in inflammation and atherosclerosis. *Science* 2015;349(6245):237–238.]

It has been demonstrated that AGEs can react with corresponding receptors called *receptors for advanced glycation end products* (RAGE) (85) and other scavenger receptors on macrophages, vascular endothelial cells, and smooth muscle cells. Such a receptor/ligand interaction leads to the activation of endothelial cells and release of VCAM-1 which further attracts monocytes to the vessel wall (86). AGE interaction with binding sites on monocytes and macrophages activates a host of intracellular signaling pathways. Activation of these signaling pathways results in the release of IL-1β, IL-6, TNF-α, and stimulation of NADPH oxidases with release of superoxide ($O2^{-}$), thereby aggravates the already existent oxidative state (87).

IL-6 is one of the mediators of increased production of acute-phase proteins of acute inflammatory response. IL-6 acts directly on the hepatocytes and increases the synthesis of C-reactive protein (CRP), fibrinogen, and serum amyloid A (88). Whether AGE can act directly on the hepatocytes and increase the synthesis and/or release of CRP remains to be determined.

Increased levels of CRP and other acute-phase proteins in apparently healthy people (89) and in dialysis patients have been demonstrated to be the potential marker of predicting cardiovascular and overall mortality independent of other well-defined traditional risk factors for cardiovascular disease (3,90).

REACTIVE OXYGEN SPECIES AND ENDOTHELIAL DYSFUNCTION

CKD is associated with impaired endothelium-derived NO bioavailability and endothelial dysfunction in the absence of other associated conventional risk factors that can lead to endothelial dysfunction. Similar findings have been demonstrated even in children with CKD. The reduced NO bioavailability in kidney disease and in dialysis patients is perhaps multifactorial such as decreased NO production (91), increased NO degradation, or both. Also, decreased NO production could be related to low levels of nitric oxide synthase (NOS) activity, as a result of decreased clearance of the endogenous NOS inhibitor such as asymmetric dimethylarginine (ADMA) in dialysis patients (92), or due to decreased bioavailability of the NOS substrate such as L-arginine, due to combination of factors such as poor intake, accompanying malnutrition, or increased losses through dialysis therapy. Another important mechanism that can deplete NO is the ability of AGEs to quench NO (92). The use of vitamin E–bonded dialyzers can reduce the level of oxidant stress and improve the endothelial function by preventing NO degradation (93).

Role of Asymmetric Dimethylarginine (ADMA) in Endothelial Nitric Oxide Synthase Uncoupling: Link between Oxidative Stress and Endothelial Dysfunction

Production of Asymmetric Dimethylarginine

ADMA is generated from posttranslational methylation of arginine residues present in a variety of specific proteins that are predominantly found in the cell nucleus (94). A number of cells elaborate ADMA, including human endothelial cells. ADMA is metabolized by the enzyme dimethylarginine dimethyl-aminohydrolase (DDAH) (95). DDAH metabolizes ADMA to L-citrulline and dimethylamine (96). ADMA and DDAH are widely distributed in tissues and may provide a mechanism for controlling NO synthesis in physiologic as well as in pathologic states. Increased ADMA levels can decrease NO synthesis by inhibiting endothelial nitric oxide synthase (eNOS) and also enhance oxidative stress by uncoupling eNOS enzyme and releasing nascent oxygen (97). However, it remains to be established whether ADMA concentrations *in vivo* in different disease states except in uremia are sufficient enough to effectively interact with eNOS activity (98).

Recently, it was demonstrated that increased levels of ADMA can further escalate the oxidative stress (97). Exposure of endothelial cells to ox-LDL and TNF-α resulted in the reduction of DDAH activity by more than 50% (99). Similarly, a high-cholesterol diet was associated with decreased DDAH activity without a change in protein expression and increased levels of ADMA. Decreased activity of DDAH may lead to local accumulation or release of intracellular ADMA and inhibition of NO synthase in disease states, including uremia. In addition, increased ADMA levels that can significantly inhibit NOS activity has been demonstrated in other disease states such as hypercholesterolemia, hypertension (HTN), hyperhomocysteinemia, tobacco exposure, and hyperglycemia (99–102) (**FIGURE 19.10**).

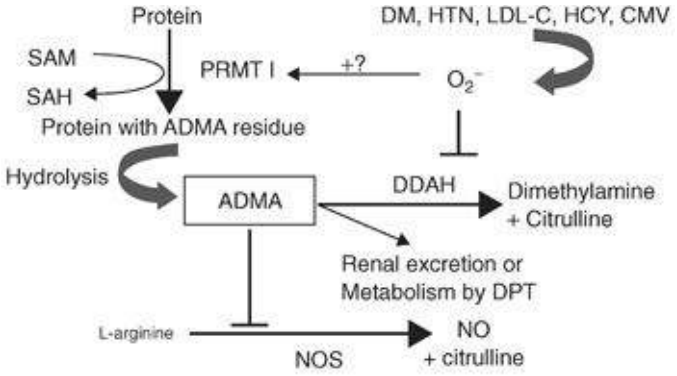

FIGURE 19.10 Biochemical pathways for generation, elimination, and degradation of asymmetric dimethylarginine (ADMA). ADMA derives from methylation of arginine residues in proteins. The reaction is catalyzed by protein arginine *N*-methyltransferases (PRMTs) that transfer a methyl group from *S*-adenosyl-L-methionine (SAM) to each guanidino nitrogen of an arginine residue. This reaction results in a methylated arginine derivative. Hydrolysis of the methylated proteins releases ADMA, a competitive inhibitor of endothelial nitric oxide synthase (NOS). All methylarginines are excreted into the urine and are in part metabolized to keto acids by dimethylarginine dimethyl-aminohydrolase (DDAH). The enzyme DDAH hydrolyzes ADMA to dimethylamine and L-citrulline. SAH, S-adenosyl homocysteine; NO, nitric oxide; DM, diabetes mellitus; HTN, hypertension; LDL-C, low-density lipoprotein cholesterol; HCY, hyperhomocysteinemia; CMV, cytomegalovirus. (Modified and reproduced with permission from Cooke JP. Asymmetrical dimethylarginine. The Über marker? *Circulation* 2004;109:1813–1818.)

ADMA plasma levels (normally less than 1.060 mmol/L in healthy humans) are significantly increased in different disease states associated with increased burden of atherosclerosis, such as twofold increase in subjects with hypercholesterolemia (99), threefold increase in elderly patients with peripheral arterial occlusive disease and generalized atherosclerosis (99), and severalfold higher in dialysis patients (103). Increased levels of ADMA are independently associated with increased mortality in dialysis patients (103). Reduced clearance of ADMA in kidney disease is associated with endothelial vasodilator dysfunction, reversible by administration of L-arginine (104) or by high-flux dialysis therapy (105).

Can We Decrease the Levels of Plasma Asymmetric Dimethylarginine (Therapeutic Options)?

Plasma ADMA levels have been shown to be amenable to modification by different interventions based on the underlying etiology for such an increase in ADMA levels. Improvement of glycemic control with the use of metformin resulted in decreased levels of ADMA (106). In patients with insulin resistance, rosiglitazone improved insulin resistance and lowered plasma ADMA levels (107). Use of angiotensin-converting enzyme inhibitor or angiotensin receptor antagonist in patients with HTN reduced plasma ADMA levels (108). L-Arginine is a precursor of NO and its supplements can improve the endothelial dysfunction (109). Other strategies to ameliorate the magnitude of oxidative stress could also indirectly decrease the levels of ADMA (108–111).

CAN DIALYSIS-ASSOCIATED INCREASED OXIDATIVE STRESS BE PREVENTED?

Therapeutic approaches to prevent or to decrease the oxidant stress are aimed at minimizing inflammatory cell activation, removing inflammatory cytokines or mediators, maintaining host antioxidant defenses, and

using strategies to adsorb or to chelate the ROS.

Minimizing Inflammatory Cell Activation and Release of Reactive Oxygen Species

The use of biocompatible membranes (to some extent) prevents complement activation and neutrophil sequestration and activation (23), although it does not completely abrogate the production of ROS. Hence, ROS continue to have a significant effect on the generation and maintenance of oxidative stress and lipid peroxidation as measured by serum levels of MDA and ox-LDL (112).

Other investigators have demonstrated that use of ultrapure water and sterile dialysate (113) could possibly decrease the inflammatory responses. These steps (combined with use of biocompatible membranes, ultrapure water, and sterile dialysate) can decrease the production of ROS and minimize the inflammatory response.

Measures to Improve the Removal of Inflammatory Cytokines

Hemolipodialysis (HLD) improves oxidant stress by decreasing inflammatory cell activation, removing inflammatory mediators, and maintaining antioxidant levels (114). HLD uses liposomes with vitamin E added in the liposomal bilayer and vitamin C added directly in the dialysate. Liposomes have a high affinity for proteins, drugs, and cytokines. Use of liposomes can increase the removal of inflammatory mediators, whereas vitamin E in the liposomal bilayer and vitamin C in the dialysate will act synergistically to replenish the antioxidant levels ordinarily lost through diffusion during dialysis (115).

Treatment Strategies for the Removal of Products of Reactive Oxygen Species/Reactive Nitrogen Species and Other Inflammatory Biomarkers

Use of Evolving Dialysis Membranes

During the last 10 years with the introduction of high-performance dialysis membranes and improvements in the quality of dialysate and water purification methods, the rate of progression of chronic inflammation and vascular disease in dialysis-dependent patients has remained unchanged due to inability of conventional dialysis membranes to remove unconventional uremic toxins such as the products of glycation and oxidation (28,29). New dialysis membranes that provide different spectrum of diffusive-convective and adsorption properties have been developed with the aim of increasing the clearance of middle molecules including LMWPs (56). Among the high-flux membranes, modified polymethylmethacrylate (PMMA) with protein-leaking dialyzer (PLD) properties, thereby defined as ultrahigh-flux protein-leaking dialyzer (HF-PLD) compared to high-flux non–protein-leaking dialyzers (HF-NPLD), has the advantage of direct removal and adsorption of LMWPs. The use of HF-PLD is devoid of other adverse events such as hypoalbuminemia and backfiltration (115). In addition, dialysis membranes that have intrinsic adsorption properties such as PMMA and polyacrylonitrile (AN 69 membranes) increase the removal of large solutes, cytokines, and LMWPs including native and oxidized β_2-microglobulin (116,117).

By combining high-volume ultrafiltration with dialysis increases connective clearance that increases the clearance of large molecular weight solutes including LMWPs along with diffusion of small solutes; it accelerates the removal of products of oxidation. High-volume ultrafiltration with regular dialysis can be achieved by using the technique of on-line hemodiafiltration (OL-HDF) which offers the advantage of

removing small to large molecular solutes. Use of this dialytic technique has been shown to reduce the burden of inflammation and endothelial dysfunction with improved patient survival (118–120).

Role of Vitamin E–Modified Hemodialysis Filters

Improved bioreactivity and biocompatibility of vitamin E–modified multilayer HD filters can reduce the production of ROS. Galli et al. (70) showed that vitamin E–modified HD filters (CL-E) as compared with cuprammonium rayon (CL-S) filters provide site-specific and time-dependent protection against ROS at the site of their generation by activated PMNs in the extracorporeal circulation. Such membranes have the potential to replenish antioxidant stores in plasma and RBCs, and inhibit the leukocyte respiratory burst and ROS production (119).

Vitamin E–coated membrane filters have been shown to prevent dialysis-induced endothelial dysfunction by maintaining the bioreactivity of endothelium-derived NO and also decreasing the levels of ox-LDL as compared with dialysis treatment with cellulose or other synthetic membranes (93). HD using vitamin E–modified membranes increases plasma and erythrocyte vitamin E content, increases plasma levels of reduced glutathione, improves leukocyte function, and decreases mononuclear cell apoptosis and complement activation (121) (**TABLE 19.2**).

TABLE 19.2 Effect of Vitamin E–Modified Dialysis Membrane on Oxidized Low-Density Lipoprotein and Malondialdehyde Levels after 9 Months of Treatment

	Oxidized LDL ng/μg LDL Protein	MDA nmol/mg LDL Protein
Normal range	0.257 ± 0.132	1.9 ± 0.5
Hemodialysis group	—	—
Month		
0	1.653 ± 0.76	4.329 ± 0.955
1	1.623 ± 0.966	4.091 ± 0.891
3	1.592 ± 1.064	3.997 ± 1.045
6	1.406 ± 0.568	3.656 ± 0.788
9	1.357 ± 0.852	3.459 ± 0.658[a]

Results are expressed as mean ± standard deviation (*SD*). Plasma oxidized-LDL and MDA levels were significantly higher in hemodialysis (HD) patients compared to controls. These values slowly decreased and were significantly lower after 9 months of treatment using vitamin E–modified dialyzer. LDL, low-density lipoprotein; MDA, malondialdehyde.

[a]$p < 0.05$ versus 0 month (before using the vitamin E–modified dialyzer).

Modified from Shimazu T, Ominato M, Toyama K, et al. Effects of a vitamin E-modified dialysis membrane on neutrophil superoxide anion radical production. *Kidney Int* 2001;59(Suppl 78):S137–S143, with permission.

Taken together, these recent studies show that vitamin E–modified dialysis membranes can reduce the release of ROS and could reduce the oxidant stress. Prospective randomized studies to compare the patient outcomes with new techniques of dialysis such as HLD, high-flux polysulfones, and vitamin E–modified filters are clearly needed.

Restoring the Host Antioxidant Defenses

Role of Vitamin E and Vitamin Supplements

Several observational and epidemiologic studies in the general population have demonstrated conflicting evidence about the efficacy of various antioxidants such as vitamins A, E, and C and beta-carotene in reducing the incidence of secondary cardiovascular outcomes or death from any cause (122,123).

Vitamin E (α-tocopherol): Vitamin E (α-tocopherol) has biochemical properties to suppress generation of ROS from monocyte-macrophage cells, along with inhibition of monocyte adhesion to endothelial cells, thereby preventing endothelial damage. Vitamin E also stabilizes the atherosclerotic plaques (124).

Secondary Prevention with Anti-Oxidants of Cardiovascular Disease in ESRD (SPACE) study: Boaz et al. (125) used vitamin E 800 IU (as naturally occurring α-tocopherol) and demonstrated significantly lower primary and secondary cardiovascular events in the treatment group as compared with the placebo group, nearly 54% reduction in cardiovascular disease events in patients who are treated with vitamin E compared to placebo. However, Heart Outcomes Prevention Evaluation (HOPE) study that enrolled nearly 993 patients with mild to moderate CKD and were treated with natural source vitamin E (400 IU/d) versus placebo, did not show any benefit with vitamin E therapy (126). There were so many differences in study designs between HOPE and SPACE study, such as HOPE enrollees received a very low dose of vitamin E, patient with mild to moderate CKD have low event rates for CVD compared to those with ESKD on dialysis as were the participants in SPACE study. Also, more than 40% of SPACE subjects used vitamin C in combination with vitamin E.

Other studies with vitamin E in other population subgroups have also yielded negative results, such as Selenium and Vitamin E Cancer Prevention Trial (SELECT) which demonstrated that use of vitamin E significantly increased the risk of prostate cancer among healthy subjects (127). A meta-analysis of several studies demonstrated that use of high-dose vitamin E (>400 IU/d) in patients with chronic disease was associated with increased risk of all-cause mortality (128).

***N*-Acetylcysteine:** *N*-Acetylcysteine (NAC) is a thiol-containing antioxidant and is a potent free radical scavenger, and hence, it is considered a potent antioxidant. Tepel et al. (129) used acetylcysteine (oral dose of 600 mg twice a day) versus placebo (n = 134), and dialysis patients and demonstrated a 30% reduction in the primary end point [composite of acute myocardial infarction (AMI), cardiovascular (CV) death, percutaneous coronary intervention (PCI), coronary artery bypass grafting (CABG), cerebrovascular accident (CVA), or pulmonary vascular accident (PVD)] with the use of NAC compared to placebo. Another small study demonstrated 36% reduction in CVD events using NAC versus placebo. In the absence of power-based randomized controlled trial (RCT), it is premature to assume the efficacy of either vitamin E or acetylcysteine for prevention of atherosclerotic cardiovascular disease (ASCVD) events in patients with CKD. Hsu et al. (130) demonstrated that treatment with NAC in HD patient resulted in improvement of anemia and decreased plasma levels of 8-isoprostane and oxidized LDL. Similarly, NAC use was associated with decreased levels of 8-isoprostane and IL-6 levels in patients on PD (131). Other studies have demonstrated that NAC use is associated with decrease in homocysteine levels and improvement in endothelial function (132). Treatment with NAC in patients with nondiabetic CKD was really disappointing (133).

Treatment of hyperhomocysteinemia (Hcy) and its role in oxidative stress: Hcy is a risk factor for vascular disease, and one of the pathways is perhaps by increasing the oxidative stress (134).

Increased levels of ADMA are often noted in patients with H-Hcy. Hcy is an important risk factor for atherosclerotic disease progression. However, strategies to decrease homocysteine level did not translate in decreasing the events related to vascular disease either in the general population (135) or in patients with CKD (136). Despite a marked decrease in the homocysteine levels, there was no difference in the mortality or cardiovascular outcomes among the three treatment groups. Another RCT (the Homocysteinemia in Kidney and End Stage Renal disease study) enrolled 2,056 patients with CKD, and 751 of these were on maintenance HD. The patients were assigned to receive a combination of high-dose folic acid (40 mg daily), pyridoxine (100 mg daily), and cyanocobalamin (2 mg daily) or placebo. It was not associated with any benefit (137).

Treatment with bardoxolone methyl: Use of bardoxolone methyl in mitigating increased oxidant stress in CKD population. Recently, a transcription factor named Nrf2 was found to be a positive regulator of human antioxidant response element (ARE) that drives expression of antioxidant enzymes such as NAD (P)H and quinone oxidoreductase 1 (NQO1) (138). A suppressor protein called Keap1 that is present in cytoplasm physically binds Nrf2, and preventing its translocation to the nucleus, and its access to ARE-containing promoters, such as those involved in glutathione synthesis and genes involved in limiting the inflammatory processes. Thus, Nrf2 activation modulates the expression of several different antioxidant gene products that protects the cells from the oxidative damage. Among one of the Nrf2 activators, bardoxolone methyl (methyl2-cyano-3,12-dioxooleana-1,9 dien-28-oate) interacts with cysteine residues on Keap1, allowing Nrf2 translocation to the nucleus, that results in upregulation of a multitude of cytoprotective genes. Additionally, bardoxolone methyl also produces anti-inflammatory effects by reducing the proinflammatory NF-KB pathway (139). A recent study demonstrated that use of bardoxolone methyl in patients with CKD had significant and sustained improvements in estimated GFR in a 52-week study (140).

Role of statins: Statins in general are considered to be antilipidemic agents to lower cholesterol and LDL levels. However, statins also have anti-inflammatory and antioxidant properties (141) and remain the cornerstone of treatment for primary as well as secondary prevention of acute coronary events as well as stroke in the general population. Three different RCT evaluated the efficacy of statins in dialysis patients and reported different results. Wanner et al. (142) reported (4D study: statin vs. placebo; n = 1,255) that despite an effective reduction in the LDL cholesterol as well as CRP, treatment with statin in dialysis patients had no effect on the primary outcome. An Assessment of Survival and Cardiovascular Events (AURORA), using rosuvastatin, again demonstrated effective reduction in the LDL cholesterol and CRP but without an impact on the primary outcome compared to the placebo group (143). Study of Heart and Renal Protection (SHARP) was an international RCT that enrolled 9,438 patients with CKD, and 3,191 were on maintenance dialysis therapy. There was a significant 17% reduction in primary outcome when all study patients were included. When primary outcome was analyzed based on patient population such as CKD versus dialysis patients, statin use resulted in 22% reduction in the primary end point in patients with CKD and only by a nonsignificant 5% reduction in primary outcome in HD-dependent patients (144). In summary, these three RCTs with different statins only resulted in less than 5% reduction in mortality from cardiovascular disease–related events in HD patients. This rate was consistent across the spectrum of RCT (4D, AURORA, and SHARP).

Treatment with folic acid and vitamin B_{12}: Use of folic acid alone or in combination with vitamin

B_{12} is associated with reduction in homocysteine levels in ESKD patients. Although use of different doses of folic acid and vitamin B_{12} supplements can lower Hcy levels, such reduction in Hcy levels have not produced positive impact on cardiovascular disease outcomes (135). However, recent meta-analysis reported that use of folic acid and vitamin B_{12} may be beneficial to reduce the cardiovascular disease events in dialysis population (Heinz, 2009 #180, 137). Use of these supplements besides lowering the Hcy levels, folic acid, and vitamin B_{12} use is also associated with reduction in the circulating precursors of oxidative injury such as reduction in the levels of micronuclei in peripheral blood lymphocytes (PBL); (micronuclei are chromatin rich products surrounded by a membrane that develop due to DNA damage and are formed during cell mitosis). Micronuclei are very sensitive indicators of exogenous as well as endogenous DNA damage if detected in PBL (146).

Omega-3 polyunsaturated fatty acids: These compounds are known to have anti-inflammatory and antioxidant properties. Long-chain omega-3 polyunsaturated fatty acids enhance endogenous antioxidant substrates such as gamma-glutamyl-cysteinyl ligase and GR (147). Experimental study in obstructive renal injury model in rats showed decreased rate of progression along with reduction in the molecular signatures of oxidative stress with the use of long chain omega-3 polyunsaturated fatty acids containing eicosapentaenoic acid and docosahexaenoic acid supplements (148).

Use of Angiotensin-Converting Enzyme Inhibitors

The use of angiotensin-converting enzyme inhibitors is associated with decreased incidence of cardiovascular events in high-risk populations, and this effect is remarkable even without significant changes in blood pressure as was demonstrated in the HOPE study. De Cavanagh et al. (149) demonstrated that treatment of dialysis patients with enalapril at 10 mg/d for 6 months resulted in higher levels of antioxidants and reduced levels of ROS. Therefore, enalapril treatment may have the potential of enhancing the endogenous antioxidant defenses and, hence, protect the cells from the oxidant-related injury.

Value and Efficacy of Chelators of Reactive Oxygen Species

Use of BetaSorb in Dialysis

BetaSorb HD is an accessory device for HD, placed upstream from the dialyzer in the HD circuit. Its intended use is to improve the removal of middle molecular weight uremic toxins like β_2-M, ROS, and proinflammatory cytokines such as complement factors, TNF-α, IL-1, and IL-8 (150,151). Hence, BetaSorb polymers remove size-selective toxins by adsorption. The BetaSorb device has been approved for human clinical testing by the U.S. Food and Drug Administration (FDA), and clinical trials are underway to assess the efficacy of BetaSorb devices to remove β_2-M in HD patients using the combination of high-flux dialyzer and BetaSorb as compared with the use of high-flux membrane dialyzers (Clinical trials.Gov: NCT00561093, NCT02461953).

CAN OXIDATIVE STRESS BE USEFUL?

Cerebral arteries constantly regulate their tone to maintain constant blood flow to the brain regardless of variations in mean arterial pressure. ROS produce different effects on the vasomotor tone in the different

arteries such as peripheral vessels compared to cerebral vessels. In the cerebral blood vessels, calcium permeable transient receptor potential ankyrin 1 (TRPA1) channels are linked to the NADPH (reduced NADPH) oxidase 2 (NOX2), a major source of ROS and is predominantly present in the cerebral vessels and has not been demonstrated in other vascular beds. Recent evidence demonstrates that ROS play an important role to maintain blood flow in the cerebral vessels. ROS produced in the endothelial cells oxidize lipids (lipid peroxidation), which triggers influx of calcium by stimulating the ion channel TRPA1. This calcium influx in turn activates calcium-dependent potassium-permeable channel, resulting in the dilatation of cerebral arteries, thus facilitating blood flow (152). However, more work needs to be done to establish the paradoxical effects of ROS in the cerebral vessels in different disease states.

SUMMARY

Patients with CKD receiving different types of dialysis are at risk for increased oxidative stress as measured by the biomarkers of oxidant stress such as ROS, AGEs, ALEs, AOPP, and ox-LDL. Increased oxidative stress may contribute directly or indirectly in the pathogenesis of accelerated atherosclerosis, the chronic inflammatory state, and the development of DRA. In light of these findings, clinical trials are needed to assess the efficacy and safety of different interventions that can abrogate the production of ROS and/or restore the function of antioxidants in the early stages of development of kidney disease and after the initiation of dialysis therapy. Similarly, dialysis modalities using high-flux polysulfones in combination with other evolving modalities of dialysis, such as the use of BetaSorb cartridges or vitamin E–modified HD filters, can be used to reduce the burden of oxidative stress and, hopefully, prevent the associated complications in patient with CKD.
