Metaphysics

Metaphysics is the philosophical study whose object is to determine the real nature of things—to determine the meaning, structure, and principles of whatever is insofar as it is. Although this study is popularly conceived as referring to anything excessively subtle and highly theoretical and although it has been subjected to many criticisms, it is presented by metaphysicians as the most fundamental and most comprehensive of inquiries, inasmuch as it is concerned with reality as a whole.

Nature and scope of metaphysics

ORIGIN OF THE TERM

Etymologically the term *metaphysics* is unenlightening. It means "what comes after physics"; it was the phrase used by early students of Aristotle to refer to the contents of Aristotle's treatise on what he himself called "first philosophy," and was used as the title of this treatise by Andronicus of Rhodes, one of the first of Aristotle's editors. Aristotle had distinguished two tasks for the philosopher: first, to investigate the nature and properties of what exists in the natural, or sensible, world, and second, to explore the characteristics of "Being as such" and to inquire into the character of "the substance that is free from movement," or the most real of all things, the intelligible reality on which everything in the world of nature was thought to be causally dependent. The first constituted "second philosophy" and was carried out primarily in the Aristotelian treatise now known as the *Physica;* the second, which Aristotle had also referred to as "theology" (because God was the unmoved mover in his system), is roughly the subject matter of his *Metaphysica.* Modern readers of Aristotle are inclined to take both the *Physica* and the *Metaphysica* as philosophical treatises; the distinction their titles suggest between an empirical and a conceptual inquiry has little foundation. Aristotle was not indifferent to factual material either in natural or in metaphysical philosophy, but equally he was not concerned in either case to frame theories for empirical testing. It seems clear, nevertheless, that if the two works had to be distinguished, the *Physica* would have to be described as the more empirical, just because it deals with things that are objects of the senses, what Aristotle himself called "sensible substance"; the subject matter of the *Metaphysica,* "that which is eternal, free of movement, and separately existent," is on any account more remote. It is also evident that the connection marked in the original titles is a genuine one: the inquiries about nature carried out in the *Physica* lead on naturally to the more fundamental inquiries about Being as such that are taken up in the *Metaphysica* and indeed go along with the latter to make up a single philosophical discipline.

The background to Aristotle's divisions is to be found in the thought of Plato, with whom Aristotle had many disagreements but whose basic ideas provided a framework within which much of his own thinking was conducted. Plato, following the early Greek philosopher Parmenides, who is known as the father of metaphysics, had sought to distinguish opinion, or belief, from knowledge and to assign distinct objects to each. Opinion, for Plato, was a form of apprehension that was shifting and unclear, similar to seeing things in a dream or only through their shadows; its objects were correspondingly unstable. Knowledge, by contrast, was wholly lucid; it carried its own guarantee against error, and the objects with which it was concerned were eternally what they were, and so were exempt from change and the deceptive power to appear to be what they were not. Plato called the objects of opinion phenomena, or appearances; he referred to the objects of knowledge as noumena (objects of the intelligence) or quite simply as realities. Much of the burden of his philosophical message was to call men's attentions to these contrasts and to impress them with the necessity to turn away from concern with mere phenomena to the investigation of true reality. The education of the Platonic philosopher consisted precisely in effecting this transition: he was taught to recognize the contradictions involved in appearances and to fix his gaze on the realities that lay behind them, the realities that Plato himself called Forms, or Ideas. Philosophy for Plato was thus a call to recognize the existence and overwhelming importance of a set of higher realities that ordinary men—even those, like the Sophists of the time, who professed to be enlightened—entirely ignored. That there were such realities, or at least that there was a serious case for thinking that there were, was a fundamental tenet in the discipline that later became known as metaphysics. Conversely, much of the subsequent controversy about the very possibility of metaphysics has turned on the acceptability of this tenet and on whether, if it is rejected, some alternative foundation can be discovered on which the metaphysician can stand.

Appearances and realities for Plato

CHARACTERIZATIONS OF METAPHYSICS

Before considering any such question, however, it is necessary to examine, without particular historical references, some ways in which actual metaphysicians have attempted to characterize their enterprise, noticing in each case the problems they have in drawing a clear line between their aims and those of the practitioners of the exact and empirical sciences. Four views will be briefly considered; they present metaphysics as: (1) an inquiry into what exists, or what really exists; (2) the science of reality, as opposed to appearance; (3) the study of the world as a whole; (4) a theory of first principles. Reflection on what is said under the different heads will quickly establish that they are not sharply separate from one another, and, indeed, individual metaphysical writers sometimes invoke more than one of these phrases when asked to say what metaphysics is—as, for example, the British Idealist F.H. Bradley does in the opening pages of his work *Appearance and Reality* (1893).

An inquiry into what exists. A common set of claims on behalf of metaphysics is that it is an inquiry into what exists; its business is to subject common opinion on this matter to critical scrutiny and in so doing to determine what is truly real.

Unreliability of common opinion

It can be asserted with some confidence that common opinion is certainly an unreliable guide about what exists, if indeed it can be induced to pronounce on this matter at all. Are dream objects real, in the way in which palpable realities such as chairs and trees are? Are numbers real, or should they be described as no more than abstractions? Is the height of a man a reality in the same sense in which he is a reality, or is it just an aspect of something more concrete, a mere quality that has derivative rather than substantial being and could not exist except as attributed to something else? It is easy enough to confuse the common man with questions like these and to show that any answers he gives to them tend to be ill thought-out. It is equally difficult, however, for the metaphysician to come up with more satisfactory answers of his own. Many metaphysicians have relied, in this connection, on the internally related notions of substance, quality, and relation; they have argued that only what is substantial truly exists, although every substance has qualities and stands in relation to other substances. Thus, this tree is tall and deciduous and is precisely 50 yards north of that fence. Difficulties begin, however, as soon as examples like these are taken seriously. Assume for the moment that an individual tree—what might be called a concrete existent—qualifies for the title of substance; it is just the sort of thing that has qualities and stands in relations. Unless there were substances in this sense, no qualities could be real: the tallness of the tree would not exist unless the tree existed. The question can now be raised what the tree would be if it were deprived of all its qualities and stood in no relations. The notion of a substance in this type of metaphysics is that of a thing that exists by itself, apart from any attributes it may happen to possess; the difficulty with this notion is to know how to apply it. Any concrete thing one selects to exemplify the notion of substance turns out in practice to answer a certain description; this means in effect that it cannot be spoken of apart from its attributes. It thus emerges that substances are no more primary beings than are qualities and relations; without the former one could not have the latter, but equally without the latter one could not have the former.

There are other difficulties about substance that cannot be explored here—*e.g.*, whether a fence is a substance or simply wood and metal shaped in a certain way. Enough has already been said, however, to indicate the problems involved in defining the tasks of metaphysics along these lines. There is, nevertheless, an alternative way of understanding the notion of substance: not as that which is the ultimate subject of predicates but as what persists through change. The question "What is ultimately real?" is, thus, a question about the ultimate stuff of which the universe is made up. Although this second conception of substance is both clearer and more readily applicable than its predecessor, the difficulty about it from the metaphysician's point of view is that it sets him in direct rivalry with the scientist. When the early Greek philosopher Thales inquired as to what is ultimately real and came up with the surprising news that all is water, he might be taken as advancing a scientific rather than a philosophical hypothesis. Although it is true that later writers, such as Gottfried Wilhelm Leibniz, a German Rationalist philosopher and mathematician, were fully aware of the force of scientific claims in this area and, nevertheless, rejected them as metaphysically unacceptable, the fact remains that the nonphilosopher finds it difficult to understand the basis on which a Leibniz rests his case. When Leibniz said that it is monads (*i.e.*, elementary, unextended, indivisible, spiritual substances that enter into composites) that are the true atoms of nature and not, for example, material particles, the objection can be raised as to what right he has to advance this opinion. Has he done any scientific work to justify him in setting scientific results aside with such confidence? And if he has not, why should he be taken seriously at all?

The ultimate stuff of the universe

The science of ultimate reality. To answer these questions, another description of metaphysics has been proposed: that it is the science that seeks to define what is ultimately real as opposed to what is merely apparent.

The contrast between appearance and reality, however, is by no means peculiar to metaphysics. In everyday life people distinguish between the real size of the Sun and its apparent size, or again between the real colour of an object (when seen in standard conditions) and its apparent colour (nonstandard conditions). A cloud appears to consist of some white, fleecy substance, although in reality it is a concentration of drops of water. In general, men are often (though not invariably) inclined to allow that the scientist knows the real constitution of things as opposed to the surface aspects with which ordinary men are familiar. It will not suffice to define metaphysics as knowledge of reality as opposed to appearance; scientists, too, claim to know reality as opposed to appearance, and there is a general tendency to concede their claim.

Components in the metaphysical conception of reality

It seems that there are at least three components in the metaphysical conception of reality. One characteristic, which has already been illustrated by Plato, is that reality is genuine as opposed to deceptive. The ultimate realities that the metaphysician seeks to know are precisely things as they are—simple and not variegated, exempt from change and therefore stable objects of knowledge. Plato's own assumption of this position perhaps reflects certain confusions about the knowability of things that change; one should not, however, on that ground exclude this aspect of the concept of reality from metaphysical thought in general. Ultimate reality, whatever else it is, is genuine as opposed to sham. Second, reality is original in contrast to derivative, self-dependent rather than dependent on the existence of something else. When Aristotle sought to inquire into the most real of all things, or when medieval philosophers attempted to establish the characteristics of what they called the *ens realissimum* ("the most real being"), or the original and perfect being, they were looking for something that, in contrast to the everyday things of this world, was truly self-contained and could accordingly be looked upon as self-caused. Likewise, the 17th-century Rationalists defined substance as that which can be explained through itself alone. Writers like René Descartes and Benedict de Spinoza were convinced that it was the task of the metaphysician to seek for and characterize substance understood in this sense; the more mundane substances with which physical scientists were concerned were, in their opinion, only marginally relevant in this inquiry. Third, and perhaps most important, reality for the metaphysician is intelligible as opposed to opaque. Appearances are not only deceptive and derivative, they also make no sense when taken at their own level. To arrive at what is ultimately real is to produce an account of the facts that does them full justice. The assumption is, of course, that one cannot explain things satisfactorily if one remains within the world of common sense, or even if one advances from that world to embrace the concepts of science. One or the other of these levels of explanation may suffice to produce a sort of local sense that is enough for practical purposes or that forms an adequate basis on which to make predictions. Practical reliability of this kind, however, is very different from theoretical satisfaction; the task of the metaphysician is to challenge all assumptions and finally arrive at an account of the nature of things that is fully coherent and fully thought-out.

The task of the metaphysician

It should be obvious that, to establish his right to pronounce on what is ultimately real in the sense analyzed, the metaphysician has a tremendous amount to do. He must begin by giving colour to his claim that everyday ways of thinking will not suffice for a full and coherent description of what falls within experience, thus arguing that appearances are unreal—although not therefore nonexistent—because they are unstable and unintelligible. This involves a challenge to the final acceptability of such well-worn ideas as time and space, thing and attribute, change and process—a challenge that metaphysicians have not hesitated to make, even though it has been treated with skepticism both by ordinary men and by some of their fellow philosophers (*e.g.*, G.E. Moore, a 20th-century British

thinker who has greatly influenced modern Analytic philosophy). Second, granted that there are contradictions or incoherences in the thought of common sense, the metaphysician must go on to maintain that they cannot be resolved by deserting common sense for science. He will not deny that the concepts of science are in many respects different from those of everyday thought; to take one aspect only, they are altogether more precise and sharply defined. They permit the scientist to introduce into his descriptions a theoretical content that is lacking at the everyday level and in so doing to unify and render intelligible aspects of the world that seem opaque when considered singly. The metaphysician will argue, however, that this desirable result is purchased at a certain price: by ignoring certain appearances altogether. The scientist, in this way of thinking, does not offer a truer description of the phenomena of which ordinary thought could make no sense but merely gives a connected description of a selected set of phenomena. The world of the scientist, restricted as it is to what can be dealt with in quantitative terms, is a poor thing in comparison with the rich if untidy world of everyday life. Alternatively, the metaphysician must try to show that scientific concepts are like the concepts of common sense in being ultimately incoherent. The premises or presuppositions that the scientist accepts contain unclarities that cannot be resolved, although they are not so serious as to prevent his achieving results that are practically dependable. Many ingenious arguments on these lines have been produced by philosophers, by no means all of whom could be said to be incapable of a true understanding of the theories they were criticizing. (Leibniz, for example, was a physicist of distinction as well as a mathematician of genius; G.W.F. Hegel, a 19th-century German Idealist, had an unusual knowledge of contemporary scientific work; and Alfred North Whitehead, a pioneer of 20th-century metaphysics in the Anglo-Saxon world, was a professor of applied mathematics, and his system developed from physics and contained a wealth of biological ideas.) The fact remains, nevertheless, that few if any practicing scientists have been seriously troubled by such arguments.

Even if the metaphysician were thus able to make good the negative side of his case, he would still face the formidable difficulty of establishing that there is something answering to his conception of what is ultimately real and of identifying it. The notion of an original being, totally self-contained and totally self-intelligible, may not itself be coherent, as the 18th-century British philosopher David Hume and others have argued; alternatively, there may be special difficulties in saying to what it applies. The fact that different metaphysicians have given widely different accounts of what is ultimately real is certainly suspicious. Some have wanted to say that there is a plurality of ultimately real things, others that there is only one; some have argued that what is truly real must be utterly transcendent of the things of this world and occupy a supersensible realm accessible only to the pure intellect, while others have thought of ultimate reality as immanent in experience (the Hegelian Absolute, for example, is not a special sort of existent, but the world as a whole understood in a certain way). That metaphysical inquiry should issue in definitive doctrine, as so many of those who engaged in it said that it would, is in these circumstances altogether too much to hope for.

The science of the world as a whole. Another way in which metaphysicians have sought to define their discipline is by saying that it has to do with the world as a whole.

The implications of this phrase are not immediately obvious. Clearly, a contrast is intended in the first place with the various departmental sciences, each of which selects a portion or aspect of reality for study and confines itself to that. No geologist or mathematician would claim that his study is absolutely comprehensive; each would concede that there are many aspects of the world that he leaves out, even though he covers everything that is relevant to his special point of view. By contrast, it might be supposed that the metaphysician is merely to coordinate the results of the special sciences. There is clearly a need for the coordination of scientific results because scientific research has become increasingly specialized and departmentalized; individual scientific workers need to be made aware of what is going on in other fields, sometimes because these fields impinge on their own, sometimes because results obtained there have wider implications of which they need to take account. One can scarcely see metaphysicians, however, or indeed philosophers generally, performing this function of intellectual contact man in a satisfactory fashion. It might then be supposed that their concern with the world as a whole is to be interpreted as a summing up and synthesizing of the results of the particular sciences. Plato spoke of the philosopher as taking a synoptic view, and there is often talk about the need to see things in the round and avoid the narrowness of the average specialist, who, it is said, knows more and more about less and less. If, however, it is a question of looking at scientific results from a wider point of view and so of producing what might be called a scientific picture of the world, the person best qualified for the job is not any philosopher but rather a scientist of large mind and wide interests. Metaphysics cannot be satisfactorily understood as an account of the world as a whole if that description suggests that the metaphysician is a sort of superscientist, unlimited in his curiosity and gifted with a capacity for putting together other people's findings with a skill and imagination that none of them individually commands. Only a scientist could hope to become such a superscientist.

Metaphysics as a unified account of the world

More hope for the metaphysician can be found, perhaps, along the following lines. People want to know not only what the scientist makes of the world but also what significance to assign to his account. People experience the world at different levels and in different capacities: they are not only investigators but also agents; they have a moral and a legal, an aesthetic and a religious life in addition to their scientific life. Man is a many-sided being; he needs to understand the universe in the light of his different activities and experiences. There are philosophers who appear to find no problem here; they argue that there can be no possibility of, say, a moral or a religious vision of the world that rivals the scientific vision. In this view, morals and religion are matters of practice, not of theory; they do not rival science but only complement it. This neutralist attitude, however, finds little general favour; for most thinking people find it necessary to choose whether to go all the way with science, at the cost of abandoning religion and even morals, or to stick to a religious or moral world outlook even if it means treating scientific claims with some reserve. The practice of the moral life is often believed to proceed on assumptions that can hardly be accepted if science is taken to have the last word about what is true. Accordingly, it becomes necessary to produce some rational assessment of the truth claims of the different forms of experience, to try to think out a scheme in which justice is done to them all. Many familiar systems of metaphysics profess to do just that; among others there are Materialism, which favours the claims of science; Idealism, which sees deeper truth in religion and the moral life; and the peculiar dualism of the 18th-century German philosopher Immanuel Kant, which holds that science gives the truth about phenomena, while reserving a noumenal, or supersensible, sphere for moral agency.

This conception of metaphysics as offering an account of the world or, as is more often said, of experience as a whole, accords more obviously with the position of those who see ultimate reality as immanent, or inherent in what is immediately known, than of those who take it to be transcendent, or beyond the limits of ordinary experience. It is possible, in fact, to subscribe to the legitimacy of metaphysics as so understood without postulating the existence of any special entities known only to the metaphysician—a claim that plain men have often taken to connect metaphysics with the occult. This is not to say, of course, that metaphysical problems admit of easy solutions when understood along these lines. There is a variety of widely different ways of taking the world as a whole: depending on which aspect or aspects of experience the individual metaphysician finds especially significant; each claims to be comprehensive and to confute the claims

of its rivals, yet none has succeeded in establishing itself as the obviously correct account. Even systems that are widely condemned as impossible, such as Materialism, turn out in practice to command constantly renewed support as new discoveries in the sciences suggest new ways of dealing with old difficulties. A cynic might take such facts as meaning that people subscribe to theories of this sort more as a matter of emotional than of rational conviction; metaphysics, as Bradley remarked with surprising frankness, consists in the finding of bad reasons for what one believes upon instinct.

The science of first principles. Another phrase used by Bradley in his preliminary discussion of metaphysics is "the study of first principles," or ultimate, irrefutable truths.

First principles as basic truths

Metaphysics could be said to provide a theory of first principles if it furnished men with a set of concepts in the light of which they could arrive at the connected account of experience as a whole just spoken of, and the two descriptions of the subject would thus be two sides of a single coin. The idea that metaphysics has to do with first principles, however, has wider implications.

The term "first principles" is a translation of the Greek word *archai*. An arche is something from which an argument proceeds—it can be either a primary premise or an ultimate presupposition. Plato, in a famous passage in *Politeia* (*The Republic*), contrasted two different attitudes to archai: namely that of the mathematician, who lays down or hypothesizes certain things as being true and then proceeds to deduce their consequences without further examining their validity; and that of the dialectician, who proceeds backward, not forward, from his primary premises and then seeks to ground them in an arche that is not hypothesized at all. Unfortunately, no concrete details exist of the way in which Plato himself thought this program could be carried out; instead he spoke of it only in the most general terms. The suggestion, nevertheless, that metaphysics is superior to any other intellectual discipline in having a fully critical attitude toward its first principles is one that still continues to be made, and it needs some examination.

As regards mathematics, for example, it might be said that mathematicians could be uncritical about the first principles of their science in the following ways: (1) They might take as self-evidently true or universally applicable some axiom or primary premise that turned out later not to possess this property. (2) They might assume among their first principles certain propositions about existence—to the effect that only certain kinds of things could be proper objects of mathematical inquiry (rational as opposed to irrational numbers, for example)—and time might indeed reveal that the assumption was inappropriate. The remedy for both sorts of error, however, is to be found within the realm of mathematics itself; the development of the discipline has consisted precisely in eliminating mistakes of this kind. It is not clear even that the discovery and removal of antinomies in the foundations of mathematics is work for the metaphysician, although philosophically minded persons like Gottlob Frege, a German mathematician and logician, and Bertrand Russell, perhaps the best known English philosopher of the 20th century, have been much concerned with them. The situation is not fundamentally different when the empirical sciences are considered. Admittedly, the exponents of these sciences give more hostages to fortune insofar as they have to assume from the first the general correctness of the results of other disciplines; there can be no question of their checking on these for themselves. Mathematicians, too, begin by assuming the validity of common argument forms without making any serious attempt to validate them, and there is nothing seriously wrong with their proceeding in this manner. If confidence in bad logic has sometimes been responsible for holding up mathematical advance, bolder mathematicians have always known in practice that the right thing to do is to let the argument take them wherever it will on strictly mathematical lines, leaving it to logicians to recognize the fact and adjust their theory at their convenience.

It thus seems that the assertion that a special science like mathematics is uncritical about its archai is false; there is a sense in which mathematicians are constantly strengthening their basic premises. As regards the corresponding claim about metaphysics, it has at one time or another been widely believed (1) that it is the business of metaphysics to justify the ultimate assumptions of the sciences, and (2) that in metaphysics alone there are no unjustified assumptions. Concerning (1), the question that needs to be asked is how the justification is supposed to take place. It has been argued that the metaphysician might, on one interpretation of his function, be said to offer some defense of science generally by placing it in relation to other forms of experience. To do this, however, is not to justify any particular scientific assumptions. In point of fact, particular scientific assumptions get their justification, if anywhere, when a move is made from a narrower to a more comprehensive science; what is assumed in geology, for example, may be proved in physics. But this, of course, has nothing to do with metaphysics. The difficulty with (2) is that of knowing how any intellectual activity, however carefully conducted, could be free of basic assumptions. Some metaphysicians (such as Bradley and his Scottish predecessor J.F. Ferrier) have claimed that there is a difference between their discipline and others insofar as metaphysical propositions alone are self-reinstating. For example, the Cartesian proposition *cogito, ergo sum* ("I think, therefore I am") is self-reinstating: deny that you think, and in so doing you think; deny that you exist, and the very fact gives proof of your existence. Even if it could be made out that propositions of this kind are peculiar to metaphysics, however, it would not follow that everything in metaphysics has this character. The truth is, rather, that no paradox is involved in denying most fundamental metaphysical claims, such as the assertion of the Materialist that there is nothing that cannot be satisfactorily explained in material terms or the corresponding principle of Aristotle that there is nothing that does not serve some purpose.

Metaphysicians as self-critical

The view that metaphysics, or indeed philosophy generally, is uniquely self-critical is among the myths of modern thought. Philosophers rely on the results of other disciplines just as other people do; they do not pause to demonstrate the legitimacy of the principles of simple arithmetic before entering on calculations in the course of their work, nor do they refrain from employing the reductio ad absurdum type of refutation (*i.e.*, showing an absurdity to which a proposition leads when carried to its logical conclusion) until they have assured themselves that this is a valid way of confuting an opponent. Even in their own field they tend, like painters, to work within traditions set by great masters rather than to think everything out from scratch for themselves. That philosophy in practice is not the fully self-critical activity its exponents claim it to be is shown nowhere more clearly than in the reception that philosophers give to theories that are unfashionable; they more often subject them to conventional abuse than to patient critical examination. It is, nevertheless, from the conviction that philosophy, and especially metaphysical philosophy, operates without unjustified assumptions that current claims about the superiority of this branch of thinking derive their force. This conviction connects with the views already mentioned, that metaphysics is the science of first principles and that the principles in question are ineluctable in the sense that they are operative in their own denial.

METAPHYSICS AND OTHER BRANCHES OF PHILOSOPHY

The view of metaphysics as the queen of the sciences

It may be useful at this point to consider the relations of metaphysics to other parts of philosophy. A strong tradition, derided by Kant, asserted that metaphysics was the queen of the sciences, including the philosophical sciences. The idea presumably was that those who worked within fields such as logic and ethics, as well as physicists and biologists, proceeded on assumptions that in the last resort had to be approved or corrected by the metaphysician. Logic could be conceived as a special study complete in itself only if the logician were allowed to postulate a correspondence between the neat and tidy world of propositions, which was the immediate object

of his study, and the world existing in fact; metaphysics might and sometimes did challenge the propriety of this postulate. Similarly, ethics, like law, could get nowhere without the assumption that the individual agent is a self-contained unit answerable in general terms for what he does; metaphysics had the duty of subjecting this assumption to critical examination. As a result of such claims it was widely believed that any results obtained by logicians or ethicists must at best be treated as provisional; followers of Hegel, who advanced these claims with passionate conviction, were inclined in consequence to regard logic and ethics alike as minor branches of philosophy. It has been a feature of 20th-century philosophical thought, especially in Britain and the United States, to dispute these Hegelian contentions and argue for the autonomy of ethics and logic; that is, for their independence of metaphysics. Thus, formal logicians of the school of Frege and Russell were apt to claim that the principles of logic applied unequivocally to all thinking whatsoever; there could be no question of their having to await confirmation, still less correction, from the metaphysician. If metaphysical arguments suggested that fundamental laws of logic such as the principle of noncontradiction—that a statement and its contradictory cannot both be true—might not be in order, the only conclusion to draw was that such arguments must be confused: without observation of the laws of logic there could be no coherent thinking of any sort.

Similarly, G.E. Moore, in a celebrated section of his *Principia Ethica* (1903), tried to show that statements like "This is good" are *sui generis* and cannot be reduced to statements of either natural or metaphysical fact; the Idealist belief that ethics ultimately depends on metaphysics rested on a delusion. Moore perhaps failed to see the force of the Idealist challenge to the individualist assumptions on which much ethical thinking proceeds, and he did not note that, in one respect at least, ethical results can be dependent on those of metaphysics: if metaphysics shows that the world is other than it is initially taken to be, conclusions about what to do must be altered accordingly. Again, the reaction among logicians to Hegelian attempts to merge logic into metaphysics certainly went too far. There is a genuine philosophical problem about the relation between the world of logic and the world of fact, and it cannot be solved by simply repeating that logic is an autonomous discipline whose principles deserve respect in themselves. None of this, however, shows that metaphysics is the fundamental philosophical discipline, the branch of philosophy that has the last word about what goes on in all other parts of the subject.

METAPHYSICS AND ANALYSIS

Modern British and American philosophers commonly describe themselves as engaged in philosophical analysis, as opposed to metaphysics. The interests of a metaphysician, according to this view, are predominantly speculative; he wants to reveal hitherto unknown facts about the world and on that basis to construct a theory about the world as a whole. In so doing he is necessarily engaged in activities that rival those of the scientist, with the important difference that scientific theories can be brought to the test of experience, whereas metaphysical theories cannot. Eschewing this conception of philosophy as impossible, the critic of metaphysics believes that philosophy should confine itself to the analysis of concepts, which is a strictly second-order activity independent of science and which need involve no metaphysical commitment.

Analysis in philosophy

The notion of analysis in philosophy is far from clear. Analysis on any account is meant to result in clarification, but it is not evident how this result is to be achieved. For some, analysis involves the substitution for the concept under examination of some other concept that is recognizably like it (as Gilbert Ryle, an English Analyst, elucidated the concept of mind by replacing it with the notion of "a person behaving"); for others, analysis involves the substitution of synonym for synonym. If the latter understanding of analysis is required, as in Moore's classic example of the analysis of brother as male sibling, not much enlightenment is likely to ensue. If, however, the philosopher is permitted to engage in what is sometimes pejoratively described as "reductive analysis," he will produce interest at the cost of reintroducing speculation. Ryle's *Concept of Mind* (1949) is a challenging book just because it advances a thesis of real metaphysical importance—that one can say everything one needs to say about minds without postulating mental substance.

A further aspect of the situation that deserves mention is this. If it is the case, as is often claimed, that analysis can be practiced properly only when the analyst has no metaphysical presuppositions, by what means does he select concepts for analysis? Would it not be appropriate for him, in these circumstances, to take any concept of reasonable generality as a suitable subject on which to practice his art? It turns out, in fact, however, that the range of concepts commonly recognized as philosophical is more limited than that, and that those concepts to which Analytic philosophers give their attention are chosen because of their wider philosophical bearings. Thus, recent philosophers have paid particular attention to the concept of knowledge not just because it is a notion whose analysis has long proved difficult but also because on one account at least it involves an immediately experienced mental act—something that many Analysts would like to proscribe as mythical. Similarly, the celebrated analysis of the idea of causality put forward by David Hume was not undertaken out of idle curiosity but with a wider purpose in mind: to undermine both the Aristotelian and the Cartesian views of the world and to substitute for them an atomism of immediate appearances in which all objects were "loose and separate"—that is, logically independent one of another. The insight into the constitution of nature promised in different ways by Aristotle and Descartes was an illusion, the truth being that scientific advance serves only to "stave off our ignorance a little." What Hume said about causation connects internally with his views about what exists. Despite his polemic against books of "divinity and school metaphysics," he had a metaphysics of his own to recommend.

Historical use of analysis by metaphysicians

The truth is that metaphysics and analysis are not separate in the way modern Analytic philosophers pretend. The speculative philosophers of the past were certainly not averse to analysis: witness the splendid discussion of the concept of knowledge in Plato's *Theaetetus*, or, for a more recent example, Bradley's account of the meanings of "self." The legend that a metaphysical philosopher has his eye so firmly set on higher things that he is entirely careless of the conceptual structure he seeks to recommend is absolutely without foundation. A metaphysical philosopher is a philosopher after all: argument and the passion for clarification are in his blood. Although some contemporary philosophers profess to undertake analysis entirely for its own sake and without explicit metaphysical motivation, it may be doubted if their claim is capable of being sustained. The "logical analysis" practiced by Russell in the early part of the 20th century was not metaphysically neutral, nor was the analysis of the Logical Positivists, who recommended a strongly scientific view of the world. Some current analytic work is motivated less by the desire to forward an overall theory than by a wish to destroy a prevailing or previously held theory that is considered objectionable. To seek to overthrow a metaphysical theory, however, is itself to engage in metaphysics—not very interesting metaphysics, perhaps, but metaphysics all the same.

It may be added, as a historical note, that the Rationalist philosophers of the 17th and 18th centuries, who emphasized the predominant role of reason in the construction of a system of knowledge, believed that the philosopher's task fell into two parts. He must first break down complex concepts into their simple parts; this was a matter of analysis. Then he must proceed to show how knowledge of these simples would serve to explain the detailed constitution of things; this would involve synthesis. That there are deep obscurities in this program—*e.g.*, whether it is a matter of analyzing concepts or getting down to the simplest elements of things—is less important in the present context than that analysis and synthesis were thus taken to be complementary. The classical statement of this point of view is to be found in Descartes's *Discours de la*

méthode (1637; *Discourse on Method*), with the corresponding passages in the *Regulae ad Directionem Ingenii* (published posthumously 1701; *Rules for the Direction of the Mind*). That the idea persisted well into the 18th century is evidenced by the remarks made by Kant in his essay *Untersuchung über die Deutlichkeit der Grundsätze der natürlichen Theologie und der Moral* (1764; *Inquiry into the Distinctness of the Principles of Natural Theology and Morals*), in which he said that metaphysics was not yet in a position to pass beyond the stage of analysis to that of synthesis. He did not mean that for the time being philosophy must remain entirely nonmetaphysical, in the way some moderns suppose it can, but rather that it needs to go on elaborating a conceptual scheme, which, however, cannot be used constructively until it is complete. Actually, Kant belied his own professions at the time insofar as he thought himself in possession of a definitive proof of God's existence, which he explained in his essay *Der einzig mögliche Beweisgrund zu einer Demonstration des Daseyns Gottes* (1763; "The Only Possible Ground for a Demonstration of the Existence of God"). This, however, only illustrates the not very surprising fact that philosophers are often less clear about the nature of their own activities than they think.

Problems in metaphysics

To give a comprehensive account of the main problems of metaphysics in the space of a few pages is clearly quite impossible. What follows is necessarily highly selective and to that extent misleading; it, nevertheless, attempts to offer an introduction to metaphysical thinking itself rather than reflection on the nature of metaphysics.

THE EXISTENCE OF FORMS, CATEGORIES, AND PARTICULARS

Forms. The early Greek philosophers asked the question *ti to on*, "What is existent?" or "What is really there?" They originally interpreted this as a question about the stuff out of which things were ultimately made, but a new twist was given to the inquiry when Pythagoras, in the late 6th century BC, arrived at the answer that what was really there was number. Pythagoras conceived what is there in terms not of matter but of intelligible structure; it was the latter that gave each type of thing its distinctive character and made it what it was. The idea that structure could be understood in numerical terms was probably suggested to Pythagoras by his discovery that there are exact correlations between the lengths of the strings of a lyre and the notes they produce. By a bold extrapolation he seems to have surmised that what held in this case must hold in all cases.

Platonic theory

The Pythagorean theory that what is really there is number is the direct ancestor of the Platonic theory that what is really there is Forms, or Ideas (*eidē*, or *ideai*). Plato's Forms were also intelligible structures and not material elements, but they differed from Pythagorean numbers by being conceived of as separately existent. There was, as Plato put it, a "place accessible to the intelligence," which was the place, or realm, of Forms. Each Form was a genuine existent, in the sense of being precisely what it pretended to be; the Form of Beauty, for example, was beautiful through and through. By contrast, the many particular things that partook of or resembled what was truly beautiful were one and all defective. However beautiful any one of them might be, it was also in another respect lacking in beauty. It turned out to possess contradictory characteristics, and as such could never be identified with true reality.

Plato had taken over from his predecessor Heracleitus, who flourished at about the beginning of the 5th century BC, the doctrine that the world of sensible things is a world of things in constant flux; as he put it in the *Theaetetus*, nothing *is* in this world because everything is in a state of becoming something else. Forms were needed to provide stable objects for knowledge as well as to answer the question of what is ultimately real. Although Plato played down the reality of sensible things, making them mere objects of opinion and describing them as falling between what is and what is not, he did not deny their existence. It was not his thesis that Forms alone exist. On the contrary, he appears to have held that God (who was certainly not a Form) had somehow fashioned the physical world on the model of the Forms, using space as his material. This is the description that is given in the *Timaeus*, in a passage that Plato perhaps meant his readers not to take quite literally but that stated his view as plainly as he thought it could be stated. In this passage God appears in the guise of the "Demiurge," although he is referred to freely in other Platonic dialogues. Souls were also distinct from Forms in Plato's thought.

In the discussions that developed around the theory of Forms, many difficulties were revealed, most of them familiar to Plato himself. The question of how the one Form was supposed to relate to the many particulars that participated in or resembled it was nowhere satisfactorily answered. The difficulty turned on how the Form was to be thought of at once as an existent and as a structure. Plato seemed on occasion to think of it as a structure hypostatized, or given real existence. This thesis led to the antinomies exposed in the "third man" argument. According to this theory, particular men were alleged to be human because of their relationship to "Man himself"; *i.e.*, the Form of man. But whence did the latter derive its nature? Must there not be a second Form to explain what the first Form and its particulars have in common, and will not this generate an infinite regress? Again, the problem of the precise population of the world of Forms never got a definitive solution, perhaps because the theory of Forms was put to more than one purpose. Sometimes it was said that there is a Form corresponding to every general word, but elsewhere the theory was that what is merely negative (*e.g.*, lifeless) has no need of a special Form, nor does what is manufactured. There is even a question as to whether trivial everyday things such as mud and hair and dirt have Forms, though it is agreed that there is a Form of man.

The problems just referred to were stated trenchantly in Plato's dialogue the *Parmenides*; the discussion there ends with the statement that the Forms must be retained if an account of intelligible discourse is to be given, but no indication is offered as to how the theory is to be refurbished. Some Platonic scholars have inferred that Plato virtually gave it up, but such evidence as there is suggests that he only transformed it into a theory of Form-numbers, more openly Pythagorean than the earlier version. There are many references in Aristotle to this theory of Form-numbers, but no writing of Plato's own on the subject has survived, and it is virtually impossible at this late stage to say what this theory really comprised.

One further feature of the theory of Forms must be mentioned here: the view that there is a supremely important Form, the Form of goodness, or of the Good, which somehow determines the contents of the world of Forms and brings order into it. In a celebrated but brief and tantalizing passage in *Politeia*, the Form of the Good is spoken of as being to the intelligible realm what the sun is to the visible realm; just as the sun makes living things grow and renders them visible, so the Good is responsible for the existence and intelligibility of Forms, though it is itself "on the other side of Being." This passage had a tremendous historical influence on the Neoplatonists, who saw it as anticipating the ultimate ineffable reality—the One, from which everything describable was in some way an emanation—in which they came to believe. It seems possible, however, that Plato had no such mystical thoughts in mind but simply wanted to say that the world of Forms is ordered through and through, everything in it being there for a purpose. The Form of Good is, in fact, the counterpart of the nous (Mind) of Anaxagoras, another of Plato's predecessors, which was supposed to arrange everything for the best.

Aristotelian doctrine

Categories and universals. The most famous critic of Plato's theory of Forms was Aristotle, who devised his doctrine of categories largely to counter it. According to this doctrine, "being is spoken of in many ways": one can say that there are such things as individual horses, but one can also say that there is such a thing as being a horse, or as being upside down. Expressions can be classified

under various heads: predicates signify substances (*e.g.*, "man" or "horse"), qualities (*e.g.*, "white"), relations (*e.g.*, "greater"), quantities (*e.g.*, "three yards long"), time (*e.g.*, "last year"), and so on—sometimes Aristotle listed ten categories, sometimes only eight. The kind of being that any predicate possesses, however, is derivative in comparison with the being of an individual substance, a particular man or a particular horse. It is such things that exist in the primary sense, and it is upon their existence that the existence of other types of being depends. Or, to put the point in not quite Aristotelian terms, primary substances are the only concrete existents; Socrates, the bearer of a proper name, exists in a way in which humanity or whiteness or being greater do not. The latter are really no more than abstractions, and nothing but confusion can arise from neglecting that fact.

Mention has already been made of the difficulties into which this doctrine led when it came to describing primary substances; it appeared that these entities could not be characterized but only named or pointed to, a conclusion accepted much later by Ludwig Wittgenstein, a 20th-century philosopher, in his *Tractatus Logico-Philosophicus* and by Russell in his lectures on logical atomism. These difficulties, however, were not seen at the time the theory was promulgated, and it is more important here to emphasize the fact that it undermined any doctrine of the Platonic type. To argue that Forms, or numbers, alone are real is to argue for the reality of abstractions; to put the point succinctly, beauty exists only so long as something is beautiful, and that something must be a concrete individual. Or if this is not quite true (for, after all, it could be said that there is such a thing as having a million sides even if nothing in fact has a million sides), concrete existence must precede abstract existence in some cases at least: the "*x*" in "*x* is red" must sometimes be replaceable by an actual rather than a merely possible entity.

The problem of universals

A prominent subject of philosophical discussion in the Middle Ages was what came to be known as the problem of universals, which concerned the ontological status, or type of existence, to be assigned to the referents of general words. One of Plato's critics had said, "I see particular horses, but not horseness"; and Plato had answered, "That is because you have eyes but no intelligence." There can be no doubt that Plato thought that horseness, the Form of horse, or Horse itself, to use his own expression, was something that existed separately; it could be discerned not by the bodily eyes but by the eye of the soul. The view that besides individual horses there also exists the Form of horse was known in the Middle Ages as Realism. Aristotle was also alleged to be a Realist, because he too thought that Forms were really there, although only as embodied in particular instances. More skeptical philosophers denied the reality of universals altogether, some identifying them with thoughts (conceptualists), others with mere names (nominalists).

The dispute about universals was in fact very confused. At least two quite separate issues were involved. First of all, there was the question about the status to be assigned to whatever it was that predicates referred to; this question seemed urgent just because, for example, geometricians were able to discuss the properties of the triangle or the circle. What and where were the triangle and the circle? In fact, the Aristotelian doctrine of categories had already indicated that the being of any predicate was necessarily different from that of primary substances; the circle did not and could not exist as this man or this horse did. When Aristotle is described as a Realist in the dispute about universals, the description is very misleading. In one sense he did not believe that universals are real at all; in another sense, however, he did, and this is where the second issue arose. Some people who denied the reality of universals wanted to say that all classification is artificial; the descriptions men give of things depend upon their interests as much as upon what is really there. Aristotle, by contrast, believed in a doctrine of natural kinds; he thought that every particular horse, for example, embodied the form or objective essence of horse, which was accordingly a genuine, if abstract, constituent of the world. The question of the extent to which classification is artificial is clearly quite different from that of the status of universals; it remains to be answered even if the latter problem is dismissed, as it is by modern philosophers who say that only proper names and individuating phrases have referents; general words do not. These differences, however, were not clearly seen either in the Middle Ages or during the 17th century, when the whole question was discussed at length by philosophers such as Thomas Hobbes and John Locke.

Basic particulars. In discussions of the problem of universals, it was frequently claimed, especially by nominalists, that only particulars exist. The notion of a particular is in many respects unclear. Strictly speaking, the terms particular and universal are correlatives; a particular is an instance of universal (for example, this pain, that noise). It would seem from this that particulars and individuals should be the same, but there are writers who distinguish them. Bradley, in his *Principles of Logic* (1883), treated particulars as mere momentary instantiations of universals and contrasted them with individuals as continuants possessing internal diversity. An individual can be not merely identified but also re-identified; because it lasts through time, it may possess incompatible attributes at different periods of its history. A particular, on the other hand, is nothing but an instantiation of an attribute and as such must possess that attribute if it is to be anything. Similarly, a particular can be met with once, but not again; as time moves on, it passes out of existence and is replaced by another particular that may resemble it but is not literally identical with it.

If particulars and individuals are thus distinguished, it is by no means clear that only particulars exist, or indeed that they exist at all; it could be that they are no more than abstract aspects of genuinely concrete entities such as persons or material things. But there are arguments on the other side, advanced in a variety of forms by David Hume and Bertrand Russell. Hume believed that the ultimate constituents of the world were either impressions or their fainter copies, ideas; both were species of perceptions. Impressions he defined as "internal and perishing existences"; they were of various kinds, embracing feelings as well as such things as experienced colours and smells, but all were at best extremely short-lived. Impressions arose in human consciousness from unknown causes; their existence could not, however, be denied. By contrast, the existence of continuing and independent material objects and of continuing minds was extremely precarious; analysis showed both to be no more than bundles of perceptions, united by certain relations, and Hume more than once referred to them as "fictions," although it turned out on examination that they were not fictions in the way ghosts are. Hume's reasons for advancing these views were primarily epistemological; he thought that statements about continuants were all open to doubt, although statements about the contents of immediate experience could not be challenged. When it was a question of what really existed, the only sure answer was items in consciousness—namely, impressions and ideas.

Hume's theory of particulars

Russell, who was generally sympathetic to this answer, added another argument derived from logic: proper names, he said, were names of particulars, which must accordingly exist. Ordinary proper names (such as "Socrates") had other functions than to denote, but logically proper names ("this" was Russell's example) served simply to pick out objects of immediate acquaintance. Russell was apparently unabashed by the consequence that such objects would be both private to the experience of particular persons and of very brief duration; he thought his doctrine of "logical constructions," which allowed for "inferred entities" on the basis of what is immediately certain, would provide the publicity and continuity necessary to do justice to actual experience. These assumptions, however, have met with serious criticism. P.F. Strawson, a British philosopher whose thought centres on the analysis of the structure of ordinary language, especially in his *Individuals: An Essay in Descriptive Metaphysics* (1959), not only attacked Russell's account of proper names but argued that experience demands a framework of basic particulars that are not Russell's momentary private objects but continuing

Russell's theory of particulars

public existents—in fact, individuals in the terminology explained above. If experience consisted of nothing but sounds, the minimum prerequisite of intelligibility would be that there should be a continuing master sound, an analogue in this medium of continuing material substance in the material order. Without such basic particulars as continuing material things, identification and reidentification would be impossible. Strawson conceded that persons as well as things were genuine continuants, but maintained all the same that the hypothesis that reality might consist of nothing but minds was quite untenable. Minds are no more than aspects of persons, and persons have bodies as well as minds. Strawson agreed that disembodied existence was logically possible, but added that such existence would make no sense except as a survival of embodied existence in a common public world.

If this is correct, what exists cannot consist, as Hume supposed, of momentary items but must rather take the form of substances in the Aristotelian sense. These act as basic particulars in the actual intellectual scheme men adopt. Strawson, however, was not content merely to assert this fact; he wanted to argue that things must be like this if reference and description in their familiar form are to be possible at all. His main theory, which plainly owes a debt to Kant as well as to Wittgenstein, was worked out with primary reference to the physical world. It would be interesting to know if an examination of social reality would yield comparable results: whether individual persons or something larger—continuing societies or institutions—should be taken as basic particulars in that sphere. Many philosophers assert dogmatically that a society is nothing but an aggregate of its individual members. Nevertheless, men are members of society in virtue of their performance of a number of social roles, and role itself is a concept that makes sense only if the notion of society is presupposed. In one sense, a society is nothing apart from its members; remove them, and it would disappear. Equally, however, the members themselves are what they are because of their various roles; it is arguable that they would be nothing apart from their social relations. Hence, the force of Bradley's remark is evident, namely, that "the 'individual' apart from the community is not anything real."

It remains to add here that a number of philosophers have tried to argue that the basic items in reality should be described not as substances but in some other terms. Russell at one stage in his career spoke of the world as consisting of events; his former colleague A.N. Whitehead made the notion of process central in his metaphysics. Developments in modern physics undoubtedly lend a certain plausibility to these and similar views. Yet it remains difficult to understand what an event could be in which nothing was concerned, or how there could be a process in which nothing was in process. Event and process, in fact, are expressions that belong to derivative categories in the general Aristotelian scheme; like all other categories, they depend on the category of substance. If the latter is removed, as these metaphysicians propose to remove it, it is hard to know what is left.

THE EXISTENCE OF GOD

Proofs of the existence of God

Perhaps the most celebrated issue in classical metaphysics concerned the existence of God. God in this connection is the name of "the perfect Being" or "the most real of all things"; the question is whether it is necessary to recognize the existence of such a being as well as of things that either are or might be objects of everyday experience. A number of famous arguments have been advanced from the time of the Greeks in favour of the thesis that such a recognition is necessary. The neatest and most ingenious was the a priori argument of St. Anselm in the 11th century, who said that "that than which nothing greater can be conceived" must exist in fact as well as in thought, for if it existed only in thought and not in fact, something greater than it could be conceived, namely the same thing existing in fact. God necessarily exists, because the idea of God is the idea of that than which nothing greater can be conceived. This is the argument later known as the ontological proof. Relatively few philosophical theologians, either in the Middle Ages or later, could bring themselves to accept this bold piece of reasoning (although Descartes, Spinoza, Leibniz, and Hegel all accepted it in principle); most preferred to ground their case for God's existence on premises that claimed to be empirical. Thus, St. Thomas Aquinas, perhaps the most influential Scholastic philosopher, in the 13th century argued that to explain the fact of motion in the world, the existence of a prime mover must be presupposed; that to account for contingent or dependent being the existence of something that is necessary or self-contained must be presumed; that to see why the world is orderly and why the different things in it fit together harmoniously, a situation that might not have obtained, a Creator who fashioned it on these lines must be postulated—adding in each case "and this all men call 'God'." These are versions of the first cause argument and the argument from design, which were to figure prominently in the thinking of later theistically inclined metaphysicians.

The first cause argument should, perhaps, be examined in somewhat greater detail, because it both has an immediate plausibility and lies at the basis of many different kinds of metaphysical systems (that of Hegel, for example, as well as that of Aquinas). The argument begins with the innocent-looking statement that something contingent exists; it may be some particular thing, such as oneself, or it may be the world in general (thus, the description of the proof as being *a contingentia mundi,* or "from the contingency of the world"). In describing oneself or the world as contingent, one means only that the thing in question does not exist through itself alone; it owes its being to the activity of some other thing, as a person owes his being to his parents. Contingent things are not self-complete; they each demand the existence of something else if they are to be explained. Thus, the move is made from contingent to necessary being; it is felt that contingent things, of whatever order, cannot be endlessly dependent on other contingent things but must presuppose a first cause that is self-complete and so exists necessarily. In Hegel the necessary being is not a separate existent but, as it were, an order of things; the loose facts of everyday life and even of science are said to point to a system that is all-embracing and in which everything is necessarily what it is. The principle of the argument, however, is unchanged despite the change in the conclusion.

Criticisms of proofs

Damaging criticism was brought against all the traditional arguments for God's existence by Hume and Kant in the 18th century. The ontological proof was undermined by the contention that "being is not a real predicate"; existence is not part of the concept of God in the way in which, for example, being all-powerful is. To say that something exists is not to specify a concept further but to claim that it has an instance; it cannot be discovered whether a concept has an instance by merely inspecting it. The first cause argument, it was contended, suffers from two fatal weaknesses. Even if it is correct in its assertion that contingent being presupposes necessary being, it cannot identify the necessary being in question with God (as happened in each of the Thomistic proofs) without resurrecting the ontological argument. If it is true, as supporters of the causal proof suppose, that God alone can answer the description of a necessary being, then whatever exists necessarily is God and whatever is God exists necessarily. Modern supporters of the causal proof have tried to meet this objection by saying that the equivalence is one of concepts, not of concept and existent; the existence of a necessary being is already established in the first part of the argument, and the equivalence in the second part of the argument is between the concept of necessary being and the concept of God. In other words, they distinguish between existence and essence. In the first part of the argument, the existence of a necessary being is proved; in the second part of the argument, the essence of that necessary being is identified with what men call God. Beyond this first contended weakness, however, there are grave difficulties in the move from contingent to necessary existence. Things in the experienced world are causally related, and some account of this relationship can be given in terms of the temporal relations of events; causal relations hold primarily between kinds of events, and a cause is, at least,

a regular antecedent of a specific kind of effect. But when an attempt is made to extend the notion of causality from a relationship that holds within experience to one that connects the experienced world as a whole to something that falls wholly outside it, there is no longer anything firm on which to hold. The activities of God cannot precede happenings in the world because God is, by definition, not in time; and how the relationship is to be understood in these circumstances becomes highly problematic. Some metaphysicians, like some recent theologians, seek to evade the difficulty by saying that God is not the cause of the world but its ground, or again by distinguishing causes of becoming, which are temporal, from a cause of being, which is not. It is doubtful whether these moves do more than restate the problem in different terms.

The argument from design is itself a form of causal argument and accordingly suffers from all the difficulties mentioned above, together with some of its own, as Hume and Kant both point out. Even on its own terms it is wrong to conclude the existence of a Creator rather than an architect. Furthermore, it infers that the being in question has unlimited powers, when all that the evidence seems to warrant is that its powers are very great. The argument lost much of its force by the publication of the English naturalist Charles Darwin's theory of natural selection. The unbroken reign of law throughout natural evolution is impressive, but as a line of reasoning it does not seem to bear close examination.

The metaphysical problem of God's existence is more of an issue today than the problem of universals; there are still thinkers who hope to restate the old proofs in more convincing ways. The ontological proof, in particular, has won renewed attention from thinkers such as Norman Malcolm, a philosopher strongly influenced by Wittgenstein, and Charles Hartshorne, an American Realist whose form of theism is called panentheism (the doctrine of a God who has an unchanging essence but who completes himself in an advancing experience). Increasingly, however, philosophers of religion are preoccupied not with these metaphysical abstractions but with the status and force of actual religious claims. "The most real of all things" is no longer at the centre of their attention: they seek to investigate God as a suitable object for worship.

THE SOUL, MIND, AND BODY

Platonic and Aristotelian theories of the soul

The soul–body relationship. As well as believing in the reality of Forms, Plato believed in the immortality of the human soul. The soul was, he thought, an entity that was fundamentally distinct from the body although it could be and often was affected by its association with the body, being dragged down by what he called in one passage "the leaden weights of becoming." The soul was simple, not composite, and thus not liable to dissolution as were material things; further, it had the power of self-movement, again in contrast to material things. Ideally the soul should rule and guide the body, and it could ensure that this situation persisted by seeing that the bodily appetites were indulged to the minimum extent necessary for the continuance of life. The true philosopher, as Plato put it in the *Phaedo,* made his life a practice for death because he knew that after death the soul would be free of bodily ties and would return to its native element. He also thought that the soul was "akin" to the Forms; it was through the intellect, the purest element in the soul, that the Forms were discovered.

Plato mentioned and attempted to refute alternative accounts of the relationship of soul and body, including a Pythagorean view that described the soul as an "attunement" of the body and thus tried to explicate it as a form or structure rather than an independently existing thing. A theory of this kind was worked out but not taken to its logical conclusion by Aristotle in his treatise *De anima* (*On the Soul*). Aristotle defined soul in terms of functions. The soul of a plant was concerned with nutrition and reproduction, that of an animal with these and with sensation and independent movement, that of a man with all these and with rational activity. The soul was, in each case, the form of some body, and the clear implication of this was that it would disappear as the body in question dissolved. To be more accurate, the soul was the principle of life in something material; it needed the material element to exist, although it was not itself either material or immaterial but, to put it crudely, an abstraction. Even though Aristotle was clearly committed by everything he said in the earlier parts of the *De anima* to the view that the soul is not anything substantial, he nevertheless distinguished toward the end of this work between what he called the active and the passive intellects and spoke of the former in Platonic terms. The active intellect was, it appears, separate from the rest of the soul; it came "from outside" and was in fact immortal. It was, moreover, essential to the soul considered as rational, for "without this nothing thinks." Aristotle thus showed the Platonic side of his thought in the very act of trying to emancipate himself from this aspect of Platonism.

Cartesian theory

The mind–body relationship. In more recent metaphysics less has been heard of the soul and more of the mind; the old problem of the relationship of soul and body is now that of the relationship of mind and body. Most, if not all, subsequent discussion of this subject has been affected by the thinking of Descartes. In his *Meditationes de Prima Philosophia* (1641; *Meditations on First Philosophy*), he argued that there was a total and absolute distinction between mental and material substance. The defining characteristic of matter was to occupy space; the defining characteristic of mind was to be conscious or, in a broad sense of the term, to think. Material substance was, so to speak, all one, although packets of it were more or less persistent; mental substance existed in the form of individual minds, with God as the supreme example. The mental and the material orders were each complete in themselves, under God; it was this fact that made it appropriate for him to use the technical term substance in this context: mental substance and material substance. The logical consequence of this view, drawn by some later Cartesians, was that there can be no interaction between mind and body; all causality is immanent, within one order or the other, and any appearance of mind affecting body or of body affecting mind must be explained as the result of a special intervention by God, who, on the occasion of changes in one substance, brings it about that there are corresponding changes in the other. Descartes himself, however, had no sympathy with this view, which was called occasionalism. On the contrary, he stated explicitly that he was not in his body as a pilot is in a ship but was "more intimately" bound up with it. Mind could affect body and vice versa because mind and body had a specially close relationship, which was particularly evident in the aspects of conscious life that have to do with sensation, imagination, and emotion as opposed to pure thought.

Descartes's conviction that, despite their intimate union in this life, mind is really distinct from body sprang from his confidence in the cogito argument. It was possible, he believed, to doubt the existence of his body (what was certain was only that he had the experience of having a body, and this might be illusory) but not the existence of his mind, for the very act of doubting was itself mental. That mind existed was evident from the immediate testimony of consciousness; that body existed was something that needed an elaborate proof, involving his doctrine of clear and distinct ideas and his attempt to establish the existence of a God who is no deceiver. Apart from this, Descartes appealed to arguments of a broadly Platonic type to bring out what was truly distinctive about mind. He admitted that sensation and imagination could be understood only if referred to the mind–body complex but contended that acts of the pure intellect and of will (here his thought was influenced by that of St. Augustine, the great 5th-century Christian thinker) belonged to the mind as it was in itself. Descartes did not claim to have a philosophical proof of the immortality of the soul—that, in his view, required the assurance of revelation—but he did think that his theory prepared the way for that doctrine by establishing the separate existence of mind.

The Cartesian account of mind and body had many critics even in Descartes's own day. Hobbes argued that nothing existed but matter in motion; there was no such thing

as mental substance, only material substance. Materialism of a sort was also supported by Descartes's correspondent Pierre Gassendi, a scientist and Epicurean philosopher.

Theory of Spinoza

A generation later Spinoza was to refashion the whole Cartesian metaphysics on bold lines. In place of the two distinct substances, each complete in itself yet each liable to external interference should God will it, Spinoza posited a single substance, God or Nature, possessed of infinite attributes, of which the mental and the material alone are known to men. The "modes," or manifestations, of this substance were what they were as a result of the necessities of its nature; arbitrary will neither did nor could play any part in its activities. Whatever manifested itself under one attribute had its counterpart in all the others. It followed from this that to every mental event there was a precisely corresponding physical event, and vice versa. A man was thus not a mysterious union of two different elements but a part of the one substance that, like all other parts, manifested itself in different ways under different attributes. Spinoza did not explain why it was that physical events could be correlated with mental events in the case of a human being but not in that of, for example, a stone. His theory of psycho-physical parallelism, however, has persisted independently of his general metaphysics and has found supporters even in modern times.

One way in which Spinoza threw fresh light on the mind–body problem was in calling attention to the influence of the body on the mind and in taking seriously the suggestion that they be treated as a single unit. In this respect, his work on the subject was far in advance of the Empiricist philosophers of the next century. Hume notoriously dismissed Cartesian substance as a "chimera" and argued that minds and bodies alike were nothing but "bundles of perceptions," interaction between which was always possible in principle; in practice, however, he stuck to the old-fashioned view that mind is one thing and body another and did nothing to explore their actual relationships. Empiricist philosophy of mind, both in Hume and in his successors, such as James Mill, was generally crude; it consisted largely in an attempt to explain the entire life of the mind in terms of Hume's ontology of impressions and ideas. Nor did Kant make much, if any, advance in this particular direction, convinced as he was of the necessity of accepting an empirical dualism of mind and body. It was left to Hegel and the Idealists to look at the problem afresh and to bring out the way in which mental life and bodily life are intimately bound together. The accounts of action and cognition given by T.H. Green and Bradley, and more recently by R.G. Collingwood, are altogether more enlightening than those of Empiricist contemporaries just because they rest on a less dogmatic basis and a closer inspection of fact.

Modern theories

No metaphysical problem is discussed today more vigorously than that of mind and body. Three main positions are held. First, there are still writers (*e.g.*, H.D. Lewis in his work *The Elusive Mind* [1969]) who think that Descartes was substantially right: mind and body are distinct, and the "I" that thinks is a separate thing from the "I" that weighs 170 pounds. The testimony of consciousness is invoked as the main support of this conclusion; it is alleged that all men know themselves to be what they are, or at least who they are, apart from their bodily lives; it is alleged again that their bodily lives present themselves as experiences—*i.e.*, as something mental. The existence of mind, as Descartes claimed, is certain, that of body dubious and perhaps not strictly provable. Second, there are writers such as Gilbert Ryle who would like to take the Aristotelian theory to its logical conclusion and argue that mind is nothing but the form of the body. Mind is not, as Descartes supposed, something accessible only to its owner; it is rather something that is obvious in whatever a person does. To put it crudely, mind is simply behaviour. Finally, there are many philosophers who, although more generally sympathetic to the second solution than to the first, wish to provide for an "inner life" in a way in which Behaviourism does not; P.F. Strawson is a typical example. To this end they try to assert that the true unit is neither mind nor body but the person. A person is something that is capable of possessing physical and mental predicates alike. This is, of course, to say that the "I" that knows simple arithmetic and the "I" that has lost weight recently are the same. How they can be the same, however, has not so far been explained by supporters of this view.

Aside from these main positions, an interesting development is the stress laid by writers—such as Stuart Hampshire, an "ordinary language" philosopher—on self-activity as the distinguishing characteristic of mind. According to this view, a human being is a body among bodies but is, as Plato said, self-moving as material things are not. That this should be so—that human beings are possessed of wills and can in favourable circumstances act freely—is taken as an ultimate fact neither requiring nor capable of explanation. It is often denied that any scientific discovery could give rational grounds for questioning this fact. It is also stressed that the causality of a human being is fundamentally different from that of a natural subject, intentional action being quite other than mere behaviour determined from without.

The problem of differentiating men and machines

Connected with these topics is the problem, much discussed in recent philosophy as a result of the rise of cybernetics, of what differentiates men from machines. Two answers used to be given: the power to think and consciousness. Now, however, there exist machines whose calculating abilities far surpass those of any human being; such machines may not literally think, but they certainly arrive at conclusions. Furthermore, it is not true that their operations are of a purely routine nature: there is a sense in which they can improve their performance in the light of their "experiences." They even have an analogue of consciousness in the sensitivity they show to external stimuli. These facts suggest that the gap between minds and machines is less wide than it has often been thought to be; they do not, however, destroy it altogether. Human beings possess powers of creative thought unlike anything found in machines; as Noam Chomsky, an American linguistics scholar, has stressed (and as Descartes urged in his *Discours de la méthode*), the ability of human beings to handle language in such a way that they comprehend any one of an infinite number of possible expressions is something that cannot be explained in mechanical terms. Again, as J.R. Lucas, a British philosopher, has argued, human beings have the ability to diagnose and correct their own limitations in a way to which there is no parallel in machines. As some older philosophers put it, man is a being with the power of self-transcendence; he can work within a system, but he can also move to another level and so see the shortcomings of the system. A machine can only work within a system; it operates according to rules but cannot change them of its own accord.

Finally, mention should be made of an extreme Materialist solution to the mind–body problem: this solution holds that states of mind are in fact states of the brain. Supporters of this theory agree that the two are separate in idea but argue that physiology shows that despite this they are contingently identical. What seems to be a state of mind, above all to its possessor, is really a state of the brain, and mind is thus reduced to matter after all. It is not clear, however, why physiologists should be granted the last word on a topic like this, and, even if it were agreed that they should be, the correlations so far established between mental occurrences and states of the brain are at best sketchy and incomplete. Central-state Materialism, as this theory is called, professes to have the weight of contemporary science behind it, but it turns out in fact to have drawn to a remarkable degree on what it thinks will be the science of tomorrow.

NATURE AND THE EXTERNAL WORLD

The problem of the existence of material things, first propounded by Descartes and repeatedly discussed by subsequent philosophers, particularly those working within the Empiricist tradition, belongs to epistemology, or the science of knowledge, rather than metaphysics; it concerns the question of how it can be known whether there is a reality independent of mind. There are, however, problems about nature and the external world that are genuinely metaphysical.

The reality of material things. There is first of all

the question of the status, or standing, of material things, the kind of being they possess. It has been repeatedly suggested by metaphysical philosophers that the external world is in some way defective in reality, that it is a mere phenomenon, something that seems to be what it is not. Plato, as has already been pointed out, held that objects of the senses generally answered this description; they each appeared to possess characteristics that they could not in fact have (water could not be at once hot and cold) and were to that extent delusive rather than real. There was no stability in the world of phenomena and therefore no true reality. In taking this view, Plato drew no contrast between the world of nature and the world of man, although he undoubtedly believed that souls had a superior status. Leibniz, a later philosopher who also followed this general line of thought, began by explicitly opposing souls to material things. To speak precisely, nothing truly existed except monads, and monads were souls, or spiritual beings: all had perceptions, although these varied enormously in degree of clarity (the perceptions of the monads constituting what is commonly called a stone were singularly faint). Although the final description of the world must thus be given in mental terms, it did not follow that nature as normally perceived is a total illusion. Men perceive as well as think, and, although perception is in fact simply a confused form of thought, it is not for that reason to be set aside altogether. The world of nature, the world of things in space and time, is, as Leibniz put it, a "well-founded phenomenon"; it is what all men must judge to be there, given that they are not pure intellects but necessarily remain to some extent prisoners of their senses.

The external world as defective in reality

A theory on somewhat similar lines was worked out by Kant in the *Kritik der reinen Vernunft* (1781; *Critique of Pure Reason*), despite Kant's explicit dissent from Leibniz' account of perception as confused thinking. Kant contrasted a realm of things as they are in themselves, or noumena, with a realm of appearances, or phenomena. The former are unknown, and indeed unknowable, though it seems clear that Kant tended to think of them on lines like those of Leibniz; phenomena do not exist independently but are dependent on consciousness, though not on any one person's consciousness. Kant expressed this position by saying that things phenomenal are empirically real but transcendentally ideal; he meant that they are undoubtedly there for the individual subject, though when examined from the point of view of critical philosophy, they turn out to be conditioned by the mind through the forms of sensibility and understanding imposed upon them. Kant's most striking argument for this conclusion was that space and time are neither, as the English physicist Sir Isaac Newton supposed, vast containers inside which everything empirical is situated nor, as Leibniz had suggested, relations between things confusedly apprehended but are rather what he mysteriously called "pure intuitions," factors inherent in the sensibilities of observers. Without observers space and time disappear along with their contents; but once the human point of view is assumed, in the form of percipients who are directly aware of the world through their senses, space and time become as real as anything—indeed, more real because of their pervasive character. There is nothing that falls within experience that does not have temporal relations, and all the data of the senses have spatial relations as well.

Kant's arguments in support of his revolutionary thesis about space and time unfortunately depend to a large extent on his mistaken philosophy of mathematics, and they have accordingly been discounted by later philosophers. In modern philosophy the issues raised in these discussions survive only in the form of an inquiry into the status of nature as investigated by the natural scientist. Descartes already pointed out that material things in fact have properties different from those they seem to have; they appear to possess secondary qualities such as colour or smell but turn out when thought about strictly to be colourless and odourless lumps of matter occupying and moving about in space. Locke endorsed this distinction between primary qualities (such as extension, motion, figure, and solidity) and secondary qualities; but George Berkeley, a major British Empiricist of the early 18th century, criticized it sharply as absurd: to imagine something that has primary but no secondary qualities is psychologically impossible. For Berkeley the world of the scientist was a fiction and perhaps not even a necessary fiction at that. It seems clear, however, that Berkeley's arguments do not undermine the important distinction between primary and secondary qualities, where the former are treated as fundamental and the latter as derivative; they are valid only against Locke's mistaken claim that primary qualities are objective and secondary qualities subjective. Whatever the explanation, the fact remains that the scientist often knows why the phenomena are as they are, in contrast to the plain man; to that extent nature as he understands it is truer, if not more real, than nature as it is taken to be in everyday experience. Why this should be is not satisfactorily explained by philosophers who follow Berkeley's lead on this question. Nor has either party to the controversy noted sufficiently the extent to which nature as commonly thought of is conceived as penetrated by mind, both when it is taken as intelligible and, still more interestingly, when poets ascribe to it moods or treat it as kindly or hostile. There is analytic work to be done here to which critical philosophers have still to address themselves.

Primary and secondary qualities of material things

The organizing principles of nature. Connected with the questions just discussed are problems about the organizing principles of nature; *i.e.,* about natural causality. It has been said that the Greeks thought of the world as a vast animal (indeed, the conceptual scheme that Aristotle devised for dealing with nature makes sense only if something like this is presupposed). Nature is the sphere in which different kinds of things are all striving to realize their characteristic form; purpose, though not perhaps explicit purpose, governs it throughout. Aristotle was not entirely insensitive to what are now known as the physical and chemical aspects of the universe, but he treated them as subordinate to the biological aspect in a way modern thinkers find surprising. Even the four elements—earth, air, fire, and water—were seen by him as each seeking its natural place in the cosmos. The contrast between this view and that favoured by Descartes could hardly be sharper. According to Descartes nature is not an organism but a mechanism; everything in it, including animal and human bodies, although not including the human mind, must be understood on mechanical principles. In taking this line, Descartes was endorsing a way of thinking that was central in the new physical science developed by Galileo at the beginning of the 17th century and that was to remain central in the thought of Newton. Descartes himself was not a pure mechanist because he believed that mind was governed by principles of its own; his work, however, undoubtedly encouraged the thought, frequently debated at the time of the Enlightenment, that mental life equally with the physical world must be explicable in mechanical terms. This was a position whose validity at the theoretical level Kant reluctantly admitted, only to try to turn its edge by his dichotomy of theory and practice. Everything in nature, including human behaviour, was subject to causal determination. The dignity and uniqueness of man, however, could be preserved because of the fact that in moral action man raised himself above the sphere of nature by thinking of himself as part of a world of free spirits.

Nature as mechanical or teleological

Kant also produced interesting thoughts on the subject of living phenomena. Reflection on the concept of an organism had convinced him that a being of this sort could never be accounted for satisfactorily in mechanical terms; it was futile to hope that someday in the future there would appear a Newton of biology capable of explaining mechanically the generation of even so apparently simple a thing as a blade of grass. To judge or speak of organic phenomena demanded a special principle that was teleological (*i.e.,* related to design or purpose) rather than mechanical. Kant, however, refused to allow that this principle had constitutive force. It belonged, he said, only to "reflective judgment" and thus did not rank alongside the principles of understanding that were so important in physical science. Men must have recourse to a principle of purposiveness in order to speak of living things, but they must not imagine that such recourse would enable

them to explain their existence and behaviour in any strict sense of the term. They have insight only into what they can produce, and what they can produce are machines, not organisms. Many of Kant's detailed remarks on this subject seem outmoded in the light of subsequent scientific developments; nevertheless, the problem he raised is still the subject of vigorous debate among philosophically minded biologists. His emphasis on the uniqueness of the concept of an organism, which he says is only imperfectly explicated in the language of ends and purposes, is particularly valuable.

It remains to mention the seemingly eccentric view of nature taken by Hegel, who regarded it as at once the antithesis to and a prefiguration of the world of spirit. Nature had to exist to provide material for spirit to overcome, although it was a gross mistake to think of it as essentially a lifeless mechanism. Instead of reducing the organic to the inorganic, men should see the latter as pointing forward to the former, which in turn offered a foretaste of the rational structure exhibited by the world of mind. Hegel's disdain for scientists of proved ability, such as Newton and John Dalton, and his endorsement against them of amateur scientists such as the German writer Goethe, make it hard to take his philosophy of nature seriously. It contains, even so, some interesting points, not least the demonstration that in finding nature to be throughout subject to law the scientist is presupposing that it is thoroughly penetrated by mind. To understand these views properly, however, it is necessary to understand Hegel's system as a whole.

SPACE AND TIME

Many metaphysicians have argued that neither time nor space can be ultimately real. Temporal and spatial predicates apply only to appearances; reality, or what is real, does not endure through time, nor is it subject to the conditions of space. The roots of this view are to be found in Plato and beyond him in the thought of the Eleatic philosophers Parmenides and Zeno, the propounder of several paradoxes about motion. Plato conceived his Forms as eternal objects whose true location was nowhere. Similarly, Christian philosophers conceived of God as existing from everlasting to everlasting and as present in all parts of the universe. God was not so much in space and time as the source of space and time. Whatever falls within space and time is thereby limited, for one space excludes another and no two times can be simultaneous. God, however, is by definition an infinite being and so must exist timelessly and apart from space.

Theories of Kant and Bradley

Reference has already been made to the way in which Kant argued for an intimate connection between time and space and human sensibility: that human beings experience things as being temporally and spatially situated is to be connected with the nature of their minds, and particularly with their sensory equipment. Kant was entirely correct to describe space and time as "intuitions," by which he meant that they are peculiar sorts of particulars; he was right again to insist on the centrality in sensing of the notions of here and now, which can be indicated but not reduced to conceptual terms. It is highly doubtful, however, whether he had sufficient grounds for claiming a priori insight into the nature of space and still more that of time; his case for thinking that space and time are "pure" intuitions was palpably inadequate. The lesson to draw from his careful discussion of this subject might well be not that there must be a form of reality lying beyond space and time but rather that nothing can be real that does not conform to spatial and temporal requirements. Space and time are bound up with particularity, and only what is particular can be real.

It was only in a weak sense that Kant denied the reality of time and space. Other philosophers have certainly been bolder, though generally on the basis of a less solid grasp than Kant possessed of what it is to experience temporally and spatially. Thus, Bradley argued against the view that space and time are "principles of individuation" by alleging that no specification of spatial or temporal position, whether in terms of here and now or by the use of spatial coordinates or dating systems, could achieve uniqueness. Any descriptions such as "at 12 o'clock precisely on January 4, 1962" or "just 75 yards due north of this spot" might apply to infinitely many times or places in the universe, for there was nothing to prevent there being infinitely many temporal and spatial orders. Bradley forgot that the whole meaning of a spatial or temporal description is not exhausted when attention is given to the connotations of the terms used; what has to be considered is the words as used in their context, which is that of a person who can indicate his position in space and time because of the fact that he is himself situated in space and time. One cannot express uniqueness in words as such, but he can use words to express uniqueness. Bradley's suggestion that it is possible to conceive of many temporal and spatial orders is by no means free from controversy. In general, men think of all events as happening before, simultaneously with, or after the moment that is called "now," all spatial positions as relating in some way or other to the point that is called "here." In circumstances where this cannot be done, as with events or places in a dream, men dismiss them as quite unreal. That there might be events or places with no relation to their own now and here is something they often refuse to take seriously, though there are theories in modern science that suggest that they are wrong to do so.

It was pointed out earlier that to say that something is unreal in a metaphysical context is often to say that it is unintelligible, and it is not surprising to find that arguments about the unreality of space and time have often turned on conceptual considerations. Thus, it is alleged that there is an incoherency in the notion of space because it claims to be a whole that is logically prior to its parts, and nevertheless turns out in practice to be merely an indefinitely extensible aggregate. Everything that occupies space falls within a wider spatial context; the thought of space as such is, as Kant saw, involved in any spatial description. Yet space as such is something that constantly eludes man's grasp; space, as man knows it, is just one spatial situation after another.

Theory of Bergson

The difficulties found in the notion of time turn on the combination in it of the idea that time is continuous and the idea that it is made up of discrete parts. Henri Bergson, a French philosopher who was concerned with the notions of duration and movement, said that time was experienced as continuous; it was only the "spatialized" time measured by clocks that was taken to have separable parts (minutes, hours, weeks, and so on), and this "public" time was merely conventional. This, however, seems altogether too easy a solution of the problem, for privately experienced time also goes by (one stretch of it follows another), and the thesis that public time is merely conventional is at best highly controversial. It must be allowed that time is commonly thought of as at once flowing and, as it were, subject to arrest. Whether this is, in fact, openly inconsistent may be doubted, but it is on points like this that the metaphysical case in question rests.

Few British or American philosophers discuss these questions now, largely because they have been persuaded by Moore that any attack on such central notions in men's thought as these must be mistaken in principle. As a result, little attention is given to a question that deserves investigation; namely, what is to take the place of space and time in metaphysical thought. Idealist writers constantly said that space and time qualified appearances, and that nothing that did so could fail to be taken up in the higher experience that was experience of reality. But how is this supposed to be done? Time is perhaps cancelled and yet preserved in the idea of eternity, space in the thought of something that is at once omnipresent yet not in any particular place. But what is there that is positive about these notions? The eternal, it is sometimes said, is not to be identified with what lasts through all time; it is, strictly, outside time altogether. But what does it mean to say this? When it is said, for example, that numbers or truths are eternal, the proper inference is that they have nothing to do with time; to inquire when they came into or will go out of existence is to ask a question that is ill posed. When God, however, is said to be eternal, the impression is often given that he has temporal characteristics, although in some higher form. What this higher form is deserves

careful consideration, the result of which might be that it is not the conception of time that is incoherent but the conception of God.

THE CONCEPTION OF SPIRIT

As well as arguing for the separate existence of mental substance, metaphysicians have claimed that mind is, as it were, the key to the understanding of the universe. What exists is spirit, or at least is penetrated by spirit. This is the thesis of Idealism, a type of philosophy that is often derided but that, like its rival Materialism, has a constantly fresh appeal. This view is worth examining in more detail than has so far been possible.

It is best to begin by distinguishing the thesis of Idealism proper from some others with which it is readily confused. Leibniz said that the true atoms of nature were monads or souls; at bottom nothing existed except minds. Berkeley claimed that sensible things have no existence without the mind; there are spirits that experience, including an infinite spirit, and there are the contents of their experiences, but there is no independently existing world of matter. For the philosophers who followed Hegel, both Leibniz and Berkeley were "subjective" Idealists: they conceived of reality in terms of the experiences of individual minds.

Theory of Hegel

Hegel's view, by contrast, was that what exists is not so much pure mind as mind writ large; *i.e.,* the universe is penetrated by mind and exists for the sake of mind, and it cannot be understood unless this fact is grasped. Hegel was thus not committed to denying that there is an independent world of nature but, on the contrary, openly proclaimed it. Nature was there for mind to master it and in so doing to discover itself.

The field in which Hegel first worked out this theory was that of human affairs. The human world may be said to be mind made objective because it consists of a series of structures—examples would be a language, a set of moral or political procedures, a science, a practical art such as medicine—that constitute mental achievements. The mind involved in structures of this kind, however, is collective rather than personal. An art such as medicine or a science such as mathematics is not the invention of any particular individual; and although individuals have contributed and are contributing to the advancement of each structure, they do so not in their personal capacity but as embodying impersonal intelligence.

Because the human world thus embodies mind, or spirit, it needs to be understood in a special way—in terms of what Hegel called "concrete universals." Concepts of this kind are in order when it is a question of grasping a particular sort of subject matter—one in which there are intimate connections between the data under consideration. Connections in nature are, on the surface at any rate, of a purely external character; striking a match, for example, has nothing internally to do with producing a flame. When, however, a historian considers the different stages of some movement or process, or when an anthropologist studies the various aspects of the life of a society, the material they confront is internally related just because it represents the work of mind—not, of course, of mind working in a vacuum but of mind facing and reacting with greater or less intelligence to particular situations. It is not surprising in these circumstances to find that the conceptual structure employed by the student of human affairs is, in important respects, profoundly different from that employed by the student of nature. In the latter, what are in question are constant conjunctions, observed but not understood; in the former, men have insight into what happens or obtains because they can reenact in their own minds the thought behind the material they study.

All this is, or should be, comparatively uncontroversial; it represents the truth behind the claim of Wilhelm Dilthey, a German philosopher and historian of ideas, that human affairs can be understood, as it were, from within, by means of what he called *Verstehen* ("understanding"). But of course it is one thing to say this and another altogether to argue that the universe at large should be construed as if it were mind writ large. What makes Hegelianism intriguing to some and totally implausible to others is precisely that it makes this extravagant claim. As has already been mentioned, the world of nature for Hegel is in one way independent of mind: its being is certainly not its being perceived. It is, nevertheless, relevant to mind in all sorts of important ways: in providing a setting in which mind can act, in constituting an obstacle that mind can overcome, in presenting mind with something seemingly alien in which it can nevertheless find itself insofar as it discovers nature to be intelligible. If Hegel were asked why there was a world of nature at all, his answer would be "for the sake of mind." Just as man's social environment affords opportunities to the individual to come to full knowledge of himself by realizing his differences from and dependence upon others, so the world of nature affords similar opportunities. By transforming the natural scene, men make it their own. In so doing they come to know what they can do, and thus what they are.

All reality as spirit

There is, perhaps, more to this doctrine than appears at first sight. It is, however, easier to assent to it in general terms than to follow Hegel over it in detail. According to the Idealist account, there is in the end only one true description of the universe, namely that which is couched in terms of the concrete universal. Reality is a single self-differentiating system, all the parts of which are intimately connected; it is spirit that expresses itself in the natural and human worlds and comes to consciousness of itself in so doing. Any other account of the matter—for example, that given by the scientist in terms of experienced uniformities—must be dismissed as inadequate. To Hume's objection that there is an absolute logical difference between propositions expressing matters of fact and existence and propositions expressing relations of ideas, Hegel replies brusquely that the distinction is untenable. At a certain level, perhaps, facts are taken as "brute." Even the scientist, however, never abandons his aspiration to understand them—it is only provisionally that he talks in terms of "ultimate inexplicabilities"—and the philosopher knows that the demand to incorporate all knowledge in a single system is not to be denied. It is a demand that, as Hegelians are willing to admit, can in practice never be met but that, nonetheless, ceaselessly makes itself felt. That such is the case is shown by the extraordinary fascination exercised by this strange but remarkable type of philosophy.

To try to understand the universe in terms of spirit is characteristic of philosophers whose main extra-philosophical interests are in the humanities, particularly in historical studies. Relatively few scientifically minded thinkers have followed this line of thought, and many Idealists of repute, including Bradley and Benedetto Croce (an Italian philosopher and literary critic whose major philosophical work was published in four volumes between 1902 and 1917 under the general title *La filosofia dello spirito* ("The Philosophy of the Spirit"), have been least convincing when writing about science. Hegel himself, perhaps, had less sympathy with scientific than with historical aspirations; this is not to say, however, that he was ill-informed about contemporary science. He knew what was going on, but he saw it all from his own point of view, the point of view of one who was entirely convinced that science could not produce any ultimate answers. He valued science but rejected the scientific view of the world.

Types of metaphysical theory

To complement and, in a way, to correct this brief survey of the problems of metaphysics it will be useful at this point to insert a short summary of a number of overall metaphysical positions. Metaphysics, as already noted, professes to deal with "the world as a whole"; the thoughts of a metaphysician, if they are to make any impact at all, must be connected in a system. The object in what follows will be to present in outline metaphysical systems that have exercised and, indeed, continue to exercise a strong intellectual appeal. In all cases but one, these systems were given classical shape by particular philosophers of genius. Relatively little attention, however, will be paid to this fact here because the present concern is with types of view rather than with views actually held. Thus, reference will be made to Platonism instead of to the philosophy of Plato, and so on in other cases.

PLATONISM

The essence of Platonism lies in a distinction between two worlds, the familiar world of everyday life, which is the object of the senses, and an unseen world of true realities, which can be the object of the intellect. The ordinary man recognizes the existence of the former and ignores that of the latter; he fails to appreciate the extent to which his beliefs both about fact and about values are arbitrarily assumed and involve internal contradictions. The philosopher is in a position to show him how insubstantial is the foundation on which he takes his stand. The philosopher can demonstrate how little thought there is in popular conceptions of good and evil, and he can show that the very concept of sense knowledge involves difficulties because knowledge presupposes a stable object, and the objects of sense are constantly changing. The claim, however, is that he can do more than this. Because of the presence in him of something like a divine spark, he can, after suitable preparation, fix his intellectual gaze on the realities of the unseen world and, in the light of them, know both what is true and how to behave. He will not attain this result easily—to get to it will involve not only immense intellectual effort, including the repeated challenging of assumptions, but also turning his back on everything in life that is merely sensual or animal. Yet, despite this, the end is attainable in principle, and the man who arrives at it will exercise the most important part of himself in the best way that is open to him.

Distinction between the world of appearances and the world of realities

That this type of view has an immediate appeal to persons of a certain kind goes without saying. There is ample evidence in poetry and elsewhere of the frequently experienced sense of the unreality of familiar things and the presence behind them of another order altogether. Platonism may be said to build on "intuitions" of this kind; as a metaphysics, its job is to give them intellectual expression, to transfer them from the level of sentiment to that of theory. It is important, however, to notice that Platonism is not just the intellectualizing of a mood; it is an attempt to solve specific problems in a specific way. In Plato's own case, the problems were set by loss of confidence in traditional morality and the emergence of the doctrine that "man is the measure of all things." Plato thought he could counter this doctrine by appeal to another contemporary fact, the rise of science as shown in the development of mathematical knowledge. Mathematics, as he saw it, offered certain truth, although not about the familiar world; the triangle whose properties were investigated by the geometrician was not any particular triangle but the prototype that all particular triangles presuppose. *The* triangle and *the* circle belonged not to the world of the senses but to the world of the intelligence; they were Forms. If this could be said of the objects of mathematical discourse, the same should also be true of the objects of morality. True justice and true goodness were not to be found in popular opinions or human institutions but should be seen as unchanging Forms, eternally existing in a world apart.

Modern philosophers have found much to criticize in this system: as indicated already, they have objected that Forms are not so much existents as abstractions, and they have found the argument from science to morality quite inconclusive because of what they allege to be an absolute dichotomy between fact and value. It may be that nobody today can subscribe to Platonism in precisely the form given it by Plato himself. The general idea, however, has certainly not lost its hold, nor have the moral perplexities to which Plato hoped to find an answer been dissipated by further thought.

ARISTOTELIANISM

For many people, Plato is the type of an other-worldly, Aristotle of a this-worldly philosopher. Plato found reality to lie in things wholly remote from sense; Aristotle took form to be typically embodied in matter and thought it his job as a philosopher to make sense of the here and now. The contrast is to some extent overdrawn for Aristotle, too, believed in pure form (God and the astral intelligences—the intelligent movers of the planets—were supposed to satisfy this description), and Plato was sufficiently concerned with the here and now to want to change human society radically. It remains true, nevertheless, that Aristotelianism is in essentials a form of immanent metaphysics, a theory that instructs men on how to take the world they know rather than one that gives them news of an altogether different world.

Making sense of the here and now

The key concepts in Aristotelianism are substance, form and matter, potentiality and actuality, and cause. Whatever happens involves some substance or substances; unless there were substances, in the sense of concrete existents, nothing could be real whatsoever. Substances, however, are not, as the name might suggest, mere parcels of matter; they are intelligible structures, or forms, embodied in matter. That a thing is of a certain kind means that it has a certain form or structure. But the structure as conceived in Aristotelianism is not merely static. Every substance, in this view, not only has a form but is, as it were, striving to attain its natural form; it is seeking to be in actuality what it is potentially, which is in effect to be a proper specimen of its kind. Because this is so, explanation in this system must be given in teleological rather than mechanical terms. For Aristotle, form is the determining element in the universe, but it operates by drawing things on, so that they become what they have it in themselves to be rather than by acting as a constant efficient cause (*i.e.,* the agent that initiates the process of change). The notion of an efficient cause has a role in Aristotelianism—as Aristotle put it, it takes a man, a developed specimen of his kind, to beget a man; it is, however, a subordinate role and yields pride of place to a different idea, namely, form considered as purpose.

For reasons connected with his astronomy, Aristotle postulated a God. His God, however, had nothing to do with the universe; it was not his creation, and he was, of necessity, indifferent to its vicissitudes (he could not otherwise have been an unmoved mover). It is a mistake to imagine that everything in the Aristotelian universe is trying to fulfill a purpose that God has ordained for it. On the contrary, the teleology of which use is here made is unconscious; although things all tend to an end, they do not in general consciously seek that end. They are like organs in a living body that fulfill a function and yet seemingly have not been put there for that purpose.

As this last remark will suggest, an important source of Aristotelian thought is reflection on natural growth and decay. Aristotle, who was the son of a doctor, was himself a pioneer in natural history, and it is not surprising that he thought in biological terms. What is surprising, and gives his system a continuing interest, is the extent to which he succeeded in applying ideas in fields that are remote from their origin. He was without doubt more successful in some fields than in others: in dealing with the phenomena of social life, for instance, as opposed to those of physical reality. His results overall, however, were impressive enough for his system not only to dominate men's minds for many centuries but to constitute a challenge even today. Men still, on occasions, think like Aristotle, and, as long as that is so, Aristotelianism will remain a live metaphysical option.

THOMISM

Christian metaphysics

The advent of Christianity had important effects in philosophy as in other aspects of human life. Initially Christians were opposed to philosophical claims of any kind; they saw philosophy as an essentially pagan phenomenon and refused to allow the propriety of subjecting Christian dogma to philosophical scrutiny. Christian truth rested on revelation and did not need any certificate of authenticity from mere reason. Later, however, attempts were made to produce a specifically Christian metaphysics, to think out a view of the universe and of man's place in it that did justice to the Christian revelation and nevertheless rested on arguments that might be expected to convince Christians and non-Christians alike. St. Thomas Aquinas was only one of a number of important thinkers in medieval times who produced Christian philosophies; others—such as the philosophers John Duns Scotus in the late 13th century and William of Ockham in the first half of the 14th century—took significantly different views. In selecting the system of Aquinas for summary here, the factor

that has weighed most has been its persistent influence, particularly in postmedieval times. Aquinas was not the only medieval philosopher of distinction, but Thomism is alive as other medieval systems are not.

The central claim of Thomism is that reflection on everyday things and the everyday world reveals it as pointing beyond itself to God as its sustaining cause. Ordinary existents, such as human beings, are in process of constant change. The change, however, is not normally the result of their own efforts, and even when it is, it does not depend on them exclusively. No object in the familiar world can fully account for its own *esse* (*i.e.*, its own act of existing), nor is it wholly self-sufficient; all are affected from without, or at least operate in an environment that is not of their own making. To say this is to say that they are one and all finite. Although finite things can be, and commonly are, stimulated to activity or kept in activity by other finite things, it does not follow that there might be finite things and nothing else. On the contrary, the finite necessarily points beyond itself to the infinite; the system of limited beings, each dependent for its activity on something else of the same kind, demands for its completion the existence of an unlimited being, one that is the source of change in other things but is not subject to change itself. Such a being would be not a cause like any other but a first or ultimate cause; it would be the unconditioned condition of the existence of all other things. Aquinas believed that human reason can produce definitive proofs of the existence of an infinite or perfect being, and he had no hesitation in identifying that being with the Christian God. Because, however, the movement of his thought was from finite to infinite, he claimed to possess only so much philosophical knowledge of the Creator as could be arrived at from study of his creation. Positive knowledge of the divine nature was not available; apart from revelation, man could only say what God is not, or conceive of his attributes by the imperfect method of analogy.

Aquinas worked out his ideas at a time when the philosophy of Aristotle was again becoming familiar in western Europe after a period of being largely forgotten, and many of his detailed theories show Aristotelian influence. He assumed the general truth of the Aristotelian picture of the natural world and the general correctness of Aristotle's way of interpreting natural phenomena. He also took over many of Aristotle's ideas in the fields of ethics and politics. He gave the latter, however, a distinctively different twist by making the final end of man not philosophical contemplation but the attainment of the beatific vision of God; it was Christian rather than Greek ideas that finally shaped his view of the *summum bonum* ("greatest good"). Similarly, his celebrated proofs of God's existence proceeded against a background that is obviously Aristotelian but that need not be presupposed for their central thought to have validity. Thomism can certainly be seen, and historically must be seen, as the system of Aristotle adapted to Christian purposes. It is important, however, to stress that the adaptation resulted in something new, a distinctive way of looking at the world that still has its adherents and still commands the respect of philosophers.

CARTESIANISM

Increased understanding of the physical world

René Descartes worked out his metaphysics at a time of rapid advance in human understanding of the physical world. He adopted from Galileo the view that physical things are not what they are commonly taken to be on the strength of sense experience—namely, possessors of "secondary" properties such as colour, smell, and feel—but are rather objects characterized only by the "primary" qualities of shape, size, mass, and mobility. To understand why a constituent of the physical world behaves as it does, what should be asked is where it is, how large it is, in what direction it is moving, and at what speed; once these questions are answered, its further properties will become intelligible. Descartes held further that all change and movement in the physical world is to be explained in purely mechanical terms. God was needed to give initial impetus to the physical system as a whole, but once it had got going it proceeded of its own accord. To pretend, as the Aristotelians had, to discern purposes in nature was to make the impious claim to insight into God's mind. Descartes applied this theory to the movements of animals as much as to those of inanimate bodies; he thought of both as mere automatons, pushed and pulled about by forces over which they had no control.

Although Descartes thus acquiesced in, indeed emphasized, the mechanistic tendencies of contemporary science, he was far from being a Materialist. Besides material substance there was also thinking substance, and this was in fact wholly different from matter both in kind and in operation. Bodies had as their essence to occupy space; minds were not in space at all. Bodies, again, were determined in their movements; minds were in some sense free, because they possessed will as well as intelligence. Descartes was less explicit on this point than he might have been; the principles on which mental substance is supposed to operate are not made clear, with the result that critics have said that Descartes thought of mental activities in para-mechanical terms. Whether this is true or not, however, there was no reason for Descartes to be in any special difficulty over this point. All he needed to urge was that minds act in the strict sense of the term, which is to say that they take cognizance of their situation and respond more or less intelligently to it. That they can do this differentiates them fundamentally from material things, which are caused to do what they do and are entirely unaffected by rational considerations.

The main crux in Descartes's metaphysics was the difficulty of bringing together the two orders of being, once they were separated. Mention has already been made of the expedient to which later Cartesians were driven in trying to solve this difficulty: in effect, they made the unity of the universe a continuing miracle, dependent upon the grace of God. It is worth mentioning here another move in the same area that many have found instructive. Kant, who was in some respects both a latterday Cartesian and a latter-day Platonist, argued that human activities could be looked at from two points of view. From the theoretical standpoint they were simply a set of happenings, brought about by antecedent events in precisely the same way as occurrences in the natural world. From the standpoint of the agent, however, they must be conceived as the product of rational decision, as acts proper for which the agent could be held responsible. The moment he began to act, a man transferred himself in thought from the phenomenal world of science to an intelligible world of pure spirit; he necessarily acted as if he were not determined by natural forces. The transference, however, was a transference in thought only (to claim any knowledge of the intelligible world was quite unjustified), and because of this the problem of the unity of the universe was dissolved. There was no contradiction in a man's thinking of himself both as a subject for science and as a free originator of action. Contradiction would appear only if he were present in both respects in an identical capacity. But appeal to the doctrine of the two standpoints was thought by Kant to rule this out.

Kantian development

It is only with some hesitation that one can speak of Kant as having put forward a metaphysics. He was in general highly suspicious of claims to metaphysical knowledge, and a principal aim of his philosophy was to expose the confusions into which professing metaphysicians had fallen. Nevertheless, it is clear that Kant had metaphysical convictions, for all his denial of the possibility of metaphysical knowledge; he was committed to the view that men can conceive a non-natural as well as a natural order and must necessarily take the former to be real when they act. The language he used—particularly his talk about man as phenomenon and man as noumenon—is not to the taste of present-day philosophers, but the thought behind it certainly survives. It is in this form, indeed, that Cartesianism may still be said to present a serious intellectual challenge.

IDEALISM

Descartes and Kant were both adherents of metaphysical dualism, though they worked out their dualisms in interestingly different ways. Many thinkers, however, find dualism unsatisfactory in itself; they look for a single prin-

ciple by which to compass whatever exists. There are two broad steps that are open to the person who confronts a dualism of mind and matter and finds it unsatisfactory: he can either try to show that matter is in some sense reducible to mind, or conversely seek to reduce mind to matter. The first is the solution of Idealism, the second that of Materialism. Idealism has already been treated at length, and it will not be necessary to go into it again here. Only one point about it needs emphasis. As was pointed out, there are various forms of Idealism. In one version, this philosophy maintains that there literally is no such thing as matter; what the common man takes to be material things are, upon closer consideration, nothing but experiences in minds. Nothing exists but minds and their contents; an independently existing material world is strictly no more than an illusion. This was the view taken by Berkeley. In the more sophisticated Idealism of Hegel, however, it is not maintained that mind alone exists; material things are, in one way, taken to be as real as minds. The thesis advanced is rather that the universe must be seen as penetrated by mind, indeed as constituted by it. Spirit, to use Hegel's own word, is the fundamental reality, and everything that exists must accordingly be understood by reference to it, either as being directly explicable in spiritual terms or as prefiguring or pointing forward to spirit. Whatever the merits of this thesis, it is clear that it differs radically from that maintained by Berkeley. Idealism in the form espoused by Berkeley relies largely on arguments drawn from epistemology, though formally its conclusions are ontological, because they take the form of assertions or denials of existence. Hegel, however, had little or nothing to say about epistemology and was not even concerned to put forward an ontology. What he wanted to urge was a doctrine of first principles, a thesis about the terms in which to understand the world. The Hegelian "reduction" of matter to mind was thus reduction in a somewhat attenuated sense. It is important to get this point clear, if only because it has its parallel in the rival doctrine of Materialism.

MATERIALISM

Matter as the only substantial existent

The simplest form of Materialism is found in the claim that only matter exists. Stated thus baldly the claim is absurd, because it is clear that all sorts of things exist that are not of the nature of matter: thoughts and numbers and human institutions would be instances. In the light of these facts, the claim has to be revised to say that matter is the only substantial existent, with appeal being made to distinctions first worked out in Aristotle's doctrine of categories. According to this explanation, many things besides matter exist, but all of them are explicable (or so it is said) as modifications of matter. Thus, human institutions consist in patterns of movement among specific groups of human beings, and human beings in turn are nothing but highly complicated material bodies.

It is clear from these instances that Materialism is a controversial doctrine; it is also clear that its key word, modification, requires further explanation. When, for example, minds are said to be modifications of an underlying material substance, what is meant? A first and relatively easy point is that, like qualities and quantities, they could not exist separately. Unless there were material bodies, there could not be minds, because minds are—to put it crudely—states found in some material bodies. Minds are here equated with mentality, and mentality is clearly an abstraction. To say this, however, is not to remove the whole difficulty. When it is said that mentality is a state of some material body or bodies, is that meant literally or metaphorically? Bodies can often be described from the physical point of view as being in a certain state—for example, as being in a state of internal equilibrium. What is meant here is that the different particles of matter concerned stand in a certain relationship and as a consequence develop certain physical properties. But is mentality to be conceived as a physical property? It sounds extravagant to say so. Yet some such doctrine must be defended if Materialism is to be advanced as a form of ontology with a serious claim for attention. It is interesting in this connection to notice the arguments advanced by scholars like J.J.C. Smart, which purport to identify states of mind with states of the brain. If the two are identical—literally the same thing described from two points of view—thoughts may really be modifications of matter, and Materialism may be tenable in a strong form. If, however, the identity cannot be made out—and very few philosophers are in fact ready to accept it—Materialism can be true at most in a modified form.

Naturalism

This modified form of Materialism is perhaps better described as naturalism. Naturalism holds not that all things consist of matter or its modifications but that whatever exists can be satisfactorily explained in natural terms. To explain something in natural terms is to explain it on scientific lines; naturalism is in fact a proclamation of the omnicompetence, or final competence, of science. It is not essential to this type of view to argue that phenomena can be spoken of in one way only; on this point, as on the point about ontological reducibility, the theory can afford to be liberal. It is, however, vital to make out that the scientific account of a set of happenings takes precedence over any other. Thus, the language in which men commonly speak of action and decision, which may be called for short the language of reasons, must be held to be secondary to the language in which scientists might speak of the same facts. Scientific language is basically causal, and the thesis of this form of Materialism is that causal explanations are fundamental. Naturalism is thus the obverse of Hegelianism; it is a theory of first principles, and it draws its principles from science.

If the question is raised why anyone should take this form of Materialism seriously, the answer lies in a number of significant facts. Physiologists have established correlations between general states of mind and general states of brain activity; their hope is to extend this to the point where particular thoughts and feelings can be shown to have their physiological counterpart. Cyberneticists have produced artifacts that exhibit mindlike behaviour to a remarkable degree; the inference that man is no more than a complicated machine is certainly strengthened by their achievements. Sociologists have shown that, whatever the explicit reasons men give for their beliefs, these are often intelligible in the light of factors of which they themselves take little or no account. The old assumption that human judgments are typically grounded in reason rather than merely caused, is called in question by the results of such investigations, which gain support from findings both in Freudian and in orthodox psychology. None of this evidence is decisive by itself; there are ways in every case of blocking the conclusions that Materialists tend to draw from it. Yet it remains true that, cumulatively, the evidence is impressive. It certainly has enough force to make it necessary to take this type of theory with the greatest seriousness. Metaphysical disputes in the modern world are fundamentally arguments for or against Materialism, and the other types of theory here explored are all seen as alternatives to this compelling, if often unwelcome, view.

Argument, assertion, and method in metaphysics

Attention is now turned from description of the content of particular metaphysical views to more general treatment of the nature of metaphysical claims. The questions that will arise in this section concern such things as the nature and basis of metaphysical assertions, the character of metaphysical arguments and of what are taken to be metaphysical proofs, and the parts played in metaphysical thinking by insight and argument, respectively. They come together in the inquiry as to whether metaphysics can be said to be a science and, if so, what sort of a science it is.

METAPHYSICS AS A SCIENCE

Nature of an a priori science. Sciences are broadly of two kinds, a priori and empirical. In an a priori science such as geometry, a start is made from propositions that are generally taken to be true, and the procedure is to demonstrate with rigorous logic what follows if they are indeed true. It is not necessary that the primary premises of an a priori science should in fact be truths; for the

Hypothetical nature of a priori sciences

purposes of the system they need only be taken as true, or postulated as such. The main interest is not so much in the premises as in their consequences, which the investigator has to set out in due order. The primary premises must, of course, be consistent one with another, and they may be chosen, as in fact happened with Euclidean geometry, because they are thought to have evident application in the real world. This second condition, however, need not be fulfilled; a science of this kind can be and commonly is entirely hypothetical. Its force consists in the demonstration that commitment to the premises necessitates commitment to the conclusions: the first cannot be true if the second are false.

This point about the hypothetical character of a priori sciences has not always been appreciated. In many classical discussions of the subject, the assumption was made that a system of this kind will start from as well as terminate in truths and that necessity will attach to premises and conclusions alike. Aristotle and Descartes both spoke as if this must be the case. It is clear, however, that in this they were mistaken. The form of a typical argument in this field is as follows: (1) p is taken as true or given as true; (2) it is seen that if p, then q; (3) q is deduced as true, given the truth of p. There is no need here for p to be a necessary or self-guaranteeing truth; p can be any proposition whatsoever, provided its truth is granted. The only necessity that needs to be present is that which characterizes the argument form, "If p is true, and p implies q, then q is true," that is $[p \cdot (p \supset q)] \supset q$, in which $\cdot$ symbolizes "and," and $\supset$ means "implies"; and this is a formula that belongs to logic. It is this fact that makes philosophers say, misleadingly, that a priori sciences are one and all analytic. They are not because their premises need not answer this description. They, nevertheless, draw their lifeblood from analytic principles.

Metaphysics as an a priori science. It is clear that metaphysical philosophers have sometimes aspired to present their results in the form of a deductive system, to make metaphysics an a priori science. For this purpose they have taken a deductive system to require not just that the premises entail the conclusions but further that they themselves be necessarily true. Spinoza thus began the first book of his *Ethics* by laying down eight definitions and seven axioms whose truth he took to be self-evident and then proceeding in the body of the text to deduce, as he thought with strict logic, 36 propositions that follow in order from them. He repeated the procedure in the rest of his work. That philosophical conclusions should thus be capable of being set out "in the geometrical manner" was something that Spinoza took as axiomatic; to be worthy of attention at all, philosophy must issue in knowledge as opposed to mere opinion, and knowledge proper had to be exempt from the possibility of doubt, which meant that it must either be intuitively evident or deducible from what was intuitively evident. Spinoza took this conception of knowledge from Descartes, who had himself toyed with the idea of presenting metaphysical arguments in the geometrical manner. Descartes, however, pointed out that, although there was no difficulty in getting agreement to the first principles of geometry, "nothing in metaphysics causes more trouble than the making the perception of its primary notions clear and distinct"; the whole trouble with this discipline is that its students fail to see that they must start from what are in fact the basic truths. Descartes himself spoke as if the problem were no more than pedagogical; it was a question of making people see as self-evident what is in itself self-evident. His own "analytic" approach in the *Meditationes* was chosen to overcome these difficulties; it was, he said, "the best and truest method of teaching." But it may well be that this account is too optimistic. The difficulty with a system such as those of Descartes and Spinoza is that there are persons who cannot be brought to see that the primary propositions of the system are self-evidently true, and this not because they are lacking in attention or insight but because they see the world in a different way. This suggests that in any such system there will necessarily be an element that is arbitrary, or at least noncompulsive. However cogent the links that bind premises to conclusions, the premises themselves will lack a firm foundation. If they do, the interest of the system as a whole must be greatly diminished; it can be admired as an exercise in logic but not valued for more than that.

Deductive systems of Spinoza and Descartes

To avoid this unpalatable conclusion, two expedients are possible. The first is to say that the first premises of a metaphysical system must be not merely self-evident but also self-guaranteeing; they must be such that any attempt to deny them can only result in their reaffirmation. Descartes believed that he could satisfy this requirement by grounding his system in the cogito, though strictly this was the primary truth only from the point of view of subjective exposition and not according to the objective order of things. Aristotle somewhat similarly had argued that the logical principle of noncontradiction, which he took to express a highly general truth about the world, must be accepted as axiomatic on the ground that its correctness is presupposed in any argument directed against it.

Even the Idealists Bradley and Bernard Bosanquet at times spoke as if the first principles of their system were in some way logically compulsive; as Bosanquet put it, one had either to accept them or recognize that one could know nothing. Whatever the position may be about particular metaphysical propositions, however, it seems clear that not all truths that are taken as basic in metaphysics have the characteristic of being self-guaranteeing. A Materialist takes it as fundamental that whatever occurs happens as a result of the operation of natural causes: a theist sees things in the world as finite and thus as pointing beyond themselves to the infinite being who is their ground. No contradiction is involved in denying these positions, though of course for those who accept them the denial necessarily involves commitment to falsehood. It is, however, one thing for a proposition or set of propositions to be false, another altogether for it to be necessarily false. If the first principles of metaphysics were really self-guaranteeing, only one system of metaphysics could be coherent, and it would be true just because it was coherent. The very fact that there is an apparent choice between competing metaphysical systems, which may differ in plausibility but agree in being each internally self-consistent, rules this possibility out.

The alternative is to argue that fundamental metaphysical propositions, though not self-guaranteeing, are nevertheless not arbitrary; they have or, to be more cautious, can have a firm foundation in fact. Metaphysical speculation is not, as some opponents of metaphysics have suggested, essentially idle—that is, the mere working out of the logical consequences of premises that the metaphysician chooses to take as true. Or, rather, it does not necessarily answer this description because a metaphysician can have insight into the true nature of things and can ground his system on that. This second position in fact involves arguing that metaphysics is not an a priori but an empirical science.

Reference to experience

Metaphysics as an empirical science. If metaphysics is an empirical science, the question of whether or not to accept a metaphysical theory must be answerable, in part at any rate, by reference to experience. It will not depend on experience alone, any more than does the acceptability of a scientific theory, because here, as in the scientific case, thinking comes into the reckoning too. A metaphysician can be mistaken in his deductions, just as a scientist can. But even if these are impeccable, he will not necessarily succeed on this view of his undertaking. It may be that he argues correctly from premises that are unacceptable—unacceptable because they lack the necessary foundation in fact. He will then be like a scientist who puts forward a hypothesis and deduces its consequences without mistake only to find that experience fails to confirm the supposition on which he is working.

Scientific hypotheses are refuted, or at least called seriously into question, when predictions based on them fail to come true. As Karl Popper—who has emphasized that there is a unity of method in all generalizing or theoretical sciences—has insisted, every scientific hypothesis must be testable, and the way to test it is to look for circumstances in which it does not hold. To content oneself with favourable evidence is not enough; one must be searching all the time for unfavourable evidence. Further, it must

be possible, if the hypothesis is genuinely scientific, to specify in advance what would count as unfavourable evidence; the circumstances in which the hypothesis needs to be abandoned, or at least modified, must be indicated precisely. In ideal conditions it is possible to devise a crucial experiment that will test a hypothesis definitively; the Michelson–Morely experiment, which disposed of the theory of the luminiferous ether, was such an experiment.

It can be asked, however, what parallels there are to this in metaphysics. The difficulty with testing a metaphysical thesis is twofold. First, metaphysical theories tend to be extremely general and as such highly unspecific. They announce, for example, that every event has some cause or other, or that every change is part of a process that serves some purpose. To find counterexamples to theses of such generality is on any account exceedingly difficult: how can one be sure that all the possibilities have been explored? There is, however, another and still more serious difficulty. The scientist, once he has laid down the conditions that would have to obtain for his hypothesis to prove false, makes no bones about their occurrence; it is, typically, a matter of whether or not a certain pointer reading is registered, and this is a simple question of ascertainable fact. Fact for the metaphysician, however, is altogether more slippery. Different metaphysicians see the world each in his separate way; what they take to be the case is coloured by their metaphysical conceptions. There is no neutral body of facts to which appeal can be made to show that a metaphysical theory falls down, and this being so, the attempt to assimilate metaphysics to science must fail.

That this should be the case is perhaps not surprising. Scientific thinking proceeds within a framework of presuppositions that it is the business of the scientist to use, not to argue for and still less to challenge—presuppositions to the effect, for example, that every change has a natural explanation. No doubt scientists can change their presuppositions, but they seldom do so consciously; their usual practice is to take them for granted. Metaphysicians, however, necessarily take a very different attitude toward presuppositions. It is their business to tell men how to understand the world, and this means that they must, among other things, put forward and argue for a set of interpretative principles. Metaphysicians differ radically in the interpretative principles they accept, and it is this that explains their failure to agree upon what to take as fact. It is naive to suppose that the points at issue between, for example, a Thomist and a Materialist can be settled by observation or even by experiment; the facts to which one might appeal in support of his theory may be seen in a very different light by the other, or perhaps be dismissed as simple illusion. Reflection on the phenomenon of religious experience will illustrate what is meant here. That men undergoing this experience are affected mentally and physically in certain specific ways is perhaps common to both Thomist and Materialist. But the further description of their state is entirely controversial and owes its controversial character to the varying preconceptions that the disputants bring to their task.

INITIAL METAPHYSICAL INSIGHTS

Metaphysics as a matter of vision

Origin. If metaphysics is far from being a simple empirical discipline, however, it does not follow that it is wholly without foundation in fact. The true situation can perhaps be put as follows. Every metaphysic consists in an imaginative view of the world elaborated into a conceptual system. Metaphysics, like poetry, begins by being a matter of vision; a metaphysician sees the scheme of all things in a certain light; for example, as nothing more than a vast mechanism or as God's creation. As a metaphysician, however, he cannot be content to rest in a vision of this sort, as for example the Romantic poet William Wordsworth does in his "Intimations of Immortality." He needs to think out terms in which whatever exists can be described so as to accord with his primary insight; he needs to produce and apply a conceptual system and to argue against possible alternatives. Whatever its origins, metaphysics is strictly intellectual in its development. When the question is raised of the source from which metaphysicians gain their initial insights, the answer that occurs most readily is that they are derived from reflection on certain evident facts. Thus, the source of the Materialist view of the world is undoubtedly the practice of science; the Materialist proposes to give unrestricted validity to ways of thinking that scientists have found effective in a certain restricted sphere. The source of Idealist thought is to be found in the practice of history, or more generally in the interpersonal relations of beings who are at once rational and sensitive; the Idealist philosopher takes concepts that are appropriate in these limited areas to apply to the whole of reality. Every system of metaphysics is grounded in some real experience and owes its initial appeal to that fact. This is not to say, however, that the metaphysician builds on experience as does his scientific colleague. To think that is to take altogether too simple a view of the whole question.

Tests of validity. A question of immense importance is whether there are any means of comparing the validity of initial metaphysical insights. If it has to be answered negatively—if it has to be allowed that, as it were, all candidates in this field start and finish on an equal footing—the argument that each of them has a foundation in fact will be entirely discounted. Whatever respectability their concepts possess in their original homes will be lost once they fall into the hands of the metaphysician, because the procedure of the latter in taking them up and extending them is essentially arbitrary. For example, that one sees the sum of things as a vast machine may be suggested by what goes on in science, but this view can neither claim scientific warrant itself nor draw on scientific prestige, because it seems to spring from nothing better than mere whim. There are, however, two reasons for thinking that initial metaphysical insights are based not on mere whim but on valid grounds.

Insights as limited in number and subject to experience

First, the number of what may be called viable metaphysical insights is in practice limited: there are varying ways of taking the world as a whole, but not an infinite variety. In the outline account of metaphysical theories given above, six different kinds of view were distinguished, each of which may be said to be grounded in one or more areas of experience. It would be possible to extend the list, but probably not very far; further candidates might well turn out to be no more than variations on themes already considered. Thus, Leibniz might be seen as a latter-day Platonist, and Spinoza as offering a different version of the dualism of Descartes, one that is more sympathetic to Materialism than was Descartes himself. If these claims are true, they are certainly important; for the facts here adduced suggest that the experiences or visions on which different metaphysicians build are not peculiar to individual minds but occur commonly and regularly. They are not the product of passing moods, seized on and exploited for no good reason, but connect with thoughts that recur repeatedly in sensitive and intelligent reflection.

Second, there is a sense in which, despite everything said above, metaphysical theories are subject to the test of experience. That metaphysics aspires to give an account of the world as a whole means that each metaphysician claims that his fundamental insight illuminates every department of life. It may be that there are no neutral facts to which a metaphysician can appeal to show the shortcomings of his opponents; metaphysicians pronounce on what is to count as fact, and this puts them in the happy position of being judges in their own case. It remains true, however, that everyone who engages in that type of philosophy has the formal task of accounting for all the facts that he recognizes, and this is something that can be done more or less well. The value of different metaphysical insights is sometimes shown in the success with which they are applied. Furthermore, it is not quite true that the metaphysician need consult no opinion but his own when it comes to working out his views. What might be called public opinion has a part to play as well, though it has no absolute right to a hearing. A metaphysician who chooses to dismiss areas of experience or ways of thinking that are commonly accepted as being in order does so at his peril; he reduces the initial plausibility of his own theories the oftener he finds himself in this position. He could, of course, be right and common opinion wrong; no genuine metaphysician is put off by the thought of such a

conflict. Though he is not put off, however, he has to be wary all the same. He may be able to say what in the end is to count as fact, but if this involves him in dismissing as illusory what instructed opinion generally takes to be real, his triumph may be hollow. Whether he likes it or not, he has to frame a theory that will carry conviction with experts in the different fields concerned, or, if that is going too far, one that will strike them as not wholly implausible. A metaphysician who exercises his veto past that point is simply failing to do his job.

The test of self-consistency of theory

It must be admitted that the tests one can apply to determine the value of a metaphysical theory are at best unsatisfactory. Often one is driven back onto the expedient of asking if the theory is internally self-consistent; a surprisingly large number of philosophical theories are not. To confute a philosopher out of his own mouth is, perhaps, the most effective form of confutation. If this expedient will not apply, however, the questioner is not quite helpless. Whatever the explanation, it is a well-known fact that a philosopher can purchase consistency at the expense of plausibility; he can put forward theories that evade difficulties by simply declaring them nonexistent. In so doing, he turns his back on what instructed opinion generally takes to be fact. His hope is, of course, to persuade others to see the situation as he does, and there is always the possibility that he will succeed. If, however, after a suitable interval he has not, that must surely count against him. It is by this test that one decides, for example, that the metaphysics of Hobbes is not worth prolonged study, despite the enormous ingenuity of its author; there is too much in this system that seems to be sheerly arbitrary. The same comment could be made of certain forms of Idealism, which are so intent on the omnipresence of spirit that they neglect the materiality of the material order. Admittedly, the test is harder to apply when attention is transferred to the major theories in their most persuasive form, because here the question concerns views that have stood the test of time. It is not, however, entirely inapplicable even there. An individual, at least, may feel that this or that view will not do precisely because it achieves comprehensiveness by turning its back on fact; and, though it is unsatisfactory to fall back on personal judgment in this way, there is perhaps no other alternative in this difficult area.

Role of personal or social factors. Some writers on the philosophy of philosophy, such as Dilthey, have suggested that the persistence of a plurality of metaphysical systems is to be explained in terms of personal or social factors. Certain kinds of metaphysical outlook appeal to certain types of human being, or gain currency in social circumstances of this kind or that; to understand why they are accepted, recourse must be had to psychology or sociology or both. In the above account, stress has been laid on the historical background against which a number of famous metaphysical theories got their classical formulations; it is idle to deny that each was originally designed to solve a problem deemed to be urgent at the time. Nevertheless, the problem was, of course, an intellectual problem, and the solution offered claimed to be true, not simply comforting. No doubt wishful thinking is as rife in the field of metaphysics as anywhere; it is all too easy here to confuse what men ought to believe with what they want to believe. Philosophies reveal something about their authors and even about their historical age, as works of literature do; they constitute historical evidence as books on mathematics, perhaps, do not. Yet all this can be admitted without agreeing that metaphysics is merely of psychological or historical importance. Science does not cease to be true because it is shown to be useful. Nor is it true that metaphysical theories always in fact give comfort; there are cases in which men find themselves returning over and over again to possibilities that they would very much like to believe were not realized. A philosopher can commit himself to a view of the world that is not at all to his taste, simply because it seems to him on due consideration that this is how things are. That philosophers are godlike beings able to rise entirely above the limitations of their age seems unlikely. It is equally unlikely, however, that their opinions are determined throughout by nonrational factors, and thus that their thinking can lay no claim to truth.

METAPHYSICAL ARGUMENTS

Classes of metaphysical statements

Logical character of metaphysical statements. Metaphysical statements fall into two main classes: statements about what exists and prescriptions about how to take or understand what exists. It might seem obvious that the first is the more important; the metaphysician first lays down what he takes to exist, and then tells how to interpret it. This would be correct if metaphysics were a departmental inquiry like, for example, botany; but, of course, it is not. Metaphysicians possess no special resources for the detection of unfamiliar entities, and in consequence the realities they accept must all be argued for. The fundamental items that fill the metaphysical world are one and all theoretical; they are not so much palpable realities as artificial constructs. That being so, there is less of a gulf between the two types of metaphysical pronouncement than might at first appear. It could indeed be argued that the two go closely together to constitute what may be called a metaphysical point of view, a standpoint whose primary purpose is to provide understanding. In a metaphysical context, to say what exists is itself a step on the way to understanding; it is not something that antedates theory, but part of a theory itself.

It may be asked whether metaphysical pronouncements are empirical or a priori and, if the latter, whether they are analytic or synthetic. They are certainly not straightforwardly empirical, for reasons just set out, and cannot be merely analytic (*i.e.*, true in virtue of the definitions of their terms and of the laws of logic) if metaphysics is to retain any significance. The conclusion that they must be synthetic a priori (*i.e.* such that, unlike analytic propositions, they convey new knowledge and yet claim complete universality and necessity) seems to follow, and it is just what the opponent of metaphysics wants the metaphysician to adopt. Metaphysics, as he sees it, is a wholly unwarranted attempt to say what the world must be like on the strength of pure thinking, an attempt that is doomed to failure from the start. Before this condemnation is accepted, however, the function that the metaphysician assigns to his principles should be considered. When this is done, it becomes plain that the charge that he claims factual knowledge of a nonempirical sort is false; in one way he recognizes exactly the same facts as anyone else. Where he claims superiority is in knowing how to take facts, and the burden of his message consists in the advocacy of principles that, he alleges, will provide overall understanding. One can describe these principles as synthetic a priori if one chooses. It is probably best, however, to avoid this misleading term and simply say that they are thought of by the metaphysician as applying unequivocally to whatever falls within experience. These metaphysical principles are instructive at least in the sense of having alternatives, and they are certainly treated as being necessary. It is not true, however, that they take the form of statements of fact, even highly general statements of fact; nor is their necessity the same as that which characterizes logical truths. The principles are prescriptions rather than statements, and their necessity arises from the role they play in the constitution of experiential knowledge. It is a necessity that is in one way absolute: nothing that can claim to be real can escape their jurisdiction, because they tell how to take whatever occurs. Nevertheless, in another way the necessity of the principles is merely conditional, for other ways of interpreting the same data can be conceived, and it is admitted that there are circumstances, however hard to specify exactly, in which it would have to be agreed that they do not apply.

Deductive and inductive arguments

Logical form of metaphysical arguments. There is also the question whether metaphysical arguments are inductive or deductive or whether they have some logical form peculiar to themselves. It is obvious that much metaphysical reasoning is, or purports to be, reasoning in the strict sense, which is to say that its form is deductive. Arguments like the first cause argument for God's existence claim to be demonstrations; their exponents believe that anyone who commits himself to the truth of the premises

stands logically committed to the truth of the conclusions. This claim can stand, even if it turns out that the project to set out metaphysical results in the geometrical manner is a mistake. It may be impossible to model metaphysics on mathematics, but that does not make particular metaphysical arguments any less deductive.

As regards inductive arguments, it would be odd to find a metaphysician contending, as, for example, historians regularly do, that p is true and q is true and therefore it is reasonable to conclude that r is true. To assess probabilities in the light of established facts is too cautious for the average metaphysical mind. Yet it would be wrong to deny that metaphysicians are preoccupied with facts. Their objective is to give a reasoned account of what exists or obtains, and for this purpose attention to fact is of course indispensable. It figures in metaphysical thinking at two stages. First, at the beginning, when the metaphysician is concerned to formulate his main thesis; here there is a move from what holds in a restricted sphere (the sphere of physics, for example) to what is supposed to hold generally, a move that is possible only if the theorist concerned has an interest in the sphere in question. To arrive at his own position the metaphysician must extrapolate from what goes on outside metaphysics, and this means that he must be sensitive to significant developments in at least some of the main fields of learning and areas of practical activity. But he needs this extra-philosophical knowledge for a second purpose too: in estimating the success of his own theories. In principle he must show that his interpretation of experience covers the facts in an adequate way, and for this purpose what experts in the different spheres take to be established is of crucial importance. Metaphysics is not an empirical science—the element of speculation it includes is too strong for that—but the metaphysician can no more ride roughshod over facts than the scientist can. At the least he must explain away phenomena that seem to count against his thesis, or indicate how they might be explained away. Whether he explains or explains away, he needs to know what the main phenomena are.

Transcendental argument

Finally, it is sometimes said that metaphysics can make use of a form of argument that is neither deductive nor inductive but transcendental; a transcendental argument is supposed to proceed from a fact to its sole possible condition. A transcendental argument is simply a form of deduction, with the typical pattern: only if p then q; q is true; therefore, p is true. As this form of argument appears in philosophy, the interest, and the difficulty, reside not in the movement from premises to conclusions, which is absolutely routine, but in the setting up of the major premises—in the kinds of things that are taken as starting points. In Kant's case, it was such things as the possibility of pure mathematical knowledge, the possibility of making objectively true statements, the fact that there is a unitary system of time. Kant purported to prove a number of surprising propositions by the use of transcendental arguments; he tried to commend major premises such as his arguments about causality and substance by showing what would result if the protasis (*i.e.*, p) did not hold. What he had to say under this head has attracted particular interest in recent years. It seems clear, however, that from the logical point of view no special significance attaches to this form of argument. Although Kant had been successful in demonstrating that a sufficient is also a necessary condition, he did not make clear why it should be taken as the sole such condition. There is an important gap in his reasoning here, as there is in that of other metaphysical writers.

Criticisms of metaphysics

Metaphysics has many detractors. The man who aspires "to know reality as against mere appearance," to use Bradley's description, is commonly taken to be a dreamer, a dupe, or a charlatan. Reality in this context is, by the metaphysician's own admission, something that is inaccessible to sense; as Plato explained, it can be discovered only by the pure intelligence, and only if the latter can shake itself free of bodily encumbrances. The inference that the metaphysical world is secret and mysterious is natural enough. Metaphysics in this view unlocks the mysteries and lets the ordinary man into the secrets. It is, not to put too fine a point on it, a study of the occult.

Metaphysics as a study of the occult

METAPHYSICS AS KNOWLEDGE OF THE SUPERSENSIBLE

That there are aspects of metaphysics that lend colour to this caricature can scarcely be denied. The language of Plato, in particular, suggests an absolute distinction between the deceitful world of appearances, which can never be an object of knowledge, and the unseen world of Forms, each of which is precisely what it appears to be. Plato urged his readers not to take seriously the things of sense; he told them that everything having to do with the senses, including the natural appetites and the life of the body, is unreal and unimportant. The philosopher, in his view, needs to live an ascetic life, the chief object of which is to cultivate his soul. Only if he does this, and follows a rigorous intellectual training, has he any hope of getting the eye of his soul fixed on true reality and so of understanding why things are what they are.

Yet even this program admits of an innocuous, or relatively innocuous, interpretation. The "dialectician," as Plato called his metaphysical philosopher, is said in one place to be concerned to "give an account," and the only things of which he can give an account are phenomena. Plato's interest, despite first appearances, was not in the unseen for its own sake; he proposed to go behind things visible in order to explain them. He was not so much disdainful of facts as critical of accepted opinions; his attack on the acquiescence in "appearances" was an attack on conventional wisdom. That this was so comes out nowhere more clearly than in the fact that his targets included not just beliefs about what there is but also beliefs about what is good. It is the opinions of the many that need correction and that can happen only if men penetrate behind appearances and lay hold on reality.

Plato is often presented as an enemy of science on the ground that he was bitterly opposed to Empiricism and because he said that, if there was ever to be progress in astronomy, the actual appearances of the starry heavens must be disregarded. He understood by Empiricism, however, the uncritical acceptance of apparent facts, with the attempt to trace regularities in them; it is an attitude that, in his view, is marked by the absence of thought. As for the starry heavens, it is certainly difficult to take Plato quite literally when he compares their function in astronomy to that of a well-drawn diagram in geometry. Yet he was not wrong to suggest that no progress could be made in astronomical inquiries until appearances were seen to be what they were and not taken for absolute realities. The subsequent progress of astronomy has shown this view to be entirely correct.

There are respects in which Plato's attitude to phenomena was precisely the same as that of the modern scientist. The fact remains, nevertheless, that he believed in a realm of unseen realities, and he is of course far from being the only metaphysician to do so. Many, if not quite all, metaphysicians are committed to claiming knowledge of the supersensible, in some degree at least; even Materialists are alleged to make this claim when they say that behind the familiar world of everyday experience there lies material substance that is not accessible to the senses. It has been a commonplace among critics of metaphysics since the early 18th century that no such claims can be justified; the supersensible cannot be known about, or even known of, whether directly or by inference.

SPECIFIC CRITICISMS

Hume. An early but powerful statement of these criticisms is to be found in the writings of David Hume, *A Treatise of Human Nature* (1739–40) and *An Enquiry Concerning Human Understanding* (1748). Hume argued first that every simple idea was derived from some simple impression and that every complex idea was made up of simple ideas; innate ideas, supposed to be native to the mind, were nonexistent. There were eccentricities in Hume's conception of idea (and for that matter in his conception of impression), but these did not destroy the force of his argument that the senses provide the materials

Necessity of sense experience

from which basic concepts are abstracted. A being that lacked sense experience could not have concepts in the normal sense of the term. Next, Hume proceeded to make a sharp distinction between two types of proposition, one knowable by the pure intellect, the other dependent on the occurrence of sense experiences. Propositions concerning matters of fact and existence answer the latter description; they either record what is immediately experienced through the senses or state what is taken to be the case on the basis of such immediate experiences. Such statements about matters of fact and existence are one and all contingent; their contradictories might have been true, though, as a matter of fact, they are not. By contrast, propositions of Hume's other type, which concern relations of ideas, are one and all necessary; reflection on the concepts they contain is enough to show that they must, in logic, be true. Though, in a sense, knowledge of these propositions is arrived at by the exercise of pure reason, no real significance attaches to this fact. It is not the case of some special insight into the nature of things; the truth is rather that these propositions simply make explicit what is implicit in the definitions of the terms they contain. They are thus what Kant was to call analytic propositions, and it is an important part of Hume's case that the only truths to which pure reason can attain are truths of this nature.

Finally, Hume sought to block the argument that, even if the supersensible could not be known directly, or through pure intellectual concepts, its characteristics could, nevertheless, be inferred. His analysis of causality had this as one of its aims. According to Hume, the only means by which men can go beyond the impressions of the memory and the senses and know what lies outside their immediate experience is by employing causal reasoning. Examination of the causal relation, however, shows that it is, among other things, always a relation of types of events in time, one of which invariably precedes the other. Causality is not, as Descartes and others supposed, an intelligible relation involving an internal tie between cause and effect; it is a matter of purely factual connection and reduces on its objective side to nothing more than regular precedence and succession. The importance of this for the present inquiry lies in the consequence that causal relations can hold only between items, or possible items, of experience. According to Hume, if the temporal element is removed from causality, nothing concrete is left; if it is kept, it becomes impossible to argue that one can proceed by causal reasoning from the sensible to the supersensible. Yet it was precisely this that Aristotle, Thomas Aquinas, and Locke had all attempted.

Hume's own explicit pronouncements about metaphysics are ambivalent. There is a famous passage in which he urged men to consign volumes of divinity and "school metaphysics" to the flames, "as containing nothing but sophistry and illusion," but in at least one other place he spoke of the need to "cultivate true metaphysics with some care, in order to destroy the false and adulterate." "True metaphysics," in this connection, meant critical philosophical reflection.

Critical philosophical reflection

Kant. Hume's successor Kant made a sharper distinction between metaphysics and critical philosophy. Much of Kant's philosophical effort was devoted to arguing that metaphysics, understood as knowledge of things supersensible, is an impossibility. Yet metaphysics, as a study of the presuppositions of experience, could be put on "the sure path of science"; it was also possible, and indeed necessary, to hold certain beliefs about God, freedom, and immortality. But however well founded these beliefs might be, they in no sense amounted to knowledge: to know about the intelligible world was entirely beyond human capacity. Kant employed substantially the same arguments as had Hume in seeking to demonstrate this conclusion but introduced interesting variations of his own. One point in his case that is especially important is his distinction between sensibility as a faculty of intuitions and understanding as a faculty of concepts. According to Kant, knowledge demanded both that there be acquaintance with particulars and that these be brought under general descriptions. Acquaintance with particulars was always a matter of the exercise of the senses; only the senses could supply intuitions. Intuitions without concepts, nevertheless, were blind; one could make nothing of particulars unless one could say what they were, and this involved the exercise of a very different faculty, the understanding. Equally, however, the concepts of the understanding were empty when considered in themselves; they were mere forms waiting to be brought to bear on particulars. Kant emphasized that this result held even for what he called "pure" concepts such as cause and substance; the fact that these had a different role in the search for knowledge from the concepts discovered in experience did not give them any intuitive content. In their case, as in that of all other concepts, there could be no valid inference from universal to particulars; to know what particulars there were in the world, it was necessary to do something other than think. Thus is revealed the futility of trying to say what there is on the basis of pure reason alone.

Differences between Hume's and Kant's criticisms

Kant's distinction between analytic and synthetic propositions has peculiarities of its own, but for present purposes it may be treated as substantially identical with Hume's distinction set out above. Similarly, the important differences between Kant and Hume about causality may be ignored, seeing that they agreed on the central point that the concept can be properly applied only within possible experience. If it is asked whether there are substantial differences between the two as critics of metaphysics, the answer must be that there are but that these turn more on temperament and attitude than on explicit doctrine. Hume was more of a genuine iconoclast; he was ready to set aside old beliefs without regret. For Kant, however, the siren song of metaphysics had not lost its charm, despite the harsh words he sometimes permitted himself on the subject. Kant approached philosophy as a strong believer in the powers of reason; he never abandoned his conviction that some of man's concepts are a priori, and he argued at length that the idea of the unconditioned, though lacking constitutive force, had an all-important part to play in regulating the operations of the understanding. His distinction between phenomena and noumena, objects of the senses and objects of the intelligence, is in theory a matter of conceptual possibilities only; he said that, just as one comes to think of things sensible as phenomena, so one can form the idea of a world that is not the object of any kind of sense experience. It seems clear, however, that he went beyond this in his private thinking; the noumenal realm, so far from being a bare possibility invoked as a contrast with the realm that is actually known, was there thought of as a genuine reality that had its effects in the sense world, in the shape of moral scruples and feelings. A comparison of what was said in Kant's early essay *Träume eines Geistersehers erläutert durch Träume der Metaphysik* (1766; *Dreams of a Spirit-Seer*), with the arguments developed in the last part of his *Grundlegung zur Metaphysik der Sitten* (1785; *Fundamental Principles of the Metaphysic of Morals*), would seem to put this judgment beyond serious doubt.

Though Kant remained convinced of the existence of things supersensible, he, nonetheless, maintained throughout his critical writings that there can be no knowledge of them. There can be no science of metaphysics because, to be true to fact, thinking must be grounded in acquaintance with particulars, and the only particulars with which human beings are acquainted are those given in sense. Nor was this all. Attempts to construct metaphysical systems were constantly being made; philosophers repeatedly offered arguments to show that there must be a first cause, that the world must consist of simple parts, that it must have a limit in space, and so on. Kant thought that all such attempts could be ruled out of court once and for all by the simple expedient of showing that for every such proof there was an equally plausible counterproof; each metaphysical thesis, at least in the sphere of cosmology—*i.e.*, the branch of metaphysics that deals with the universe as an orderly system—could be matched with a precise antithesis whose grounds seemed just as secure, thus giving rise to a condition that he called "the antinomy of pure reason." Kant said of this antinomy that "nature itself seems to have arranged it to make reason stop short in its bold pretensions and to compel it to self-examination."

Admittedly, the self-examination led to more than one result: it showed on the one hand that there could be no knowledge of the unconditioned and demonstrated on the other that the familiar world of things in space and time is a mere phenomenon, thus—to Kant—clearing the way to a doctrine of moral belief. Though this doctrine could not be expunged from Kant's philosophy without destroying it altogether, it is quite wrong to present it, as some modern German writers do, as amounting to the advocacy of an alternative metaphysics. What Kant was concerned with here is what must be thought, not what can be known.

Logical Positivists. Despite what has just been said, it must be admitted that Kant's constant talk about the supersensible makes many critics of metaphysics regard him as a dubious ally. This was certainly true in the case of the Logical Positivists, the philosophical school that has attacked metaphysical speculation most sharply in the 20th century. The Positivists derived their name from the "positive" philosophy of Auguste Comte, a 19th-century Frenchman who had represented metaphysical thought as a necessary but now superseded stage in the progression of the human mind from primitive superstition to modern science. Like Comte, the Logical Positivists thought of themselves as advocates of the cause of science; unlike Comte, they took up an attitude toward metaphysics that was uniformly hostile. The external reason for this was to be found in the philosophical atmosphere in the German-speaking world in the years following World War I, an atmosphere that seemed to a group of thinkers known as the Vienna Circle to favour obscurantism and impede rational thought. But there were, of course, internal reasons as well.

According to the Positivists, meaningful statements can be divided into two kinds, those that are analytically true or false and those that express or purport to express matters of material fact. The propositions of logic and mathematics exemplify the first class, those of history and the natural and social sciences the second. To decide whether a sentence that purports to state a fact is meaningful, one must ask what would count for or against its truth; if the answer is "nothing," it cannot have meaning, or at least not in that way. Thus, they adopted the slogan that the meaning of a (nonanalytic) statement is the method of its verification. It was this verification principle that the Positivists used as their main weapon in their attacks on metaphysics. Taking as their examples statements from actual metaphysical texts—statements such as "The Absolute has no history" and "God exists"—they asked first if they were supposed to be analytically or synthetically true, and then, after dismissing the first alternative, asked what could be adduced as evidence in their favour or against them. Many metaphysicians, of course, claimed that there was empirical support for their speculative conclusions; thus, as even Hume said, "the order of the universe proves an omnipotent mind." The very same writers, however, proved strangely reluctant to withdraw their claims in the face of unfavourable evidence; they behaved as if no fact of any kind could count against their contentions. It followed, said the Positivists, that the theses in which they were interested were compatible with any facts whatsoever and thus were entirely lacking in significance. An analytic proposition, such as "It either will or will not rain tomorrow," tells nothing, though there may be a point in giving voice to it. A metaphysical proposition claims to be very different; it purports to reveal an all-important truth about the world. But it is no more informative than a bare tautology, and, if there is a point in putting it forward, it has to do with the emotions rather than the understanding.

The verification principle

In point of fact, the Positivists experienced great difficulty in devising a satisfactory formulation of their verification principle, to say nothing of a satisfactory account of the principle's own status. In the early days of the movement the demand for verifiability was interpreted strictly: only what could be conclusively verified could be significant. This had the effect of showing that statements about the past and propositions of unrestricted generality, to take only two instances, must be without meaning. Later a move was made toward understanding verifiability in a weak sense: a statement was meaningful if any observations bore on its truth. According to A.J. Ayer, an English disciple of the Vienna Circle, writing in 1936,

> It is the mark of a genuine factual proposition, not that it should be equivalent to an experiential proposition, or any finite number of experiential propositions, but simply that some experiential propositions can be deduced from it in conjunction with certain other premises without being deducible from those other premises alone.

As Ayer admitted in his second edition, however, this formulation lets in too much, including the propositions of metaphysics. From "The Absolute has no history" and "If the Absolute has no history, this is red," it follows that "This is red," which is certainly an experiential proposition. Nor were subsequent attempts, by Ayer and others, to tighten up the formulation generally accepted as successful, for in every case it was possible to produce objections of a more or less persuasive kind.

This result may seem paradoxical, for at first glance the Positivist case is extremely impressive. It certainly sounds odd to say that metaphysical sentences are literally without meaning, seeing that, for example, they can be replaced by equivalent sentences in the same or another language. But if the term meaning is taken here in a broad sense and understood to cover significance generally, the contention is by no means implausible. What is now being said is that metaphysical systems have internal meaning only; the terms of which they consist may be interdefinable but perhaps do not relate to anything outside the system. If that were so, metaphysics would in a way make sense but for all that would be essentially idle; it would be a game that might amuse but could hardly instruct. The Positivists confront the metaphysician with the task of showing that this criticism is not correct. Whatever difficulties are involved in formulating a principle of verifiability, the challenge can hardly be ignored.

Moore and Wittgenstein. The Positivists were not the only modern critics of metaphysics. G.E. Moore never argued against metaphysics as such, but nevertheless he produced criticisms of particular metaphysical theses that, if accepted, would make metaphysical speculation difficult, if not impossible. It was characteristic of a certain type of philosopher, according to Moore, to advance claims of a highly paradoxical nature—to say, for instance, that "Time is not real" or that "There are no such things as physical objects." Moore's case for rejecting such claims was that they go against the most central convictions of common sense, convictions that people accept unhesitatingly when they are not doing philosophy. Men constantly say that they did this before that, that things are better or worse than they were; from time to time they put off things until later or remark that tomorrow will be another day. Moore took these facts as definitive proof of the reality of time and definitive disproof of any metaphysical theory that denied it. Supporters of Bradley, the philosopher here criticized, replied that Moore had missed the point. Bradley never denied the truth of temporal propositions as used in the description of appearances; what he questioned was the coherence and ultimate tenability of the whole temporal way of thinking. As Rudolf Carnap, a Logical Positivist, was to put it, he raised an external question and was given an internal answer by Moore. It was an answer, however, that carried considerable conviction. The simple denial of what seem to be obvious facts had always been part of the stock-in-trade of metaphysicians; they make much of the distinction between appearance and reality. Moore may not have demonstrated the impropriety of this insistence, but at least he made it necessary for the metaphysician to be more circumspect, to explain explicitly what he was denying and what he was ready to accept, and so to make his own case sharper and thus easier to confirm or reject.

Common-sense criticisms

Moore's implied criticisms of metaphysics lead on naturally to those of Wittgenstein. Moore took his stand on common sense, whereas Wittgenstein based his on living language. Arguing that men are each involved in a multitude of language games or autonomous linguistic activities, insofar as they are scientific investigators, moral agents, litigants, religious worshipers, and so on, Wittgenstein asked in what language game the claims and questionings of philosophers arose. He replied that there was no genuine

Language criticisms

linguistic context to which they belonged; philosophical puzzlement was essentially idle. Philosophers were preoccupied with highly general questions; they aspired to solve *the* problem of meaning or *the* problem of reality. Against that Wittgenstein argued that words and sentences have meaning as used in particular contexts; there is no single set of conditions that has to be fulfilled if they are to be thought meaningful. Equally, there is no single set of criteria that has to be satisfied by everything one takes to be real. Sticks and stones and men are taken as real in everyday discourse, but so are numbers in the discourse of mathematicians, and so is God in the discourse of religious men. There is simply no warrant for preferring one of these above the others—for saying, for example, with persons of an Empiricist turn of mind, that nothing can be real that does not have existence in space and time.

Wittgenstein's antipathy to metaphysical philosophy was in part based on self-criticism; in his early work the *Tractatus Logico-Philosophicus,* published in 1922, he had himself tried to give a general account of meaning. At least one doctrine of that enigmatic book survived in his later thought: the distinction between saying and showing. Wittgenstein in the *Tractatus* sought to pronounce on "what can be said" and came to the conclusion that only "propositions of natural science" can be. Though at this stage he spoke as if metaphysical statements were senseless, his motives for doing so were very different from those of the Positivists. The latter saw metaphysics as an enemy of science; in their view there was only one way to understand the world, and that was in scientific terms. But Wittgenstein, though agreeing that science alone can be clear, held that scientific thought has its limitations. There are things that cannot be said but can, nonetheless, be shown; the sphere of the mystical is perhaps a case in point. Unlike his Viennese contemporaries, Wittgenstein had no wish to rule out of court the thought that there are more things in heaven and earth than can be compassed in the language of science; writers whom he admired—such as Blaise Pascal, a 17th-century French scientist and writer on religious subjects, and Søren Kierkegaard, a Danish philosopher and theologian who is regarded as the founder of modern Existentialism—had discoursed of such matters in a way that was highly illuminating. They had made clear, however, that, just as one here went beyond the province of science, so also one went beyond that of philosophy. For them the idea that the metaphysician is privy to the most important of all things is absurd. There may be a sense in which men transcend everyday experience in moments of religious feeling or artistic insight, but there is no justification for thinking that when they do they arrive at the metaphysician's Absolute. As Kierkegaard said, the man who looks for speculative proofs in the sphere of religion shows that he does not understand that sphere at all.

Religious philosophers. It is important, in considering current criticisms of metaphysics, to appreciate that this discipline is now under double attack. In the first place, it must face the assault of those who regard it as a rival to science; it is against this assault that sympathizers like R.G. Collingwood, a British philosopher, historian, and archaeologist, seek to defend it. But metaphysics is also in disfavour among many religious philosophers. In earlier days, partisans of religion, and more generally believers in a spiritual order, looked to metaphysics to vindicate their claims against skeptical attack; now they are altogether more reluctant to do so. The continuing controversy about metaphysics has no doubt influenced this development; it scarcely seems sensible to take refuge in a fortress whose walls are so frequently breached. There is, however, another motive that operates here: the feeling that metaphysics is not only dubious but, worse, unnecessary. In an age whose tendencies are antiphilosophical rather than philosophical, there is widespread acceptance of the view that religion and morals, and for that matter science and history, are their own justification; none of them stands in need of a certificate of respectability from philosophy, and any pretense by metaphysicians to supply or refuse such a certificate must be without foundation. Though this view is widespread, it is even so not unchallenged; there are persons who find the fragmentation it involves—belief in God on Sundays, belief in science for the rest of the week—intolerable. For such persons, at least, the search for metaphysical truth and metaphysical answers must retain its fascination. (W.H.W.)

Tendencies in contemporary metaphysics

Background: the thought of Kant and Hegel

Kant's efforts to limit metaphysics opened new lines for its development. He had thought that reason is established by being limited and that some truths are certain independent of anything that can happen in experience because experience is structured by the interpretive categories reflected in these truths. Thus, it is possible to be certain of the world in its general structure but only insofar as it is an experienced, or phenomenal, world—that is, a world known by man, not a world as it is in itself. Hegel, however, argued persistently that knowledge of a thing unknowable in itself is a contradiction and that reason can know all that is real if the mind first accepts the given thing as "always already within experience as other." The mutual implication of knowing mind and reality known is accepted, and a science of self-consciousness that relates all categories and all reality to the knowing subject is envisaged. Thus, Kant's mutual implication of knowing subject and phenomenal thing was given ultimate metaphysical validity by Hegel, and Kant's reformulations of traditional dualisms—*e.g.,* subject–object, appearance–reality, perceptual–categorial, immanent–transcendent, regulative–constitutive—became momentous for metaphysics.

TENDENCIES IN THE UNITED STATES

John Dewey. In this milieu, John Dewey, an American educational reformer and pragmatic philosopher, published his "Kant and Philosophic Method" in 1884 in the journal of a group known as the St. Louis Hegelians. Although Dewey later rejected the full-scale Hegelianism expressed in the article, he did so only after gathering up in a partial synthesis the thought of both Kant and Hegel. In this he sounded the thematic notes of much contemporary American and continental metaphysics. Whether or not this metaphysics is explicitly termed transcendental (that is, concerned with experience as determined by the mind's conceptual and categorial makeup), it does two things: (1) it affirms Kant's insight that physical particulars cannot first be identified and later interrelated by means of the categories, but, to be identified at all, they must be assumed to be already categorized, and reasoning must proceed to expose those categorial structures that make the actuality of knowledge possible; (2) it agrees with Hegel's critique at least to the extent that Kant's idea that the source of sensations is external to the mind in a noumenon is regarded as a transgression of Kant's own doctrine that the categories, particularly that of causation, can be applied only within phenomenal experience. Dewey thought that Kant confused the empirical and transcendental standpoints by mixing analysis of the organism as sensationally responsive with analysis of mind. Kant forgot that it is only because the knowing subject already grasps the world through its categories that it can self-deceivingly regard its sensations as subjective and as caused by something not known. Thus, for Dewey, "The relation between subject and object is not an external one; it is one in a higher unity that is itself constituted by this relation."

In Dewey's extended later thought, metaphysics became the study of "the generic traits of existence." Concern with God and immortality slips nearly from view, and this is typical of much contemporary philosophy. Even so, Dewey's rethinking of the subject–object relation engenders a concept of a democratic and scientific community of persons, bound to each other through common ideals, which has religious overtones. Vague and ambivalent as this concept may be, it helps undermine the whole contrast between immanent and transcendent and leads metaphysics on new paths.

Location of the role of science in knowledge

William James. The work of William James, a leader of the Pragmatic movement, was typical of many contemporary tendencies, one of which was the attempt to locate the role of science in knowledge and culture. Trained in medicine, James hoped to protect the autonomy of psy-

chology as a science by adopting a dualistic view of mind and matter. He "supposes two elements, mind knowing and thing known, and treats them as irreducible. Neither gets out of itself or into the other, neither in any way is the other." He presumed that mental states could be identified independent of a commitment to the metaphysical status of the things known by them and that they could then be correlated to the brain. Ironically, his attempts to identify mental states involved him in commitments to the nature of the world as presented to mind. The only meaning that can be given things is in terms of the anticipated consequences of one's actions upon these things in the world; this anticipation also supplies the meaningfulness of thoughts. This is the basis of the "instrumental" view of thoughts—*i.e.,* reflecting upon thoughts as "tools," or as "plans of action," tells one something about the things known by them, the "tooled"; the converse also occurs.

Each realm of the world is experienced in terms of temporal standards of thought natural to that realm; *e.g.,* standards of mathematics are peculiar because of their ideal, changeless objects. These criteria are not derived from mind alone or from things alone but from their relationship in what is termed experience. This is a "double-barreled" term—that is, an experiencing of experienced things. The mind cannot be specified independent of things that appear to the mind, and things cannot be specified independent of their modes of appearing to the mind. Phenomena regarded abstractly as singular, or "pure," are neutral between mind and matter, which are different contexts of the very same pure experiences—contexts that comprise a single world.

James would not claim that his method is transcendental. Yet the fact remains that for him subject and object cannot be specified independent of each other, and James undercuts dualism and moves toward a transcendental explanation of the conditions of knowledge.

James tried to avoid what can be called logicism, physicalism, and psychologism. The last claimed that, because knowing is a psychical act, all that is known about must be subject to psychological laws. James replied that the known-about, the experienced, has its own autonomy, either as pure experience, a "specific nature" studied by philosophy, as a physical context studied by physics, or, finally, as a psychical context, a human history, studied by psychology. The latter two are both dependent, at least for their ultimate meaningfulness, upon the first. Physicalism attempts to infer the nature of the psychical directly from the physical, thus reducing it to the physical. Most logicisms claimed that pure reason can grasp the real in itself. James agreed that reason entertains ideal objects, the relations between which are fixed independent of the sequence of sensory experience, but he asserted that this experience must decide which necessary truths apply to the world. Although some always do apply, the ascertainment of what is categorial for the world is always incomplete. Just when the world "plays into the hands of logic" is decided in that endless interaction of "worlds" or "orders of experience"—such as the perceptual, the imaginary, the mathematical—occasioned by a thing experienced sifting through the orders trying to find one that can contain it without contradiction; Pegasus, for example, is a mythical creature just because it cannot find a place in the world of real horses. The world of perceptual things, experienced as experienceable by all and as existing simultaneously, serves as a paradigm of reality even though other orders of experience are not reducible to it. Existence is an unusual predicate for James; it means that practical relationship of doing and concern within which things must be able to stand to men if they are to be counted as fundamentally real. James was not giving a subjectivistic account of reality, however, because he included in the fundamentally real all that can be related spatially and temporally to what can stand over against men's bodily selves. This was commonly forgotten by critics of James's popularized theory of truth, Pragmatism, which was thus systematically misunderstood.

James's contemporaries Charles Sanders Peirce and Josiah Royce stood in close dialectical exchange with him on these themes. Differences between them concerned the scope and conditions to be assigned experience. In general, Peirce argued that experience is to be construed more narrowly, in terms of mathematical logic and physics, whereas Royce argued that the understanding of truth, error, and meaning requires the assumption of an absolute knower or experiencer. Peirce was a seminal thinker whose thoughts were often beginnings in the more systematically developed philosophies of the other Americans.

TENDENCIES IN CONTINENTAL EUROPE

Edmund Husserl and Phenomenology. Edmund Husserl, the German philosopher, used the term Phenomenology to name a whole philosophy. In order to rid his transcendental investigation of empirical prejudgments and to discover connections of meaning that are necessary truths underlying both physical and psychological sciences, Husserl bracketed and suspended all judgments of existence and empirical causation. He did not deny them; rather, he no longer simply asserted them. He reflected upon their intended meaning. In reflection he claimed to see that things have meaning in terms of how they appear to men in their pre-reflective life and that awareness is in terms of this "how." In pre-reflective life, however, men are not aware of the "how" as such. By exposing this basic meaning through which men refer to things, he can free their eyes of the "cataracts" of the stereotyped and the obvious and can summon them "back to the things themselves."

Reflection on pre-reflective life

Husserl took traditional metaphysics to be infested with precritical commitments to existence, either physicalistic, psychologistic, or logistic. He used the term ontology, however, to apply to his study of objects of consciousness and even appropriated the Aristotelian term first philosophy. The world appears within the reflective bracket as existentially neutral (that is, as regards whether things have existence in themselves or exist for men) but ontologically ordered because, if various orders of beings exist, then what they are can be nothing but what they are intended to be. And what they are cannot be known until all they are intended to be is known.

Husserl distinguished two types of ontologies: formal ontologies, which are the domain of meanings, or essences, such as "one," "many," "whole," or "part," that are articulated by formal logic and which Husserl referred to as empty; and material ontologies, which discover and map the meaning and structure of sensory experience through transcendental investigation. In material ontology, for example, the essence of any physical thing is discovered by varying in the imagination the object that is given within its strictly correlative mode of perceptual consciousness; the essence is that identical something that continuously maintains itself during the process of variation. It is intuited that the perceived thing cannot vary in the imagination beyond the point of something given perspectively and incompletely to any given perceiving glance; hence, this is the essence of any physical thing. This is a truth of eidetic necessity and comprises a first principle in Husserl's projected philosophical science; *e.g.,* numbers are what they are because of the ways in which they are not like things.

The Existentialists. Husserl had early distinguished the primary task of description of "morphological essences" (those with "floating" spheres of application in the sensory life) from description of essences like those in geometry, which described closed, or definite, manifolds; but the question of the theoretical status of the ordinary perceptual world, or lived world (*Lebenswelt*), became increasingly disputed among Existentialists. They asked whether there can be a philosophical science that has made all its presuppositions transparent to itself. If transcendental elucidation of the *Lebenswelt,* with its historically established sediments of meaning, is really essential to show how theoretical sciences are grounded, then one may reasonably ask how Phenomenology can be sure it has accomplished the elucidation completely because it is itself a theory. The question gained urgency by Husserl's nearly imperceptible slide into what appeared to be an Idealist position regarding the source of all meaning, a commitment to an absolute ego. If this ego is regarded as individual in any

way, the problem arises of how any other individual can be as other because it is constituted in this primal ego.

Husserl's theory of the ego was rejected by French Existentialists such as Jean-Paul Sartre and Maurice Merleau-Ponty. For the latter, the bracketing of meanings can never be completed, for consciousness is not an enclosed individual that could grasp through reflection all its possible motivations to experience and give meaning to a world. Knowers are subjects with bodies, whose perceptual life is articulated only incompletely and discloses the world in progressively surprising ways. More meaning is found in existence than can at any moment be expressed, and even the meaning of existence is not reducible to any definable set of meanings.

Husserl's approach was not nearly radical enough for Martin Heidegger, a German thinker sometimes called an Existentialist. In thinking that he could prescind so neatly from facts and retain the essence of facts, Husserl was still involved to some extent in the prejudgments—the psychologistic, physicalistic, and logistic dualisms—that he inveighed against. For Heidegger there is no realm of consciousness that constitutes meaning, and he does not think that some sharp but harmless line could be drawn between essence and fact. The ambiguity in Husserl's thought between "object" as sense of the particular and as the encountered particular in its bodily presence is not harmless. It is unjustifiable to think that consciousness can finally demarcate the essential sense of a thing. Thus, Heidegger discarded the very concept of consciousness and proposed a "fundamental ontology" of human being (*Dasein*). Man as a subject in the world cannot be made the object of sophisticated theoretical conceptions such as "substance" or "cause"; man, furthermore, finds himself already involved in an ongoing world that cannot as a whole be made the object of such conceptions; yet the structure of this involvement is the transcendental condition of any science of objects. For example, a man can band with other men in philosophical groups and can think about the metaphysical status of other men only because he is already essentially with others. He cannot hope to so purify his own thinking that it becomes that of an impersonal thinker, an absolute ego.

Ontology of *Dasein*

According to Heidegger, to rethink the problem of reality at its roots, it is necessary to rethink the fundamentally temporal, already-given structures of human involvement. Prejudice in the West, which construes reality, or being, on the basis of beings (that is, being as the most general feature of beings), must be overturned, and the problem of the real, the "transcendent," must be rethought on a ground on which distinctions between immanent and transcendent and between perceptual and categorial have been reconstructed. The being of the world transcends any constitution of the meaning of the world and is a condition of experience. Thus, a sense is required of being not as object but as the underlying condition for the reality of the being of all objects.

Heidegger wanted to propose a genuine phenomenology, a study that would presuppose nothing of the traditionally formulated distinctions such as subjective–objective or phenomenal–real. The transcendence of the world can be understood only as it appears; *i.e.,* when they are encountered openly, things appear as appearing in part, as both revealing and concealing themselves. If to the uneducated eye the Sun appears to be smaller than it is, the naive inference can be corrected only by educating the person to interpret appearances—to calculate, for example, the speed and direction of light. The real is given in and through its appearances.

THE THOUGHT OF WHITEHEAD

The thought of Alfred North Whitehead is a distinctive variation on these contemporary themes. Dualisms are undermined by a phenomenology that does not bracket factual assertions. Logical and mathematical deductive schemes must be able to be interpreted in relationships crudely observable in experience, and abstractions of physics and common sense parading as realism (*e.g.,* that things exist separately within their own surfaces) must be revealed for what they are, namely, abstractions. The basic units of reality are organismic unities, "actual occasions," which are spatial and temporal extensions that cannot be exhaustively expressed in terms of distributions of matter at an instant. Their unity is constituted in a perception-like responsiveness to the universe that, though usually lacking consciousness or apprehension, is an appropriation to and for itself of the whole. This appropriation cannot be exhaustively expressed by point-instant mechanics (mechanics that is worked out in connection with the physics of relativity and thus measures not only the distance but also the time intervals between points) but is minimally a "prehension" (a term proper to Whitehead indicating the point-transcending function of perception and consciousness).

Organismic unities

Each enduring object of ordinary perception—tables, chairs, animals—is, for Whitehead, a "society" of actual occasions inheriting, through a process of appropriation and reenactment in a predictable way, characteristics of its predecessors. Human perception is understood as a special case of prehension, in which qualities of the environment are mediated and projected on the basis of organic and affective experience of the perceiver's body, but in such a way that some of this process can be acknowledged by the percipient upon reflection. Because human consciousness is regarded as only a special case of prehensive relations, and because vacuous realisms and notions of transcendence are regarded as "fallacies of misplaced concreteness and simple location," mind–body dualisms are rejected.

Whitehead thought of "the primordial nature of God" as a general ordering of the process of the world, the ultimate basis of all induction and assertion of law, a "conceptual prehension" that functions in the selection of those "eternal objects," or repeatable patterns that are enacted in the world. God, however, does not create actual entities. He provides them with initial impetus, in the form of their subjective aim, to self-creation. Even God is the outcome of creativity, the process by which the events of the world are synthesized into new unities. It is the creative, not fully predictable, advance into novelty of a pluralistic process. The freedom of man and the determinism of nature were regarded by Whitehead as another artificial dualism.

The future of metaphysics is uncertain, not mainly because of 20th-century critics, the Logical Positivists, but because of its own not fully predictable nor controllable dynamisms.

BIBLIOGRAPHY. These works deal mainly with the nature and possibility of metaphysics.

For a discussion of the apparently conflicting views of Plato and Aristotle, see the commentary in ARISTOTLE, *Metaphysics,* ed. by W.D. ROSS, rev. ed., 2 vol. (1924, reissued 1966); and WERNER JAEGER, *Aristotle: Fundamentals of the History of His Development,* 2nd ed. (1948, reprinted 1968; originally published in German, 1923). Modern discussions of the methods of metaphysics are found in RENÉ DESCARTES, *The Philosophical Works of Descartes,* trans. by ELIZABETH S. HALDANE and G.R.T. ROSS, 2 vol. (1911–12, reprinted with corrections, 1981), and *Philosophical Letters,* trans. from the French and ed. by ANTHONY KENNY (1970). On the geometrical form of metaphysics, see the essay by BENEDICT SPINOZA, "Ethica, more geometrico demonstratis," available in a translation by W. HALE WHITE and rev. by AMELIA H. STIRLING, *Ethic: Demonstrated in Geometrical Order . . .* , 4th ed. rev. (1927, reprinted 1930). CHRISTIAN WOLFF combined both the practice and theory of metaphysics in his voluminous metaphysical writings: *Vernünfftige* [sic] *Gedanken von Gott, der Welt und der Seele der Menschen,* new enlarged ed. (1751, reprinted 1983), *Philosophia Prima Sive Ontologia,* 2nd ed. (1736, reprinted 1962), *Cosmologia Generalis,* rev. ed. (1737, reprinted 1964), *Psychologia Rationalis,* rev. ed. (1740, reprinted 1972), and *Theologia Naturalis,* rev. ed., 2 vol. (1739–41, reprinted 2 vol. in 3, 1978–81). ALEXANDER GOTTLIEB BAUMGARTEN, *Metaphysica,* 7th ed. (1779, reprinted 1963), was in effect a digest of these last four works. The problem of the origin of ideas was first posed in JOHN LOCKE, *An Essay Concerning Humane* [sic] *Understanding* (1690, reissued 1979), on which G.W. LEIBNIZ wrote a critical commentary, *Nouveaux essais sur l'entendement humain* (1765), available also in an English translation ed. by PETER REMNANT and JONATHAN BENNETT, *New Essays on Human Understanding* (1981). GEORGE BERKELEY criticized Materialism in his *Treatise Concerning the Principles of Human Knowledge* (1710, reissued 1983), available also in a contemporary edition ed. by COLIN M. TURBAYNE. DAVID HUME applied Empiricist principles with

complete generality in *A Treatise of Human Nature,* 3 vol. (1739–40, reprinted in 1 vol., 1975), and *An Enquiry Concerning Human Understanding* (1748, reissued 1977).

IMMANUEL KANT first discussed metaphysical method in his essay "Inquiry into the Distinctness of the Principles of Natural Theology and Morals," available in a translation by LEWIS WHITE BECK, *Critique of Practical Reason and Other Writings in Moral Philosophy* (1949); and Kant examined the whole question of the possibility of metaphysical knowledge in *Critique of Pure Reason* (1982; originally published in German, 4th ed., 1794), and *Prolegomena to Any Future Metaphysics That Will Be Able to Come Forward as Science,* trans. by PAUL CARUS (1902, rev. ed. 1977). For a sustained criticism of Kant's critical point of view, see the writings of G.W.F. HEGEL, especially *The Phenomenology of Mind,* 2nd ed. (1931, reissued 1977; originally published in German, 1807), *The Logic of Hegel,* trans. from the German by WILLIAM WALLACE (1873, reprinted with the title *Hegel's Logic,* 1975), *Hegel's Philosophy of Nature,* 3 vol., ed. and trans. from the German by M.J. PETRY (1970), and *Hegel's Philosophy of Mind,* trans. from the German by WILLIAM WALLACE, enlarged ed. (1971). These last three are translations from various editions of Hegel's *Encyclopädie der philosophischen Wissenschaften,* first published in 1817.

Only a few 19th-century philosophers added to the fundamental criticisms of metaphysics developed by earlier writers. See, for example, AUGUSTE COMTE, *Cours de philosophie positive,* 6 vol. (1830–42), available also in an edition of selections, ed. by STANISLAV ANDRESKI, *The Essential Comte* (1974); and JOHN STUART MILL, *System of Logic,* 2 vol. (1843, reissued 1978). Mill was sharply criticized by THOMAS HILL GREEN, *Prolegomena to Ethics,* 5th ed. (1907, reprinted 1969); and F.H. BRADLEY, *The Principles of Logic,* 2nd ed. rev. (1922, reissued 1963).

For American metaphysical thought of the same period, see CHARLES SANDERS PEIRCE, *Collected Papers of Charles Sanders Peirce,* ed. by CHARLES HARTSHORNE, PAUL WEISS, and A.W. BURKS, 8 vol. (1931–58, reissued in 4 vol., 1974–79); and WILLIAM JAMES, *A Pluralistic Universe* (1909, reprinted 1979).

There are interesting remarks on the philosophy of philosophy in the works of WILHELM DILTHEY, especially vol. 5 of his *Gesammelte Schriften,* 5th ed., 12 vol. (1962). Twentieth-century criticisms of metaphysics derive mainly from the work of the Vienna Circle; see VIKTOR KRAFT, *The Vienna Circle: The Origin of Neo-Positivism* (1953, reissued 1969; originally published in German, 1950). LUDWIG WITTGENSTEIN, *Tractatus Logico-Philosophicus* (1922, reissued 1983), was read as an improved version of Empiricism. Among the authors who influenced the Logical Positivists were ERNST MACH, *The Science of Mechanics: A Critical and Historical Account of Its Development,* 6th ed. (1974; originally published in German, 9th ed., 1933); ALFRED NORTH WHITEHEAD and BERTRAND RUSSELL, *Principia Mathematica,* 2nd ed., 3 vol. (1925–27, reprinted 1968–73); and BERTRAND RUSSELL, *Our Knowledge of the External World as a Field for Scientific Method in Philosophy,* rev. ed. (1926, reprinted 1972). A.J. AYER (ed.), *Logical Positivism* (1959, reprinted 1978), anthologizes in translation some of the most famous papers from the Vienna Circle's periodical *Erkenntnis.* Ayer's own book, *Language, Truth and Logic,* 2nd ed. rev. (1946, reprinted 1970), was extremely successful in spreading Positivist ideas in America and Britain, where the work of GEORGE EDWARD MOORE, especially "Defence of Common Sense," in his *Philosophical Papers,* pp. 32–59 (1959, reprinted 1977), had created an atmosphere in which metaphysical claims were viewed with suspicion. Another influential book along the same lines as Ayer's was HANS REICHENBACH, *The Rise of Scientific Philosophy* (1951, reprinted 1968); see also MORRIS LAZEROWITZ, *The Structure of Metaphysics* (1955, reprinted 1968), which attempts to explain the activities of metaphysicians in terms of psychoanalysis. For criticism of Positivist ideas, see WINSTON H.F. BARNES, *The Philosophical Predicament* (1950); D.F. PEARS (ed.), *The Nature of Metaphysics* (1957, reprinted 1970); and KARL R. POPPER, *Conjectures and Refutations: The Growth of Scientific Knowledge,* 4th ed. rev. (1974). R.G. COLLINGWOOD, *An Essay on Metaphysics* (1940, reprinted 1979), purports to answer Ayer but instead contains an unconventional view of metaphysics as historical analysis. A division of metaphysical systems into "descriptive" and "revisionary" is proposed in P.F. STRAWSON, *Individuals: An Essay in Descriptive Metaphysics* (1959, reprinted 1964). For further discussions, see W.H. WALSH, *Metaphysics* (1963, reprinted 1966); A.J. AYER, *Metaphysics and Common Sense* (1969, reprinted 1973); ANTHONY QUINTON, *The Nature of Things* (1973, reprinted 1978); STEPHAN KÖRNER, *Metaphysics, Its Structure and Function* (1984); and D.W. HAMLYN, *Metaphysics* (1984). For a very different approach, compare MARTIN HEIDEGGER, *An Introduction to Metaphysics* (1959, reissued 1961; originally published in German, 1953).

Recent European thought is summarized in RÜDIGER BUBNER, *Modern German Philosophy* (1981), trans. by ERIC MATTHEW from an unpublished manuscript, which provides a critical survey of recent philosophy in Germany and compares it to philosophical work in the English-speaking world; VINCENT DESCOMBES, *Modern French Philosophy* (1980; originally published in French, 1979), a survey of contemporary philosophy in France; and ALAN MONTEFIORI (ed.), *Philosophy in France Today* (1983), a collection of essays by French philosophers describing their own work and interests. ANDRÉ DE MURALT, *The Idea of Phenomenology: Husserlian Exemplarism* (1974; originally published in French, 1958), studies the main themes in phenomenological philosophy. A useful introductory guide with an extensive bibliography is DAVID STEWARD and ALGIS MICKUNAS, *Exploring Phenomenology: A Guide to the Field and Its Literature* (1974). HERBERT SPIEGELBERG, *The Phenomenological Movement: A Historical Introduction,* 3rd rev. ed. (1982), discusses central themes in Phenomenology; and in *The Context of the Phenomenological Movement* (1981), he explains the background to that movement.

KARL-OTTO APEL, *Towards a Transformation of Philosophy* (1980; originally published in German, 1972), is an influential study of objectivity, subjectivity, and interpretation. JÜRGEN HABERMAS, *Knowledge and Human Interests,* 2nd ed. (1978; originally published in German, 1968), is a critique of Positivism. HANS-GEORG GADAMER, *Truth and Method* (1975, reissued 1982; originally published in German, 2nd ed., 1965), gives a Heideggerian account of the interpretation of experience. Another influential contribution to recent philosophy is EMMANUEL LÉVINAS, *Totality and Infinity: An Essay on Exteriority* (1969, reissued 1979; originally published in French, 1961).

Works that analyze the thought of specific philosophers include: R.E. AQUILA, "Two Problems of Being and Nonbeing in Sartre's Being and Nothingness," *Philosophy and Phenomenological Research,* 28(2):167–186 (December 1977); SUZANNE BACHELARD, *A Study of Husserl's "Formal and Transcendental Logic"* (1968; originally published in French, 1957); JOHN D. CAPUTO, *The Mystical Elements in Heidegger's Thought* (1978); JACQUES DERRIDA, *Edmund Husserl's "Origin of Geometry": An Introduction* (1978; originally published in French, 2nd rev. ed., 1974); JOSEPH P. FELL, *Heidegger and Sartre* (1979); WOLFGANG WALTER FUCHS, *Phenomenology and the Metaphysics of Presence: An Essay in the Philosophy of Edmund Husserl* (1976); AGNES HELLER (ed.), *Lukács Reappraised* (1983; U.K. title, *Lukács Revalued*); SANG-KI KIM, *The Problem of the Contingency of the World in Husserl's Phenomenology* (1977); A.M. MIRVISH, "Merleau-Ponty and the Nature of Philosophy," *Philosophy and Phenomenological Research,* 43(4):449–476 (June 1983); MARIE-LUISE SCHUBERT KALSI, *Alexius Meinong on Objects of Higher Order and Husserl's Phenomenology* (1978); and ANTHONY THISELTON, *The Two Horizons: New Testament Hermeneutics and Philosophical Description with Special Reference to Heidegger, Bultmann, Gadamer, and Wittgenstein* (1980).

Mexico

Mexico, or the United Mexican States (Spanish: Estados Unidos Mexicanos), is a federal republic located in North America. Sharing a common border throughout its northern extent with the United States, the country is bounded on the west and south by the Pacific Ocean, to the east by the Gulf of Mexico and the Caribbean Sea, and on the southeast by Guatemala and Belize. Roughly triangular in shape, Mexico covers an area of 756,066 square miles (1,958,201 square kilometres). While it is more than 1,850 miles (3,000 kilometres) across the country from northwest to southeast, the width varies from less than 135 miles at the Isthmus of Tehuantepec to more than 1,200 miles in the north.

Mexico has a vast wealth of mineral resources, a limited amount of agricultural land, and a rapidly growing population. More than half of the people live in the central core, while vast areas of the arid north and the tropical south are sparsely settled. The long-held stereotype of Mexico as a country where life is slow-paced and the population consists mostly of subsistence farmers has little truth. Petroleum and tourism have come to dominate the economy, and industrialization is increasing in many parts of the country. Internal migration has caused urban centres to grow dramatically, and more than two-thirds of Mexicans now live in cities; in population, Mexico City, the capital, is the largest city in the world (though the Mexico City metropolitan area ranks third in population when compared to other metropolitan areas). Despite impressive social and economic gains made during the 1960s and '70s, most Mexicans remain poor. Beginning in the 1980s the country was wracked by severe inflation and an enormous foreign debt.

These growing pains of modernization are in sharp counterpoint to the traditional life-styles that prevail in the more isolated rural areas. Small communal villages remain, where Indian peasants live much as did their ancestors. The cultural remnants of great Indian civilizations, such as those at Chichén Itzá or Tulum, provide a contrast to colonial towns like Taxco or Querétaro. In turn, these towns appear as historical relics when compared to the modern metropolis of Mexico City. It is this tremendous cultural and economic diversity, distributed over an enormously complex and varied physical environment, that gives Mexico its character.

Physical and human geography

THE LAND

Relief. Mexico is located in one of the Earth's most dynamic tectonic areas. It is a part of the circum-Pacific "Ring of Fire," a region of active volcanism and frequent seismic activity. Towering peaks, such as Citlaltépetl (also called Orizaba; 18,701 feet [5,700 metres]) and Popocatépetl (17,883 feet [5,452 metres]), are extremely young in geologic terms (late Tertiary) and are examples of the volcanic forces that built much of the central and southern parts of the country. Mexico is situated on the western, or leading, edge of the huge North American Plate, whose interaction with the Pacific, Cocos, and Caribbean plates has, over geologic time, given rise to the earth-building processes of the area. The complexity found in southern Mexico's physiography is due to the interaction among these tectonic plates, which produces numerous and severe earth movements. It is in this dynamical but often unstable physical environment that the Mexican people have built their nation.

On the basis of geologic history and surface configuration, Mexico can be divided into eight major landform regions. The largest, and most important for human habitation, is the Mexican Plateau. Extending from the Isthmus of Tehuantepec northward to the U.S. border, this region consists of a central plateau and its dissected borders. The central plateau tilts gently upward from the north toward the south. At its northern end the plateau is about 4,000 feet above sea level, and it rises to more than 8,000

feet south of Mexico City. Throughout the plateau, flat-tish intermontane basins and *bolsones* (ephemeral interior drainage basins) are interrupted by mountainous outcrops.

The central plateau is divided into two major parts. The Mesa del Norte begins near the U.S. border and ends near San Luis Potosí. In this arid, lower part of the Mexican Plateau, interior drainage (that is, without outlet to the ocean) predominates, and there are few permanent streams. The Mesa Central stretches from San Luis Potosí to just south of Mexico City. Formed largely by volcanic action, the surface of the Mesa Central is higher (7,000 to 9,000 feet above sea level), moister, and generally flatter than the Mesa del Norte. The Mesa Central is divided into a series of fairly level intermontane basins separated by eroded volcanic peaks. The largest valleys, such as those of Mexico, Puebla, and Guadalajara, rarely exceed 100 square miles in area, while many others are quite small. The basins are generally fertile; the traditional breadbasket of the country, the Guanajuato Basin, is located in the northern part of the Mesa Central. Many of the basins were sites of major lakes that were drained to facilitate European settlement. Around Mexico City the weak, structurally unstable soils that remain have caused buildings to shift on their foundations and over many years to sink slowly into the ground.

The Mexican Plateau is flanked by dissected mountainous borders. To the west is the largely volcanic Sierra Madre Occidental, with an average height of 8,000 to 9,000 feet. It has been highly incised by westward-flowing streams that eroded a series of deep canyons, or *barrancas,* the most spectacular of which is the Barranca del Cobre ("Copper Canyon"), Mexico's Grand Canyon. The Sierra Madre Oriental, a range of folded mountains formed of shales and limestones, is situated on the eastern side of the Mexican Plateau. With average elevations similar to those of the Sierra Madre Occidental, this highly dissected highland region has peaks exceeding 12,000 feet. The Neo-Volcánica Cordillera (also called the Transverse Volcanic Axis), with spectacular snowcapped peaks such as Popocatépetl, Iztaccíhuatl (17,342 feet [5,286 metres]), and Toluca (14,954 feet [4,558 metres]), forms the southern boundary of the Mexican Plateau.

Coastal lowlands

East and west of the Mexican Plateau lie the country's coastal lowlands. The Gulf Coastal Plain extends some 900 miles along the Gulf of Mexico from the Texas border to the Yucatán Peninsula. Characterized by lagoons and low-lying swampy areas east of the abrupt escarpment formed by the Sierra Madre Oriental, the triangular northern portion of the plain is more than 100 miles wide near the U.S. border but tapers toward the south. North of Tampico, an outlier of the Sierra Madre Oriental reaches the sea and interrupts the continuity of the Gulf Coastal Plain. South from there the plain is narrow and irregular, widening at the northern end of the Isthmus of Tehuantepec and then encompassing the horizontal limestone formations that underlie the Yucatán Peninsula.

The Pacific Coastal Lowlands, much narrower and less well defined than their east coast counterpart, begin near the Mexicali Valley in the north and terminate near Tuxpan, some 900 miles to the south; despite their name, for most of this distance, the lowlands face the Gulf of California. Bounded on the east by the steep-sided Sierra Madre Occidental, the Pacific Coastal Lowlands are a series of coastal terraces, mesas, and small basins interspersed with riverine deltas and restricted coastal strips. Parts of this arid region have become important sites of irrigated agricultural production.

Baja California

An isolated strip of extremely arid land, the Baja California Peninsula is nearly 800 miles long but seldom more than 100 miles wide. The central core of the peninsula is a huge granitic fault block with peaks of more than 9,000 feet above sea level in the San Pedro Martír and Sierra de Juárez. The gently sloping western side of these mountain ranges is in contrast to the steep eastern escarpment, which makes access from the Gulf of California extremely difficult.

The Balsas Depression, which takes its name from the major river draining the region, lies immediately south of the Mexican Plateau. The depression is formed of small, irregular basins interrupted by hilly outcrops, which gives this hot, dry area a distinctive physical landscape.

The Southern Highlands are a series of highly dissected mountain ranges and plateaus. On their southwestern side, approximately from Puerto Vallarta to the Gulf of Tehuantepec, are a series of ranges known collectively as the Sierra Madre del Sur. These relatively low (7,000 to 8,000 feet above sea level) crystalline mountains often reach the sea to create a rugged coastal margin, part of which is known as the Mexican Riviera. Picturesque coastal sites, such as Ixtapa-Zihuatanejo, Acapulco, and Puerto Escondido, are favourite tourist destinations, while the less hospitable inland basins provide a difficult environment for traditional peasant farmers. Farther northeast is the Mesa del Sur, with numerous stream-eroded ridges and small, isolated valleys some 4,000 to 5,000 feet above sea level. The Oaxaca Valley is the largest and most densely settled of these valleys. With its predominantly Indian population, it is one of the most picturesque yet poorest parts of Mexico.

A low-lying, narrow constriction of land, the Isthmus of Tehuantepec reaches an elevation of less than 900 feet. Its hilly central area is bordered on either side by narrow coastal plains.

The Chiapas Highlands, an extension of the mountain ranges of Central America, are composed of a series of fault block mountains surrounding a high rift valley. The low, crystalline Sierra de Soconusco range lies along the Pacific coast. To the northwest and paralleling the coast is the rift valley of the Grijalva River. A group of highly dissected, folded, and faulted mountains is located between the valley and the Tabasco Plain, a southeastern extension of the Gulf Coastal Plain.

To the northeast of the Tabasco Plain and extending into the Gulf of Mexico is the Yucatán Peninsula. The peninsula's limestone terrain is generally flat to rolling and seldom exceeds 500 feet in elevation. There is little surface drainage, and subterranean erosion has produced caverns and sinkholes, the latter being formed when cavern roofs collapse. The islands of Cozumel and Mujeres lie off the peninsula's northeastern tip.

Drainage. Because of its climatic characteristics and arrangement of landforms, Mexico has few major rivers or natural lakes. The largest are found in the central part of the country. The Lerma River has its headwaters in the Toluca Basin, west of Mexico City, and flows westward to form Lake Chapala, the country's largest natural lake. The Santiago River then flows out of the lake to the northwest, crossing the Sierra Madre Occidental on its way to the Pacific. The eastward-flowing Moctezuma-Pánuco river system, which drains much of the eastern portion of the Mesa Central, has carved gorges through the Sierra Madre Oriental to reach the Gulf of Mexico. Lakes Pátzcuaro and Cuitzeo, west of Mexico City, are remnants of the numerous lakes that once were found in the Mesa Central.

The Balsas River and its tributaries drain the Balsas Depression as well as much of the southern portion of the Mesa Central. Dammed where it crosses the Sierra Madre del Sur, the Balsas is a major source of hydroelectric power. Farther southeast, the Grijalva-Usumacinta river system drains most of the humid Chiapas Highlands. Together with the Papaloapan River, which enters the Gulf of Mexico south of Veracruz, the Grijalva and Usumacinta account for about 40 percent of the total volume of Mexico's rivers.

In the north, aridity and interior drainage limit the size and number of rivers. By far the most important stream in this part of the country is the Río Bravo del Norte (Rio Grande in the United States), which forms part of the international border. The Conchos River, a tributary of the Río Bravo, drains much of the Mesa del Norte. Because the Sierra Madre Occidental and the Sierra Madre Oriental originate close to the coastal margins, streams on the west and east coasts are short and steep. Along the Pacific Coastal Lowlands the Yaqui, Fuerte, and Culiacán rivers have been dammed and support major irrigated acreages. Aridity in Baja California and the porous limestones that underlie the Yucatán Peninsula cause these regions to be virtually devoid of permanent surface streams.

Soils. In the tropical areas of southern Mexico, lateritic soils predominate. Throughout southeastern Mexico, leaching produces infertile reddish or yellow soils high in iron oxides and aluminum hydroxides. The richest soils in the country are the chenozem-like volcanic soils found in the Mesa Central. Deep, easily crumbled, and rich in base minerals, these dark soils have been, in some areas, farmed continuously for several centuries. Because of their excellent drainage and good structural properties, they can be used for crops even on extremely steep slopes, but overuse has caused serious sheet erosion and exposure of tepetate (a lime hardpan) in many areas. In the arid north, gray-brown desert soils occupy the largest expanses. High in lime and soluble salts, these soils can be extremely productive when irrigated, but salt buildup is sometimes a serious problem.

Volcanic soils

Climate. Because of its topographic diversity and latitudinal range, Mexico has a wide array of climatic conditions, often occurring over short distances. More than half of the country lies south of the Tropic of Cancer. In these areas, tropical maritime air masses from the Gulf of Mexico, the Caribbean, and the Pacific, which are attracted by the relatively low pressures that occur over the land, are the main sources of precipitation that is heaviest during the period from May through August. Tropical hurricanes, which are spawned in oceans on both sides of the country, are common in the coastal lowland areas during the months of August through October. The climates in northern Mexico, situated latitudinally within one of the world's great desert regions, are strongly influenced by the semipermanent Pacific subtropical anticyclone, which minimizes precipitation.

Within the tropics temperature variations from season to season are small, often only about 10° F (5° C) between the warmest and coldest months. In these areas winter is defined as the rainy rather than the cold season. Because elevation rather than latitude is the primary climatic influence in southern Mexico, several vertical climatic zones are recognized. In the Mexican tropics, from sea level to just over 3,000 feet, is the *tierra caliente* ("hot land"), with uniformly high temperatures. Veracruz, located on the Gulf of Mexico, for example, has an average daily temperature of approximately 77° F (25° C). The *tierra templada* ("temperate land") extends to about 6,000 feet. Located at an elevation of more than 4,600 feet, Jalapa has an average daily temperature of 66° F (19° C). *Tierra fria* ("cold land") extends as high as 11,000 feet. Pachuca, at just under 8,000 feet, has an average annual temperature of 59° F (15° C). Above the *tierra fria* are the *paramos,* or alpine pastures, while the *tierra helada* ("frozen land"), or permanent snow line, in central Mexico is found between 13,000 and 14,000 feet.

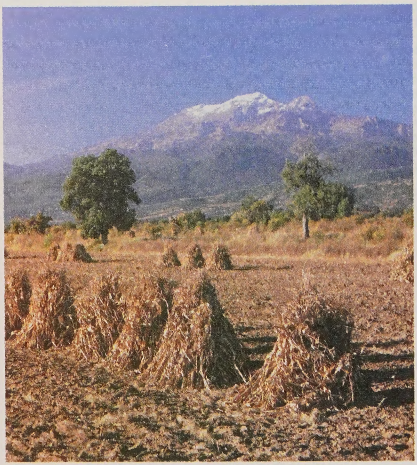
North of the tropics, temperature ranges increase substantially and are greatest in the north central portion of the Mesa del Norte. In the northern interior, summer and winter temperatures are extreme. The highest temperatures in the country, exceeding 110° F (43° C), occur in July and August in central Baja California and in the northern Sonoran and Chihuahuan deserts. Outside of the high mountainous areas of northern Mexico and the north central portion of the Mesa del Norte, the lowest temperatures normally do not descend below 32° F (0° C).

Rainfall

Most of Mexico lacks adequate precipitation at least during a part of the year. With the exception of the highland areas of the Sierra Madre Occidental, the Sierra Madre Oriental, and the Gulf Coastal Plain, all of the area north of the Tropic of Cancer generally receives less than 20 inches (500 millimetres) of precipitation annually and is classified climatically as either tropical desert or tropical steppe. Nearly all of Baja California, much of Sonora state, and large parts of Chihuahua state receive less than 10 inches of rainfall yearly. Much of central and southern Mexico receives less than 40 inches of precipitation annually, most from May through August, and is classified as having tropical savanna or highland savanna climates. Only the Gulf Coastal Plain and the adjacent mountains, from roughly Tampico southward to Villahermosa, the Chiapas Highlands, and the southern part of the Yucatán Peninsula receive abundant rainfall year-round. In combination with uniformly high temperatures, this creates a tropical rain forest climate in these areas.

Plant and animal life. The tropical deserts of Baja California, Sonora, and north central Mexico are characterized by sparse desert scrub vegetation. On the higher portions of the Sonoran and Chihuahuan steppes, as well as in much of Coahuila and Tamulipas, there have evolved distinctive ecosystems composed of short grasses, scattered shrubs, and a variety of cacti and other succulents. Sonora and Chihuahua are the archetypes for flora groups that bear their names. The boojum tree is unique to a limited portion of Sonora and central Baja California.

Most of the Sierra Madre Occidental and large parts of the Mesa Central, including its dissected borders, originally were covered by forests of coniferous, evergreen deciduous, and deciduous trees. Similar forests extended southward into the Southern Highlands. Long periods of human occupation in these regions have decimated most of the natural vegetation. Major areas of coniferous forests are found at higher elevations in the Sierra Madre Occidental. The semiarid Balsas Depression has a tropical scrub vegetation composed of shrubs, low deciduous trees, and scattered cacti.



The high-precipitation zones of the Gulf Coastal Plain, the adjacent east-facing mountain slopes, the Chiapas Highlands, and the southern part of the Yucatán Peninsula are dominated by tropical rain forest, or selva, vegetation. These dense stands of broadleaf evergreen trees of varying heights are among the most luxuriant and diversified in the world. Valuable tropical hardwoods, as well as ferns, epiphytes, and a variety of palms, make these selva areas of particular interest. A large portion of the Pacific coastal area, from Mazatlán to the Guatemalan border, is covered by tropical deciduous or semi-deciduous forests, which lack the variety and density of tropical rain forests.

Mexico sits astride the commonly accepted boundary dividing North and Middle American animal species and, therefore, has a diverse array of fauna, especially in the selva regions of the south. The rain forests of the Gulf Coast and Chiapas Highlands and the semi-deciduous forests of the Pacific coast still provide a largely undisturbed habitat for monkeys, parrots, jaguars, tapirs, anteaters, and other tropical species. In contrast, the natural wildlife of northern Mexico was severely affected by the introduction of European grazing animals more than 400 years ago. While rabbits, snakes, and armadillos abound in the deserts and steppes, larger animals such as deer, pumas, and coyotes are found mainly in isolated or mountainous areas. Countless ducks and geese migrate into the northern part of the Sierra Madre Occidental to winter. A millennium of human habitation has brought about the decimation of natural fauna throughout much of the Mesa Central and parts of the Southern Highlands, especially in the Oaxaca Valley.

Settlement patterns. *Traditional regions.* Because of distinctive differences in physical environment, ethnic and racial characteristics, and settlement histories, specific cultural areas have evolved. Mexico traditionally has been divided between the Spanish-mestizo north and the Indian-mestizo south. This corresponds roughly to the pre-Columbian boundary that separated the highly developed Indian cultures of the Mesa Central and the south from the more primitive groups to the north.

Northern Mexico is a sparsely populated area with isolated clusters of settlement; it can be divided into four separate cultural regions. The largest region is the North, which closely corresponds in area to the Mesa del Norte. Mining and ranching were introduced there by the Spanish in the 16th and 18th centuries, respectively, and these industries have continued to characterize the region, though modern irrigation projects and industrialization programs along the border with the United States have diversified the economy.

The Northeast stretches from Tampico to the U.S. border and inland to the Sierra Madre Oriental. The Indian population of the area was eliminated by early European settlers, who established farms and ranches in the area. Although it was long one of the country's poorest regions, the emerging petroleum and steel industries and the develop-

Volcanic peak of Iztaccíhuatl overlooking a field of corn shocks in the agricultural region of Puebla state in the Mesa Central of Mexico.
Chip and Rosa María de la Cueva Peterson

ment of irrigation projects along the Río Bravo del Norte have greatly improved the region's economic condition.

The Northwest is an extensive region lying west of the crest of the Sierra Madre Occidental and stretching southward from the U.S. border to northern Nayarit state. This physiographically complex area had a substantial Indian population before the Spanish conquest, and the Tarahumara and Seri are among the Indian peoples still found in isolated parts of the region. As in the North, mineral resources originally attracted the Spanish, but agriculture, especially ranching, now characterizes the region.

Baja California, historically one of the more isolated parts of Mexico, is largely a desert, with major concentrations of settlement in urban areas at both ends of the peninsula. The original Indian population, scattered and culturally poorly developed, was decimated by diseases introduced by missionaries in the late 18th century. Europeans and mestizos established themselves in farming communities at oases, originally at sites such as San Ignacio and Mulejé.

Southern Mexico was much more strongly influenced by its Indian heritage than was the northern part of the country. The cultural core of the nation has been the Central region, which includes the central and eastern portions of the Mesa Central and its surrounding highlands. This was the centre of the Aztec Empire as well as numerous other Indian homelands. It became the core of New Spain and the political and economic capital of Mexico. In addition to being the primary centre of urbanization, this is also one of the nation's most important agricultural areas. Numerous basins, such as those of Mexico, Toluca, Puebla, and Morelos, are densely settled. Racial mixing has been intense in this region, but Indian groups are still found in the more isolated portions of Michoacán, Mezquital, Puebla, and Toluca. Nowhere is the contrast between modern urban Mexico and traditional rural Indian lifestyles sharper than in this region.

The Central region

The West region is centred on the city of Guadalajara and encompasses the state of Jalisco along with portions of Colima, Nayarit, Aguascalientes, Zacatecas, and Guanajuato states. With its relatively high rural population, fertile basins, and access to the Pacific, it was historically the most important agricultural region in the nation. The Guanajuato Basin has long been called the "breadbasket of Mexico." Despite its agricultural prominence, a large number of small urban centres, such as Querétaro, Salamanca, Irapuato, and León, are developing industrially, while Manzanillo has become the most important port on the Pacific. Many of the things often thought of as distinctively Mexican—such as tequila, mariachi music, and the ornate embroidered sombrero and charro costume—originated in the West.

The Balsas cultural region, which closely corresponds to the physiographic area of the same name, is arid, hot, and sparsely settled. Cattle ranching has been the mainstay of the economy, although subsistence-level slash-and-burn agriculture is widely practiced by impoverished peasant farmers.

The Southern Highlands, encompassing much of the states of Michoacán, Guerrero, and Oaxaca, is poverty-stricken. This region has the highest concentration of Indians in the country; and the Zapotec, Mixtec, and other Indian groups farm *minifundia* (small plots of land), using traditional methods. The picturesque, "crazy-quilt" landscape that results belies the widespread poverty. Modern coastal tourist centres, such as Acapulco and the more recently developed Puerto Escondido, are a marked contrast to the traditional rural life-styles of the region.

The Gulf Coast region includes the coastal zones of Veracruz and Tabasco as well as the adjacent east-facing slopes of the Sierra Madre Oriental. The population of the coastal area is overwhelmingly mestizo, but Indian groups are found in the mountains north of Veracruz. Veracruz, the cultural centre of this region, has long been the country's major nonpetroleum port. Cattle ranching and commercial agriculture are important components of the rural economy. The southern parts of the region were disease-infested, swampy, and nearly devoid of settlement until the Papaloapan and Grijalva-Usumacinta river projects allowed commercial exploitation of the rich alluvial soils.

Most of the Chiapas region is relatively isolated from the rest of Mexico. Commercial agriculture, particularly cotton production, is practiced on the Soconusco (Pacific) coast, while livestock grazing and subsistence agriculture are important elsewhere. Indian peoples are the majority in the northern highlands around San Cristóbal de las Casas, but mestizos are the dominant population in the southern half of the region.

The Yucatán

The centre of the lowland Maya civilization, the Yucatán has a predominantly Indian rural population. This low-lying area is known for its archaeological sites, such as Chichén Itzá, Uxmal, and Tulum. Mérida, the only major city in the region, was the centre for the production of henequen (a type of *Agave*), which led to a regional economic boom in the late 1800s. In the tropical rain forests to the south, the sparse population depends on subsistence agriculture or hunting and gathering.

Rural settlement. Before the arrival of Europeans, the indigenous population was highly concentrated in the Central, West, and Southern Highland regions. The Spanish settled in existing Indian communities in order to exploit their labour in agriculture and mining. As a result, these areas have remained the most densely populated throughout Mexico's history.

Away from this central core, settlement was sparse and was attracted to specific opportunities, such as mines, mission sites, or military outposts. Mining had the largest impact on population redistribution. Silver-mining towns, such as Durango, San Luis Potosí, Aguascalientes, Pachuca, and Zacatecas, were founded in the middle to late 1500s and represented the first settlements outside the central core. By contrast, it was not until the mid-1800s that large-scale ranching was introduced into northern Mexico. This clustered pattern of settlement, with large areas effectively devoid of population, has characterized the nation's rural settlement pattern.

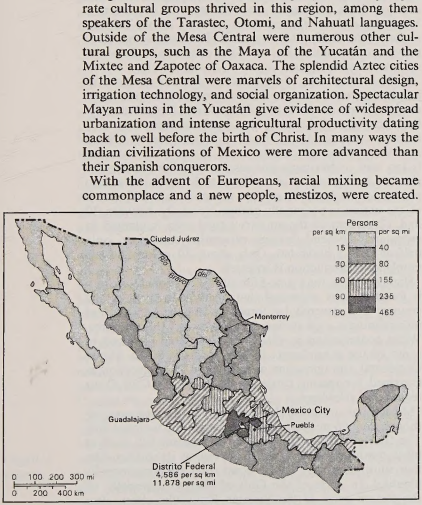
Urban settlement. Urbanization is taking place at a rapid pace in Mexico. While the largest urban places are growing the most rapidly in absolute numbers, small- and intermediate-sized cities have the highest percentage increases. By the mid-1980s the country had more than 100 urban centres with 50,000 or more people. The major axis

of urbanization stretches as a narrow band across central Mexico from Puebla to Guadalajara, but the growth of the northern border cities has been the most spectacular.

Major cities

Within the hierarchy of Mexican urban places, Mexico City is the undisputed primary city. It is the political, economic, social, educational, and industrial capital of the nation. With a population of almost 10,000,000 in the mid-1980s, it is the largest city in the world (see MEXICO CITY).

Guadalajara is the nation's second largest urban area. It is a much more traditional city in structure and appearance than is Mexico City. As the regional capital of Jalisco and much of the West, Guadalajara is a major market centre and has developed a substantial industrial base. With a well-respected university and medical school, it is also a major educational and cultural centre.



Monterrey developed as the iron and steel centre of the nation. Because the modern city dates only to the beginning of the 20th century, and because much of its growth is recent, it is singularly unremarkable in appearance, and the arid Mesa del Norte provides a stark, somewhat barren setting. High-grade coal from the nearby Sabinas fields was a major consideration in siting the steel industry in Monterrey. A number of heavy industries also have been located in the urban area. As the centre of the National Action Party (PAN), Monterrey is a stronghold of political conservatism.

THE PEOPLE

Ethnic composition. Mexico's population is composed of many ethnic groups. At the time of European arrival in the early 1500s, the country was inhabited by people who are thought to have migrated into the New World from Asia some 40,000 to 60,000 years ago by crossing a former land bridge in the Bering Strait. After their arrival into what is now Mexico, centuries of isolation allowed the evolution of unique cultural traits among the many separate clusters. Highly organized civilizations occupied various regions for at least 2,000 years before European discovery.

By far the greatest number of people lived in the Mesa Central. At the time of European arrival, most lived under the general rule of the Aztec Empire, but many separate cultural groups thrived in this region, among them speakers of the Tarastec, Otomi, and Nahuatl languages. Outside of the Mesa Central were numerous other cultural groups, such as the Maya of the Yucatán and the Mixtec and Zapotec of Oaxaca. The splendid Aztec cities of the Mesa Central were marvels of architectural design, irrigation technology, and social organization. Spectacular Mayan ruins in the Yucatán give evidence of widespread urbanization and intense agricultural productivity dating back to well before the birth of Christ. In many ways the Indian civilizations of Mexico were more advanced than their Spanish conquerors.

With the advent of Europeans, racial mixing became commonplace and a new people, mestizos, were created.

Population density of Mexico.

Over the past four centuries mestizos have become the dominant racial group in Mexico, accounting for at least half of the total population. Northern Mexico is overwhelmingly mestizo in both urban and rural areas. Because the number of Europeans in the total population has been small, the Indian contribution to the mestizo racial group has been relatively large. Indian racial characteristics therefore predominate in many Mexican mestizos. Europeans, including those who immigrated during the 20th century, account for about 15 percent of the population and are largely concentrated in urban areas, especially Mexico City, and in the West.

Although mestizos form the bulk of the population throughout the country, there are several areas where Indian speakers still represent the dominant population group. Maya speakers are the majority ethnic group in the rural Yucatán and the Chiapas Highlands. In the Southern Highlands, especially the Oaxaca Valley and remoter parts of the Sierra Madre del Sur, Indian (primarily Zapotec) communities abound. Despite their decreasing numbers, enclaves of Indians are still significant in isolated mountain areas on the eastern margin of the Mesa Central.

Linguistic composition. Spanish, which is the official national language and the language of instruction in schools, is spoken by more than 95 percent of the population. Although Indians are thought to represent about a quarter of the population, less than 10 percent of them speak an Indian language. There are, however, more than 50 Indian languages spoken by more than 100,000 people, including Maya in the Yucatán; Huastec in northern Veracruz; Nahuatl, Tarastec, Totonac, Otomi, and Mazahua mainly on the Mesa Central; Zapotec, Mixtec, and Mazatec in Oaxaca; and Tzeltal and Tzotzil in Chiapas.

Religion. There is no official religion in Mexico, as the constitution guarantees separation of church and state. However, Roman Catholicism is practiced by more than 95 percent of the population. The shrine of the Virgin of Guadalupe, the nation's patron saint, is located in Mexico City and is the site of annual pilgrimage for hundreds of thousands of people, many of them peasants. A significant proportion of Indians retain traditional religious beliefs and practices, despite their adherence to Roman Catholicism. Protestant missionaries are active in the country and have been especially successful in converting the urban poor.

Demographic trends. One of the most important characteristics of Mexico's population since 1940 has been the rapid rate of natural increase. Even though the rate slowed during the 1980s, the population is still growing about 50 percent faster than the world average and three times as rapidly as that of the United States. This growth rate is a reflection of the improved health care standards that were introduced beginning in 1940. There have been drastic declines in the death rate, and infant mortality, although still quite high in comparison to more developed countries, has been significantly reduced. The crude death rate, a gross measure of deaths within the population, has declined by as much as 50 percent since 1960.

Given the rapid growth, the population is disproportionately young; about 40 percent of the population is under 15 years of age. Life expectancy at birth has nearly doubled since 1930 and, at 70 years, is close to that in more developed countries.

The total population has increased more than 500 percent since 1915. Such growth has severely taxed the ability of the Mexican government to provide basic social services and economic opportunities for the people. Although the government traditionally has opposed limiting population growth, the position was modified in the late 1970s because of recurring economic difficulties.

Internal migration has altered the distribution of the population. Large numbers of peasants from rural areas and small towns have moved to cities since mid-century. An estimated 70 percent of Mexicans live in cities, 50 percent in cities of more than 50,000. This represents a substantial proportional decline in rural population, which accounted for half of all residents in 1960, although their absolute numbers have remained fairly constant. A lack of agricultural land, limited job opportunities, and the availability

of few social amenities push people from the rural areas.

The perception of increased chances for social and economic mobility as well as the dynamic character of urban places attracts rural people to the cities. Many internal migrants go to large regional centres such as Guadalajara, Puebla, and Monterrey, but Mexico City is the principal destination. Because of favourable employment prospects, increasing numbers of migrants have moved to cities on the U.S. border. As a result, Ciudad Juárez, Mexicali, and Tijuana are among the fastest growing cities in the nation.

Emigration

In addition to internal migration, the number of people who have emigrated from Mexico to the United States has grown sharply since the late 1970s. Estimates are highly inaccurate and vary drastically, but it is believed that somewhere between 4,000,000 and 8,000,000 Mexicans relocated illegally to the United States between 1970 and 1985. While a large proportion of these emigrants have low educational levels and limited technical skills, an increasing number of highly qualified technicians and professionals have found their way north, causing a "brain drain" for the country.

Illegal migration has acted as a safety valve in that it eases the social and economic problems associated with overly rapid population growth. The nation's resources would be stressed even further if large-scale emigration had not occurred. Remission of income earned outside of the country also represents a significant part of the nation's economy.

THE ECONOMY

Since the Revolution of 1910, Mexico's most notable economic achievement has been the sharp reduction of foreign ownership of the means of production while maintaining overall national growth. The economy is a combination of private, state, and mixed-capital enterprises. The state regulates the operation of private concerns in a number of ways, including the issuance of import licenses, the establishment of production quotas, and the control of prices on some products. In addition, private capital is barred from investment in certain activities. Private capital interests, with a majority of shares owned by Mexican nationals, control most industrial manufacturing activities, while semiautonomous state corporations operate the petroleum industry, generate and distribute electricity, run the banks, and oversee the telephone and telegraph systems. The government also controls foreign capital investment, usually by prohibiting it from certain industries, such as insurance, petroleum, and forestry, or by limiting it to a minority interest in others, such as mining, transportation, broadcasting, and soft-drink production.

State regulation of commerce

Mexico is a developing nation economically. Nonetheless, in constant pesos, the gross domestic product per capita increased more than one and a half times between 1960 and 1980. Given very rapid population growth during the same period, the nation's economic growth has been impressive, with an average annual rate of nearly 7 percent. Services account for almost 50 percent of the total gross domestic product, manufacturing about 25 percent, and agriculture about 10 percent.

The nation's active labour force is equivalent to about one-third of the total population. The service sector accounts for the largest proportion of workers, about 30 percent. Slightly more than 25 percent of workers are employed in agriculture and about 12 percent in manufacturing. Nearly half of the nonagricultural labour force is unionized. The largest and most powerful union, the Confederation of Mexican Workers, is closely related to the ruling political party, the Institutional Revolutionary Party.

The economic boom that began in the 1970s was sustained by petroleum exports and spurred substantial capital investment from both the public and private sectors. The increase in capital created jobs and expanded the market for goods and services. Much of this development, however, was financed through loans from private banks and international lending institutions. The resulting debt, coupled with plummeting petroleum prices on the world market in the early 1980s, precipitated an economic crisis unparalleled in Mexico's history.

Resources. *Mineral resources.* Minerals have been an important part of the economy throughout Mexico's history, and some 40 are now extracted in commercial quantities. Silver was long the most valuable product mined in the country, and Mexico continues to be the world's leading producer of that commodity. The major mining area during the colonial period was the so-called Silver Belt, a region that extended from Guanajuato and Zacatecas in the Mesa Central to Chihuahua in the Mesa del Norte, with outposts such as San Luis Potosí farther east.

The Silver Belt

The Silver Belt is still the primary region of nonfuel mineral production in the country, although now both industrial and precious minerals are sought. Silver is still taken from the older centres of Guanajuato, Pachuca, and Zacatecas, but zinc, lead, gold, mercury, cadmium, and such trace minerals as antimony and manganese are more important in total value. Iron ore deposits have been worked near Durango since the early 1900s and have provided the raw materials used in iron and steel production at Monterrey. Coking-quality coal is mined at the Sabinas fields to the north of Monterrey. Rich copper deposits were discovered in the late 1800s near Santa Rosalía in Baja California, but these deposits have been largely depleted. The country's largest deposits of copper are located at Cananea and La Caridad in northern Sonora state.

Since the mid-1970s, petroleum products have been Mexico's primary economic asset. Nearly 70 percent of the nation's foreign exchange earnings is derived from the sale of oil, the overwhelming majority of which is exported to the United States. The country's first commercially productive oil fields were discovered about 1900 off of Tampico on the Gulf Coast. Shortly thereafter additional producing zones were found farther south, near the Isthmus of Tehuantepec. Foreign capital was invested in the exploitation of petroleum, and most oil was exported until the industry was nationalized in 1938 with the creation of Petróleos Mexicanos (Pemex), a semiautonomous governmental agency charged with the exploration, production, and marketing of oil and natural gas.

Petroleum products

Several major oil-producing fields are now in operation in the Gulf of Mexico and along its coast; the main fields include the Poza Rica (near Tuxpan), the Tampico-Misantla basin, and the Chiapas-Tabasco sites. Major natural gas fields are located near Reynosa in northeastern Mexico and near Veracruz and in the Chiapas-Tabasco region of the Gulf of Mexico coast. The country has huge proven and potential reserves of petroleum and substantial reserves of natural gas.

Biologic resources. Largely because of the diversity of its physical environment, Mexico produces a wide array of agricultural products in different areas. Despite the fact that farming and ranching have been the basic economic activities throughout its history, Mexico has a limited amount of good agricultural land. Much of the country is too arid or too mountainous for crops or grazing. Irrigation is required in many areas to bring the land into production. It is estimated that no more than 20 percent of the nation is potentially arable. Normally, between 10 and 12 percent of the country's total area is planted to crops annually, and, because of weather conditions, only half of that is harvested. Only about 20 percent of the cropland in production is irrigated.

Slightly more than one-fifth of the national territory is forested. It is estimated that nearly two-thirds of the country was covered by forests in the mid-1500s, but indiscriminate exploitation has decimated this resource. While conservation methods are now being practiced in some of the pine forests in the northern Sierra Madre Occidental, the uprooting of rain forest for conversion to grassland for rearing cattle continues in the Gulf Coast region and elsewhere.

Mexico has a bountiful supply of marine resources, although they do not form a major part of the national diet. The Gulf of California is known for its game fish, such as black marlin and other billfish, as well as its shrimp. Farther south along the Pacific coast tuna are commercially plentiful. In parts of the Gulf of Mexico, especially off the eastern coast of the Yucatán Peninsula, clean, clear waters teem with tropical fish. Large shrimping grounds

are found in the northern part of the Gulf of Mexico as well as in the south near Campeche.

Hydroelectric resources. Oil and natural gas account for more than three-fourths of the fuels used by Mexican industry, but this represents a recent change brought about by abundant new supplies. In the 1940s and '50s hydroelectric power was seen as vital for the nation. Because of their proximity to major population clusters, most of the early projects were located on the streams exiting the eastern and southern escarpments of the Mesa Central. Better transmission technologies have permitted newer projects to be located farther away, such as the Malpaso Project on the Grijalva River on the margins of the Chiapas Highlands.

Agriculture, forestry, and fishing. *Agriculture.* About one-tenth of the gross domestic product is derived from agriculture, which employs one-fourth of the total work force. A significant proportion of Mexican agriculture still relies on traditional farming methods, especially in the regions having predominantly Indian populations. In these areas intensive subsistence agriculture based on corn (maize), beans, and squash is practiced on small plots of land, often as parts of communal village holdings. The system is highly labour-intensive and has low per capita productivity, which limits the opportunities for economic advancement.

The ejido system

While not its major objective, one of the legacies of the Revolution of 1910 was land reform, which produced the ejido system. At the time of the revolution, the rural peasantry was virtually landless and worked under a debt peonage system on haciendas (large estates). The Constitution of 1917 contained a statute limiting the amount of land that a person could own and, through the concept of social utility, legalized the federal government's expropriation and redistribution of land. Initially, small parcels were granted to communal groups whose members worked holdings individually (usually cropland) or in common (usually pasture or woodland). Later modifications brought about cooperative ejidos. By the end of the 1930s haciendas had all but disappeared from the Mesa Central, Balsas Depression, and Southern Highlands. Land redistribution produced a large number of small holdings, from 10 to 20 acres (four to eight hectares) in size. These small farms are barely viable as economic units, but although much of what is grown is used for subsistence, a considerable proportion of what they produce enters into commercial markets to supply the towns and cities of central and southern Mexico. Corn is the staple crop in most areas, but many crops and animal products are produced.

Commercial agricultural products come from three major regions of the country—the tropical regions of the Gulf Coast and Chiapas Highlands, the irrigated lands of the North and Northwest, and the Guanajuato Basin in the Mesa Central. Tropical crops have been grown on the Gulf Coastal Plain and its adjacent highlands since the early colonial period. Production now extends southeastward from near Tampico to the Chiapas Highlands and inland to the eastern slopes of the Sierra Madre Oriental. Coffee and sugarcane are the most important crops in value and acreage. They are produced in quantities sufficient to meet the country's internal demands as well as to provide sizable amounts for export. Coffee is Mexico's most valuable export crop. Increased local demand for sugar, however, has caused exports of that commodity to drop since the late 1970s. Bananas, pineapples, papayas, mangos, cacao, and rice are grown primarily for the domestic market. Mexico is one of the world's leading producers of vanilla, which is also grown in these areas. Smaller areas of cacao, coffee, and sugar production are found in western Chiapas. Cotton has become a major crop along the Pacific Coastal Plain near the Guatemalan border.

Irrigation projects

Irrigated agriculture has brought large-scale commercial production to the North and Northwest. Cotton has become the major crop in the areas developed by irrigation projects since the 1930s. The Laguna Project near Torreón was the nation's first attempt at providing water to the arid North, and huge cooperative ejidos were formed to farm cotton using modern mechanized methods. This was followed by the Las Delicias Project near Chihuahua, which also featured cotton but later brought substantial acreages of wheat into production. Much of the region's wheat is grown from drought-resistant hybrids. Despite its new producing areas, rapid population growth has made Mexico a net importer of grain since 1980.

Several new areas in the Northwest have been brought into production since the 1940s. The largest of the saline land reclamation projects are in the Fuerte and Yaqui river valleys, but a series of projects extends from Hermosillo in the north to Culiacán in the south. Much of the land is worked by cooperative ejidos, though significant areas of private land are also farmed there. Wheat, especially north of Sinaloa, is the most important crop in the region, which is now the country's centre of grain production. Cotton, vegetables, and oilseeds also make important contributions to the area's agricultural economy. Winter vegetables, especially tomatoes and lettuce, are grown mainly for markets in the United States. Cotton is the major crop of the Mexicali Valley.

Within the Mesa Central, the Guanajuato Basin traditionally has been considered the "breadbasket" of Mexico. Wheat, corn, vegetables, peanuts (groundnuts), strawberries, and beans are produced on small holdings. While still a major producing region with the advantage of proximity to major urban markets, the Guanajuato Basin has been eclipsed in agricultural preeminence by the Northwest.

Livestock ranching has been concentrated in the North since Mexico gained independence. Open-range cattle operations, frequently exceeding 250,000 acres in size, were created in the 1800s, and a number of large holdings persist despite agrarian reform. Because of the arid conditions and limited natural vegetation, the region's capacity for grazing animals is low. Nonetheless, a significant proportion of livestock is raised on relatively small ranches. In combination, these ranches have provided meat for the domestic market as well as substantial quantities for export.

Since the 1960s major improvements have been made in the ranching industry in the North. Many of the criollo cattle, descendants of stock introduced from Spain in the 1500s, have been replaced by Herefords, Brahman, and other breeds, while open-range methods are giving way to rotational grazing systems. Some natural pastures are being improved by means of irrigation, top-seeding, and fertilization. Supplemental feeding of stock has also become more common.

Cattle are also raised commercially for the domestic market in tropical areas, mainly in the Northeast, Gulf Coast, and Chiapas regions. In these areas Brahman, or Zebu, cattle are favoured because of their tolerance of heat and high humidity. Luxuriant vegetation and ample moisture make the animal-carrying capacity of the land much higher than in the North. Rain forests are being cleared and planted with imported African grasses to facilitate grazing.

Mexico produces two specialized crops that are rarely grown elsewhere. Henequen, a member of the genus *Agave,* yields a fibre used in furniture manufacturing and cordage. The plant was introduced into the northern Yucatán in the 1880s, and for many years this area was the sole source of henequen. Extensive plantations survived until the mid-1930s, when land reform led to their demise. Still an important export crop for the region, henequen is now grown on small farms and by cooperatives.

Maguey, also of the genus *Agave,* is planted in many parts of the Mesa Central. Originally used in making pulque, an inexpensive alcoholic beverage, maguey was a crop grown by many small farmers because it could be planted on infertile, rocky soils. Tequila, Mexico's national liquor, also is derived from maguey. Tequila takes its name from the town of Tequila in the state of Jalisco, the centre for its production and distilling. Yet another alcoholic drink derived from an agave is mescal, which is produced primarily in Oaxaca.

Forestry. By far the largest part of the forest area is located in the tropical east and south of the country. These tropical forests yield a wide variety of valuable products, including hardwoods, such as oaks and mahogany, and an assortment of fragrant woods, such as cedar and rosewood. In addition, the rain forests of Chiapas and the southern

Yucatán contain sapodilla trees, which are the principal source for chicle, the latex used in the manufacture of chewing gum. Softwoods are found in the Sierra Madre Oriental and the Sierra Madre Occidental above 6,000 feet. Stands of ponderosa, lodgepole, and other pines are especially well developed in the Sierra Madre Occidental, especially in the states of Chihuahua and Durango.

Fishing. Two shrimping areas of the Gulf Coast, from Tampico north to the U.S. border and from Veracruz south to Campeche, have been fished commercially since the 1940s. The Gulf of California shrimping grounds, first exploited on a large scale in the late 1950s, are now the most important in the nation. Deepwater fish abound off the Pacific coast of Baja California. Since the formation of a commercial fishing fleet in the 1960s, this area has become the country's main fishing ground, producing most of the total commercial catch. Sardines, anchovies, and tuna are the leading species taken. In the near-shore zone of the Pacific coast of Baja California, lobster and abalone are captured in commercial quantities. The rest of the commercial marine catch comes from the Gulf of Mexico, especially off the Campeche Bank north of the Yucatán Peninsula.

Industry. Mexico is one of the most industrialized countries in Latin America. Industry accounts for one-fourth of the gross domestic product and provides jobs for one-tenth of the total work force. A disproportionate share of manufacturing is located in the Mexico City metropolitan area, largely because of its huge market and superior infrastructure. An impressive array of industries has located there, including agricultural processing, automotive assembly, electronics manufacturing, iron and steel production, and the manufacture of a wide variety of consumer goods. The efforts of the federal government to disperse industry to sites outside the capital have had only modest success. In fact, much of the industrialization so dispersed has been to neighbouring cities of the Central region. One exception has been the growth in important border cities, spurred by the *maquiladora,* or "twin plant," program. This arrangement allows duty-free importation and exportation between the United States and Mexico of raw materials or parts made within a narrow border zone. The overwhelming majority of the plants are foreign-owned and have been located in Mexico to take advantage of low labour costs.

Mineral production and processing

Most of the mining of metals, industrial raw materials, and coal is found in the North, while oil and natural gas production is concentrated in the Northeast and Gulf Coast regions. Open-pit mining is used for extracting copper at Cananea and La Caridad, coal at Sabinas, and iron ore at Las Truchas and Monclova. The government-operated steel mills north of Mexico City were shut down in the late 1980s.

Pemex, Latin America's largest oil company, produces several hundred billion barrels of oil annually. A system of oil and gas pipelines has been constructed to move these products to major cities in the Mesa Central and to the U.S. border, where they formerly linked up with pipelines in the United States. Large, new oil refineries have been built near the Gulf of Mexico at Minatitlán and Reynosa to augment the older productive capacity of those at Ciudad Madero near Tampico. Additional refineries are located at Salamanca, Tula and Atzcapotzalco near Mexico City, Poza Rica, and Salina Cruz. Sulfur is found in conjunction with petroleum in many of the Gulf fields and is used in the manufacture of a wide variety of products. Petrochemical plants have been built in Veracruz state at Coatzacoalcos, the major export centre for sulfur products, and at Ciudad Pemex in Tabasco. Both are located in formerly unpopulated rain forest regions. A number of petrochemical sites are also found near refineries in the Mesa Central.

Manufacturing

The mechanical engineering sector is engaged in the production of automobiles and trucks. Auto assembly plants have been established in Puebla, Toluca, and Hermosillo in the Northwest. Textile production was traditionally more dispersed, with older centres located in Puebla and Guadalajara and newer ones in Torreón and Ciudad Juárez. The border industrialization program has seen a growing concentration of "high-tech" industries such as electronics assembly, including television and computer components, and other manufacturing in cities such as Tijuana and Ciudad Juárez.

Before the economic slowdown of the early 1980s, public-works projects such as housing and transportation infrastructure accounted for as much as half of the construction activity in the nation. Such programs were subsequently reduced, and privately financed construction was essentially curtailed because of high interest and inflation rates. A massive rebuilding program is needed to repair damage caused by the 1985 Mexico City earthquake.

The Federal Commission of Electricity operates the electrical power network for the country. Thermal generation, using oil and natural gas, has replaced hydroelectric power as the main source of electricity.

Tourism

Tourism is a major growth industry and Mexico's second largest economic asset after petroleum. Tourists once traveled mainly to Mexico City and the surrounding colonial towns of the Mesa Central or to the Mayan ruins of the Yucatán. More recently, tourists have discovered the country's beaches, and the government has invested heavily in this sector. The world-famous resorts of Acapulco, Puerto Vallarta, Ixtapa-Zihuatanejo, Cancún, Cozumel, Mazatlán, and Cabo San Lucas have been developed or significantly improved since the 1960s through the construction of new hotels, airports, and other tourist facilities. Given an exotic cultural diversity, tropical settings, relatively low prices, and easy accessibility, Mexico exerts a strong attraction on American tourists, who now represent most of its visitors.

Foreign debt

Finance. Mexico accumulated more than two-thirds of its foreign debt after the mid-1970s, largely in conjunction with the decline in international prices for petroleum. The country had to renegotiate its obligations to foreign lenders in the 1980s in order to meet debt service payments, and additional loans were secured to pay interest on the debt as well as to restructure payments. Many of the nation's most basic economic dilemmas stemmed from the foreign debt problem. To solve this problem the government embarked upon an austerity program, which included limiting federal spending and controlling prices and wages.

As a result of internal financial problems, there was a major outflow of capital to money markets in other countries, especially the United States. A general lack of confidence in the government's ability to overcome the debt problem stymied economic recovery, and foreign investment, except in *maquiladora* operations, was drastically reduced.

Banking structure

Until 1982 Mexico had a dual banking structure consisting of governmental financial institutions and private banks that were owned by commercial and industrial groups. The private banking sector was nationalized in an effort to reduce the perceived manipulation and exploitation of the financial markets by private capital. The Bank of Mexico has the sole right to issue bank notes; it also enforces credit controls, fixes reserve requirements, and sells gold to the public. There are other state financial institutions, the most important being the National Development Bank. It is one of the primary financial institutions through which foreign funds are channeled into industrial development projects.

The nation's stock exchange plays only a minor role in providing capital. Most funds are secured through government bonds or bank securities.

Trade. Mexican imports increased rapidly in the 1970s, especially capital goods and agricultural products. The value of exports during this time also increased substantially because of high petroleum prices on the world market. Since the early 1980s, however, the value of oil exports has been substantially reduced.

The United States is Mexico's major trading partner. Almost two-thirds of all exports go to the United States, mainly in the form of petroleum, while more than two-thirds of all imports are from the United States.

Transportation. Because of its physical diversity and developing economy, Mexico has had a difficult time creating an integrated transportation network. It was one of the first countries in Latin America to promote railway development, but the extensive state-owned railway sys-

tem remains inefficient. Major rail routes extend outward from Mexico City northwestward along the Pacific coast to Mexicali, northward through the Central Plateau to El Paso and Laredo, Texas, eastward via the Gulf Coastal Plain to the Yucatán Peninsula, and southeastward to Oaxaca. Rail traffic, for both passengers and freight, is slow and unreliable.

Highways

As a result, highways are the major mode of transporting passengers and goods. Cross-country trucking accounts for most freight movement within the nation, and interstate buses carry most of the passengers. While they have been improved tremendously since the late 20th century, Mexico's highways are barely adequate to serve the national need. As with rails, all major roads lead to Mexico City. Several highways link northern border cities to the capital. Similar highways connect the Yucatán Peninsula and the Guatemalan border with the Mesa Central. The 1,250-mile Pan-American Highway runs from Ciudad Cuauhtémoc, on the border with Guatemala, to Nuevo Laredo, on the border with the United States, passing through Mexico City. Several parts of the country lack good rail and road connections, especially from east to west across northern Mexico. In addition, many secondary roads are in poor condition.

Air travel has become a major mode of transportation within Mexico. Two national airlines, Aeroméxico and Mexicana, serve all tourist locations and medium-sized urban centres within the country as well as many international destinations.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Mexico is a federal republic composed of 31 states and the Federal District. Governmental powers are divided between executive, legislative, and judicial branches, but in practice the president has strong control. The Constitution of 1917 guarantees personal freedoms and civil liberties and also establishes economic and political principles for the country. Suffrage is universal for those over 18 years of age, and voting is mandatory.

The legislative branch has a Senate of 128 members, four from each state and the Federal District, as well as a Chamber of Deputies with 500 members. Senators serve six-year terms and deputies three-year terms; members of the legislature cannot be reelected for the immediately succeeding term. Three-fifths of the deputies are elected directly by popular vote while the remainder are selected in proportion to the votes received by each political party. The legislature ratifies elections and thus has been able to declare candidates elected, regardless of vote totals. Although it has the right to verify presidential elections, pass the budget, and initiate tax bills, the legislature seldom does so and thus has lost much of its power and prestige.

The president of Mexico is popularly elected and can serve only one six-year term. The president is empowered to select a Cabinet, the attorney general, diplomats, high-ranking military officers, and supreme court justices (who serve life terms) and traditionally approves legislative and state gubernatorial candidates. The president also has the right to issue *reglamentos,* or basic rules that have the effect of law.

During the period 1929–2000 the president, as leader of the Institutional Revolutionary Party (Partido Revolucionario Institucional; PRI), typically selected the party's next presidential candidate—thus effectively choosing his own successor, because the PRI was the dominant political party and had never lost a presidential election. Ernesto Zedillo broke from that tradition in 1999, causing the PRI to hold a primary election to choose a candidate; Zedillo also instituted other electoral reforms. In 2000 the PRI's presidential candidate was defeated by Vicente Fox of the conservative National Action Party (Partido Acción Nacional; PAN), marking the end of 71 years of continuous rule by the PRI. The PRI also lost a large number of legislative seats to PAN, the leftist Party of the Democratic Revolution (Partido de la Revolución Democrática; PRD), and other smaller parties.

Defeat of the PRI

At the state and local levels, governors, unicameral legislatures, and mayors are elected by popular vote. Governors serve for six years, deputies for three. States can levy taxes and have all powers not delegated to the federal government, but in fact they have relatively little revenue-generating potential or political power.

The courts are responsible for the administration of justice. The Supreme Court of Justice is the highest tribunal, and there are state superior courts as well as civil and criminal courts. The constitution protects the rights of the accused and guarantees a free trial with due process.

The military has long been an apolitical force in the country, but its high-ranking officers are appointed by the president. Conscripts serve a year's compulsory service. The military's primary role is maintenance of internal order, and for this reason about three-fourths of military personnel are in the army.

Education. Mexico has made significant efforts to improve educational opportunities for its people. School attendance is required for children aged six to 14. The number of schools for children has been increased, and adult literacy programs have been promoted vigorously since the 1970s. By the mid-1990s Mexico's literacy rate was estimated to be approximately 90 percent, up nearly 20 percent since 1970.

Public schools in Mexico are funded by the federal government. Although nearly three-fourths of all primary public schools are located in rural areas, such schools are the least well-developed in the nation and often do not cover the primary cycle. Many internal migrants move to cities because of the availability of better schools for their children. In rural areas, as well as in many low-income urban areas, teachers need only a secondary education to be certified to teach. Despite increases in the numbers of schoolrooms, teachers, and educational supplies, about one-seventh of all school-age children do not attend school.

Secondary schools are virtually nonexistent in rural areas, and universities are found only in the largest cities. As with primary education, private secondary schools are considered vastly superior to public ones, and families who can afford it send their children to private schools. This helps to maintain the socioeconomic imbalance that greatly favours the middle and upper classes.

Universities

Of the more than 50 universities in the country, one-fifth are located in Mexico City, and a high proportion of all university students study there. The National Autonomous University of Mexico, the College of Mexico, and the Monterrey Institute of Technology and Higher Education are among the most prestigious institutions of higher education in the country. A college degree is a passport to social mobility in Mexico.

Health and welfare. Federally subsidized medical and hospital care is available to all Mexican citizens. Several government institutions, including the Mexican Social Security Institute and the Security and Social Services Institute for Government Workers, operate hospitals. Public medicine, like public education, is considered inferior to private care, however, and those who can afford it avail themselves of private physicians and hospitals.

Clinics, though sometimes attended only by a nurse, are found throughout the country. Anything more than the most basic medical needs, however, must be handled in the cities. The quality of medical service varies throughout the country, with Mexico City by far the principal centre for specialized treatment. The overall quality of medical care in Mexico lags behind that available in the United States and Europe, and many Mexicans travel outside the country for more sophisticated surgical procedures or treatments.

There are strong differences in health conditions from region to region within Mexico. In general, rural areas have much higher mortality and morbidity levels than do urban areas. Regions with large Indian populations, such as Chiapas, Oaxaca, and portions of Guerrero, as well as isolated mountainous sections of the Mesa Central, have especially low health standards and high death rates. There also are great differences in health conditions among social classes in cities.

Housing. A lack of adequate housing is one of Mexico's most serious problems. Although substandard housing is more visible in urban areas, living conditions are probably

worse in rural areas. Within the cities, the federal government has built multiunit housing projects. The problem has increased more rapidly than new units can be constructed, however, and economic difficulties have reduced the funds available for new construction.

Economic and social divisions. Mexican society is sharply divided by income and educational level. Although a middle class is developing in the cities, the principal division is between the wealthy, well-educated elite and the urban and rural poor.

Widespread rural poverty is a serious problem. Agrarian reform in the central and southern parts of the country has institutionalized much of the rural peasantry, *ejidatarios* and *minifundistas,* into barely more than subsistence agriculturalists, with limited opportunities for economic or social advancement. An increasing proportion of the rural population is landless and depends on day labour, often at less than minimum wages, for survival. In many areas, but particularly in the northern half of the country, large landholders form an agricultural elite. Controlling extensive holdings and often using modern mechanized farming methods, they control nearly half of the income generated by agriculture. A rural middle class has evolved, but it represents only a small percentage of total agriculturalists.

Widespread poverty

By far the largest segment of the urban population is in the lowest socioeconomic class. It is estimated that at least 40 percent of city dwellers have incomes below the official poverty level, including a significant percentage of workers who are government employees. Extensive squatter settlements, often lacking basic services, are a common element of all Mexican cities. As an example, Nezahualcóyotl, on the eastern side of Mexico City, has more than 1,000,000 residents living in substandard housing and unsanitary conditions. In contrast, the relatively affluent middle- and upper-income groups enjoy the amenities of urban life and control most of the social, political, and economic activity of the country.

Wages and cost of living. Minimum wage laws have been in effect since 1934. Wages are determined by the type of work and the cost of living in specific regions. Urban job classifications pay higher minimum wages than rural categories, and the highest minimum wages are paid in Mexico City and the border cities of Tijuana, Mexicali, and Ciudad Juárez. Wage rates are theoretically adjusted every two years, but they have been changed more frequently since the 1970s.

Until about 1980 Mexico's inflation rate was relatively modest for a developing nation. The cost of living rose by less than 3 percent annually between 1960 and 1970, increasing to between 10 and 20 percent in the 1970s. Inflation rose to triple digits during the late 1980s.

CULTURAL LIFE

Because of its ethnic and regional diversity, as well as the socioeconomic divisions within the population, Mexico is culturally heterogeneous. Among rural peoples there are strong regional affinities and allegiances, often referred to as *patria chica* ("small homeland"), which help to perpetuate cultural diversity. The large number of Indian languages and customs still extant, especially in the south, also accentuate cultural differences. In an attempt to unite the nation culturally by identifying a uniquely Mexican culture, the government has supported indigenous folk arts and crafts as well as the European-inspired classical arts. Since the 1930s, *indigenismo,* or pride in the Indian heritage, has been a major unifying theme of the country.

The arts. Mexican writers and artists have received worldwide acclaim for their creativity and innovativeness. Within their work both a folk and classical tradition have been strong.

The country's best-known writers have gained their reputations by dealing with questions of universal significance, as did Samuel Ramos, whose philosophical speculations on man and culture in Mexico influenced post-1945 writers in several genres. The prolific critic and cultural analyst Octavio Paz is considered by many to be the foremost poet of Latin America. The novels of Carlos Fuentes are honoured throughout the world, Gustavo Sainz is a leader in Spanish-language literature, and Juan José Arreola's fantasies are widely admired. Among dramatists, Rodolfo Usigli has been extremely influential, and Luisa Josefina Hernández and Emilio Carballido have made important contributions.

Perhaps the most widely recognized Mexican art form is the mural, and the Mexican Muralist school counted among its members the most powerful figures of the genre. The murals created by Diego Rivera and David Alfaro Siqueiros, depicting aspects of the Mexican Revolution, the nation's modernization, and class struggle, have become legendary, and, among others, Rufino Tamayo and Juan Soriano have achieved stature. Perhaps the most popular of Mexico's folk artists is José Clemente Orozco, whose animated plaster-of-paris skeleton characters are both satirical and lifelike.

Mexican popular music, especially ranchero and mariachi music, has attracted a wide following throughout the Spanish-speaking world, and Mexico City has become one of the major recording centres for the Americas. The country's motion-picture and television industries are among the largest in Latin America, producing films and programs that circulate throughout the region.

Cultural institutions. To encourage and help disseminate Mexican art in all its forms, the federal government sponsors the National Institute of Fine Arts. Under its auspices are the programs of the National Symphony Orchestra, the Ballet Folklorico, and the Modern and Classical Ballet, all of which perform nationally and internationally to promote Mexican culture. Folk and popular culture also receive support through government bodies, among them the Native Institute, which seeks to preserve and stimulate traditional craftsmanship.

A number of internationally acclaimed museums, including the National Museum of Anthropology and the Museum of Folk Art, are supported by the Secretariat of Public Education. The National Autonomous University of Mexico, College of Mexico, and Cultural Seminary are important institutions contributing to the arts and humanities.

Recreation. Bullfighting is the country's national sport, and the Plaza México in Mexico City is one of the great venues for this spectacle. Soccer is still the most popular participatory sport, but baseball has attracted increasing numbers of spectators and players at both the professional and the amateur level. Mexico has produced a number of world champions in the lighter weight classes in professional boxing.

Bullfighting

Press and broadcasting. Mexico City has a large number of daily newspapers, some of which are respected for their objectivity and relative independence. Although newspapers are guaranteed freedom of the press under the constitution and there is no official censorship, nearly all are muted in their criticism of the president and his policies. There are regional tabloids outside the capital, but they have little national impact. In publishing, Mexico City is now one of the leading centres for Spanish-language books and magazines.

History

PRE-COLUMBIAN MEXICO

Early Hunting Period. It is assumed that the first inhabitants of Middle America were early American Indians, of Asian and Mongoloid derivation, who migrated into the area at some time during the final stage of the Pleistocene Epoch. The date of their arrival in central Mexico remains speculative. The assertions of some archaeologists that early man resided in Mexico 30,000 to 40,000 years ago, before developing technology for big-game hunting, are rejected by most scholars. More generally accepted claims for early man in Mexico pertain to a somewhat later period and to hunters of large herd animals such as the mammoth. Human artifacts and mammoth bones dated to approximately 9000 BC have been found together in the same geologic strata in the Valley of Mexico at Santa Isabel Ixtapan.

Food-Collecting and Incipient Cultivation Period. With the increased dryness and change of fauna following the glacial retreat of the last Wisconsin substage (approximately 7500 BC), the inhabitants of Middle America were forced to turn from big-game hunting to other means of subsistence. These were the hunting of small game and the collecting of wild food plants. This mode of existence is best seen in the archaeological discoveries made in the Tehuacán Valley of Puebla.

In the earlier El Riego (7000–5000 BC) and Coxcatlán (5000–3400 BC) phases of this sequence the inhabitants of the Tehuacán Valley were seasonal nomads who divided their time between small hunting encampments and larger temporary villages, which were used as bases for collecting plants such as various grasses and maguey and cactus fruits. Maize (*Zea mays*), a wild grass, first came under cultivation in this time, probably as early as 5000 BC. Avocados, chili peppers, amaranth, zapotes, tepary beans, and squashes were also primitive cultigens. During the Abejas phase (3400–2300 BC) use of cultivated plants increased at the expense of wild plants and, probably, at the expense of hunting. A hybrid maize, crossed with the wild grass teosinte, appeared for the first time, and pumpkins and the common bean were introduced. Toward the end of the phase, settlement assumed a more permanent form in what appear to have been year-round pit-house villages. In the Purron phase (2300–1500 BC) the first pottery was produced in vessel forms that duplicate earlier stone vessels.

Cultivation of maize

Early Formative Period. By 2000 BC some village communities in Middle America were sustained largely or wholly by agriculture. Because these villages are located largely in southern Mesoamerica, it is likely that agriculture originated there. It soon spread to other areas. During the Early Formative Period the Middle American agricultural plant complex was assembled and improved by hybridization and more sophisticated cultivation techniques.

Middle Formative Period. The Middle Formative Period was a time of transition from the simple agricultural village to more complex societies organized around politico-religious capitals or nuclei. This trend had probably begun in the latter part of the Early Formative, but the first large ceremonial centres and the first monumental stone sculpture occur at about 1000 BC in southern Veracruz and Tabasco. The sites in question, San Lorenzo and La Venta, are locations of characteristic Olmec art. This art is amazingly sophisticated, with consummate control of both full round and bas-relief forms. The human theme predominates, although humans are frequently depicted with jaguar mouths and nostrils. The Olmec artists made great stone heads, altars, and stelae, and they also worked as lapidaries in exquisite jade figurines and other small objects. Olmec stylistic influence reached to Oaxaca, Chiapas, Guatemala, El Salvador, and the Valley of Mexico.

Olmec art

Late Formative Period. The Late Formative Period saw the spread of complex societies throughout much of Middle America. Hieroglyphics and complex calendrical calculations appeared. These elements of civilization are first noted in association with the Tres Zapotes, Izapan, and early Oaxacan art styles. The true city or urban centre also came into being during this period. One of the earliest manifestations of densely settled city life occurred in the Valley of Mexico at Teotihuacán, where the Late Formative urban zone covered some two square kilometres.

Classic Period. The characteristic Middle American aesthetic and religious patterns that began in the Late Formative crystallized in the Classic Period. In the Maya Lowlands polychrome ceramics, the use of the corbeled vault in temple construction, the foreshadowings of typical Maya art, and the probable beginnings of Initial Series calendrics all belong to the end of the Late Formative Period (100 BC–AD 300). The full Maya artistic, architectural, and calendric-hieroglyphic traditions were then ushered in during an Early Classic sub-period (AD 300–600). Tikal, Uaxactún, and Copán all attained their first glories in these centuries. In the Late Classic sub-period, between AD 600 and 900, ceremonial centres in the Maya Lowlands proliferated in number, as did the carving and erection of the inscribed and dated stelae and monuments.

The breakdown of the Classic Period civilizations began with the destruction of the city of Teotihuacán in about AD 700. This commercial, political, and religious metropolis appears to have fallen before the warlike Toltec, peoples of Uto-Aztecan speech who invaded central Mexico from the north and who established their capital at Tula.

Postclassic Period. Four trends characterized the Postclassic Period. First, there was a completion of the breakup of the old regional Classic Period cultures, with their distinctive art and architectural styles and religious traditions. Second, the new Postclassic cultures displayed more secular orientation. Third, fortifications and an increase of warlike themes in art bespoke a more militaristic attitude throughout much of Middle America. Fourth, the urban-type community, which first appeared in the Late Formative and was known through the Classic Period, was emphasized even more than previously.

In the later Postclassic Period Tenochtitlán, the Aztec capital, located where Mexico City now stands, became the dominant force in Middle America. An Aztec empire reached from coast to coast through central and southern Mexico; however, many tributary nations were held by the Aztecs in rather loose bonds, and when Cortés marched from Veracruz to Tenochtitlán he was aided by tribes anxious to free themselves from the Aztec yoke. In the Maya Lowlands the Toltec-controlled centre of Chichén Itzá lost its position of leadership in about AD 1200. Thereafter, there seems to have been something of a Maya resurgence, with the Yucatecan capital being eventually established at the walled city of Mayapán. (G.R.W./M.C.M.)

The Aztecs. The word Azteca is derived from Aztlán ("White Land"), where, according to Aztec tradition, their tribe originated. Aztlán probably is merely a general reference to the northwestern region of Mexico. The Aztecs are also known as Tenochca, a name derived from a legendary patriarch called Tenoch. Tenoch, or Tenochca, gave the name to Tenochtitlán ("Stone Rising in the Water"), a city founded by the Aztecs on an island in Lake Texcoco, in the Valley of Mexico. The Aztecs were also known as Mexica. The name Mexica came to be applied not only to the ancient city of Tenochtitlán but also to the modern Mexican nation and its inhabitants (Mexico, Mexicans).

The language of the Aztecs was Nahuatl, part of the Uto-Aztecan linguistic family which, at the time of the early explorations of America by Europeans, was making its influence felt intermittently in western North America from the Yellowstone River to Panama. Once the Aztecs achieved political ascendancy, their language gained currency in an area almost as large as present-day Mexico.

The Nahuatl language

The empire the Aztecs established was equaled in the New World only by that of the Incas of Peru, and the brilliance of their civilization is comparable to that of other great ancient cultures of America and the Old World. From their legendary land of Aztlán, the Aztecs came into contact with the highly developed Toltec civilization located in central Mexico and having as its capital the city of Tula. The appearance of the Aztecs is linked, however, not to the splendour of Tula and of the Toltec but to their decline. For reasons not fully known but having to do with internal social, political, and religious conflicts, a tremendous cultural catastrophe, which has been compared to the fall of the Roman Empire, occurred at the beginning of the 12th century AD. The city of Tula was attacked and destroyed, as were other important Toltec centres. Tribes of less-developed cultures—hunters and gatherers—took advantage of the situation and added to the chaos, traveling from the arid plateau of northern Mexico toward the fertile, civilized central zone. In their legends the Aztecs portray themselves as part of that wave of barbarian invaders known by the general term Chichimec ("Sons of the Dog").

The decline of the Toltec

From the beginning of the 12th century to the beginning of the 13th, the Aztecs wandered in search of a new place to settle. During that time a group of Chichimec, under the leadership of Xólotl, succeeded in gaining power in the Valley of Mexico, establishing their centre first in Tenayuca and later in Texcoco. Xólotl's Chichimec joined forces with the remaining Toltec, who were firmly entrenched in Culhuacán. The combination of strong

Chichimec power in rapid process of assimilating a higher culture and the restoration of Toltec power in Culhuacán led to a period of relative peace and cultural progress in the Valley of Mexico. The stabilization of this new situation attracted immigrants from all parts of the disturbed country, among them the Aztecs, who by then had established a precarious home near the ruins of Tula.

During their stay in Tula the Aztecs perfected their technological knowledge, especially with regard to agriculture. According to their traditions, it was there that they undertook irrigation cultivation and built *chinampas* (the famous, but misnamed, "floating gardens"). Aztec religion took definite form, centring on the god Huitzilopochtli ("Hummingbird-on-the-Left"), sun worship, and human sacrifice. Aztec tradition has it that Huitzilopochtli ordered them to take leave again in search of a permanent home.

Their long pilgrimage ended in the year of "two house," according to their calendar (AD 1325), when the wanderers found the land spoken of in their prophecies. On a small island in Lake Texcoco, the elder members of the tribe spotted an eagle, symbol of the sun and of Huitzilopochtli, resting on a nopal cactus. There they built the temple of their tribal god and, around it, the first dwellings of what was to become the powerful city of Tenochtitlán, the capital of the Aztec empire, of the viceroyalty of New Spain, and of the modern Mexican nation.

The founding of Tenochtitlán

The swamp-surrounded island on which the Aztecs were forced to take refuge was so uninviting that none of the powers in the Valley of Mexico had claimed it. Tenochtitlán was thus located at the edge of the lands occupied by the valley's three powers: the Chichimec of Texcoco, the Toltec of Culhuacán, and the Tepanec of Atzcapotzalco. It was not long before the Aztecs used their strategic position to advantage, placing their military forces at the service of the Tepanec, who were waging war against the Toltec and the Chichimec. It was in this capacity that the Aztecs began to form their notions about empire building. Under a succession of ambitious kings they established a dominion that eventually stretched over most of present-day Mexico.

The task of attempting to organize the empire along lines other than mere Aztec military strength was left to Montezuma II, the ninth Aztec king (1502–20). It was Montezuma's reign that produced the codices in which Aztec officials recorded the organization of the empire into provinces and the payment of tribute according to the production of each region. A gigantic political, military, and religious bureaucracy was built up, with governors, tax collectors, courts of justice, military garrisons, mail and messenger services, and other civil offices. Despite their feverish efforts at political organization, the Aztecs still had the strength to subjugate their allies, Texcoco and Tacuba, and to undertake new campaigns. It is probable that in this period Aztec troops pushed as far south as Central America.

The demise of Aztec hegemony

But the days of the Aztecs' greatest glory were also their last. Since 1517, Spanish expeditions led by Francisco Hernández de Córdoba, Juan de Grijalva, and Hernán Cortés had been exploring the coasts along the Gulf of Mexico. Rumours of ships as large as houses reached Tenochtitlán, and to them were added prophecies of the imminent return of the benign deity and cultural hero Quetzalcóatl; they could mean only disaster for the Aztecs and their god Huitzilopochtli. Cortés' bold march against Tenochtitlán set the stage for the final scene of the Aztec Empire. Spanish might, combined with a general revolt of the peoples under Tenochtitlán domination, proved superior to the Aztecs' strength. Under the last two Aztec kings, Cuitláhuac and Cuauhtémoc, Tenochtitlán was besieged and destroyed after a heroic Aztec defense. Over the still-smoldering ruins of Tenochtitlán a new city began to rise. Symbolizing the future Mexico, a Christian cathedral was erected on the stones of Huitzilopochtli's temple.

The almost incredible story of a small wandering tribe that was able to build an empire in one century (from the beginning of the 14th century to the beginning of the 15th) can be largely explained by three main factors: Aztec religion, the economy of the Valley of Mexico, and Aztec sociopolitical organization.

Aztec religion centred around the cult of Huitzilopochtli, a young warrior and symbol of the sun who died every evening to be born anew the following day. At dawn Huitzilopochtli began his daily struggle against the stars and the moon, driving them away with a shaft of light. At sunset he died and returned to the bosom of the earth, his mother (Coatlicue), where he renewed his strength in order to take up the fight against darkness. In order to guarantee human existence, Huitzilopochtli had to be well-nourished; his sustenance was human blood. The Aztecs were people of the sun, chosen by Huitzilopochtli to provide him nourishment. War was, therefore, not only their favourite occupation but also, more importantly, a religious obligation in which captured enemies were sacrificed to the sun. As Aztec power grew, the number of human sacrifices increased. Prisoners from all parts of the country were put to death in Tenochtitlán so that the universe and man might survive.

The economic basis of the Aztec hegemony was the Valley of Mexico's agriculture, characterized by *chinampas* and irrigation systems. It was mainly from the Toltec that the Aztecs had learned these techniques. Nevertheless, these methods date even further back in Mexican history; almost certainly they were in existence in the 6th century BC. The high productivity of the systems resulted in a heavy density of population in the Valley of Mexico and the development of large urban centres. In the early 16th century the population of the valley fluctuated around 2,000,000, with some cities approaching or exceeding 100,000. Because of this enormous concentration of population and economic resources, the Valley of Mexico became the pivotal key to power in the central part of the country. The group successful in uniting the valley under a single authority could go on to conquer the neighbouring valleys of Morelos, Mexico, Puebla, and Hidalgo, and, thence, the rest of the country.

From very early times, another factor contributed to the strategic importance of the Valley of Mexico: a system of lakes (Texcoco, Chalco, Xochimilco, Xaltoca, and Zumpango) that were connected naturally and by means of artificial canals. Extensive water transportation on the lakes compensated for the lack of the wheel and of domesticated animals and, in no small measure, furthered the early economic and political unification of the valley.

All these factors served as powerful stimuli to trade. Probably in keeping with an ancient tradition, the merchants (*pochteca*) of Aztec society were organized in powerful guilds, which even started wars on their own and sent trading expeditions to remote places. It was on the basis of the geographic data collected by their merchants that the Aztecs drew up maps not only of what is now Mexico but also of Central America. It is virtually impossible to separate the Aztecs' trade policy from their military and expansionist policy.

The third essential factor in Aztec imperialism was the sociopolitical organization of the tribe. Aztec society in the early 16th century displayed many features described as "primitive," together with manifestations of a highly advanced civilization. For example, the division of the tribe into *calpulli* ("big houses"), pseudo-family units established in Tenochtitlán, has sometimes been interpreted as proof of an egalitarian organization. Yet, evidence of social stratification is indisputable.

Aztec society has also been interpreted as "feudal." This assertion is based on the existence of an Aztec hereditary "nobility," behind which was a group of knighted commoners with access to land rights. Nevertheless, the relation of these noble groups to the Aztec kings, to the rest of society, and to land ownership cannot be compared with Old World feudalism. At the time it came into contact with the Spaniards, Aztec society was characterized by an Oriental-type political organization, in which the king was absolute. Particularly during the reign of Montezuma II, Aztec society and the empire itself were vigorously reorganized. A gigantic bureaucracy, completely dominated by the king, was charged with administering the immense empire and gradually absorbed the old social groups of nobles, knights, and merchants. dle American civilizations, see the article PRE-COLUMBIAN CIVILIZATIONS.

CONQUEST OF MEXICO

Diego Velázquez, governor of Cuba, laid the foundation for the conquest of Mexico. In 1517 and 1518 Velázquez sent out expeditions headed by Francisco Hernández de Córdoba and Juan de Grijalva that explored the coasts of Yucatán and the Mexican Gulf. Velázquez commissioned Hernán Cortés to outfit an expedition to investigate their tales of great wealth in the area. Spending his own fortune and a goodly portion of Velázquez', Cortés left Havana in November 1518, following a break in relations with Velázquez. Cortés landed in Mexico and then freed himself from Velázquez' overlordship by founding the city of Veracruz and establishing a town council (*cabildo*) that in turn empowered him to conquer Mexico in the name of Charles I of Spain. Divining that Mexico was a fabulously wealthy realm held together by sheer force and that the Aztec ruler Montezuma held him in superstitious awe, Cortés pushed into central Mexico with only about 500 Europeans and several thousand Indian allies. In an incredible campaign lasting two years, Cortés took the capital city of Tenochtitlán on Aug. 13, 1521. His success was the result of a combination of factors: the hatred of the conquered tribes for the Aztec overlords; Montezuma's belief that Cortés was a returning god; Cortés' personal qualities of leadership and diplomacy; European arms—crossbows, muskets, and steel swords—and horses; disease; and the aid of Cortés' interpreter-mistress, Malinche.

EXPANSION OF SPANISH RULE

After taking possession of the Aztec Empire, the Spaniards quickly subjugated most of the other Indian tribes in southern Mexico, and by 1525 Spanish rule had been extended as far south as Guatemala and Honduras. The only area in southern Mexico of effective Indian resistance was Yucatán, inhabited by the Maya tribes. Francisco de Montejo undertook the conquest of this region in 1526, but, because Maya bands were so dispersed, it was nearly 20 years before the Spaniards won control of the northern end of the peninsula. Some Indians in the interior remained independent for another century and a half.

The occupation of northern Mexico, which was thinly populated and largely arid, proceeded more slowly than did that of central and southern Mexico. Spanish expansion in this area was motivated chiefly by the hope of discovering precious metals, the need for defense against nomadic Indian raiders, and the desire to forestall incursions by the British and French.

Between 1530 and 1536 Jalisco and other Pacific coast regions were conquered by Nuño de Guzmán. The Indians of Jalisco rebelled in 1541 but were suppressed after hard fighting; this episode became known as the Mixton War. In order to complete the subjugation of the Indians, the Spaniards began to move into Zacatecas, where in 1546 they discovered immensely valuable silver mines. Similar discoveries in Guanajuato and San Luis Potosí and the occupation of most of this north central region quickly followed. Meanwhile Álvar Núñez Cabeza de Vaca, shipwrecked on the coast of Texas in 1528, had spent eight years making his way across northern Mexico before reaching a Spanish settlement on the Pacific coast and had brought back stories of rich Indian civilizations that supposedly existed somewhere in the north. During the years 1540–42 Francisco Vázquez de Coronado led an expedition to search for these mythical kingdoms, exploring as far as Kansas before turning back in disappointment. The effective occupation of northern Mexico occurred later in the century and involved prolonged fighting with nomadic Indian tribes. Throughout much of the north, the first Spanish settlers were Franciscans and Jesuits who established Indian missions. At the same time that exploration and settlement were bringing new areas under effective control, an administrative bureaucracy was being put into place. New Spain was organized as a viceroyalty governed by a viceroy appointed by the king.

Near the end of the 16th century, the northern frontier of New Spain in most areas was close to the present Mexican–U.S. boundary line. Within the area that is now the United States, a settlement had been made in Florida in 1565. In 1598 Juan de Oñate began the conquest of New Mexico, though the Indians of the region rebelled in 1680 and were not reconquered until 1694. Later northern expansion was undertaken mainly to check rival European powers. After the French had established colonies in Louisiana, Spanish settlements were made in Texas in 1716, while on the Pacific coast the threat of Russian expansion caused the Spaniards in 1769 to begin the occupation of Upper California. Throughout the 18th century there were incessant boundary disputes between Spain, Britain, France, and subsequently the United States, and some territories changed hands several times. Florida was ceded to Britain in 1763, restored to Spain in 1783, and sold to the United States in 1819. Louisiana became Spanish in 1763 but was regained by France in 1800 and sold to the United States three years later. The northern boundary of New Spain remained largely indeterminate until the Adams–Onís Treaty of 1819, by which the United States acquired Florida but recognized Spanish sovereignty over Texas, New Mexico, and California.

(H.B.P./M.C.M.)

COLONIAL PERIOD, 1701–1821

A fundamental shift in the governance of New Spain occurred as a result of the War of the Spanish Succession (1701–13), when Bourbons replaced Habsburgs on the Spanish throne. Ruling by divine right, the Bourbon kings were enlightened despots whose major interests lay in increasing the economic returns from the Spanish Empire; they introduced many French practices and ideas into overseas administration.

Among the notable administrative reforms undertaken by Charles III in 1784 was the creation of 18 intendancies. In place of the numerous *alcaldías mayores* and *corregimientos,* which were abolished, *partidos* of about the same size were created within each intendancy. Headed by the intendancy of Mexico, each intendant was given considerable autonomy in increasing economic production within his sphere, developing useful arts and sciences, and bettering education and social conditions, all of the latter less for altruistic than for economic reasons.

Fed by currents of rationalism from England and Europe, the Enlightenment in Spain and Mexico spurred the spread of new scientific knowledge and, especially, its application to mining and agriculture. Political liberalism became a factor when the American and French revolutions called into question the divine right of kings. A later development was the proliferation of the military establishment under the impact of British and Russian pressures on the frontiers of New Spain. Having strung a series of missionforts across northern Mexico, authorities in Madrid and Mexico augmented the few regular Spanish troops that could be spared from the peninsula by fostering a local militia with special exemptions (*fueros*) granted to Creole (Mexican-born) officers. Thus, an explosive combination resulted from the almost simultaneous appearances of new ideas, guns, and administrative confusion between the old Habsburg and the new Bourbon administrative systems.

The turmoil of Napoleonic Europe was the immediate background of the move for Mexican independence. Napoleon Bonaparte occupied Spain in 1808, imprisoned King Ferdinand VII, and attempted unsuccessfully to impose his brother Joseph Bonaparte as monarch. Rebelling, the Spanish resurrected their long-defunct Cortes (representative assembly) to govern as regent in the absence of the legitimate king, and, with representation from the overseas realms, the Cortes in 1812 promulgated a liberal constitution in the King's name. The document provided for a constitutional monarch, popular suffrage, a representative government, and other features taken from the French and U.S. constitutions. Continental events stimulated rivalries in Mexico as contradictory commands were being received from the mother country. The viceregal establishment put down sporadic rebellions by those who professed loyalty to the imprisoned king but who demanded some form of self-government.

Factionalism and rebellion

The most important local revolt was sparked by Miguel Hidalgo y Costilla, a parish priest in Dolores. On Sept. 16, 1810, Hidalgo issued the "Grito de Dolores" ("Cry of Dolores"), calling for the end of rule by Spanish peninsulars, for equality of races, and for redistribution of land. Mexican Independence Day commemorates this event.

Warning that the Spaniards would deliver Mexico to the godless French, Hidalgo exhorted his followers to fight and die for the Mexican Virgin, Our Lady of Guadalupe. When Hidalgo left his tiny village, he marched with his followers into Guanajuato, a major colonial mining centre peopled by Spaniards and Creoles. There the leading citizens barricaded themselves in a warehouse. Hidalgo captured the warehouse on September 28, but he quickly lost control of his rebel army. Most of the Creole elite were massacred, and the town was pillaged.

The Guanajuato massacre swung moderate and undecided support behind the viceroy's efforts to crush the Hidalgo rebellion, lest a full-scale caste war ensue. Royalist forces defeated Hidalgo at the Bridge of Calderón on Jan. 18, 1811. On March 19 he was captured along with other major insurgent leaders. On July 31 Hidalgo was executed, ending the first of the political civil wars that were to wrack Mexico for three-quarters of a century.

The Hidalgo cause was taken up by his associate José María Morelos y Pavón, another parish priest, who won control of substantial sections of southern Mexico. The constituent congresses, which Morelos called at Chilpancingo in 1813, issued at Apatzingán in 1814 formal declarations of independence and drafted republican constitutions for the areas under his military control.

At about the same time Napoleonic troops were withdrawing from Spain, and in 1814 Ferdinand VII returned from involuntary exile. One of his first acts was to nullify Spain's liberal 1812 constitution drawn up by the Cortes. The departure of the French freed Spanish troops needed to crush the Morelos revolution. Captured and defrocked, Morelos was shot as a heretic and revolutionary on Dec. 22, 1815. Scattered but dwindling guerrilla bands kept alive the populist, republican, nationalist tradition of Hidalgo and Morelos.

Mexican independence came about almost by accident when constitutionalists in Spain led a rebellion that, in 1820, forced Ferdinand VII to reinstate the liberal constitution of 1812. Conservatives in Mexico, alarmed that anticlerical liberals would threaten their religious, economic, and social privileges, saw independence from Spain as a method of sparing New Spain from such changes. They found a spokesman and able leader in Agustín de Iturbide, a first-generation Creole. Iturbide, who had served as a loyal royalist officer against Hidalgo and others, had been given command of royal troops with which he was to snuff out remnants of the republican movement, then headed by the future president Vicente Guerrero.

The Plan de Iguala

While ostensibly fighting Guerrero, however, Iturbide was in fact negotiating with him to join a new independence movement. In 1821 they issued the so-called Plan de Iguala, a conservative document that declared that the Mexican nation was to be independent, that its religion was to be Roman Catholicism, and that its inhabitants were to be united, without distinction between Mexican and European. It stipulated further that Mexico would become a constitutional monarchy under Ferdinand VII, that he or some Spanish prince would occupy the throne in Mexico City, and that an interim junta would draw up regulations for the election of deputies to a congress, which would write a constitution for the monarchy.

United as the Army of the Three Guarantees (independence, union, preservation of Roman Catholicism), the combined troops of Iturbide and Guerrero gained control of most of Mexico by the time Juan O'Donojú, appointed Spanish captain general, arrived in the viceregal capital. Without money, provisions, or troops, O'Donojú felt himself compelled to sign the Treaty of Córdoba on Aug. 24, 1821, thus officially ending New Spain's dependence on Old Spain. The convention provided that the Mexican nation, thenceforth to be styled the Mexican Empire, was to be recognized as independent. Under the treaty, the new empire's congress was to elect an emperor if no suitable European prince could be found. In one of the ironies of history a conservative Mexico had gained independence from a temporarily liberal Spain.

INDEPENDENCE

Although Spain at first disavowed O'Donojú's recognition of Mexican independence, the date now recognized as that of separation of New Spain from Old Spain is in fact Aug. 24, 1821.

The Mexican Empire, 1821–23. The first Mexican Empire spanned only a short transitional period from colony to republic. Independence had been the point on which republicans and conservatives alike could agree. The new constitutional monarchy shielded the conservatives from a Spanish government that had suppressed religious orders, tried clerical cases in civil courts, and decreed that the church could not acquire real property. Such a government was also palatable to the insurgents, whose major objective was independence.

Iturbide became president of a council of regents, which convoked a Sovereign Constituent Congress. Deputies to the congress represented the intendancies, the name they retained during the empire. When representatives from the Central American intendancies, part of the old viceroyalty of New Spain, decided that their areas did not wish to remain part of the Mexican Empire, they were allowed to withdraw and to organize their own independent governments.

On the evening of May 18, 1822, military groups proclaimed Iturbide Emperor Agustín I, and on the next day a majority in congress ratified the "people's choice" and recommended that the monarchy be hereditary, not elective. Agustín I was crowned in a long ceremony on July 21. The empire was recognized by the United States on Dec. 12, 1822, when the Mexican minister was officially received in Washington, D.C. But even then Agustín's power and prestige were already ebbing, and conflict soon developed between the military hero Iturbide and the primarily civilian congress. On Oct. 31, 1822, the Emperor dismissed congress and ruled through an appointed 45-man junta. The act, which was condemned by many as arbitrary, provided discontented military men with a pretext to revolt. Among their leaders was General Antonio López de Santa Anna, whom Agustín had first promoted for services in the Army of the Three Guarantees. In Veracruz, Santa Anna proclaimed a Mexican Republic on Dec. 2, 1823, and was supported by old guerrillas. Other military men had similar plans. Agustín was forced to reconvene congress and to abdicate. In 1824 he returned from European exile but was arrested and shot. This first epoch of independent Mexican national life thus foreshadowed many problems of the succeeding republic.

Troubles of the new republic

The early republic. When a republican constitution was adopted in 1824, the Mexican people had had little or no previous experience in self-government. Their economy was precarious; mining, a mainstay in colonial times, had declined during the many years of fighting, and widespread anti-Spanish feelings had caused an exodus of Spaniards, depleting both the nation's capital reserves and its pool of trained people. Political instability made borrowing abroad expensive, and nearly all public revenues had to come from customs receipts, which were pledged well in advance. As Mexico's national debt mounted, so did its problems. A vicious, seemingly unbreakable cycle marked the first half century of Mexican national life. Whenever public monies were insufficient to pay the army, its officers revolted, captured the government, and negotiated international loans. The high interest payments on such loans reduced available funds for education and other social and cultural improvements, which many Mexican leaders thought were urgent requirements.

The constitution of 1824 provided for a federal republic, consisting of 19 states, four territories, and a federal district; it also set a number of goals, toward which the nation subsequently inched its way. Although the monarchical idea survived for nearly half a century more, Mexico remained a republic. The constitution abolished slavery, which was never a major issue, and enfranchised all male inhabitants; Indians thus lost their special colonial status,

and accompanying protections, as wards of the government. In many ways they were worse off during the 19th century than they had been under the paternalism of the Spanish crown. Restrictive state legislation excluded the great mass of peasantry from the political process.

Under various labels, two factions contended for control. Generally conservative, the Centralists favoured a strong central government in the viceregal tradition, a paid national army, and Roman Catholicism as the exclusive religion. Opposed to them were the Federalists, who favoured limited central government, local militia, and nearly autonomous states; they tended to be anticlerical and opposed the continuance of colonial *fueros,* which gave special status to ecclesiastics and the military and exempted them from various civil obligations.

The pendulum of power swung back and forth between the two groups. In 1824 Guadalupe Victoria, a Federalist and a leader in the independence movement, was elected president. Centralists replaced Federalists in 1828. A Federalist revolt in 1829 put Vicente Guerrero in the presidential chair, but he was soon overthrown by the Centralists, who held power until 1832. In 1833 another change placed Federalists in power until 1836, when Centralists again regained control and held it for nearly a decade.

The age of Santa Anna: Texas and the Mexican War. After the downfall of Iturbide, Mexican politics revolved for some time about the enigmatic personality of Antonio López de Santa Anna, a charismatic general with seemingly few fixed ideological or political beliefs. Allied with the Federalists, Santa Anna was first chosen president in 1833, but, rather than serve, he placed the liberal vice president Valentín Gómez Farías at the head of the government until Farías and his group in 1834 attacked the privileges of the clergy. Then Santa Anna assumed his presidential post and nullified the anticlerical legislation.

Problems over Texas

Santa Anna was president when difficulties over Texas first began to mount. Under favourable terms, some 30,000 U.S. immigrants had populated that previously desolate area. Fearful that their growing numbers posed a threat, the Mexican government in 1830 closed the border to further immigration and imposed on the Texans oppressive restrictions that contravened the Mexican constitution. When Santa Anna adopted a new constitution in 1836, and in the process eliminated all vestiges of states' rights, Texas declared itself an independent republic. Santa Anna quickly gathered an army to crush the revolt. He met with initial success when he trapped a small Texas garrison at the Alamo and totally eliminated it, but he was defeated and captured by Texas forces in April 1836 and subsequently freed. Though Mexico made no further efforts to reconquer Texas, it refused to recognize its independence.

At that time a doctrine now known as Manifest Destiny was at its height in the United States. It expressed a belief that it was the destiny of the United States to occupy all the North American continent and perhaps all of Mexico. The United States annexed the Republic of Texas in 1845, a move that caused the Mexican government to break off diplomatic relations. Santa Anna was overthrown for his apparent willingness to negotiate with the United States.

Although the United States claimed that the southern boundary of Texas was the Rio Grande, the boundary had always been the Nueces River. Shortly after his election in March 1845, U.S. President James K. Polk tried to secure an agreement on the Rio Grande boundary and to purchase California, but the Mexican government refused to discuss either matter. Polk ordered U.S. troops to occupy the disputed territory between the rivers. When Mexican and U.S. patrols clashed in April 1846, Polk asserted that American blood had been shed on American soil—an outrage that required action. Less warlike politicians, such as the Illinois congressman Abraham Lincoln, to no avail submitted resolutions asking Polk to point out the precise location of this outrage. Polk's congressional majority formally declared war on Mexico in April.

War with the United States

Without major difficulty, U.S. troops captured New Mexico and Upper California (now the state of California). General Zachary Taylor led the main U.S. force to quick victories in northeastern Mexico. At that juncture the government of Mexican president Mariano Paredes y Arrillaga was overthrown, and Santa Anna reemerged as president in September 1846. Almost immediately, Santa Anna mobilized Mexican forces and marched northward, boasting that the superior numbers and courage of his men meant that he would sign a peace treaty in Washington. Although Taylor and Santa Anna fought a close battle at Buena Vista, Santa Anna was beaten and forced to retreat on Feb. 23, 1847. Both sides sustained heavy losses.

A change in U.S. strategy left Taylor holding ground in northern Mexico; it was decided that Mexico could be beaten only by capturing Mexico City, via Veracruz. General Winfield Scott was given command of the expedition. On April 18, 1847, he defeated Santa Anna in the critical battle at Cerro Gordo. Though Mexican resistance continued to be formidable, Scott captured Mexico City on Sept. 14, 1847. Santa Anna went into voluntary exile while a new Mexican government negotiated peace.

Dated Feb. 2, 1848, the Treaty of Guadalupe Hidalgo terminated the war. Under its terms Mexico ceded all territory north of an irregular line of the Rio Grande and the Gila River across the Colorado to the Pacific. The United States paid Mexico $15,000,000 and assumed $3,250,000 in claims held by U.S. citizens against Mexico.

After the war Santa Anna figured in one more major episode before the political scene changed. In 1853 conservatives seized power and invited him to become dictator. Among other things, on Dec. 16, 1853, Santa Anna decreed that the dictatorship should be prolonged indefinitely and that he should be addressed as "His Most Serene Highness." To raise funds for an expanded army, he sold territory south of the Gila River to the United States for $10,000,000; this Gadsden Purchase, as it is now called, was the last significant boundary change of the Mexican Republic.

The Reform. Since independence a new generation of Mexicans had been born; appalled at the easy victory the United States had won, the more thoughtful among them felt that Mexico's survival as an independent nation depended on fundamental reform. Among the new faces was Benito Juárez, a Zapotec Indian educated as a middle-class liberal, who had moved to New Orleans and had discussed and planned Mexico's future with fellow expatriates. With no military force to implement their plans, they bided time until their opportunity came, in 1854, when Juan Álvarez, a surviving hero of independence, and Ignacio Comonfort, a political moderate, proclaimed a liberal rebellion against Santa Anna and forced him out of the presidency.

Neither Álvarez, who served a short term as president, nor Comonfort, who succeeded him, had any clearly defined program. The role of the returned expatriates was to act as a brain trust to carry out La Reforma ("The Reform"). Its aims were to abolish remnants of colonialism by removing special ecclesiastical and military privileges; to separate church and state by secularizing education, marriages, and burials; to reduce the economic power of the church by forcing it to sell its properties; to foster an economic development that envisaged Mexico as a country of yeoman farmers and small industrialists; and, above all, to establish a single standard of legal justice.

Juárez was made minister of justice. Among his first reforms was the so-called Ley Juárez (Nov. 23, 1855), which abolished *fueros* and the use of special military and ecclesiastical courts in civil cases. The minister of finance, Miguel Lerdo de Tejada, sponsored the Ley Lerdo (June 25, 1856), which restricted the right of ecclesiastical and civil corporations to own lands by decreeing that church lands not directly used for religious purposes must be sold and lands held in common by Indian communities (*ejidos*) be distributed to individual villagers.

Constitution of 1857

The reformers called a convention to draft a new constitution, which would provide a legal base for the reform. It was promulgated on Feb. 12, 1857, but did not become effective until the following September 16, the 47th anniversary of the "Grito de Dolores." The Constitution of 1857 prohibited slavery and abridgments of freedom of speech or press; it abolished special courts and prohibited civil and ecclesiastical corporations from owning property, except buildings in use; it eliminated monopolies; it

prescribed that Mexico was to be a representative, democratic, republican nation; and it defined the states and their responsibilities. This constitution, which remained in force until it was modified in 1917, increased the power of the central executive.

Neither the religious community nor the military accepted the 1857 constitution, and both inveighed against the reform, calling for retention of "religion and *fueros*." The church excommunicated all civil officials who swore to support the constitution. When civil war erupted, Comonfort went into exile after his efforts at compromise had failed; Juárez automatically succeeded him as constitutional president. The conservatives captured Mexico City and set up a competing regime. Juárez and his government moved to Veracruz, where they controlled the customs receipts.

Foreign powers became involved in the Mexican struggle. On April 6, 1859, the United States recognized the Juárez government; President James Buchanan permitted war matériel to be shipped to Juárez' forces. Americans were encouraged to serve the liberal cause as volunteers; Spain and France generally favoured the conservatives, as did Great Britain.

In July 1859 Juárez issued a series of decrees: all church property except buildings used for worship was to be confiscated without compensation; all marriages apart from civil were declared annulled; the formal separation of church and state was proclaimed; cemeteries were declared public property, and burial fees were abolished. Moneys from the sale of confiscated church property, though less than anticipated, speeded the end of the civil war. On Dec. 22, 1860, the liberals won a critical battle, and, when the conservative president, Miguel Miramón, fled, the conservative cause collapsed. The victorious liberal army of about 25,000 men entered Mexico City on New Year's Day, 1861. On his return (January 11) Juárez was greeted by an enthusiastic populace who welcomed the end of the long and devastating civil war and the reestablishment of government under the constitution of 1857.

French intervention. Exiled Mexican conservatives, who continued to intrigue, enlisted the help of a powerful ally, the French ruler Napoleon III, who wanted to create a Latin league that would include the Mediterranean lands and the former possessions of Spain and Portugal in the New World as well. (The term Latin America dates from this time and concept.) With its strategic position and its economic potential, Mexico seemed especially attractive to the Napoleonic imperial scheme. A French bastion in Mexico would check the Manifest Destiny of the United States and provide a base from which Central and South American protectorates could be added. The fact that the United States was engaged in a civil war (1861–65) was a determining element. In 1861 Napoleon III was willing to believe the Mexican conservatives' assertions that the masses of Mexican people would support his intervention to restore religion and set up a monarchy.

Ambitions of Napoleon III

Mexico's chaotic economic situation afforded Napoleon III the perfect opportunity to implement his scheme. The government of Benito Juárez had a huge foreign debt, and in 1861 the Mexican government suspended all payments to Spain, Britain, and France. The three European powers prepared to send a punitive expedition to Mexico. The intervention was spearheaded by Spain, the forces of which landed at Veracruz on Dec. 14, 1861, and were followed soon after by French and British contingents. When the allies fell into dispute over the $15,000,000 French claim for payment of certain questionable bonds, both Spain and Great Britain disengaged from the joint venture.

The French expeditionary force began its march toward Mexico City. When the Mexican army made a stand at Puebla on May 5, 1862, the French retreated to await reinforcements. Napoleon dispatched 30,000 more troops under the command of the French general Élie-Frédéric Forey. The Mexicans could not withstand French might, and on June 10, 1863, Forey rode as conqueror into Mexico City. The French rapidly secured much of central Mexico, forcing Juárez and his government to keep constantly on the move in the north.

Napoleon III had already identified a pair of puppets to place on the Mexican throne: Maximilian of the House of Habsburg and his wife, Charlotte (Carlota), daughter of the King of Belgium. Assured of Napoleon's continued military support and the economic backing of the British, Maximilian and Charlotte arrived in Veracruz on May 28, 1864, having passed through Rome to confer with the Pope before they embarked. On June 12 Emperor Maximilian was welcomed in Mexico City.

Emperor Maximilian

Maximilian attempted to follow a policy of national conciliation, hoping to unite Mexican factions and interests. But he proved too much a Habsburg to be an effective tool of Napoleon's schemes, too much a liberal to please the conservatives who had engineered his coronation, and too tainted by conservative sponsorship to win republican support.

Maximilian was perhaps less naive than he has been pictured. Not fully convinced that a majority of Mexicans welcomed him as emperor nor sure that he should place full reliance on French troops, he tried to create a Mexican rural guard and a separate imperial army around a nucleus of Austrian and Belgian volunteers. His proposal to reduce the number of regular Mexican army generals to 18 brought early disillusionment to the army, a mainstay of conservatism, which had expected Maximilian to be a puppet. The Mexican officers became further irritated when, with Maximilian's approval, French officers outranked them. At this time the Habsburg emperor and the French commander, Achille-François Bazaine, were following conflicting army policies, Napoleon having ordered Bazaine to Mexicanize the army to cut time and costs of occupation.

At the same time, clerical groups, eager to reap rewards for their efforts on the Emperor's behalf, pressed him to reverse the Reform. A papal nuncio from Rome arrived with a message asking that Maximilian revoke the anticlerical laws, establish Roman Catholicism as the exclusive religion, restore the religious orders, remove the church from its dependence on civil authorities, turn education over to ecclesiastics, and return properties confiscated and sold by the republicans. Replying that he, not outsiders, would decide such matters, Maximilian issued decrees establishing religious toleration, with Roman Catholicism favoured but still dependent on the state. He confirmed that the previous sales of church property under the Reform laws were legal and that revenues the church had received from property Juárez had nationalized were to be ceded to the state. Thus, Maximilian's conservative support further dwindled because the clergy and their followers felt betrayed.

In September 1864 Maximilian took what amounted to a guided tour of the cities that supported his empire. The warm welcomes he received from the people led him to conclude that a majority of Mexicans wanted peace and justice, which the activities of the republican guerrillas threatened. He therefore decreed on November 4 that, thenceforth, republicans would be considered bandits and brigands, subject to extreme penalties; this negated Maximilian's attempts to woo their supporters by inviting them into his council of state.

In 1865 French troops chased Juárez to, but not over, the U.S. border. Believing that the Mexican president had left national territory and that republicanism had therefore collapsed, Maximilian on October 2 issued a strong decree, ordering that all guerrillas be court-martialed and shot within 24 hours; the same penalties were to apply to persons who hid, aided, or otherwise helped them. Juárez had earlier issued a parallel decree (January 1862) against those who aided the French interventionists and imperialists.

French troops, though they were effective in keeping republicans on the outskirts of major productive areas, were also costly. Napoleon's Mexican adventure came under heavy press and parliamentary fire in France as costs in men and money mounted without economic or political advantages to compensate for the expenditures. There was criticism from overseas as well; with its civil war ended, the United States turned to the international scene. William H. Seward, the U.S. secretary of state, brought mounting diplomatic pressure on Napoleon to withdraw

Withdrawal of foreign troops

French troops; in February 1866 Napoleon agreed to clear foreign troops from Mexico by November 1867. A U.S. request to the Austrian government to stop enrollment of volunteers for the Mexican imperial army also brought an affirmative response.

In liquidating his Mexican venture, Napoleon said that, since Maximilian had not carried out his part of the pact to bring peace and orderly government to Mexico, the French were relieved of their obligations for military and financial support. Stunned, Maximilian sought to have the decision reversed. The empress Charlotte tried without success to persuade the French ruler to honour his solemn pledge. From Paris she traveled to Rome to plead with the Pope; there she went mad and was taken to Belgium, where she lingered insane until her death in 1927. Bazaine, ordered to withdraw all French troops immediately, auctioned off military material not worth shipping to France—including horses and saddles—and destroyed large supplies of powder and projectiles rather than turn them over to Maximilian. In February 1867 Bazaine left Mexico City, and by March 12 all 28,690 men had embarked. Napoleon made Bazaine the scapegoat of the Mexican fiasco, blaming its high costs and lack of results on his mismanagement, and implied personal dishonesty.

As French power withdrew, republican forces reconquered Mexico, and Maximilian was left with only a regiment of Austrian hussars, a battalion of infantry, and a small army of relatively untrained Mexican draftees. After first considering abdication, Maximilian decided to defend his imperial status and his honour as a Habsburg by making as strong a stand as possible, though planning, in the event of defeat, to negotiate an honourable exile. With these resolves he concentrated most of his troops—9,000 men—at Querétaro, a city loyal to the imperial cause. On May 5, 1867, the republican forces laid siege, initially with 32,000 men, later with an additional 10,000. By May 14 the starving imperialist force, reduced to about 5,000, had decided to withdraw and take a stand in the mountains. A disaffected imperial officer, in return for a promise that Maximilian be spared, placed republican soldiers, whom he passed off as relief troops, at strategic places in Querétaro. The siege ended the next day when Maximilian and his generals surrendered.

Under Juárez' decrees of 1862, Maximilian and his two leading generals were court-martialed and sentenced to death by firing squad. President Juárez refused to be swayed by the petitions for mercy that poured in from foreign governments. He wanted to demonstrate that Mexico could act independently; that, as the Reform contended, all men were equal under law; that foreign monarchical adventures in Mexico were futile; and that the honour of the Mexican dead would be redeemed. Maximilian and the generals were executed on June 19, 1867, terminating a bizarre interlude of Mexican history.

The restored republic. At least 50,000 persons lost their lives in the struggles between republic and empire, and when Juárez reentered Mexico City on July 15, 1867, his immediate task was to abate the rancors of civil war. The vindicated Juárez regime took few major reprisals—principal imperialists were fined, some were imprisoned for short terms, and a few were exiled. One of Juárez' first acts was to start rebuilding the shattered economy. In an era of goodwill engendered by the sympathy and aid the United States had extended to the Mexican cause, the claims of the two countries against each other were settled by peaceful arbitration. Diplomatic relations were gradually reestablished with Europe.

Rebuilding the republic

In December 1867 Juárez was reelected president. Apart from trying to foster political tranquillity, his main aims were to improve public education and to put the economy on a sound footing. To avoid the problems of dogma and religious opinion that had divided Mexicans, Juárez entrusted the development of a national educational system to Gabino Barreda, a follower of the French thinker Auguste Comte, who had said that the human mind and society passed through three successive stages—religious, metaphysical, and positive. Known as positivists, Barreda and his followers contended that the Reform, by displacing the church and militarism, had done away with the earlier two stages and that Mexico was in the third, or positivist, stage. The public-education law for the Federal District, which was to serve as the national model, stressed the secular state as the inculcator of scientific ethical norms, with "Liberty, Order, and Progress" as the means, base, and product of the system.

The chief architect of economic rehabilitation was Matías Romero, who had been Juárez' minister in Washington and who believed that Mexico's development was dependent on three basic elements: immigration, communication networks, and the exploitation of natural resources. In 1867 and '68 the government renewed concessions to British capitalists for the completion of the Veracruz–Mexico City railway and issued concessions for others; it authorized the opening of new roads and the extension of the telegraph system. Work was begun on reforming the tax systems and tariff schedules.

The reelection of Juárez in 1871 was contested more heatedly than that of 1867 had been. Thereafter, despite formidable opposition in congress, tariff reform was approved, as was Mexico's adoption of the metric system, which ended the chaotic colonial system of weights and measures.

After a short illness, Juárez died suddenly on July 18, 1872, his death closing one era and opening another. Behind him lay Mexico's long colonial history and its partial survivals through the early 19th century. The notion of a Mexican monarchy had been forever buried with Maximilian. Under Juárez, Mexicans had begun to modernize the economy and some of the social institutions, to expand rail, road, and telegraph networks, and to develop secular education.

Juárez' death also brought temporary political peace. Without incident, Sebastián Lerdo de Tejada, the president of the supreme court, and next in line of succession, was sworn in as acting president on July 19. Congress immediately began to lavish posthumous honours on Juárez, who by his innate abilities and great strength of character had led his people through unprecedented travail. He remains a major figure in the history of Mexico.

Temporary political peace

A national election placed Lerdo in the presidential chair in his own right on Nov. 16, 1872. The course Juárez had charted remained unchanged. On New Year's Day, 1873, the Veracruz–Mexico City railway was inaugurated. Other works were commissioned. Congress and the executive branch of government continued to dole out railway and telegraph concessions. To safeguard the nation against future bloodshed, congress on May 31 added specific reform laws to the constitution of 1857—church and state were explicitly declared independent of one another; freedom of religion was proclaimed; church acquisition of real estate was abolished; religious oaths were banned in civil courts; forced labour was forbidden; and liberty of man in respect to labour, education, and religion was declared inviolable. The degree to which the Reform had triumphed was evidenced by the fact that no national movement developed against these additions to the organic laws. The Lerdo government in 1874 renewed diplomatic relations with France, Spain, and Prussia.

The age of Porfirio Díaz. From 35 years, from 1876 until a political revolution unseated him in 1911, the personality of Porfirio Díaz dominated the history of his country. Like Juárez, Díaz was a poor Indian from Oaxaca but of Mixtec rather than Zapotec heritage. Educated locally, he had chosen a military career and had become an outstanding general in the republican cause against the French intervention and empire. Although he vied for the presidency against Juárez in 1867 and again in 1871, their ideological differences were not great. When in 1875 Lerdo ran for reelection, Díaz led a successful revolt and assumed the presidency in November 1876.

Díaz took the blueprint for Mexico's future that Juárez and Lerdo had elaborated and implemented it. While clearing out pockets of political resistance, he turned the presidency over to Manuel González, a companion in arms. Díaz won the election again in 1884 and was regularly returned to that office through 1908. During his long regime he scrupulously kept democratic and constitutional forms intact, partly in the conviction that it was

the president's duty to train the unready Mexican people to use them properly.

The *científicos*

Around him Díaz gathered many intellectuals (the *científicos*). They were positivists who stressed the need for rational planning and development. The emphasis was on economic development to assure social progress. How such development was to be achieved was translated into one of Díaz' political slogans, "*pan o palo*" ("bread or the club"), meaning that acquiescence to official policies would ensure livelihood, even wealth, but failure to agree would bring sure reprisals—harassment, imprisonment, death. Another slogan was "few politics, much administration." Liberty was dropped from the earlier positivist triad of liberty, order, and progress. It was the price the Mexican people were expected to pay for the benefits the *científicos* policies would provide.

Capital, though badly needed, could not be attracted until Mexico had tidied up its international and national fiscal affairs. Mexican finances were placed on a solid base, and a stable currency was established. With guarantees of political and social tranquillity, foreign investment was encouraged and obtained. European and U.S. funds built some 15,000 miles of railways, provided electricity and streetcars for the cities, created industrial complexes, rehabilitated port facilities, and developed the mining of industrial metals. Early petroleum concessions to foreigners laid the groundwork for serious problems later, when world navies shifted from coal to oil and when automobiles were mass-produced.

A complex mechanism in which all major and most minor decisions rested in the hands of the president evolved during the first two decades of the Díaz regime, or Porfiriato. The success of the practice rested on self-interest; Díaz made it worthwhile for everyone to support the system. For the most part, the small body of intellectuals was absorbed into the expanding bureaucracy or the subsidized press. The army and the church were made handmaidens of the regime rather than its adversaries; generals were encouraged to become entrepreneurs. While retaining the Reform laws on the books, Díaz was purposely conciliatory toward the church and allowed it to regain some of its former economic power without letting it develop significant political influence.

The Porfiriato

The regime also perfected instruments of repression and control, though for many years it used them sparingly. Forced military conscription lay in the hands of the president's appointees. Troublesome elements such as the Yaqui Indians were inducted en masse and shipped as cheap labour to the sisal plantations of Yucatán or the tobacco fields of Oaxaca. Governors were personal appointees of the president. Their actions were monitored by *jefes políticos* ("political chiefs"), who reported directly to the president and on his authorization intervened in municipal and state affairs. An elite constabulary, the *rurales*, like the Texas Rangers and Canadian Mounted Police, created a myth of ubiquity that eliminated the brigandage and banditry characteristic of earlier 19th-century Mexican countrysides.

In an era in which material success was highly regarded, Díaz' accomplishments were praised, but his popularity began to decline, perhaps about 1895. Prosperity had been preempted by a relatively small group, many of whom were foreigners. The Mexican economic and social elite self-consciously aped European (especially French) modes of dress, education, and even language. Between the affluent and the growing urban and rural proletariat there was an expanding middle-class body. Meanwhile, a new generation, which could recall none of the chaos of the days before Porfirio Díaz took charge, began to question the system. As criticism increased, so did repression. It was from this interaction that the Mexican Revolution resulted.

PRECURSORS OF THE REVOLUTION

The Regeneration group

Shortly after 1900 many Mexicans began to question the nation's apathetic acceptance of the Porfirian peace. The earliest and most vocal critics were Mexican radical groups, perhaps the most important of which called itself Regeneration. Its members were anarchists who adapted their dogmas to the Mexican scene. While always small in numbers and often ineffective in actions, this group had great influence. Many of the reforms and programs it advocated were embodied in the Mexican constitution of 1917.

The leader of the Regeneration group was Ricardo Flores Magón, who had been born in Oaxaca of an Indian mother and a mestizo father and had been sent for further education to Mexico City, where he had turned to idealistic student activism. For leading a small demonstration against the reelection of Porfirio Díaz in 1892, he was jailed for the first of many times. The group's movement took form in 1900, when Camilo Arriaga, a well-to-do engineer in San Luis Potosí, organized first a club and then a small party to restore the liberalism of Juárez. Arriaga called a national meeting of liberal clubs in 1901, and a short time later most of the small band were jailed, and their newspaper, *Regeneracion,* which Flores Magón edited, was suppressed. After they had served their prison sentences the young radicals fled north to the United States and Canada, settling for a while in St. Louis, Mo., where they formally organized the Mexican Liberal Party. Although its name suggests the earlier Reform, in fact it was anarcho-syndicalist, dedicated to the overthrow of the Mexican government and the total renovation of Mexican society.

In 1906 the Regeneration group published a comprehensive program in the form of a manifesto that had wide, if clandestine, circulation in Mexico. It advocated a one-term presidency, guarantees of civil liberties, breaking the hold of the Roman Catholic Church, vast expansion of free public education, and land reform. It asked that Mexican citizenship be a prerequisite to property ownership and that unused land be distributed to the landless. The manifesto proposed confiscation of the wealth that Díaz and the *científicos* had illegally acquired, the abolition of child labour, guaranteed minimum wages, and bettered working conditions for workers. In muted tones it criticized capitalism as a system of exploitation. The Regeneration group drew its main lines of thought from Mikhail Bakunin, a Russian revolutionary writer who believed that the power of any institution, including government, that exercised controls over individuals should be reduced.

Many charges by the Regeneration and similar groups were borne out when the Díaz troops, in bloody fashion, broke strikes in the textile region of Veracruz and the copper-mining regions of the northwest state of Sonora. Several of these strikes had been fomented by Regeneration organizers at the same time that U.S. muckrakers were exposing the evils of corrupt government, big business, and other aspects of life in the United States and abroad. Possibly to refute their unfavourable reports, Díaz gave an interview in 1908 to an American reporter, James Creelman, that became a milestone in prerevolutionary history. To blunt charges of one-man rule, Díaz very carefully but clearly said that in his view the time had come for Mexico to advance toward democracy, that he would welcome an opposition party in the 1910 presidential election, that he would be most happy to sustain and guide the opposition party, and that to inaugurate a democratic government in Mexico he would forget himself. This fell like a bombsheli in Mexico, where most readers failed to note that he had not specified a time. It was widely believed that this implied he would not run for the presidency in 1910. Mexican newspapers not only reprinted the interview but also began openly to discuss Mexican political questions, long forbidden by the regime. Pamphlets and then books added to the political rumblings.

Political opposition to Díaz

Two main opposition groups soon emerged. One backed General Bernardo Reyes as vice presidential candidate over Díaz' handpicked candidate. Reyes forthrightly opposed *científico* theories and practices and, as governor of the progressive northern state of Nuevo León, had initiated a state workman's compensation law.

The other main party, anti-reelectionist, had been created largely through the efforts of Francisco I. Madero, then a political unknown, whose efforts elevated him to the highest place in the revolutionary pantheon as the "Apostle of Democracy." Born into one of the 10 richest

families in Mexico, whose agricultural enterprises spread over much of northern Mexico, Madero was educated in the United States and France. In his own right he became an enlightened entrepreneur and amassed a considerable personal fortune.

Madero became concerned with how badly Mexico was faring in comparison to the rest of the world. Mexican food prices were rising, and rural and urban standards of living were dropping. He attributed Mexico's retrograde position to the prolonged political dictatorship. He helped journalists to expose these matters and provided considerable early financial support to the Regeneration group, but he disassociated from them after about 1907, when it became clearer that they intended to destroy, not reform, the system.

Madero, setting about to organize a national party to compete in the 1910 elections, published *La sucesión presidencial en 1910* ("The Presidential Succession in 1910") as a campaign document, two-thirds of which dealt with the history of Mexico and the corrupting influences of absolute power and the rest with his program to revive the democratic usages that had atrophied for so long. The initial aim was to win the vice presidency.

Despite harassment, Madero carried on a vigorous and wearying campaign in the summer of 1909. During an interview with Díaz, he was surprised by the dictator's advanced old age and his remoteness from current issues. Díaz' condition and the enthusiasm of Madero's crowds led the anti-reelectionists to modify their goals. Rather than accept Díaz as the inevitable president in 1910, they decided to try for the presidency themselves.

On June 14 Madero was arrested and jailed and thus became the martyr and victim of the system he was trying peacefully to change. Since it was perfectly clear that Díaz was not going to permit free and honest elections, Madero and his followers decided that the only hope of improving Mexico was through armed revolt. On Oct. 4, 1910, the Chamber of Deputies, which had assembled as the electoral college, declared that Díaz had been reelected. On October 5 Madero managed to escape from the San Luis Potosí jail. He arrived on October 7 in San Antonio, Texas, where with aides he prepared and issued, as of the day of his escape, the Plan of San Luis Potosí, which proclaimed the principles of "effective suffrage, no reelection." Madero declared that Díaz was illegally president of Mexico. Designating Sunday, November 20, as the day when citizens should take up arms against the government of Porfirio Díaz, he promised that a successful revolution would institute political reforms.

The Plan of San Luis Potosí

But on November 20, the official birthday of the Mexican Revolution, no mass uprisings took place. Small bands of guerrillas, most of them in northern Mexico, kept the rebellion alive while Madero used his family fortune to supply them with arms from Texas. Under the leadership of Pascual Orozco and Pancho Villa, the northern rebels began to defeat Federalist forces, who held most of the strategic rail lines, especially those emanating from Ciudad Juárez, on the U.S. border, where the Federalist troops had consolidated. Until the revolutionists laid siege to that city, no more than 2,500 armed men were engaged in the Madero revolution.

THE MEXICAN REVOLUTION AND ITS AFTERMATH, 1910–40

When armed outbreaks initiated the Mexican Revolution in 1910, the immediate object was to replace Díaz as president. What began as a relatively simple political movement broadened into a major economic and social upheaval that gave Mexico many unique characteristics. During the long struggle, the Mexican people developed a sense of identity and purpose, unmatched by any Latin-American republic. Many reforms had been established by 1940, when the goals of the revolution were institutionalized as guidelines for future Mexican policies.

The military revolution. On Feb. 14, 1911, Madero crossed into Mexico near Ciudad Juárez to head his forces. In the next few months the rebels learned how debilitated the Díaz army had become; led by aged generals, the Federalist troops lacked discipline, cohesion, unity of command, and effectiveness. Under these circumstances, the revolution gained ground and momentum. On May 10 the Federal commander surrendered at Ciudad Juárez, which marked the beginning of the end. An agreement negotiated with the Díaz regime provided that Díaz would resign, that an interim president, Francisco León de la Barra, would call general elections, and that revolutionary forces would be discharged. On May 25 Díaz resigned and sailed for Paris. Several revolutionary bands, including that of Emiliano Zapata, resisted being disarmed by the Federal army.

In the heated political atmosphere, congress on November 2 declared that Madero had won the presidency in an election held the previous month. The new government was able to withstand constant attacks from the right and left for only 15 months. A series of unsuccessful counterrevolutionary revolts culminated in a successful plot in February 1913. Following 10 days of cannonading the heart of Mexico City, with high civilian casualties, Victoriano Huerta, commandant of government forces, betrayed Madero and arranged for his arrest and that of his vice president, José María Pino Suárez, so that Huerta could assume the presidency himself. These plans were made with the knowledge, if not the connivance, of the U.S. ambassador, Henry Lane Wilson, who was thus defying President William H. Taft's instructions to remain aloof from domestic Mexican politics.

Shortly thereafter, presumably on Huerta's orders, Madero and Pino Suárez were shot while being transferred from one prison to another. Their deaths rekindled revolutionary fires. In northern Mexico, Venustiano Carranza, refusing to recognize Huerta as president, demanded that the office be elective, as specified in the constitution. He called his new movement the Constitutionalist Revolution. Former chieftains such as Pancho Villa made loose alliances with Carranza. The revived revolution took on highly local and regional aspects.

The new president of the United States, Woodrow Wilson, was determined to oust Huerta and, on flimsy pretexts, landed U.S. troops at Veracruz and occupied it. All of the revolutionary leaders except Villa rejected this external intervention in a national struggle. The combined revolutionary forces unseated Huerta in 1914 but then split over who was to exercise presidential power. Zapata in Morelos and Villa in the north joined to fight the revolutionary groups under Carranza, the most important of which was headed by General Álvaro Obregón. Obregón won a decisive victory over Villa at Celaya in April 1915 but failed to bring the civil war to an immediate end. Sporadic fighting continued for the next five years.

Split among revolutionary groups

The constitution of 1917. With most of central and southern Mexico under constitutionalist control, Carranza in 1916 convoked a constituent congress in Querétaro to revise and update the constitution of 1857.. In the course of fighting, the economic and social demands of the radical precursors had become common slogans as contending revolutionary bands bid for popular support. The constitution of 1917 incorporated the aspirations of those groups involved in the revolution. A major concern of Zapata's followers was land reform. Carranza's advisers had prepared a draft document that included not only most of the revolutionary decrees about land reform but also the most advanced European social legislation.

The constitution of 1917 specifically incorporated the major features of the 1824 and 1857 charters regarding territorial organization, civil liberties, democratic forms, and anticlerical and antimonopoly clauses. The constitution completely reversed the concept widely held in Mexico that government should take only a limited, passive role. Its philosophy was that the national government had an obligation to take an active role in promoting the social, economic, and cultural well-being of its citizens. Article 3 sketched a vast plan of secular, free, compulsory public education. Article 14 reaffirmed the sanctity of private property and contracts, but article 27 interjected concepts of social utility and national benefit to limit the untrammeled use of private property. The most important new concepts came in Articles 27 and 123. The former reasserted national ownership of subsoil resources and outlined alternative land-reform and agrarian programs.

The latter, the magna carta of labour and social welfare, was set apart to highlight its importance; in addition to guaranteeing minimum wages and the right to organize and strike, it gave labour social status and destroyed the concept of it as an economic commodity to be bought at the lowest rates to maximize profits. Article 123 also outlined a comprehensive system of social security, including public health and welfare programs. Reflecting the nationalistic feelings of the revolutionaries, foreigners and foreign interests were placed under limitations. Article 33, for instance, permitted the president to deport foreigners at will.

The constitution of 1917 set the goals toward which presidents were to work. As expected, Carranza was elected president and given de jure recognition by the United States. When Zapata was betrayed and killed in 1919, the last organized opposition to the Carranza-Obregón reorganization dissolved. Pancho Villa retired from active campaigning after his raids across the border, especially one in Columbus, N.M. (March 9, 1916), had failed to embroil the United States in conflict with Carranza. Villa was ambushed and shot by political enemies in 1923.

The northern dynasty: Obregón and Calles. When Carranza failed to move toward immediate social reforms, General Obregón enlisted two other powerful north Mexican chieftains, Plutarco Elías Calles and Adolfo de La Huerta, to join him in an almost bloodless coup; together they formed the northern dynasty. Carranza was killed as he fled from Mexico City, and Obregón took office as president Dec. 1, 1920. The dynasty agreed that peace was needed to rehabilitate Mexico from the devastations of nearly a decade of civil upheaval. Using a combination of force and political incentives, Obregón placated many ambitious military leaders.

Overthrow of Carranza

Obregón began to implement the ideals set forth in the constitution. Administrative machinery was set up to distribute land to the landless and to restore communal holdings (ejidos) to villages. The government supported the Regional Confederation of Mexican Labour (Confederación Regional de Obreros Mexicanos; CROM). José Vasconcelos, who was named minister of education, was to implement the program of rural education. He sponsored a cultural program that brought Mexico worldwide fame and importance. Radical mural painters such as Rivera, Orozco, and Siqueiros, who were commissioned to portray Mexican and especially revolutionary history on public buildings, exalted the Indian past, as did creative writers.

At the end of his term, Obregón stepped aside for Calles. Calles' presidency followed the same general lines as had Obregón's. Land distribution was stepped up, an irrigation program was begun, and in 1925 renewed pressure was put on the petroleum companies to exchange for leases the titles they had obtained from Díaz. Problems with the church developed when Calles instituted vigorously anticlerical measures; in retaliation, the church suspended all religious ceremonies and approved and possibly sponsored a rebellion in western Mexico known as the Cristeros. Mediation of the church–state controversy was unofficially accomplished by Dwight W. Morrow, the U.S. ambassador to Mexico, whose sympathetic and skillful diplomacy also eased tensions between the two countries.

In 1928 the presidential term was extended from four to six years, and the doctrine of "no reelection" was modified to mean "no successive reelection." Obregón was the successful presidential candidate, but, before he could take office, he was assassinated by José de León Toral, a religious fanatic. With Calles unable to succeed himself, a peculiarly Mexican single-party system came into being.

Single-party system

Calles formed the National Revolutionary Party, a coalition of regional and local military bosses and labour and peasant leaders. To safeguard the gains of the revolution, he excluded the church and other possible reactionary elements. With Calles as chief, the official party governed in the name of the revolution. A congress, drawn from party ranks, named successive, short-term presidents to fill out the Obregón term.

In the period 1928–34 a worldwide depression and increasing personal vested interests caused many of the older, now conservative revolutionaries, including Calles, to go slowly in implementing the reform mandates of the constitution. The ruling clique continued to be militantly anticlerical, but government support was withdrawn from CROM, which disintegrated. Land distribution slowed down, and educational programs were curtailed. On the positive side, the Calles years saw the beginnings of an irrigation and road-building program.

Resurgence under Cárdenas. Within the revolutionary family, General Lázaro Cárdenas was a respected if not outstanding revolutionary. Having quietly and faithfully worked his way up the ladder of politico-military power during the Obregón and Calles years, he seemed a safe candidate in the 1934 elections. He was also acceptable to a powerful group within the party, which drafted a six-year plan incorporating extended revolutionary reforms.

With his election to the presidency for a six-year term beginning in 1934, Cárdenas strengthened the labour movement and took other steps that defied Calles. When the inevitable test of power came, Cárdenas won, and Calles fled into temporary exile, after which Cárdenas renamed and reorganized the party on a functional national basis—the agrarians formed one sector; labour another; the military yet another; and bureaucrats, teachers, and miscellaneous groups made up the popular sector. The four sectors agreed to support the slate of candidates the party designated. The local, state, and national representatives made party policy and ratified the president's choice of candidates.

With massive popular support and with the power elites under control, Cárdenas tirelessly pushed toward revolutionary goals. He and his advisers elaborated the land-reform programs; using land expropriated from private owners, they created communal cooperatives and gave them ejido status. By the end of his term about 40 percent of the rural working force was under the ejido program. Cárdenas also nationalized railways and placed them under the management of labour.

Perhaps Cárdenas' single most spectacular action was the expropriation of foreign petroleum companies following a labour dispute in which unions demanded not only wage increases but also participation in what management considered its exclusive role. A series of court cases and special boards found in favour of the workers. When the companies refused to accept the decisions, Cárdenas on March 18, 1938, decreed expropriation of their holdings, thus nationalizing the petroleum industry. Petróleos Mexicanos (Pemex), then a small agency, was designated to administer the industry for the nation. The British government, whose nationals had a far larger stake than U.S. firms, immediately broke diplomatic relations. After a short delay U.S. President Franklin D. Roosevelt indicated that, if Mexico would make prompt and fair payments, he would not intervene diplomatically on behalf of the oil companies. This sympathetic reaction was based largely on the advice of the U.S. ambassador, Josephus Daniels, who as secretary of the navy had ordered the occupation of Veracruz in 1914 but who over the years had become a warm friend of the Mexican people.

Expropriation of foreign petroleum companies

Mexicans consider March 18, 1938, as the anniversary of Mexican economic independence. Cárdenas had not only restored an important resource to national patrimony but also showed that national honour and dignity could not be flouted by foreign entrepreneurs, however powerful. After engaging in propaganda campaigns, boycotts, blacklists, and other forms of economic warfare, the oil companies eventually were forced to settle their claims on essentially Mexican terms.

Once the initial bungling was over, Pemex developed the capacity to fuel the industrial revolution that marked Mexico's next epoch. No one realized at the time how important petroleum would become on the world political and economic scene in the decades ahead.

General Manuel Ávila Camacho, whom Cárdenas supported, and General Juan Andreu Almazán fought a close and bitter contest for the presidency in 1940. When Almazán lost, he sought U.S. support for a revolution. But to emphasize the U.S. position toward Ávila Camacho and Mexico, Roosevelt sent Vice President Henry A. Wallace to attend the inauguration. When Cárdenas left the presi-

dency in November 1940, a major chapter of the Mexican Revolution had closed.

Ávila Camacho's domestic policy was conciliatory. While retaining earlier forms, he placated Roman Catholics by announcing, "I am a believer." These words had political importance that transcended their immediate religious significance. They meant that the social programs of the Mexican Revolution would slow down after 1940. The overriding issues of the day, however, were diplomatic and economic; the Cárdenas resurgence had increased Mexico's self-respect but had left its economy in a depressed state. The economy would be tested during World War II.

WORLD WAR II, 1941–45

Industrialization

World War II brought profound changes to Mexico. Its basic economic structure was transformed, as to a lesser degree were its political, social, and cultural institutions. To offset wartime shortages, industrialization and urbanization were accelerated to meet local needs.

Even before Mexico entered the war, it supplied raw materials to the United States. Mexico and the United States in November 1941 signed a general agreement that resolved most of their outstanding quarrels. The old problem of U.S. agrarian claims was settled, a reciprocal-trade treaty was outlined, and the Mexican peso was stabilized and supported. The United States agreed to continue silver purchases at world prices and to provide long-term loans to Mexico. Separate agreements were reached on military aid, primarily to professionalize the Mexican Army and its small air force. To that end, the military ceased to act as a separate bloc in politics.

Mexico became an active belligerent in World War II in 1942 after Germany had sunk two of its tankers. The Mexican foreign secretary, Ezequiel Padilla, took the lead in urging other Latin-American countries to support the Allies as well. A Mexican–North American joint defense committee planned cooperative operations to be carried out in case the Japanese attacked Mexico's west coast. Former president Lázaro Cárdenas served on the committee and became minister of defense when that post was created in 1944. A small Mexican air unit operated with the United States in the Philippines. But Mexico's major contribution to the war effort was the steady supply of raw materials for U.S. industry.

If Mexico had only a minor impact on the outcome of the war, the war exerted a major impact on Mexico. With most of the free world producing war matériel, traditional Mexican imports became scarce or were unavailable. To fill this vacuum, Mexican light industry developed, almost exclusively with Mexican capital.

MEXICO SINCE 1945

Mexico's population exploded at the end of World War II. The industrialism spawned by the war became a major element in the economy. The military increasingly faded into the background as arbiters of national policy, and Mexico had an unbroken line of civilian presidents, beginning with the election of Miguel Alemán in 1946. With him the emphasis shifted from the Cárdenas approach—dividing Mexico's small agricultural land area among many persons—to the development of new resources. Massive hydraulic projects were undertaken to furnish electric power, open new lands, provide flood control, and become the nuclei of regional agricultural-industrial complexes. The nationalized oil industry became a major producer of natural gas and petrochemicals in an effort to meet burgeoning domestic needs. Economic integration was accomplished by the extension of railroad, highway, and airline networks to nearly all regions.

Postwar Mexico was marked by a continuity of basic policies unprecedented in Mexican history and by the peaceful constitutional transfer of presidential power from one civilian regime to the next. President Alemán was the chief architect of new departures in the official party. The name was changed from the Party of the Mexican Revolution to the Institutional Revolutionary Party (Partido Revolucionario Institucional; PRI). Suffrage in Mexico doubled when President Adolfo Ruiz Cortines enfranchised women, who first voted in 1958. Electoral reform laws broadened the political base, but opposition parties grew slowly as the PRI dominated the political power mechanisms of the state. By the 1990s the conservative National Action Party (Partido de Acción Popular; PAN) and the leftist Revolutionary Democratic Party (Partido de la Revolución Demócrata; PRD) had become significant.

In the latter part of the 20th century, despite some notable periods of economic strain, Mexico experienced unprecedented prosperity. Mexico's economic growth in the 1970s was financed with international loans totaling almost $80 billion. Government planners calculated easy repayment from projected oil revenues, including income from the huge reserves discovered in 1976 in Tabasco and Chiapas states. They were unable, however, to predict the world oil glut of the early 1980s and the sharp fall in oil prices. Mexico found it increasingly difficult to pay even the interest on its huge foreign debt.

Economic crisis

Other problems included high unemployment and underemployment, an unfavourable balance of trade, and an alarming inflation rate. A lack of confidence in the economy prompted wealthy Mexicans to reinvest their assets abroad. The Mexican peso declined rapidly in foreign-exchange markets. President José López Portillo, elected in 1976, nationalized the country's banks and imposed strict foreign-currency controls to achieve some economic stability. Miguel de la Madrid Hurtado, who was elected to succeed López Portillo in 1982, established a program of economic austerity that gradually restored international confidence in the Mexican economy. (H.F.C./M.C.M.)

In September 1985 an earthquake killed some 7,000 people in Mexico City, and many blamed the federal government for the slow pace of reconstruction. Economic liberalization, narcotics traffic, and the flow of immigrants across the U.S.-Mexico border also continued to garner attention. De la Madrid was succeeded in 1988 by PRI candidate Carlos Salinas de Gortari. Salinas signed the North American Free Trade Agreement (NAFTA) with the United States and Canada in 1992, fostering increasing overland trade and the opening of new *maquiladoras* (foreign-owned assembly plants). Rebellion erupted on Jan. 1, 1994, when the Zapatista National Liberation Army seized several towns in Chiapas state and demanded social justice for Mexico's Indians. More than 145 people died in the initial fighting.

In 1994 PRI candidate Ernesto Zedillo replaced Salinas in the presidency. Zedillo faced a sudden economic crisis, public demonstrations in Mexico City, and ongoing civil unrest in Chiapas. He continued his predecessor's neoliberal social and economic policies while instituting reforms that effectively loosened the PRI's grip on power. The party subsequently lost key electoral races, including the presidential election of 2000, which was won by Vicente Fox of PAN, thus ending 71 years of uninterrupted rule by the PRI. Mexico City

Founded in the 14th century by the Aztecs, who named it Tenochtitlán, the future Mexico City soon became the centre of the largest empire in pre-Columbian Mesoamerica. Modern Mexico City (Spanish: Ciudad de México) is the capital of the United Mexican States and the centre of the country's political, economic, and cultural life. Although it was once called the "City of Palaces" and was said to have the world's "most transparent air," rapid population growth and industrial development have led to overcrowding, pollution, and social tensions. Still, the city retains considerable charm and has notable examples of colonial and modern architecture.

Mexico City is located in the central Mexican plateau, in the Valley of Mexico—more properly a basin—just north of the Neo-Volcánica Range. Although in 1970 Mexico City was officially equated for the first time with the Federal District—the federally controlled area designated as the nation's capital—the term Mexico City continues to be used for the entire metropolitan area. Whereas the Federal District has an area of 571 square miles (1,479 square kilometres), the metropolitan area is more than twice that size. The metropolitan area has tripled in size since the 1980s and is one of the fastest growing urban centres in the world.

Physical and human geography

CHARACTER OF THE CITY

Mexico City is a metropolis of contrasts. Although it is one of the world's largest and most populous urban areas, the former small towns engulfed in its growth have preserved much of their traditional character. Distinctively Latin-American and proud of its origins—both Indian and Spanish—it has nonetheless acquired, by virtue of its proximity to the United States, a clear North American character in some areas. The city's colonial and 19th-century buildings stand side by side with steel-and-glass constructions. The wealth of the west side and of some of the southern suburbs contrasts with the poverty of the northeast and of the illegal settlements known as *ciudades perdidas* ("lost cities") in the metropolitan area.

A centre of power

Mexico City has long been a symbol of the centralization of power: first in the Aztec empire, then in the Viceroyalty of New Spain, and finally in independent Mexico. Resentment of the capital's perceived privileges has long been a source of friction with the rest of the country, but Mexico City and some of its monuments are regarded nonetheless as symbols of the entire nation.

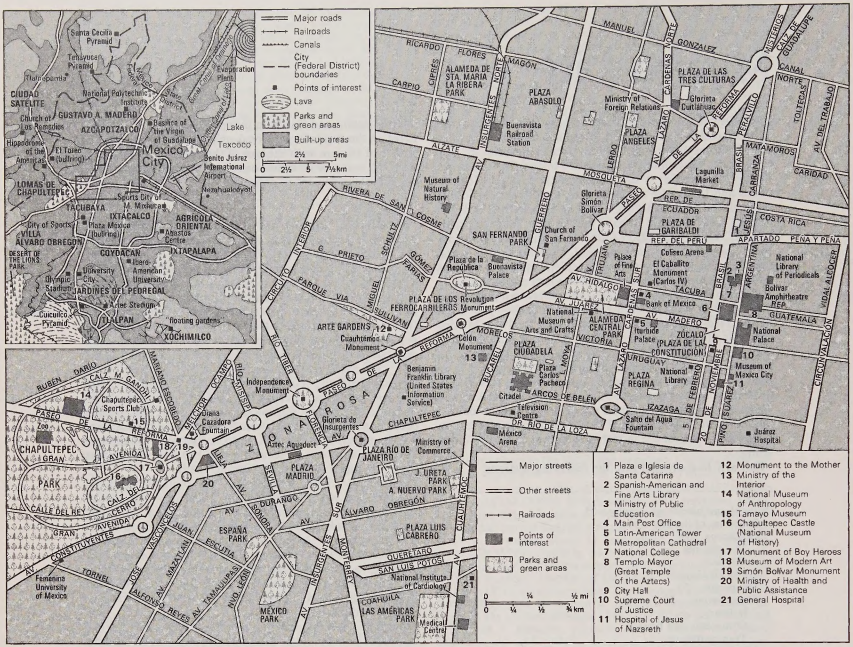
LANDSCAPE

The city site. Mexico lies in an endorheic (characterized by interior drainage) basin at an altitude of approximately 7,350 feet (2,240 metres). It is walled in by the sierras of Monte Alto and Monte Bajo to the west, the Sierra de las Cruces to the southwest, and the sierras of Ajusco and Chichinautzin to the south. Toward the east, the city ends in a plain that meets the Sierra Nevada, with its two volcanoes, Ixtacihuatl (17,342 feet) and Popocatépetl (17,883 feet). Both volcanoes had been considered dormant, but in 1994 Popocatépetl began to emit smoke, ash, and gases (it had last been active in the 1920s). Volcanic activity continued, and in December 2000 Popocatépetl began spewing hot rocks. Further pyroclastic flows have occurred, putting the area on alert and causing occasional evacuations of those living close to the volcano. To the north, Tepeyac Hill and the Sierra de Guadalupe were the traditional limits of the city, but new urban areas have developed around and beyond them.

The surrounding mountains

The island where Tenochtitlán was built—surrounded by lakes that would eventually be dried out—was chosen as the site of the colonial city. Construction expanded to the lake beds as these were desiccated. Their soft subsoil has proved highly unstable during earthquakes and accounts for a gradual sinking of some downtown sections, a process that has threatened many historical landmarks. Although the city's central area is flat, the land rises gently as it approaches the western and southwestern mountains.

Climate. Mexico City is located within the world's tropical zone, but high altitude accounts for its relative coolness. The annual median temperature is 64° F (18° C); seasonal changes are small. Night frosts occur in December and January, the coldest months, but even then temperatures rise to the mid-70s during the day. April and May are the warmest months. The rainy season, which usually lasts from late May until September, brings temperatures down and moderates the usual dryness of the air.



Effects of air pollution

Air pollution—made up mostly of ozone, suspended particles, and sulfur dioxide—has affected the climate by partially blocking the Sun's rays. Poor air circulation out of the mountain-walled city aggravates pollution. The prevailing winds, especially strong during February and March, blow from the northeast and sweep dust particles into the city, although the partial regeneration of Lake Texcoco has begun to alleviate this problem. Thermal inversions often trap smog in the valley during winter.

The weather is not homogeneous throughout the city. The higher and more wooded areas of the west and southwest are cooler and receive more rainfall than the rest. The north and northeast, largely depleted of vegetation, are the driest and hottest areas.

The central plaza

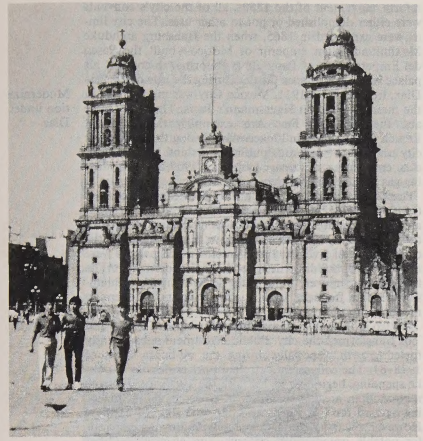
The city layout. The island where the Aztecs built their capital became the central area of Mexico City. The Zócalo (previously known as the Plaza Mayor and now officially called the Plaza de la Constitución) is the traditional hub of the city. On the Zócalo's northern side, close to the former site of the main Aztec temple, stands the Metropolitan Cathedral. The National Palace, formerly the viceroy's palace, which is the official seat of the republic's executive power, was built over the ruins of the Aztec emperor's palace. The colonial city extended just a few blocks around the Zócalo, and in that area, known as the historical centre, many buildings predating independence still stand.

Central Mexico City and (inset) its metropolitan area.

The Alameda Central (Central Mall) roughly marks the western edge of the old colonial city. From its vicinity the Paseo de la Reforma—a wide, tree-lined boulevard—sweeps southwest toward Chapultepec. This wooded hill has been transformed into a public park, and its 18th-century castle is now a history museum. Upon reaching Chapultepec, Reforma turns west and advances into some of the city's wealthiest *colonias* (neighbourhoods), such as Polanco and Lomas de Chapultepec.

Chapultepec and environs

Avenida Insurgentes is Mexico City's main north–south axis. It crosses Paseo de la Reforma near the historical centre and continues both north and south to the end of the urban area. The Pink Zone ("Zona Rosa") is the main tourist and entertainment area. The city becomes increasingly residential and middle-class toward the south, although Avenida Insurgentes preserves its commercial and business nature. A number of former small towns in the south, such as Tacubaya, Mixcoac, San Ángel, and Coyoacán, have been incorporated into the city. Insurgentes traverses University City, the campus of the National Autonomous University of Mexico, before ending in Tlalpan, another formerly independent town and now the southern edge of the city. West of the southern portion of Insurgentes is the Pedregal de San Ángel, a wealthy residential *colonia* with notable examples of modern architecture.



At the southeastern tip of the city, Xochimilco, another small town subsumed by the city, is a popular tourist destination because of its *chinampas,* or "floating gardens," boats made out of reeds on which the Indians have grown plants since pre-Columbian times. The artificially preserved Xochimilco Lake is one of the few remnants of the old lake system in the basin. A number of middle-class *colonias* spread to the north of Xochimilco, but in the north the city becomes increasingly poor and more densely populated. East of the historical centre the Benito Juárez International Airport, once outside the city, is now surrounded by heavily populated working-class areas. North and northeast of the airport there are miles of poverty-ridden *colonias,* many lacking essential services. Outside the Federal District, but still part of the metropolitan area, lies Ciudad Nezahualcóyotl, one of the metropolis's poorest areas; it would be one of the largest cities in the country if measured on its own.

Xochimilco Lake

North of the historical centre stands Tlatelolco, a lower-middle-class residential development on the site of a former Indian city conquered by the Aztecs. Farther north is the Villa de Guadalupe Hidalgo, famed for its shrine of the Virgin of Guadalupe, a pilgrimage destination for Mexicans from throughout the country. Although "la Villa" was traditionally considered the northern edge of the city, urbanization has continued northward into the State of Mexico. To the northwest there are industrial zones, some within the Federal District (Azcapotzalco, for example) and some beyond it (Naucalpan). Farther northwest, around Ciudad Satélite, lies another cluster of middle-class residential suburbs, also in the State of Mexico.

Owing to the metropolitan area's enormous dimensions, each of its sections has developed its own commercial and service areas. The city centre, once the preferred middle-class shopping district, is now of marginal importance. Huge suburban shopping malls, such as Plaza Satélite in the northwest and Perisur in the south, have usurped the downtown area's commercial importance. THE PEOPLE

Mexico City is one of the fastest-growing urban areas in the world. With a population of some 3,000,000 in 1950, it grew at rates of more than 3 percent annually in the following decades. By the 1980s it was the home of more than one-fifth of the country's population.

Racial composition

The city was traditionally inhabited by mestizos (people of mixed European and Indian descent) and criollos (Mexicans of European descent), but steady immigration from the countryside has given it a more Indian character. Although there is no formal racial discrimination, criollos constitute a disproportionate number of the upper and upper-middle classes.

Most Mexico City dwellers are Roman Catholic, although a number of Protestant churches have gained converts. There is also a small but influential Jewish community.

THE ECONOMY

Industry. Mexico City's metropolitan area accounts for more than 30 percent of the nation's industrial production. A trend to move heavy industry out of the city began in the 1950s, but a number of major plants remain within the urban area, especially in the northwest. The main industries are construction and the production of chemicals, plastics, cement, and yarns and textiles. Light industry is becoming predominant in the city's economy.

Commerce and finance. Because of the relative affluence of its residents and the fact that the city serves as the main supply centre for the country's central area, more than 40 percent of the nation's domestic sales occur in Mexico City. With the emigration of heavy industry, services constitute an increasingly important part of the local economy. Tourism is a major source of income.

Even more than other economic activities, Mexico's financial services are concentrated in the capital. The number of banking institutions, more than 50 in the late 1970s, dropped to less than 20 as a result of mergers following the government takeover of private banks in 1982. The country's only stock exchange operates in the city, where the Bank of Mexico, the central bank, is also located.

Transportation. Mexico City is the hub of the national transportation system. Five main highways link the capital with all regions of the country as well as with the United States and Guatemala. Railway lines run south, east, and north from the city. The Benito Juárez International Airport handles both national and international flights. In the late 1980s some flights began to land and depart from the Toluca airport in order to alleviate the former's perennial congestion.

The city's internal transportation system is chaotic and overextended. By the late 1980s close to 4,000,000 motor vehicles circulated in the urban area, and their number is growing rapidly. They creep at an average speed of about 12 miles an hour, and "rush hour" in many areas lasts virtually all day. In 1982 the Federal District's private bus system was expropriated by the government, while massive investments have been made to expand the efficient but overcrowded Metro (subway) system.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Most residents of Mexico City do not elect their own local government. The country's president appoints a regent, or mayor, who heads the administration of the Federal District. The regent appoints delegates who assume executive responsibility over the Federal District's 16 *delegaciones* (city districts), each of which functions with considerable autonomy. Many of these *delegaciones* have populations larger than those of most cities and some states within the country. The areas outside of the Federal District choose their own mayors (*presidentes municipales*) and participate in the election of the governor of the State of Mexico. Federal District residents vote for deputies (representatives) and senators to the federal Congress, as well as for the nation's president. In the late 1980s an elective advisory committee was established. Mexico City is the seat of the executive, legislative, and judicial powers of the country.

Administrative units

Services. Water supply has long been a problem for Mexico City. After its own reserves were virtually exhausted, expensive conveyance systems were built to bring drinking water from increasingly remote areas. The drainage system was partially renovated in the 1970s and '80s. Some electricity is produced within the city, but most is purchased from outside plants. The telephone system, always inadequate, suffered a major blow when the 1985 earthquake destroyed the city's main exchange; in the late 1980s a new decentralized system was installed. Propane gas, commonly used for cooking and for heating water, is distributed in portable tanks or by tanker trucks that fill home containers; home heating is virtually nonexistent.

Health. The oldest hospital in the Western Hemisphere—the Hospital of Jesus of Nazareth—was founded in Mexico City by Hernán Cortés in the early 16th century. The government operates numerous health facilities, including the gigantic General Hospital and the Medical Centre, a conglomerate of specialized units. There are also many private hospitals. Patients from throughout the country often travel to the capital for treatment.

Although sanitary standards are higher than in the rest of Mexico, gastrointestinal diseases remain common, particularly among lower-class children. Also prevalent are respiratory illnesses, a consequence of pollution, and psychological disorders stemming from overcrowding. With the improvement in general sanitary conditions, illnesses more characteristic of developed countries, such as cardiovascular problems and cancer, have become more common.

Education. Mexico City boasts a literacy rate of more than 90 percent, significantly higher than that of the rest of the country, and its educational facilities are unsurpassed in Mexico. The public school system is complemented by a large number of private schools. Dropout rates at the elementary and secondary school levels remain high.

The National Autonomous University of Mexico

The capital has the largest concentration of higher-education facilities in the nation. The National Autonomous University of Mexico, founded in 1551, is one of the largest in the world, with more than 350,000 students. Its buildings are beautifully decorated with murals by painter Diego Rivera and others. The National Polytechnic Institute and the Metropolitan Autonomous University are among the other important public institutions of higher education. Private universities include the Ibero-American

University, the Anáhuac University, and the United States International University. There are a number of specialized postgraduate and research institutions, including the prestigious College of Mexico.

CULTURAL LIFE

Mexico City has always been one of the prominent cultural centres of Latin America. There are several symphony orchestras and dozens of art galleries and museums, theatre groups, and dance companies in the city. The downtown Palace of Fine Arts is the traditional concert and opera hall. The University Cultural Centre, at the National University campus, houses the National Library, a major symphony hall, and a number of theatres. The National Museum of Anthropology is generally considered the world's finest in its specialty. Mexico City is also home for the country's most important art, music, and dance schools.

Mexico City is one of the main book- and newspaper-publishing centres in the Spanish-speaking world. There are numerous news, literary, and other specialized magazines.

Each neighbourhood has its own parks and gardens. Chapultepec Park, the largest and most beautiful of these, encompasses about 1,600 acres (647 hectares) in the southwest. Its grounds contain museums, a zoo, botanical gardens, an amusement park, lakes, and fountains. Desert of the Lions ("El Desierto de los Leones"), another park 10 miles southwest of the city, occupies a wide expanse of mountains, pine forests, springs, and aqueducts. The Alameda Central, west of the Zócalo, was created in 1592.

The most popular spectator sports are association football (soccer) and bullfighting. Soccer is played in the Aztec Stadium and in the National University's Olympic Stadium. Plaza México is the largest bullring in the world.

History

THE EARLY PERIOD

Origins. The Aztecs arrived in the Valley of Mexico in the 13th century. According to tradition, they founded Tenochtitlán ("Place of the High Priest Tenoch") after much wandering when they saw on an island in Lake Texcoco the sign that their god Huitzilopochtli had indicated—an eagle perched on a cactus, eating a serpent. Tenochtitlán quickly spread over the island, marshes, and swamps. As it developed into a city, it was divided into *calpulli,* or districts, each with communal lands and schools.

When the Spaniards led by Hernán Cortés arrived in 1519, Tenochtitlán had about 100,000 inhabitants. The island was connected to the mainland by three causeways—Tepeyac to the north, Ixtapalapa to the south, and Tacuba to the west—which converged on the ceremonial centre near the main temple and the emperor's palace.

The colonial city. Cortés razed Tenochtitlán in 1521 and constructed a Spanish city on its ruins. The city was chartered and its *cabildo,* or town council, recognized in 1522; it was given leadership over other *cabildos* of New Spain in 1535. It soon became the most important city of the Americas, with jurisdiction extending well into the present United States and as far south as Panama.

Rise to preeminence

Mexico City continued as a lakeside centre until constant floods necessitated the filling of the lakes of the valley floor. During the 17th century the capital comprised a well-laid-out assemblage of homes, public buildings, churches, and convents. In their execution of European designs, the colonists and Indian artisans employed local *tezontle,* a light and porous volcanic rock, to create elaborate facades. This Baroque style reached its ultimate expression in the 18th century, the golden age of architecture in New Spain, after which Neoclassical ideas were introduced by the sculptor and architect Manuel Tolsá.

THE CITY AFTER INDEPENDENCE

Before the revolution. After the brief reign of Emperor Agustín de Iturbide of Mexico, the republican constitution of 1824 established the Federal District to centralize the country's government in Mexico City. The capital was captured by U.S. troops in the 1840s. During the anticlerical reform movement of the 1850s, all of the city's convents were either demolished or put to other uses. The city limits were expanded in 1865, when the Habsburg archduke Maximilian—then emperor of Mexico—built the Paseo del Emperador (now Paseo de la Reforma) to connect his palace with Chapultepec Castle. During the rule of Porfirio Díaz, from 1876 to 1911, Mexico City was modernized in the manner of Baron Haussmann's Paris. The Post Office and the Palace of Fine Arts exemplify the dominant French architectural influence. Also during this period the city undertook numerous public works and utilities projects, completing a drainage system in 1907 and introducing gas and electric lighting and streetcars.

Modernization under Díaz

The 20th century. During the Mexican Revolution (1910–17), the city became a battlefield. Disruption in rural areas resulted in an exodus from the countryside to the capital. In 1924 urban works were renewed with the construction of Avenida Insurgentes. French palaces were replaced with buildings designed in the modern style. The first skyscrapers were built in the 1930s, but the soft subsoil and the frequent seismic activity restricted them to modest proportions.

Mexico's prosperity and stability during the 1950s and '60s transformed the city. Public investment subsequently fueled growth, especially during the oil-boom years of 1978–81. The collapse of petroleum prices decreased public spending, beginning in 1982. In the 1980s and '90s the metropolitan area's population increased rapidly, spreading beyond the Federal District into the state of Mexico. However, the city failed to keep up with growing demands for potable water, sewer systems, and electricity. Other problems included worsening violent crime, air pollution, and seismic activity. In 1985 an earthquake killed some 7,000 people, and from the late 1990s the nearby volcano Popocatépetl erupted intermittently. The Mexican government relinquished control of the Federal District in 1997 in an effort to improve local planning, services, and accountability. That year Cuauhtémoc Cárdenas Solorzano was elected to a two-year term as the district's first mayor; his leftist Party of the Democratic Revolution (PRD; Partido de la Revolución Democrática) continued to play a leading role in the government at the beginning of the 21st century.

Michelangelo

Michelangelo was considered the greatest living artist in his lifetime, and ever since then he has been held to be one of the greatest artists of all times. A number of his works in painting, sculpture, and architecture rank among the most famous in existence. Although the frescoes on the ceiling of the Sistine Chapel (Vatican) are probably the best known of his works today, the artist thought of himself primarily as a sculptor. His practice of several arts, however, was not unusual in his time, when all of them were thought of as based on design, or drawing. Michelangelo worked in marble sculpture all his life and in the other arts only at certain periods. The high regard for the Sistine ceiling is partly a reflection of the greater attention paid to painting in the 20th century and partly, too, of the fact that it, unlike many of the artist's works in the other media, was completed.

A side effect of Michelangelo's fame in his lifetime was that his career was more fully documented than that of any artist of the time or earlier. He was the first artist whose biography was published while he was alive, and there were two rival biographies. The first was the final chapter in the series of artists' lives (1550) by the painter and architect Giorgio Vasari. It was the only chapter on a living artist and explicitly presented Michelangelo's works as the culminating perfection of art, surpassing the efforts of all those before him. Despite such an encomium, Michelangelo was not entirely pleased and arranged for his assistant Ascanio Condivi to write a brief separate book (1553); probably based on the artist's own spoken comments, this account shows him as he wished to appear. After Michelangelo's death Vasari in a second edition (1568) offered a rebuttal. While scholars have often preferred the authority of Condivi, Vasari's lively writing, the importance of his book as a whole, and its frequent reprinting in many languages have made it the most usual basis of popular ideas. Michelangelo's fame also led to the preservation of countless mementos, including hundreds of letters, sketches, and poems, again more than of any contemporary. Yet despite the enormous benefit that has accrued from all this, in controversial matters often only Michelangelo's side of an argument is known.

Early life and works. Michelangelo Buonarroti was born March 6, 1475, to a family that had for several generations been small-scale bankers in Florence but had in the case of the artist's father failed to maintain its status. The father had only occasional government jobs, and at the time of Michelangelo's birth he was administrator of the small dependent town of Caprese. A few months later, however, the family returned to its permanent residence in Florence. It was something of a downward social step to become an artist, and Michelangelo became an apprentice relatively late, at 13, perhaps after overcoming his father's objections. He was apprenticed to the city's most prominent painter, Domenico Ghirlandajo, for a three-year term, but he left after one year, having (Condivi recounts) nothing more to learn. Several drawings, copies of figures by Ghirlandajo and older great painters of Florence, Giotto and Masaccio, survive from this stage; such copying was standard for apprentices, but few examples are known to survive. Obviously talented, he was taken under the wing of the ruler of the city, Lorenzo de' Medici, known as the Magnificent. Lorenzo surrounded himself at table with poets and intellectuals, and Michelangelo was included. More important, he had access to the Medici art collection, which was dominated by fragments of ancient Roman statuary. (Lorenzo was not such a patron of contemporary art as legend has made him; such modern art as he owned was to ornament his house or make political statements.) The bronze sculptor Bertoldo, a Medici friend and in charge of the collection, was the nearest to a teacher of sculpture he had, but Michelangelo did not follow his medium or in any major way his approach. Still, one of the two marble works that survive from the artist's first years is a variant on the composition of an ancient Roman sarcophagus, and Bertoldo had produced a similar one in bronze. This composition is the "Battle of the Centaurs" (*c.* 1492). The action and power of the figures foretell the artist's later interests much more than does the "Madonna of the Stairs" (*c.* 1491), a delicate low relief that reflects recent fashions among such Florentine sculptors as Desiderio da Settignano.

Apprenticeship with Ghirlandajo

Florence was at this time regarded as the leading centre of art, producing the best painters and sculptors in Europe, and the competition among artists was stimulating. The city was, however, less able than earlier to offer large commissions, and leading Florentine-born artists, such as Leonardo da Vinci and Leonardo's teacher, Verrocchio, had moved away for better opportunities in other cities. The Medici were overthrown in 1494, and even before the end of the political turmoil Michelangelo had left.

In Bologna he was hired to succeed a recently deceased sculptor and carve the last small figures required to complete a grand project, the tomb and shrine of St. Dominic (1494–95). The three marble figures are original and expressive. Departing from his predecessor's fanciful agility, he imposed seriousness on his images by a compactness of form that owes much to classical antiquity and to the Florentine tradition from Giotto onward. This emphasis on seriousness is also reflected in his choice of marble as his medium, while the accompanying simplification of masses is in contrast to the then more usual tendency to let representations match as completely as possible the texture and detail of human bodies. To be sure, although these are constant qualities in Michelangelo's art, they often are temporarily abandoned or modified because of other factors, such as the specific functions of works or the stimulating creations of other artists. This is the case with Michelangelo's first surviving large statue, the "Bacchus," produced in Rome (1496–97) following a brief return to Florence. (A wooden crucifix, recently discovered, attributed by some scholars to Michelangelo and now housed in the Casa Buonarroti, Florence, has also been proposed as the antecedent of the "Bacchus" in design by those who credit it as the artist's work.)

"Bacchus"

The "Bacchus" relies on ancient Roman nude figures as a point of departure, but it is much more mobile and more complex in outline. The conscious instability evokes the god of wine and Dionysiac revels with extraordinary virtuosity. Made for a garden, it is also unique among Michelangelo's works in calling for observation from all sides rather than primarily from the front.

The "Bacchus" led at once to the commission (1498) for the "Pietà," now in St. Peter's Basilica. The name refers not (as often presumed) to this specific work but to a common traditional type of devotional image, this work being today the most famous example. Extracted from narrative scenes of the lamentation after Christ's death, the concentrated group of two is designed to evoke the observer's repentant prayers for sins that required Christ's sacrificial death. The patron was a French cardinal, and the type was earlier more common in northern Europe than Italy. The complex problem for the designer was to extract two figures from one marble block, an unusual undertaking in all periods. Michelangelo treated the group as one dense and compact mass as before so that it has an imposing impact, yet he underlined the many contrasts present, of male and female, vertical and horizontal, clothed and naked, dead and alive, to clarify the two components. The artist's prominence, established by this work, was reinforced at once by the commission (1501) of the "David" for the cathedral of Florence. For this huge statue, an exceptionally large commission in that city, Michelangelo reused a block left unfinished about 40 years before. The modeling is especially close to the formulas of classical antiquity, with a simplified geometry suitable to the huge scale yet with a mild assertion of organic life in its asymmetry. It has continued to serve as the prime statement of the Renaissance ideal of perfect humanity.

"David"

On the side Michelangelo produced in the same years (1501–04) several Madonnas for private houses, the staple of artists' work at the time. These include one small statue, two circular reliefs that are similar to paintings in suggesting varied levels of spatial depth, and the artist's only easel painting. While the statue ("Madonna and Child") is blocky and immobile, the painting ("Holy Family") and one of the reliefs ("Madonna and Child with the Infant St. John") are full of motion; they show arms and legs of figures interweaving in actions that imply movement through time. The forms carry symbolic references to Christ's future death, common in images of the Christ Child at the time; they also betray the artist's fascination with the work of Leonardo. Michelangelo regularly denied that anyone influenced him, and his statements have usually been accepted without demur. But Leonardo's return to Florence in 1500 after nearly 20 years was exciting to younger artists there, and recent scholars have generally agreed that Michelangelo was among those affected. Leonardo's works were probably the most powerful and lasting outside influence to modify his work, and he was able to blend this artist's ability to show momentary processes with his own to show weight and strength, without losing any of the latter quality. The resulting images, of massive bodies in forceful action, are those special creations that constitute the larger part of his most admired major works.

The influence of Leonardo da Vinci

The middle years. After the success of the "David" in 1504 Michelangelo's work consisted almost entirely of vast projects. He was attracted to these ambitious tasks while at the same time rejecting the use of assistants, so that most of these projects were impractical and remained unfinished. In 1504 he agreed to paint a huge mural for the Florence city hall to form a pair with another just begun by Leonardo. Both murals recorded military victories by the city, but each also gave testimony to the special skills of the city's much vaunted artists; Leonardo's design shows galloping horses, Michelangelo's active nudes—soldiers stop swimming and climb out of a river to answer an alarm. Both works survive only in copies and partial preparatory sketches. In 1505 the artist began work on a planned set of 12 marble Apostles for the Florence cathedral, of which only one, the "St. Matthew," was even begun. Its writhing ecstatic motion for the first time shows the full blend of Leonardo's fluid organic movement with his own monumental power. This is also the first of Michelangelo's unfinished works that have fascinated later observers. His figures seem to suggest that they are fighting to emerge from the stone. This would imply that their incomplete state was intentional, yet he undoubtedly did want to complete all of the statues. He did, however, write a sonnet about how hard it is for the sculptor to bring the perfect figure out of the block in which it is potentially present. Thus, even if the works remained unfinished due only to lack of time and other external reasons, their condition, nonetheless, reflects the artist's intense feeling of the stresses inherent in the creative process.

Pope Julius II's call to Michelangelo to come to Rome spelled an end to both of these Florentine projects. The Pope sought a tomb for which Michelangelo was to carve 40 large statues. Recent tombs had been increasingly grand, including those of two popes by the Florentine sculptor Antonio Pollaiuolo, those of the doges of Venice, and the one then in work for Holy Roman Emperor Maximilian I. Pope Julius had an ambitious imagination, parallel to Michelangelo's, but because of other projects, such as the new building of St. Peter's and his military campaigns, he evidently became disturbed soon by the cost. Michelangelo believed that Bramante, the equally prestigious architect at St. Peter's, had influenced the Pope to cut off his funds. He left Rome, but the Pope brought pressure on the city authorities of Florence to send him back. He was put to work on a colossal bronze statue of the Pope in his newly conquered city of Bologna (which the citizens pulled down soon after when they drove the papal army out) and then on the less expensive project of painting the ceiling of the Sistine Chapel (1508–12).

The Sistine Chapel had great symbolic meaning for the papacy as the chief consecrated space in the Vatican, used for great ceremonies such as electing and inaugurating new popes. It already contained distinguished wall paintings, and Michelangelo was asked to add works for the relatively unimportant ceiling. Twelve Apostles were planned as the theme—ceilings normally showed only individual figures, not dramatic scenes. Traces of this project are seen in the 12 large figures that Michelangelo produced: seven prophets and five sibyls, or female prophets found in classical myths. The inclusion of female figures was very unusual though not totally unprecedented. Michelangelo placed these figures around the edges of the ceiling and filled the central spine of the long curved surface with nine scenes from Genesis: three of them depicting the creation of the world, three the stories of Adam and Eve, and three the stories of Noah. These are naturally followed, below the prophets and sibyls, by small figures of the 40 generations of Christ's ancestors, starting with Abraham. The vast project was completed in less than four years; there was an interruption perhaps of a year in 1510–11 when no payment was made.

Sistine ceiling

The work began at the end, with the Noah scenes placed over the entrance door, and moved toward the altar in the direction opposite to that of the sequence of the stories. The first figures and scenes naturally show the artist reusing devices from his earlier works, such as the Pietà, since he was starting on such an ambitious work in an unfamiliar medium. These first figures are relatively stable, and the scenes are on a relatively small scale. As he proceeded, he quickly grew in confidence. Indeed, recent investigations of the technical processes used show that he worked more and more rapidly, reducing and finally eliminating such preparatory helps as complete drawings and incisions on the plaster surface. The same growing boldness appears in the free, complex movements of the figures and in their complex expressiveness. While remaining always imposing and monumental, they are more and more imbued with suggestions of stress and grief. This may be perceived in a figure such as the prophet Ezekiel halfway along. This figure combines colossal strength and weight with movement and facial expression that suggest determination to reach a goal that is uncertain of success. Such an image of the inadequacy of even great power is a presentation of heroic and tragic humanity and is central to what Michelangelo means to posterity. Nearby

the scene of the creation of Eve shows her with God and Adam, compressed within too small a space for their grandeur. This tension has been interpreted as a token of a movement away from the Renaissance concern with harmony, pointing the way for a younger generation of artists like Pontormo, often labeled Mannerists. Michelangelo's work on the ceiling was interrupted, perhaps just after these figures were completed. When he painted the second half, he seemed to repeat the same evolution from quiet stability to intricacy and stress. Thus he worked his way from the quietly monumental and harmonious scene of the creation of Adam to the acute, twisted pressures of the prophet Jonah. Yet in this second phase he shows greater inward expressiveness, giving a more meditative restraint to the earlier pure physical mass.

As soon as the ceiling was finished, Michelangelo reverted to his preferred task, the tomb of Pope Julius. In about 1513–15 he carved the "Moses," which may be regarded as the realization in sculpture of the approach to great figures used for the prophets on the Sistine ceiling. The control of cubic density in stone evokes great reserves of strength; there is richer surface detail and modeling than before, with bulging projections sharply cut. The surface textures also have more variety than the earlier sculptures, the artist by now having found how to enrich detail without sacrificing massiveness. Of about the same date are two sculptures of bound prisoners or slaves, also part of the tomb project but never used for it, since in a subsequent revised design they were of the wrong scale. Michelangelo kept them until old age, when he gave them to a family that had helped him during an illness; they are now in the Louvre. Here again he realized in stone types painted in many variants on the ceiling, such as the pairs of nudes that hold wreaths above the prophets' thrones. The complexity of their stances, expressive of strong feeling, was unprecedented in monumental marble sculpture of the Renaissance. The only earlier works of this nature were from the Hellenistic period of classical antiquity, well known to Michelangelo through the discovery of the Laocoön group in 1506. The old man and his two adolescent sons forming that group certainly stimulated the three statues by Michelangelo as well as the related figures on the ceiling. Yet the first of the ceiling figures in 1508 were not so affected; Michelangelo utilized the Hellenistic twists and complications only when he was ready for them, and he had been moving in this direction even before the Laocoön was found, as is evident in the case of the "St. Matthew" of 1505.

Julius II's death in 1513 cut off most of the funds for his tomb. Pope Leo X, his successor, a son of Lorenzo the Magnificent, had known Michelangelo since their boyhoods. He chiefly employed Michelangelo in Florence on projects linked to the glory of the Medici family rather than of the papacy. The city was under the rule of Leo's cousin Cardinal de' Medici, who was to be Pope Clement VII from 1523 to 1534, and Michelangelo worked with him closely in both reigns. The Cardinal took an active interest in Michelangelo's works. He made detailed suggestions, but he also gave the artist much room for decision. Michelangelo was moving into architectural design with a small remodeling project at the Medici mansion and a large one at their parish church, San Lorenzo. He approached such work with enthusiasm, caused no doubt by the large scale and the involvement with masses of stone to be manipulated expressively. The larger project never materialized, but Michelangelo and the Cardinal did better with a more modest related one, the new chapel attached to the same church for tombs of the Medici family.

The Medici Chapel

The immediate occasion for the chapel was the deaths of the two young family heirs, named Giuliano and Lorenzo after their forebears, in 1516 and 1519. Michelangelo gave his chief attention up to 1527 to the marble interior of this chapel, to both the very original wall design and the carved figures on the tombs; the latter are an extension in organic form of the dynamic shapes of the wall details. The result is the fullest existing presentation of Michelangelo's intentions. Windows, cornices, and the like have strange proportions and thicknesses, suggesting an irrational, willful revision of traditional classical forms in buildings. Abutting these active surfaces, the two tombs on opposite walls of the room are also very original, starting with their curved tops. A male and a female figure sit on each of these curved bases; these are allegories symbolizing on one tomb day and night, according to the artist's own statement, and dawn and dusk on the other, according to early reports. Such personifications had never appeared on tombs before, and they refer, again according to Michelangelo, to the inevitable movement of time, which is circular and leads to death. The figures are among the artist's most famous and accomplished creations. The immensely massive figures of "Day" and "Dusk" are relatively tranquil in their mountainous grandeur, though "Day" perhaps implies inner fires. Both female figures have the tall, slim proportions and small feet considered beautiful at the time, but otherwise they form a contrast: "Dawn," a virginal figure, strains upward along her curve as if trying to emerge into life; "Night" is asleep, but in a posture suggesting stressful dreams.

These four figures are naturally noticed more immediately than the effigies of the two Medici buried there, placed higher and farther back in wall niches. These effigies, more usual in execution, also form a contrast; they are traditionally described as active and thoughtful, respectively. Rendered as standard types of young soldiers, they were at once perceived not as portraits but as idealized superior beings, both because of their high rank and because they are souls beyond the grave. Both turn to the same side of the room. It has naturally been thought that they focus on the "Madonna," which Michelangelo carved and which is at the centre of this side wall, between two saints. The heads of the two effigies, however, are turned in differing degrees, and their common focus is at a corner of the chapel, at the entrance door from the church. On this third wall with the "Madonna" the architectural treatment was never executed.

The Laurentian Library

During the same years Michelangelo designed another annex to the same church, the Laurentian Library, required to receive the books bequeathed by Pope Leo; it was traditional in Florence and elsewhere that libraries were housed in convents. The design for this one was constrained by the existing buildings, and it was built on top of older structures. A small available area on the second floor was used as an entrance lobby and contains a staircase leading up to the larger library room on a new third floor. The stairhall, known as the *ricetto,* contains Michelangelo's most famous and original wall designs. The bold and free rearrangement of traditional building components goes still further, for instance, to place columns recessed behind a wall plane rather than in front of it as is usual. This has led to the work's being cited frequently as the first and a chief instance of Mannerism as an architectural style, when it is defined as a work that intentionally contradicts the classical and the harmonious, favouring expressiveness and originality, or as one that emphasizes the factors of style for their own sake. By contrast the long library room is far more restrained, with traditional rows of desks neatly related to the rhythm of the windows and small decorative detail in the floor and ceiling. It recalls that Michelangelo was not invariably heavy and bold but modified his approach in relation to the particular case, here to a gentler, quiet effect. For that very reason it has often been less noticed in the study of his work. At the opposite end of the long room, across from the stairway, another door led to a space intended to hold the library's rarest treasures. It was to be a triangular room, a climax of the long corridor-like approach, but this part was never executed on the artist's plan.

Michelangelo as a designer of fortifications

The sack of Rome in 1527 saw Pope Clement ignominiously in flight, and Florence revolted against the Medici, restoring the traditional republic. It was soon besieged and defeated, and Medici rule permanently reinstalled, in 1530. During the siege Michelangelo was the designer of fortifications. He showed understanding of modern defensive structures built quickly of simple materials in complex profiles that offered minimum vulnerability to attackers and maximum resistance to cannon and other artillery. This new weapon, which had come into use in the middle of the 14th century, had given greater power to the offense

in war. Thus, instead of the tall castles that had served well for defensive purposes in the Middle Ages, lower and thicker masses were more practical. The projecting points, which also assisted counterattack, were often of irregular sizes in adaptation to specific hilly sites. Michelangelo's drawings with rapid lively execution reflecting this flexible new pattern have been much admired, often in terms of pure form.

When the Medici returned in 1530, Michelangelo returned to work on their family tombs. His political commitment probably was more to his city as such than to any specific governmental form. Two separate projects of statues of this date are the "Apollo" or "David" (its identity is problematic), used as a gift to a newly powerful political figure, and the "Victory," a figure trampling on a defeated enemy, an old man. It was probably meant for the never forgotten tomb of Pope Julius because the motif had been present in the plans for the Julius tomb. Victor and loser both have intensely complicated poses; the loser seems packed in a block, the victor—like the "Apollo"—forms a lithe spiral. The "Victory" group became a favourite model for younger sculptors of the Mannerist group, who applied the formula to many allegorical subjects.

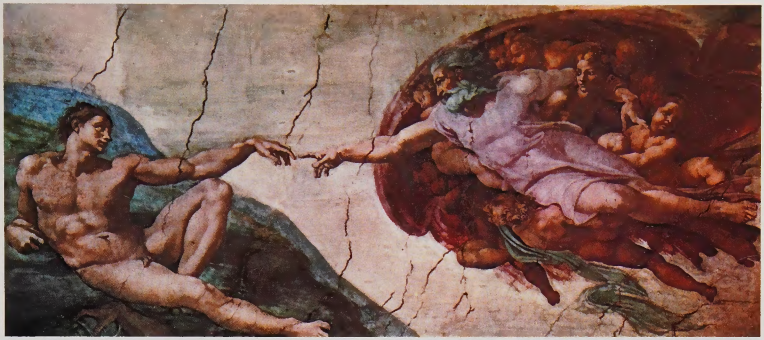
In 1534 Michelangelo left Florence for the last time, though he always hoped to return to finish the projects he had left incomplete. He passed the rest of his life in Rome, working on projects in some cases equally grand but in most cases of quite new kinds. From this time on a large number of his letters to his family in Florence were preserved; many of them concentrated on plans for his nephew's marriage, essential to preserve the family name. Michelangelo's father had died in 1531 and his favourite brother at about the same time; he himself showed increasing anxiety about his age and death. It was just at this time that the nearly 60-year-old artist wrote letters expressing strong feelings of attachment to young men, chiefly to the talented aristocrat Tommaso Cavalieri, later active in Roman civic affairs. These have naturally been interpreted as indications that Michelangelo was a homosexual, but such a reaction according to the artist's own statement would be that of the ignorant. The idea seems even less likely when one considers that no similar indications had emerged when the artist was younger. The correlation of these letters with other new events seems consistent instead with the view that he was seeking a surrogate son, choosing for the purpose a younger man who was admirable in every way and would welcome the role.

Michelangelo's poetry is also preserved in quantity from this time. He apparently began writing short poems in a way common among nonprofessionals in the period, as an elegant kind of letter, but developed in a more original and expressive way. Among some 300 preserved poems, not including fragments of a line or two, there are about 75 finished sonnets and about 95 finished madrigals, poems of about the same length as sonnets but of a looser formal structure. In English-speaking countries people tend to speak of "Michelangelo's sonnets," as though all of his poems were written in that form, partly because the sonnets were widely circulated in English translations from the Victorian period, partly because the madrigal is unfamiliar in English poetry. (It is not the type of song well known in Elizabethan music, but a poem with irregular rhyme scheme, line length, and number of lines.) Yet the fact that Michelangelo left a large number of sonnets but only very few madrigals unfinished suggests that he preferred the latter form. Those written up to about 1545 have themes based on the tradition of Petrarch's love poems and a philosophy based on the Neoplatonism that Michelangelo had absorbed as a boy at Lorenzo the Magnificent's court. They give expression to the theme that love helps human beings in their difficult effort to ascend to the divine.

Michelangelo's poetry

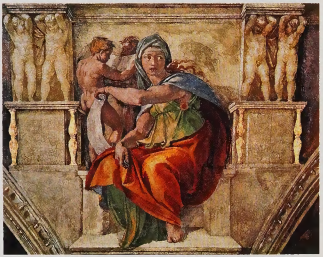
In 1534 Michelangelo returned after a quarter century to fresco painting, executing for the new pope, Paul III, the huge "Last Judgment" for the end wall of the Sistine Chapel. This theme had been a favoured one for large end walls of churches in Italy in the Middle Ages and up to about 1500, but thereafter it had gone out of fashion. It is often suggested that this renewal of a devout tradition came from the same impulses that were then leading to the Counter-Reformation under the aegis of Paul III. The work is in a painting style noticeably different from that of 25 years earlier. The pervasive colour harmony is a simple one of brown bodies against dark blue sky. The figures have less energy and their forms are less articulate, the torsos tending to be single fleshy masses without waistlines. At the top centre Christ as judge lifts an arm to save those on his right and drops the other arm to damn those on his left, suggesting in the idiom of the period a scale to weigh men in the balance. The saved souls rise slowly through the heavy air, as the damned ones sink. At the bottom of the wall skeletons rise from tombs, a motif taken directly from medieval precedents. To the right Charon ferries souls across the River Styx, a pagan motif which Dante had made acceptable to Christians in his *Divine Comedy* and which had been introduced into painting about 1500 by the Umbrian artist Signorelli. Michelangelo admired this artist for his skill in expressing dramatic feeling through anatomical exactitude.

"The Last Judgment"



The last decades. In his late years Michelangelo was less involved with sculpture and, along with painting and poetry, more with architecture, an area in which he did not have to do physical labour. He was sought after to design imposing monuments for the new and modern Rome that were to enunciate architecturally the city's position as a world centre. Two of these monuments, the Capitoline Square and the dome of St. Peter's, are still among the city's most notable visual images. He did not finish either, but after his death both were continued in ways that probably did not depart much from his plans.

The small Capitoline Hill had been the civic centre in ancient Roman times and was in the 16th century the centre of the lay municipal government, a minor factor in a city ruled by popes, yet one to which they wished to show respect. Michelangelo remodeled the old city hall on one side of the square and designed twin buildings for the two sides adjacent to it. He gave them rich and powerful fronts, using as his main device the juxtaposition of colossal columns, which rise through two stories to the top, with much smaller one-story columns crowded next to them. This invention creates a forcefully dynamic rhythm while also articulating in a rational way the structure behind the facades. He also produced a special floor design for the square between these two new buildings—an oval pattern that frames a statue at its centre (the ancient Roman monument of the emperor Marcus Aurelius) and gives the whole area the effect of a monumental room. Because of the hilly site, the square is not rectangular but wider on the city hall side and narrower on the opposite side, which was left open. This open side is the entrance for the public, reached by climbing a long flight of stairs. The visitor finds the two facades to his left and right inclined away from each other as they recede from the entrance; this counteracts the tendency of perspective to make walls seem to move nearer each other as they are farther off and so reinforces the effect of a grand expanse.



Capitoline Square

The dome of St. Peter's functions chiefly as a visual focus for the observer at a distance, representing a physical goal as well as expressing the dominant meaning of the city. It has been copied for this dual purpose many times, as, for instance, in the Capitol at Washington, D.C. It derives from the dome of the cathedral of Florence, which is 100 years older, perhaps the first great dome to be oriented chiefly outward in its effect rather than being meant chiefly to cover the interior. But it was Michelangelo's dome that gave this shift its universal acceptance. The dome, however, was not built until after Michelangelo's death, and the extent to which it follows his intentions has been much debated. As built by his successor, the dome is more pointed than the pure hemisphere seen in Michelangelo's best known project. But Michelangelo changed his ideas and may well have moved in that direction too.

During his life Michelangelo's major energy in working at St. Peter's was given to the lower part. He discarded the ideas of the architects who had been working on it just before him, approving only those of the original designer, Bramante. He reverted to the earlier plan for a church with four equal cross arms instead of the more conventional Latin cross plan of the more recent altered

scheme. He also disliked the quantity of repeated smaller decorative elements added by the most recent architect, which diminished the effect of great size. He modified Bramante's interior in specifics, making it still more nearly a unified space. This is enclosed by huge semicircular sections of wall on the four sides, creating spaces comparable to the hemispherical space inside the dome. Most of his actual construction work was on the curving wall behind the altar, and there he carried still further the contrast between colossal and smaller supports next to each other, seen already on the Capitoline Hill. This time they are not load-carrying columns but thin pilasters that fit against the continuously curving walls on the exterior. They thus impart both a strong upward thrust and an equally strong horizontal rhythm as the direction of the wall continuously changes, producing an architecture of pulsing dynamism on a gigantic scale. One still can see the approach of the sculptor, who uses the projections and recessions of stone as his vehicle.

Around the base of the dome Michelangelo placed a columned walkway. The tops of the columns are tied to the dome by beams, but there is no roofing of the intervals between columns. Thus, the columns have the effect of flying buttresses on Gothic buildings, supporting the dome's heavy downward thrust. Yet the design is formally classical, and its horizontal aspect as a colonnade solves the problem of a visual transition between the dome and the horizontal lower structure of the building.

While remaining head architect of St. Peter's until his death, Michelangelo worked on many smaller building projects in Rome. He completed the main unit of the Palazzo Farnese, the residence of Pope Paul III's family. The top story wall of its courtyard is a rare example of an architectural unit fully finished under his eye. Some very imaginative and distinctive late designs, such as those for a city gate, the Porta Pia, and for the church of the Florentine community in Rome, were either much reworked later or never went beyond the plan stage in the form Michelangelo had proposed.

His last paintings were the frescoes of the Pauline Chapel in the Vatican, which still is little accessible to the public. Unlike his other frescoes, they are in the position normal for narrative painting, on a wall and not exceptionally high up. They consistently treat spatial depth and narrative drama in a way that brings them closer to other paintings of the age than to the artist's previous paintings. Among the artists Michelangelo came to know and admire was Titian, who visited Rome during the period of this project (1542–50), and the frescoes seem to betray his influence in colour. The poetry of his last years also took on new qualities. The poems, chiefly sonnets, are very direct religious statements suggesting prayers. They are no longer very intricate in syntax and ideas.

There are only two late sculptures, which Michelangelo did for himself, both presenting the dead Christ being mourned, neither one finished. The first and larger one was meant for his tomb, and the figure of the mourning Joseph of Arimathea (or, possibly, Nicodemus) is a self-portrait. (Michelangelo had introduced himself earlier in his works in the role of a sinner or penitent, notably in the "Last Judgment" in the face on the flayed skin of the martyred St. Bartholomew.) Becoming dissatisfied with this sculpture, Michelangelo broke one of the figures and abandoned the work. This constitutes still another variation on the theme of incompletion running through the artist's work. His last sculpture also went through several revisions on the same block of stone and in its current state is an almost dematerialized sketch of two figures leaning together. Michelangelo certainly had a powerful sense of his own imperfection, yet he was also aware of the quality of his work and angry at patrons for not meeting what he judged to be their obligations. He died on Feb. 18, 1564.

Assessment and influence. For posterity Michelangelo has always remained one of the small group of the most exalted artists, who have been felt to express, like Shakespeare or Beethoven, the tragic experience of humanity with the greatest depth and universal scope.

In contrast to the great fame of the artist's works, their visual influence on later art is relatively limited. This cannot be explained by hesitation to imitate an art simply because it appeared so great, for artists like Raphael were considered equally great but were used as sources to a much greater degree. It may be instead that the particular type of expression associated with Michelangelo, of an almost cosmic grandeur, was inhibiting. The limited influence of his work includes a few cases of almost total dependence, the most talented artist who worked in this way being Daniele da Volterra. Otherwise, Michelangelo was treated as a model for specific limited aspects of his work. In the 17th century he was regarded as supreme in anatomical drawing but less praised for broader elements of his art. While the Mannerists utilized the spatial compression seen in a few of his frescoes, and later the serpentine poses of his sculpture of "Victory," the 19th-century master Auguste Rodin exploited the effect of unfinished marble blocks. Certain 17th-century masters of the baroque perhaps show the fullest reference to him, but in ways that have been transformed to exclude any literal similarity. Besides Bernini, the painter Rubens may best show the usability of Michelangelo's creations for a later great artist.

(1948); and LEO STEINBERG, *Michelangelo's Last Paintings: The Conversion of St. Paul and the Crucifixion of St. Peter in the Cappella Paolina, Vatican Palace* (1975). Scholarly interest in the Sistine Chapel, always intense, has only increased since the chapel's restoration. A good introduction to the subject is CARLO PIETRANGELI *et al., The Sistine Chapel: A New Light on Michelangelo: The Art, the History, and the Restoration* (1986), which presents a collection of photographs documenting the restoration project, accompanied by critical essays of art historians and theologians. Other important studies of the chapel include FREDERICK HARTT, *The Sistine Chapel,* 2 vol., trans. from Italian (1991), with a commentary by GIANLUIGI COLALUCCI and a note on the restoration by FABRIZIO MANCINELLI; MARCIA HALL, *Michelangelo: The Sistine Ceiling Restored* (1993); CARLO PIETRANGELI *et al., The Sistine Chapel: A Glorious Restoration* (1994, reissued 1999); and FRANCESCO BURANELLI, *The Last Judgment: The Restoration,* 2 vol. (1999). Aspects of the restoration campaign are documented in the video presented by EDWIN NEWMAN, *Return to Glory: Michelangelo Revealed* (1986), produced by NIPPON TELEVISION NETWORK CORPORATION.

Related to the artist's paintings are his drawings, which are studied in LUITPOLD DUSSLER, *Die Zeichnungen des Michelangelo: kritischer Katalog* (1959); LUDWIG GOLDSCHEIDER (ed.), *Michelangelo Drawings,* 2nd ed. (1966); FREDERICK HARTT, *Michelangelo Drawings* (1970, reissued 1976); and CRAIG HUGH SMYTH (ed.), *Michelangelo Drawings* (1992). The artist's achievements in architecture are examined in JAMES S. ACKERMAN, *The Architecture of Michelangelo,* 2nd ed. (1986), an analysis of the artist's buildings expressed in terms usually applied to sculpture. Also of note are CAROLE CABLE, *Michelangelo as an Architectural Draftsman* (1981); and LAURA S. KLINE, *Michelangelo's Architecture: A Selected Bibliography* (1983). The artist's poems and letters are also a fertile ground for study. Good examinations include ROBERT N. GILBERT (ed.), *Complete Poems and Selected Letters of Michelangelo,* 3rd ed., trans. by CREIGHTON GILBERT (1980); E.H. RAMSDEN (trans., ed.), *Letters* (1963); JAMES M. SASLOW (trans.), *The Poetry of Michelangelo: An Annotated Translation* (1991, reissued 1993); and JOHN FREDERICK NIMS (trans.), *The Complete Poems of Michelangelo* (1998).

For further study of the artist's life and work, major bibliographies are a good starting point. Microscopes

The microscope is an instrument that produces enlarged images of small objects, allowing them to be viewed at a scale convenient for examination and analysis. The image may be formed by optical, acoustic, or electronic means, and it is received by direct imaging, electronic processing, or a combination of these methods. The microscope may be static, in which the object is viewed directly, or dynamic, in which the image is built up by successive scans of the object.

The magnifying power of a microscope is an expression of the number of times the object being examined appears to be enlarged. Magnifying power is a dimensionless ratio. The resolution of a microscope is a measure of the size of the smallest detail on the object that can be observed. Resolution is expressed in linear units, usually millimetres.

The most familiar type of microscope is the optical, or light, microscope, in which lenses are used to form the image. Optical microscopes can be simple, consisting of a single lens, or compound, consisting of several optical components in tandem. Simple optical magnifiers may have magnifying powers of from 1 to 10 magnitudes, with resolutions to about 0.01 millimetre (mm) possible. Compound optical microscopes have magnifying powers ranging from about 2.5 to 1,000 magnitudes and provide resolutions of 0.01 to 0.0002 mm.

Other types of microscopes utilize the wave nature of various physical processes, the most important being the electron microscope, which uses a beam of electrons in its image formation. Electron microscopes have magnifying powers of 1,000 to 1,000,000 magnitudes possible, with resolutions ranging from 0.001 to 0.000 000 01 mm. Special microscopes, such as acoustic microscopes or scanning tunneling microscopes, use other physical effects, further extending the range of objects that can be viewed. Indeed, with a scanning tunneling microscope, even individual molecules and atoms can be seen. Some of these specialized microscopes, as well as the more common optical and electron microscopes, are described in this article. A brief history of microscopy is also included.

THE SIMPLE MICROSCOPE

General considerations. The simple microscope consists of a single or compound lens usually called a magnifier, or loupe. There are many mechanical forms in which a magnifier can be packaged to provide convenience in carrying or in use. For example, when supplied in a mount with a convenient handle, such a lens is frequently called a reading glass. A pair of lenses of low to moderate magnifying power set in a spectacle frame is often used as a magnifying aid for persons with poor vision. Higher magnification lenses are frequently packaged in a cylindrical form that can be held in place immediately in front of the eye. These are generally referred to as eye loupes or jewelers' loupes.

Basically, a simple magnifier permits the user to place his eye close to an object of interest. The closer the object is to the eye, the larger the angle that it subtends at the eye, and thus the larger the object appears. If an object is brought too close, however, the eye can no longer form a clear image. The use of the magnifying lens between the observer and the object enables the formation of a virtual image located a sufficient distance from the eye for the viewer to focus on it. To obtain the best possible image, the magnifier should be placed directly in front of the eye. The object of interest is then brought toward the eye until a clear image of the object is seen. The highest magnification will be achieved when the object is brought to the closest position at which a clear virtual image is observed. For most people, this image distance is about 25 centimetres (roughly 10 inches). As an individual ages, the nearest point of distinct vision recedes to longer distances, thus making a magnifier a useful adjunct to vision for older people.

Magnifying power and field of view

The magnifying power, or extent to which the object being viewed appears enlarged, and the field of view, or size of the object that can be viewed, are related by the geometry of the optical system. An approximate value for the magnifying power of a lens can be found by dividing the least distance of distinct vision (25 centimetres) by the focal length of the lens. Thus, for example, a lens with a focal length of 5 centimetres will have a magnifying power of about 5 magnitudes (often written as 5×).

If the diameter of the magnifying lens is sufficient to fill or exceed the size of the eye pupil, the virtual image that is viewed will appear to be of substantially the same brightness as the original object. The field of view of the magnifier will be determined by the extent to which the magnifying lens exceeds this working diameter, as well as

by the distance of the lens from the eye. The appearance of the magnified virtual image will depend upon both the aberrations present in the lens and the manner in which the lens is used.

Various aberrations influence the sharpness or quality of the image. Chromatic aberrations produce coloured fringes about the high-contrast regions of the image. Spherical aberration produces a fuzzy image. Field curvature requires users to refocus as they look over the field of view. Distortion produces curved lines from straight lines on the object. The type and degree of distortion visible is intimately related to the possible spherical aberration in the magnifier and is usually the most severe in high-power magnifiers.

The aberrations of a lens increase as the relative aperture (*i.e.*, the working diameter divided by the focal length) of the lens is increased. Therefore, the aberrations of a lens whose diameter is twice the focal length will be worse than those of a lens whose diameter is less than the focal length. There is thus a conflict between a short focal length, which permits a high magnifying power but small field of view, and a longer focal length, which provides a lower magnifying power but a larger linear field of view.

Types of magnifiers. There are several types of magnifiers available. The choice of an optical design for a magnifier depends upon the required power and the intended application of the magnifier.

For low powers, about 2–3 magnitudes, a simple double convex lens is applicable. The image can be improved if the lens has specific nonspherical or aspheric surfaces, as can be easily obtained in a plastic molded lens. Some improvement of the distortion is easily noted when an aspheric surface is used, and the manufacture of such low-power aspheric plastic magnifiers is a major industry. In order to make the magnifier lighter in weight, a Fresnel lens can be used. A Fresnel lens, usually of embossed plastic, is in the form of a thin sheet, with the lens curvature placed in a series of concentric grooves on the surface of the sheet. This has many of the same options as a normal simple lens and can have some of the advantages of the aspheric form of the lens. The necessary presence of many symmetrical grooves on the Fresnel lens does reduce the quality of the image through light scattering, however.

Compound lenses

For higher powers of 3–10 magnitudes, there are a number of forms for magnifiers in which the simple lens is replaced by a compound element made up of several lenses mounted and sometimes cemented together. Aspheric surfaces would be useful but are generally quite expensive to use in such compound magnifiers.

A direct improvement in the distortion that may be expected from a magnifier can be obtained by the use of two simple lenses, usually plano-convex (flat on one side, outward-curved on the other). This type of magnifier is based upon the eyepiece of the Huygenian telescope, in which the lateral chromatic aberration is corrected by spacing the elements a focal length apart. Since the imaging properties are provided and shared by two components, the spherical aberration and the distortion of the magnifier are greatly reduced over those of a simple lens of the same power.

A Coddington lens combines two lens elements into a single thick element, with a groove cut in the centre of the element to select the portion of the imaging light with the lowest aberrations. This is a simple and inexpensive design but suffers from the requirement that the working distance of the magnifier be very short.

More complex magnifiers, such as the Steinheil or Hastings forms, use three or more elements to achieve better correction for chromatic aberrations and distortion. In general, a better approach is the use of aspheric surfaces and fewer elements.

THE COMPOUND MICROSCOPE

General considerations. The limitation upon magnifying power imposed by the realities of the geometry of a simple magnifier can be overcome by the use of a compound microscope, in which the image is relayed by two lenses or lens systems (Figures 1 and 2). One lens, called the objective, has a short focal length and is placed close to the object being examined. It is used to form a real image in the front focal plane of the second lens, called an eyepiece, or ocular. The eyepiece then operates in a manner similar to that of the simple magnifier to form an enlarged virtual image that can be viewed by the observer. The magnifying power of the compound microscope is the product of the magnification of the objective lens and that of the eyepiece.

In addition to the two lenses, a basic compound microscope consists of a body tube, in which the lenses can be housed and kept an appropriate distance apart, and an illumination system, which either transmits light through or reflects light from the object being examined. Generally, some method for focusing the microscope must also be provided, as well as a means of supporting and positioning the object to be viewed.

The basic form of a compound microscope is monocular—that is, a single tube is used, with the objective at one end and a single eyepiece at the other. In order to permit viewing with two eyes and thereby increase comfort, a single objective can be employed in a tube with a binocular eyepiece on the other end. The binocular eyepiece has a matched pair of individual eyepiece lenses; beam-splitting prisms are used to send half of the light from the image formed by the objective to each eye. These prisms are mounted in a rotating mechanical assembly so that the separation between the eyepieces can be made to match the required interpupillary distance for the observer. (A stereoscopic microscope is configured by using two objectives and two eyepieces, enabling each eye to view the object separately, making it appear three-dimensional.)

Monocular and binocular microscopes

Optics. There are some obvious geometric limitations that apply to the design of microscope optics. The attainable resolution, or the smallest distance at which two points can be seen as separate, or resolved, when viewed through the microscope, is the first important property. This is generally set by the ability of the eye to discern detail, as well as by the basic physics of image formation.

The eye's ability to ascertain detail is in turn determined by several parameters, including the level of illumination and the degree of contrast between light and dark regions on the object. Under reasonable light conditions, a normal eye with good visual acuity is capable of seeing two high-contrast points if they subtend a visual angle of at least one arc minute in size. Thus, at a nominal viewing distance of

25 centimetres, the points must be at least 0.1 millimetre apart or the eye will not be able to see them as separate. With a simple magnifier of 10 power, an observer can see two points separated by perhaps 0.01 millimetre. With a compound microscope of 100 power, one might expect the observer to be able to distinguish two points only 0.001 millimetre apart, but an additional complication arises for the high magnifications encountered in a compound microscope. When the dimensions to be resolved approach the wavelength of light, consideration must be given to the effect of diffraction upon the eye's ability to resolve details upon objects (see below *The theory of image formation*).

Numerical aperture

The resolution and the light-collecting capability of the microscope are determined by the numerical aperture of the objective. The numerical aperture is defined as the sine of half the angle of the cone of light from each point of the object that can be accepted by the objective multiplied by the index of refraction of the medium in which the object is immersed. Thus, the numerical aperture increases as the lens becomes larger or the refractive index increases. Typical values for microscope objective numerical apertures range from 0.1 for low-magnification objectives to 0.95 for dry objectives and 1.4 for immersed objectives. A dry objective is one that works with the object in air. An immersion objective requires using a liquid, usually a transparent oil, to fill the space between the object and the first element of the objective.

The limit of resolution is set by the wavelength of light and the numerical aperture. The resolution can be improved either by increasing the numerical aperture of a lens or by using light with a shorter wavelength. In an immersion objective, the effective wavelength of the light is reduced by the index of refraction of the media within which the object being examined resides. The use of immersion imaging techniques in microscopy improves the resolution capabilities of the microscope.

Mechanical components. The microscope tube separates the objective and the eyepiece and assures continuous alignment of the optics. It is a standardized length, which permits objectives and eyepieces of different powers to be interchanged with the assurance that the image quality will be maintained. Traditionally this length has been defined from the end of the screw thread that attaches the objective to the tube to a specific location at the eyepiece end of the tube. A standard length of 160 millimetres was accepted for most uses, and of 250 millimetres for metallographic microscopes. Most microscope objectives are designed to minimize aberrations at one of these distances. Use of other distances will affect the aberration balance for high-magnification objectives. Therefore, focusing of the traditional microscope requires moving the objective, the tube, and the eyepiece as a rigid unit. To achieve this, the entire tube is fitted with a rack-and-pinion mechanism that allows it, together with the objective and the eyepiece, to be moved toward or away from the specimen as needed.

The specimen in question is usually mounted on a glass slide and placed on the microscope stage (located directly below the objective). The stage is generally supplied with a pair of knobs featuring a rack-and-pinion arrangement. This permits the glass slide to be moved across the stage in two directions so that different areas of the specimen can be examined.

The accuracy with which the focusing and the movement of the slide have to be maintained increases as the depth of focus of the objective decreases. For high-numerical-aperture objectives, this depth of focus can be as small as one or two micrometres, which means that the mechanical components must provide stable motion at even smaller increments.

Several approaches have been introduced to achieve such precise stable motion at reasonable cost. Some designers have eliminated the sliding mechanism of the body tube, incorporating adjustments for the vertical movement needed for focusing, as well as the lateral motion of the object, in a single mechanical system. A more common approach has been to mount a relay objective doublet of 160-millimetre focal length into the lower end of the tube. This tube lens is attached to the tube in a fixed position and is designed to accept light from an image relayed by the objective to an infinite distance. The microscope objective itself is then designed to have aberrations corrected for an infinite object distance. An advantage of this approach is that, since the relayed image is at infinity, the microscope objective itself, a very lightweight component, can be moved to effect focusing without upsetting the aberration balance.

Because users of a microscope often desire the ability to choose between objectives of several different magnifications in order to suit the magnification to the requirements of the object, some microscopes are equipped with readily interchangeable nosepieces carrying different objectives. Others feature a rotating nosepiece that carries several objectives in a turret. In many cases, the eyepiece is designed as a portion of a zoom lens, which permits continuous variation of the magnification over a limited range.

The illumination system. The illumination system of the standard optical microscope is designed to transmit light through a translucent object for viewing. In a modern microscope, it consists of a light source, usually an electric lamp of some form, and a lens or lens system known as a condenser. The condenser concentrates the light, providing bright, uniform illumination in the region of the object under observation. Typically, the condenser focuses the image of the light source directly onto the plane of the specimen, a technique called critical illumination, or the image of the source is focused onto the condenser, which is then focused onto the entrance pupil of the microscope objective, a process called Köhler illumination. The advantage of the latter approach is that nonuniformities in the source are averaged in the imaging process. To obtain optimum use of the microscope, it is important that the light from the source both cover the object and fill the entrance aperture of the objective of the microscope. Usually, the quality of the image formation from the condenser is not critical, as it is primarily intended to provide uniform illumination. There are applications, such as phase-contrast imaging, where the quality of the source image is important, however.

The condenser

The objective. The optics of the microscope objective are defined by the focal length, numerical aperture, and field of view. Objectives that have been corrected for aberrations are further defined by the wavelength requirements and the tube length of the microscope.

magnifications ranging from 2× to 100×. The focal length of the objective is inversely proportional to the magnification and, in the majority of modern microscopes, equals the tube length (usually 160 millimetres) divided by the magnification. The field of view of the eyepiece is usually set to be a standard size of about 20-millimetre diameter. The field of view of the objective is then set to range from 10 millimetres for an objective with a magnifying power of 2× to 0.2 millimetres for an objective with a magnification of 100×. As a result, the angular field of view is about a total of 7° for all objectives.

Aberration correction. The numerical aperture and the complexity of the objective increase as the magnification increases. Low-power objectives, of the order of two to five magnitudes, are generally simple two-element, or doublet, lenses. Ordinary crown glass and flint glass (optical glasses with, respectively, low and high refractive indexes) can be used to obtain correction for the spherical aberration and chromatic aberration.

For objectives with magnifying powers of 10×, the required numerical aperture increases to 0.25, and a more complex type of lens is required. Most microscope objectives of this magnification use a separated pair of doublets, sharing the refractive power. The correction of spherical aberration is readily achieved, but residual chromatic aberration is obtained when normal optical glasses are used for the lens elements. For most optical applications, this is not important. For the critical high-magnification microscope objectives (magnifications greater than 25×), this aberration is visible as chromatic blur. The only method of correcting this residual aberration is through the use of special optical glasses whose dispersion properties vary from the normal glasses. There are only a few such glasses or crystalline materials that are useful for this purpose. Objectives designed using these special glasses are called apochromats.

Apochromatic lenses

Most traditional microscope objectives do not produce a flat image surface. The intrinsic field curvature is generally of little importance in the visual use of the microscope because the eye has a reasonable accommodative capability when examining the image. Field curvature is, however, a problem for video or photographic systems. Special objectives with flat-field lenses have been designed for these purposes.

High-power objectives. High-power objectives pose several design problems. Because the focal length of an objective decreases as the numerical aperture and magnifying power increase, the working distance, or distance from the objective to the object, is shortened for higher-power objectives. The need to use additional elements in the lens system for high magnifications further shortens the working distance to only 10 to 20 percent of the focal length. Thus, an objective with a magnification of 40× and a focal length of 4 millimetres may have a working distance of less than 0.4 millimetre, which clearly becomes a problem. A number of objectives with increased working distance have been designed. These use a negative lens element between the object and the eyepiece, which has the added attraction of providing some field flattening as well. These objectives are especially of value in use with video detectors.

In objectives with magnifying powers of 25× or greater, meniscus-shaped aplanatic elements are designed into the microscope objective in the space between the object and the pairs of doublets that carry out the relayed imaging. These aplanatic components have the optical property of converging the light without adding spherical aberration to the image and are important in that they provide some increase in the numerical aperture without introducing considerable additional aberration.

The highest-power microscope objective available is the immersion objective. When this type of objective is used, a drop of oil must be placed between the object on the microscope slide and the bottom of the objective. The objective is then moved toward the slide until it contacts the drop of oil, capturing a region of oil between the slide and the objective. The oil used typically has an index of refraction which matches that of the glass in the first component of the objective and which is greater than that of air. Increasing the refractive index in this way increases the numerical aperture, thus permitting higher magnifications. The first component used in immersion objectives is generally a hyper-hemisphere (a small optical surface shaped like a hemisphere but with a bounding curve exceeding 180 degrees), which acts as an aplanatic coupler between the slide and the rest of the microscope objective. An immersion objective with a high numerical aperture typically consists of a hyper-hemisphere followed by one or two aplanatic collectors and then two or more sets of doublets. Such objectives are made with magnifying powers greater than 50×, the extreme being about 100×.

Depth of focus. The large numerical aperture of most microscope objectives severely restricts the focusing requirements of the objective. The depth of focus is shown in the table as the accuracy with which the focal plane must be located in a direction along the axis of the microscope optics in order that the highest possible resolution can be obtained.

Maximum Resolving Power and Depth of Focus for a Visual Microscope

objective focal length (mm)	numerical aperture (N.A.)	maximum useful magnification in compound microscope	maximum resolution on object (mm)	objective depth of focus (mm)
32	0.10	100×	0.002 5	0.025
16	0.25	250×	0.001	0.003 8
8	0.50	500×	0.000 5	0.000 86
4	0.95	1,000×	0.000 26	0.000 24
3	1.38	1,500× (oil immersion)	0.000 18	0.000 10

The eyepiece. The eyepiece is selected to examine the relayed image under conditions that are comfortable for the viewer. The magnifying power of the eyepiece generally does not exceed 10×. The field of view is then about 40° total, a convenient value for a relatively simple optical design. The observer must place his eye in the exit pupil of the eyepiece, the point at which the light rays leaving the eyepiece come together. In most cases an eye relief (or distance from the exit pupil to the last element of the eyepiece) of about one centimetre is desirable. Too short an eye relief makes viewing difficult for observers who wear corrective eyeglasses.

All the objectives described above are nominally intended to relay an image through an eyepiece for direct viewing by an observer. The use of a photographic recording method requires that a real image be provided to a film holder or camera without a lens. One approach is to remove the eyepiece and place the film holder directly in the focal plane of the eyepiece and thus intercept the image from the objective directly. A better approach is to use a specifically designed projection eyepiece, which can be adjusted to provide the appropriate magnification coupling the image to the film. Such an eyepiece can incorporate a change in the chromatic aberration correction to accommodate the requirements of the photographic system.

Photomicrography

Even more prevalent today is the use of an electronic detector to capture the magnified image as a video signal. This video signal can be observed directly on a monitor or sent to a computer via a frame "grabber" that captures a single frame (or perhaps several averaged frames) of video data. The computer can then be used to provide some image processing.

THE THEORY OF IMAGE FORMATION

The geometric optics of image formation in the compound microscope are easy to understand. The objective collects a fan of rays from each object point and images the ray bundle to the front focal plane of the eyepiece. All the rules of ray tracing apply to the image formation. In the absence of aberration, geometric rays form a point image of each object point. In the presence of aberrations, each object point is represented by a blurred point. The eyepiece images the rays to a focal point at a convenient distance for viewing the image. In this direct view approach, the brightness of the image is determined by the sizes of the apertures of the lenses and by the size of the

pupil of the eye. The focal length and resulting magnification of the objective should be chosen to attain the desired resolution of the object at a size convenient for viewing with the eyepiece.

The actual image formation in the microscope is complicated by the diffraction and interference that take place in the imaging system and by the requirement to use a light source that is imaged into the focal plane.

The modern theory of image formation in the microscope was initiated by the German physicist Ernst Abbe in 1873. The starting point for the Abbe theory is that objects in the focal plane of the microscope are illuminated by convergent light from a condenser. The convergent light from the source can be considered as a collection of many plane waves propagating in a specified set of directions and superimposed to form the incident illumination. Each of these effective plane waves is diffracted by the details in the object plane: the smaller the detail structure of the object, the wider the angle of diffraction.

The structure of the object can be represented as a sum of sinusoidal components. The rapidity of variation in space of the components is defined by the period of each component, or the distance between adjacent peaks in the sinusoidal function. The spatial frequency is the reciprocal of the period. The finer the details, the higher the required spatial frequency of the components representing the object detail. Each spatial frequency component produces diffraction at a specific angle dependent upon the wavelength of light. For example, spatial frequency components having a period of one micrometre would have a spatial frequency of 1,000 lines per millimetre. The angle of diffraction for such a component for visible light with a wavelength of 550 nanometres will be 33.6°.

The microscope objective collects these diffracted waves and directs them to an image plane, where interference between the diffracted waves produces an image of the object. Because the aperture, of the objective is limited in size, not all the diffracted waves from the object can be transmitted by the objective. Abbe showed that the greater the number of diffracted waves reaching the objective, the finer the detail that can be reconstructed in the image. He designated the term numerical aperture as the measure of the objective's ability to collect diffracted light and thus also of its resolving power. On this basis, it is obvious that the greater the magnification of the objective, the greater the required numerical aperture of the objective. The largest numerical aperture theoretically possible in air is 1.0, but practical optical design questions limit the largest achievable numerical aperture to 0.95 or less.

For the example above of a component with a spatial frequency of 1,000 lines per millimetre, the required numerical aperture to collect the diffracted light would be 0.55. Thus, an objective of 0.55 numerical aperture or greater must be used to observe and collect useful data from an object with details spaced one micrometre apart. If the objective has a lower numerical aperture, the details of the object will not be resolved. Attempts to enlarge the image detail by use of a high-power eyepiece will yield no more useful resolution. This latter condition is called empty magnification.

Empty magnification

For resolving the smallest possible details, it is possible to use the principle that the wavelength of light is shortened when propagating through a dense medium. This explains why immersion objectives are able to collect light diffracted by smaller details than can dry objectives. The numerical aperture is multiplied by the index of refraction of the medium, and working numerical apertures of 1.25 to 1.4 are possible. At the extreme, spatial frequency components with periods as small as 0.4 micrometre can be observed.

SPECIALIZED TYPES OF MICROSCOPES

Stereoscopic microscopes. Binocular stereomicroscopes are, fundamentally, a matched pair of microscopes mounted side by side, usually with a small angle between the optical axes. The object is imaged independently to each eye, and the stereoscopic effect, which permits discrimination of height on the object, is retained. The effect can be exaggerated by proper choice of the design parameters for the microscopes. For practical reasons, the magnifying power of such instruments is usually in the range of 5 to 50 magnitudes. These microscopes are important in any work in which fine adjustment of tools or devices is to be made. For example, much use of the stereomicroscope is made in biological laboratories for dissection of subjects and in the operating room for microsurgical procedures. Moderate-power stereomicroscopes are even more widely used in the electronics manufacturing industry, where they enable human workers, as well as computer-controlled machines, to bond leads to tiny integrated-circuit chips.

Polarizing microscopes. Polarizing microscopes are conventional microscopes with additional features that permit measurement of the details of polarization effects. The light source of such an instrument is equipped with a polarizing filter, or polarizer, so that the light it supplies is linearly polarized (*i.e.*, the light waves vibrate in a specific direction rather than randomly in all directions as in ordinary light). When this linearly polarized light passes through the object under examination, it may be unaffected or, if the object is birefringent, it may be split into two beams with different polarizations. A second filter, a polarization analyzer, is fitted to the eyepiece, where it blocks out all but one polarization of the light. The analyzer can be rotated to obtain maximum contrast in the image, and so the direction of polarization of the light transmitted through the object can be determined. The eyepiece can also be equipped with a polarization retarder, which shifts the phase of the light between selected polarization directions and which can be rotated to measure the amount of elliptic polarization produced by the object.

Many precautions must be taken in the design and construction of a polarizing microscope to avoid using optical components that introduce undesirable polarization retardation in the beam of light after it has left the object. There is a basic limitation placed upon the use of objectives with high numerical apertures wherein the necessary high angles of incidence on the surface produce some depolarization. Specialized microscope objectives that minimize this effect have been designed and produced. Polarizing microscopes are primarily used to examine the nature of crystals in geologic samples and to analyze the details of birefringence and stress in biological structures.

Metallographic microscopes. Metallographic microscopes are used to identify defects in metal surfaces and to determine the crystal grain boundaries in metal alloys. This type of microscope employs a type of illumination, called vertical illumination, in which the light source is inserted into the microscope tube below the eyepiece by means of a beam splitter. Light progresses through the objective and is imaged through the objective onto the object. The light reflected or scattered back to the objective is then imaged back at the eyepiece. In this manner, opaque objects such as metals can be examined under the microscope.

Vertical illumination

Reflecting microscopes. Microscopes of this type feature reflecting rather than refracting objectives. They are used to carry out microscopy over a wide range of visible light and especially in the nonvisible ultraviolet or infrared regions, where conventional optical glasses do not transmit. The reflecting microscope objective usually consists of two components, a relatively large, concave primary mirror and a smaller, convex secondary mirror, which is located between the primary mirror and the object and serves to relay the image from the primary mirror to the focal plane of the eyepiece. Although reflecting objectives do not have chromatic aberrations, they usually need to be corrected for spherical aberrations, either by using aspheric reflecting components or by adding appropriate refracting lenses. One disadvantage of the reflecting microscope is that the secondary mirror causes a small obstruction in the centre of the exit pupil of the eyepiece. The shape of the pupil is annular, with out-of-focus blurs having unusual shapes because of the obstruction.

Phase-contrast microscopes. Many biological objects of interest consist of cell walls, cell nuclei, and other structures that are transparent; they transmit as much light as the mounting medium that surrounds them does. Because there is no colour or transmission contrast in such an

object, it is not possible to observe the structure using a conventional microscope. The index of refraction of the structure varies slightly from the surrounding material, however. Thus, the propagation of light through such an object provides a change in the optical path across the object, as well as a resulting shift in the phase of the light that has passed through the structure of interest relative to light passing around the structure. This phase-shift information can be used to form a visible image if it is converted into intensity variations that are detectable by the observer, and in 1934 the Dutch physicist Frits Zernike developed a method for doing just that. In a phase microscope, the phase difference between light that is diffracted by a specimen and light that is direct and undeflected is one-quarter of a wavelength or less. By placing an appropriate mask in the back focal plane of the objective to provide selective filtering of the diffracted light, Zernike increased this phase difference by another quarter wavelength. Waves that differ in phase by half a wavelength cancel one another. In places in the phase image where this occurs, no light is transmitted. As a result, phase differences caused by variations in the specimen appear as intensity variations in the image.

Zernike's contribution

There are several approaches to achieving a good-quality image by this technique. One of the most common is the use of an annular light source imaged onto an annular mask in the back focal plane. Other techniques use edges, small dots, or other combinations of source shape and mask shape.

Scanning optical microscopes. The size of the field of view of a microscope is limited by the geometric optics and by the ability to design optics that provide a constant aberration correction over a large field of view. If a scanning arrangement is used, the objective can be used over a series of small fields, and the results from each field can be used to build up an image of a large region. In addition, scanning permits the acquisition of an image while only a small portion of the field is illuminated at a time. This eliminates extraneous light scattered by objects other than the one of interest in the centre of the field.

The simplest design for a scanning microscope is using a microscope in a reverse direction. The light source is focused by a condenser upon a small aperture. The light passing through this aperture is in turn focused on the object by the objective to form a small spot with very little diffraction. The light transmitted by the object being examined is then collected by a condenser working in reverse, with a photodetector located at the point where a light source would normally be located. The object is scanned in a raster pattern, and the varying electrical signal from the photodetector is collected and displayed on a monitor. Since the only light passing through the object at each point is the light used in forming each picture element, extraneous light scattered by the object is eliminated, and considerably higher contrast in the image is obtained.

Variants in scanning patterns include employing a rapid scan over a short distance along a slowly moving object. Usually a high-speed rotating mirror is used to move the illuminated spot repeatedly over a line crossing the object. A slower, but synchronized, motion moves the object past the high-speed scanned line. This scanning method requires the use of an objective with sufficient field coverage to accommodate only the high-speed scan line length.

Scanning microscopes can be used for detailed investigation of the properties of objects, including the evaluation of spectral absorption by collecting light of different colours at each point in the scanning. An additional possibility is the measurement of fluorescence effects, in which the incoming light is blocked by a filter that permits only the fluorescent colours to reach the photodetector.

Confocal scanning microscopy

The most interesting new development in scanning optical microscopy is confocal scanning microscopy. In this technique, two microscopes are used, examining the same region of an object from opposite sides of the object. A small illuminated aperture is focused onto the object by the illuminating microscope. The receiving microscope is configured identically, with a photodetector following a small aperture in the magnified focal plane of the receiving microscope. The two microscopes are adjusted to focus on the same region in space. This effectively prevents any extraneous light or any light scattered at the confocal image region from reaching the detector. The object is then scanned to build up an image from the detected signal.

The confocal scanning microscope has the unique ability to produce images of a single plane, or optical section, of an object. Because the rejection of scattered and extraneous light is excellent in the confocal arrangement, the image is formed only by light from a specific region. If several scans are made with the pair of microscopes successively focused upon different depth planes in the object, a three-dimensional structure can be inferred from this complete set of imagery. Electron microscopes

GENERAL CONSIDERATIONS

Fundamental research by many physicists in the first quarter of the 20th century suggested that cathode rays (*i.e.,* electrons) might be used in some way to increase microscope resolution. Louis de Broglie, a French physicist, in 1924 opened the way with the suggestion that electron beams might be regarded as a form of wave motion. De Broglie derived the formula for their wavelength, which showed, for example, that, for electrons accelerated by 60,000 volts, the effective wavelength would be 0.05 angstrom—*i.e.,* 1/100,000 that of green light. If such waves could be used in a microscope, then a valuable increase in resolution would result. In 1926 it was demonstrated that magnetic or electrostatic fields could serve as lenses for electrons or other charged particles, and this discovery initiated the study of electron optics. In 1931 a two-lens electron microscope was devised. It produced enlarged images of the electron source. Later, in 1933, a true electron microscope was built. A year or so later, the resolution of the optical microscope was surpassed, but the specimen was severely damaged by the heating effects of the electron beam, a problem that was not solved for some years. In 1935 the construction of the first commercially built electron microscope was begun in England, and it was soon followed by the production of microscopes in Germany and the United States. Progress in the construction of electron microscopes was rapid, with a great impetus to the achievement of high resolution being the introduction, in 1946, of a device called a stigmator, which compensates for astigmatism of the objective lens.

Electron microscopes are now available that are easy to operate and reliable and that give point-to-point resolutions of less than 0.2 nanometre (Figure 3). Such high resolutions, coupled with suitable advances in the methods of specimen preparation, permit the direct visualization of many molecules and some atoms. There are two basic types of electron microscope: the transmission electron microscope (TEM), which can only image specimens a fraction of a micrometre or less in thickness, and the scanning electron microscope (SEM), in which a beam of electrons is scanned over the surface of a solid object and used to build up an image of the details of the surface structure. There are also several special types of electron microscope. Among the most valuable is the electron-probe microanalyzer, which allows a chemical analysis of the composition of materials to be made by using the incident electron beam to excite the emission of characteristic X radiation by the various elements composing the specimen. These X rays are detected and analyzed by spectrometers built into the instrument. Such probe microanalyzers are able to produce an electron scanning image so that structure and composition may be easily correlated.

Types of electron microscopes

Differences of types. There are many differences between optical and electron microscopes. The electron microscope requires that the electron beam be in a vacuum, because electrons cannot travel any appreciable distance in air at atmospheric pressure. The column of the electron microscope is evacuated by pumps, and the specimen, photographic plates, and any other necessary apparatus are introduced into the vacuum by means of air locks. Unlike the optical microscope, in which the lenses are of fixed focus and the distance between specimen and objective lens is varied, the electron microscope has variable-

focus lenses, and the distance between specimen and objective lens and separation of the lenses remain constant. The magnification is determined mainly by the value of the current (for magnetic lenses) through the intermediate and projector lens coils. The image is focused by changing the current through the objective lens coil. Another difference is that the optical microscope is usually operated so that the image is a virtual one, while in the electron microscope the final image is invariably real and is visualized on a fluorescent screen or recorded for study on a photographic plate.

In the optical microscope the image is formed by absorption of light in the specimen; in the electron microscope the image results from a scattering of electrons by atoms in the specimen. A heavy atom is more effective in scattering than one of low atomic number, and the presence of heavy atoms will increase the image contrast. The electron microscopist may incorporate more heavy atoms into the specimen for this purpose.

Lenses. Although early microscopes relied on electrostatic lenses, modern instruments use electromagnetic lenses. These consist of a solenoid of wire together with a magnetic pole piece that concentrates and shapes the magnetic field. The lenses used for the condenser and for the projector system of the microscope differ from the objective lens only in details. For example, the manufacturing and performance tolerances for a condenser or projector lens are less demanding than for an objective lens.

Efforts to improve the resolution of the electron microscope have tended toward production of a single-field condenser-objective lens of low aberrations. In such a lens, the upper part acts as a condenser and the lower as the objective; the specimen is inserted into the centre of the lens, where the axial magnetic field (the field along the axis of the instrument) is at a maximum.

Electron lens aberrations

All electron-optical lenses show spherical aberration, distortion, coma, astigmatism, curvature of field, and chromatic aberration due to variations in the wavelengths of the electrons. Such changes of electron velocity may be due either to variations in the high-voltage supply to the electron gun or to energy losses from collisions of electrons with atoms in the specimen. The first effect may be minimized by careful stabilization of the high-voltage supply, and, for the very thin specimens and the high electron energies commonly used, the second effect may usually be neglected. The resolving power of the microscope is ultimately limited by the spherical aberration of the objective lens. It is not possible to correct this aberration by adding a second lens of opposite characteristics, as can be done for the optical microscope, because magnetic electron lenses are always convergent. Computer-aided lens design has led to great improvements in performance, but electron lenses still require much smaller numerical apertures than do optical lenses in order to function optimally.

Astigmatism in the electron microscope is largely due to deviations from cylindrical symmetry in the radial components of the magnetic field of the lens and is the result of imperfect construction of the lens. The interaction of the electron beam with residual gas molecules in the column may also lead to deposits along the beam path that charge up under the influence of the beam and introduce asymmetries. Astigmatism may usually be completely corrected by use of the stigmators fitted to the objective lens.

THE TRANSMISSION ELECTRON MICROSCOPE

Principal components

The transmission electron microscope has three essential systems: (1) an electron gun, which produces the electron beam, and the condenser system, which focuses the beam onto the object, (2) the image-producing system, consisting of the objective lens, movable specimen stage, and intermediate and projector lenses, which focus the electrons passing through the specimen to form a real, highly magnified image, and (3) the image-recording system, which converts the electron image into some form perceptible to the human eye. It usually consists of a fluorescent screen for viewing and focusing the image and a camera for permanent records. In addition, a vacuum system, consisting of pumps and their associated gauges and valves, and power supplies are required.

The electron gun and condenser system. The source of electrons, the cathode, is a heated, V-shaped tungsten filament or, in high-performance instruments, a sharply pointed rod of lanthanum hexaboride. The filament is surrounded by a control grid, sometimes called a Wehnelt cylinder, with a central aperture arranged on the axis of the column; the apex of the cathode is arranged to lie at or just above or below this aperture. The cathode and control grid are at a negative potential equal to the desired accelerating voltage and are insulated from the rest of the instrument. The final electrode of the electron gun is the anode, which takes the form of a disk with an axial hole. Electrons leave the cathode and shield, accelerate toward the anode, and, if the stabilization of the high voltage is adequate, pass through the central aperture at a constant energy. The control and alignment of the electron gun are critical in ensuring satisfactory operation.

The intensity and angular aperture of the beam are controlled by the condenser lens system between the gun and the specimen. A single lens may be used to converge the beam onto the object, but, more commonly, a double condenser is employed. In this the first lens is strong and produces a reduced image of the source, which is then imaged by the second lens onto the object. Such an arrangement is economical of space between the electron gun and the object stage and is more flexible, because the reduction in size of the image of the source (and hence the final size of illuminated area on the specimen) may be varied widely by controlling the first lens. The use of a small spot size minimizes disturbances in the specimen due to heating and irradiation.

The image-producing system. The specimen, mounted on a copper grid, is carried in a small holder in a movable specimen stage that allows an area of up to three millimetres in diameter to be examined. The objective lens is

usually of short focal length (one to five millimetres) and produces a real intermediate image with a magnification of 20–200 magnitudes. This image is in turn further magnified by the projector lens or lenses. A single projector lens may provide a range of magnification of 5:1, and by the use of interchangeable pole pieces in the projector a wider range of magnifications may be obtained. Modern instruments employ two projector lenses (one called the intermediate lens) to permit a greater range of magnification and to provide a greater overall magnification without a commensurate increase in the physical length of the column of the microscope.

For practical reasons of image stability and brightness, the microscope is often operated to give a final magnification of 1,000–250,000 magnitudes on the screen. If a higher final magnification is required, it may be obtained by photographic enlargement. The quality of the final image in the electron microscope depends largely upon the accuracy of the various mechanical and electrical adjustments with which the various lenses are aligned to one another and to the illuminating system. The lenses require power supplies of a high degree of stability; for the highest standard of resolution, electronic stabilization to better than one part in a million is necessary.

Image quality

Image recording. The electron image must be made visible to the eye by allowing the electrons to fall on a fluorescent screen fitted at the base of the microscope column. Such a screen is satisfactory for quick observations and for focusing and aligning the instrument. A low-power binocular optical microscope fitted outside the column allows the image on the screen to be inspected at a magnification of about 10 magnitudes, but the image suffers from poor contrast, lack of brightness, and the inherent grain of the screen. By allowing the electrons to fall on the emulsion of a photographic plate, the latent image can then be developed and fixed exactly as in ordinary photography, and prints at any degree of further enlargement may be obtained from the negative. Such further enlargement allows all the detail present in the image to be resolved by the eye and also allows some control over the contrast.

Image-intensification systems have been developed using some form of television tube, with the final image presented on a cathode-ray-tube monitor. Because image intensifiers permit electronic amplification, beam currents that are too low to register an image for direct viewing on a fluorescent screen may be used to permit examination of materials susceptible to radiation damage, such as polymers and biological tissue.

THE SCANNING ELECTRON MICROSCOPE

The scanning electron microscope, designed for directly studying the surfaces of solid objects, utilizes a beam of focused electrons (of 5–25 kilovolts energy) as an electron probe that is scanned in a regular manner over the specimen. The electron source and electromagnetic lenses that generate and focus the beam are similar to those described for the transmission electron microscope (Figure 4). The action of the electron beam stimulates emission of high-energy backscattered electrons and low-energy secondary electrons from the surface of the specimen. These are collected and passed to a scintillator, which produces light when bombarded with electrons. The light is passed to a photomultiplier tube, where it is converted back to an electric signal with an effective gain of 10,000 times or more. The resultant amplified current is used, in turn, to modulate the brightness of a display cathode-ray (television) tube that is scanned in synchronism with the probe beam in the microscope column. There is thus a one-to-one relation between the brightness of each point on the display tube and the number of electrons emitted from the corresponding point on the surface of the specimen. In this way, a map of the specimen is built up, with a magnification equal to the ratio between the sizes of the picture on the display tube and the area scanned by the probe. In modern instruments, a point-to-point resolution of one nanometre is attainable (Figure 5).

No elaborate specimen-preparation techniques are required for examination in the scanning electron microscope, and large and bulky specimens may be accommodated. It is desirable that the specimen be rendered

electrically conducting, otherwise a sharp picture will not be obtained. Conductivity is usually achieved by evaporating a film of metal 50 to 100 angstroms thick onto the specimen in a vacuum (such a thickness does not materially affect the resolution of the surface details). If, however, the scanning electron microscope can be operated at between one and three kilovolts of energy, then even nonconducting specimens may be examined without the need for a metallic coating.

Scanning instruments have been combined with transmission electron microscopes to form scanning transmission electron microscopes. These have the advantages that very thick sections may be studied without chromatic aberration limitation and that electronic methods may be used to enhance the contrast and brightness of the image.

HIGH-VOLTAGE INSTRUMENTS

Several different types of instrument have been constructed to operate at accelerating voltages in excess of the 200–300 kilovolts normally used in the conventional transmission instrument. High-voltage microscopes now in commercial production are designed for accelerating voltages of up to 1,500 kilovolts.

These instruments have several advantages over the conventional TEM: (1) the theoretical resolving power of the instrument increases as the accelerating voltage increases; (2) thick specimens are easily penetrated by the beam; (3) chromatic aberration caused by energy losses and scattering in the specimen is decreased; and (4) specimen heating and irradiation damage of organic samples are decreased. Many metals and semiconductors suffer increased damage at these high energies, however, because the incident electrons may knock an atom from its correct position in the crystal lattice.

Although the gain in resolution at 1,000 kilovolts is theoretically about two and a half times that of a 100-kilovolt instrument, such increases have not been fully achieved in practice. It is primarily for the increased penetrating power and consequent reduction in chromatic aberration that the high-voltage instruments are used, as, for example, in the study of metals and alloys. Some biological systems, such as bacteria and whole cells, may also be examined with advantage at high voltage.

THE ELECTRON-PROBE MICROANALYZER

A limitation of the conventional electron microscope is that it provides no chemical information. Electron-probe microanalyzers have been developed (since 1947) to carry out nondestructive elemental analysis at resolutions approaching those of the transmission electron microscope. This is done by measuring the energy and intensity of the characteristic X rays emitted by a specimen when a focused electron beam impinges on it. As in the scanning electron microscope, the probe is scanned so that an image of the distribution of a chosen element may be built up on a cathode-ray tube.

X-ray microprobe analysis has proven to be so valuable that a majority of scanning electron microscopes, as well as many transmission electron microscopes, are now equipped with X-ray spectrometers as accessories. The technique has found wide applications in mineralogy, metallurgy, and solid-state science, as well as in the clinical and life sciences.

X-ray microprobe analysis

THE FIELD-EMISSION MICROSCOPE

In this instrument a wire with a sharpened tip is mounted in a cathode-ray tube. Electrons are drawn from the tip by a high electrical field and travel toward the screen on which the image is formed. Only strong metals, such as tungsten, platinum, and molybdenum, can be examined in this way because the high field at the tip exerts a large mechanical stress. The magnification is proportional to the ratio of the radius of curvature of the screen on which the image forms to the radius of the metal tip; it may reach up to one million magnitudes.

A development of the field-emission microscope is the field-ion microscope, in which the tip is surrounded by a low pressure of helium gas. The gas is ionized at the atom planes on the tip and produces an image that can have a magnification of up to 10 million magnitudes. The field-ion microscope has been applied mainly to the study of metals and semiconductors, but a few biological images have been obtained. A further development of the field-ion microscope is the atom probe. In this instrument, individual atoms are removed from the tip by pulsing the electric field. The atoms pass through a time-of-flight spectrometer, which measures their energy and charge-to-mass ratio. In this way, the chemical nature of each atom in the field-ion image may be determined.

OTHER PARTICLE MICROSCOPES

In principle, microscopes can be made that utilize any beam of energetic particles, and instruments employing ions, protons, and positrons have been demonstrated. The efficiency of the practical sources of such beams is very low by comparison with those of electrons, however, and consequently the application of such microscopes has been restricted to specialized studies. (S.Br./Da.C.J.)

Acoustic microscopes

GENERAL CONSIDERATIONS

The optical microscope reveals much of the microscopic world, but its domain is restricted; it does not include opaque materials, opalescent liquids, nor media that absorb light completely. Sergei Y. Sokolov at the V.I. Ulyanov (Lenin) Electrotechnical Institute, Leningrad, suggested that these restrictions could be lifted if sound waves were used in a new form of microscope. Sokolov recognized that a microscope using sound waves with a frequency of 3,000 megahertz (MHz) would have a resolution equal to that of the optical microscope. He advanced his idea in the early 1940s, at a time when the required technology did not exist. Since then, however, the technology has been developed, and the high frequencies required for Sokolov's microscope are found in the microwave systems used for radar and for satellite communications. During the 1970s, several groups of researchers in the United States employed these frequencies to build sound systems. The microscope that evolved from this effort is known as the scanning acoustic microscope.

Sound is a term commonly associated with the waves in air that can be detected by the human ear. The phenomenon is more general, however; sound waves travel through liquids and solids as well. The descriptive term "acoustics" is used for these waves. Acoustic waves easily propagate through materials impervious to optical waves. The energy is carried by the periodic motion of particles, where alternate regions of compression and rarefaction move through the media at the velocity of sound.

The differences between the optical and acoustic instruments can be clarified with a short description of three

Characteristics of waves

parameters used to characterize waves—wavelength, wave velocity, and frequency. These parameters are easily visualized by observing ocean waves. The wavelength is the distance between the crests, the wave velocity is the speed of the moving crests, and the frequency is the frequency of impact of the crests on the shoreline. If the spacing between crests is 10 metres and if they move with a velocity of 10 metres per second, the crests will hit the shoreline with a frequency of 1 per second. If the velocity is reduced to 0.1 metre per second and a distance of 10 metres is maintained between crests, the frequency of impact will be reduced to 0.1 per second. Similarly, in sound systems, where the velocity is reduced by a factor of 100,000 below the velocity of optical waves, the acoustic wavelength is comparable to the optical wavelength if the sound frequency is reduced by the same factor of 100,000 below the frequency of optical waves. The resolution of an acoustic microscope operating at 3,000 MHz is equal to the resolution of the optical microscope.

INSTRUMENTATION

The instrumentation of an acoustic microscope is completely different from that of a traditional optical microscope. The central component of the acoustic system is a small sapphire rod. A thin film of piezoelectric material is deposited on the flat end of the sapphire crystal, and a spherical depression on the opposite end of the crystal rod acts as the lens. The endface with the cavity is immersed in water, along with the specimen. The thin film of piezoelectric material, usually zinc oxide (ZnO), expands and contracts when a periodic electric field is applied across it. The film acts as a transducer to convert electromagnetic energy into acoustic energy. The periodic expansions then travel through the crystal as acoustic waves.

The acoustic velocity in water is less than it is in sapphire, and the waves that cross the crystal-water interface are refracted through a large angle. The refraction is so large that the plane waves in the sapphire rod are converted in the liquid into spherical waves that converge to a narrow "waist," or focus, near the centre of curvature of the spherical lens. In a scanning system, the minimum resolvable feature is determined by the waist diameter. The diameter of the acoustic beam at the waist is less than one wavelength.

The elastic properties of the sample are examined with the acoustic beam that emerges from the lens. The examination is carried out point by point by mechanically scanning the lens over the area under investigation. The waves reflected from the sample travel back through the liquid, through the lens, and through the crystal to the ZnO transducer. There they are reconverted into electrical signals. In this way, the energy is quickly transferred into and out of the acoustic system. The images are displayed on the screen of a monitor and recorded by photographing the display on the screen. Mechanical scanning, together with the reconversion to electronic signals, forms the analog to the photographic film of an optical microscope.

In another configuration, a cylindrical lens is used to focus the acoustic energy into a narrow line. It is used to measure features on the surface along a given direction and characterize the anisotropic properties of surfaces.

Types of acoustic waves used

The acoustic microscope utilizes three types of acoustic waves in its various operating modes; these are (1) longitudinal waves, in which the particle motion is in the direction of wave motion, (2) shear waves, in which the particle motion is transverse to the direction of wave motion, and (3) surface waves, in which the energy clings to the interface between the sample and the liquid. (The surface wave, first described by the 19th-century scientist Lord Rayleigh, now bears his name.)

Longitudinal waves are employed in the most common mode, where the acoustic pulse reflected from the sample surface is recorded for each position of the probing beam. Changes in the elastic properties of the sample show up as differences in both amplitude and phase of the reflected signal.

Rayleigh waves are extraordinarily effective in enhancing the contrast for obscure surface structure. When the incident beam is defocused by moving the lens toward the sample, the longitudinal waves in the liquid are coupled to the surface waves on the sample interface. In this circumstance, the interchange of energy between the longitudinal and surface modes combine in such a way as to create an interference pattern at the transducer. These patterns are sensitive to small changes in the elastic properties of the surface. Minute cracks or scratches show up with excellent contrast (Figure 6).

The centre sharp line in the image is the trace of a scratch with a steel ball; the white area surrounding the line is the coating that is peeling.

The range of acoustic microscopy

The electronic components in the acoustic microscope are adapted from the technology used to generate the short pulses of radio-frequency energy in radar systems. The system operates with coherent signals over a wide range of frequencies. In water, the frequency range extends from 5 to 5,000 MHz; the wavelength ranges from 300 to 0.3 micrometres. Cryogenic instruments with liquid helium as the working fluid are used to extend the system to even shorter wavelengths. The velocity of sound in helium is about one-sixth that of water, which means that the wavelength is reduced by the same factor. Furthermore, at very low temperatures (near 0.1 K, or −459° F), the sound absorption in helium is less than it is in water. These two factors have been exploited to build an instrument operating at 16,000 MHz with a resolution of 15 nanometres.

APPLICATIONS

The acoustic microscope is employed for different purposes at the different frequency ranges. At higher frequencies, it is used primarily to study the elastic properties of surfaces and the internal constituents of biological cells. At lower frequencies, below 500 MHz, where the acoustic energy penetrates deeply into the sample, the instrument is used to reveal the structures that lie beneath the surface.

The acoustic microscope is especially effective for identifying defects in various materials. For example, a metal heat sink of some kind is used to dissipate the heat in silicon devices that generate power. These devices are attached to the heat sink with a thin layer of solder. Inhomogeneities and imperfections in the solder layer will decrease the amount of heat transferred to the heat sink, increase the temperature, and degrade the operation. When the layer of solder is examined with an acoustic microscope, the inhomogeneities show up with strong contrast.

Another example occurs in the fabrication of silicon devices, in which thin films of metals and oxides are frequently deposited on the silicon surface. The adhesion between the film and the substrate is a parameter that must be controlled. If this adhesion is faulty, the reflection coefficient for the acoustic waves is increased, and the defective sections are thus sharply defined in the images.

Some of the other unique and valuable applications of the acoustic microscope include examining the integrity

of the bonds between layers in laminated and composite materials, studying the density and distribution of glass and carbon fibres used to strengthen composite materials, detecting the presence of microcracks and voids near the surface, and monitoring the strain associated with the fabrication of microstructures.

Scanning tunneling microscopes

Basic operation

The scanning tunneling microscope (STM) appeared in 1981 when Gerd Binnig and Heinrich Rohrer of the IBM Zürich Research Laboratory in Rüschlikon, Switz., set out to build a tool for studying the local conductivity of surfaces. Its principle of operation is based on the quantum mechanical phenomenon known as tunneling, in which the wavelike properties of electrons permit them to "tunnel" beyond the surface of a solid into regions of space that are forbidden to them under the rules of classical physics. The probability of finding such tunneling electrons decreases exponentially as the distance from the surface increases. The scanning tunneling microscope makes use of this extreme sensitivity to distance. The sharp tip of a tungsten needle is positioned a few angstroms from the sample surface. A small voltage is applied between the probe tip and the surface, causing electrons to tunnel across the gap. As the probe is scanned over the surface, it registers variations in the tunneling current, and this information can be processed to provide a topographical image of the surface.

Binnig and Rohrer chose the surface of gold for their first image. When the image was displayed on the screen of a television monitor, they saw rows of precisely spaced atoms and observed broad terraces separated by steps one atom in height. Binnig and Rohrer had discovered in the scanning tunneling microscope a simple method for creating a direct image of the atomic structure of surfaces. Their discovery opened a new era for surface science, and their impressive achievement was recognized with the award of the Nobel Prize for Physics in 1986.

INSTRUMENTATION

The advance of this new form for surface microscopy was impeded by four instrumental problems: (1) the isolation of the experiment from the natural vibrations that are present in every laboratory, (2) the approach of the probe tip to the sample surface, (3) the scanning of the probe across the sample surface, and (4) the sharpening of the tip. The techniques that Binnig and Rohrer employed to solve these problems are elegant and straightforward and are briefly described here. Their solutions are used almost unaltered to the present time.

The sample and the scanning probe are protected from vibrations by being placed on a stage that is suspended from springs within another section or stage. This outer stage is in turn suspended from springs within a stainless steel frame. The structure is equipped with magnets and copper plates that will, if necessary, induce eddy currents that damp any motion of the stages. The placement and scanning movement of the probe are controlled by a tripod made of piezoelectric materials (which expand or contract when voltage is applied) and by a piezoelectric plate with three metal feet that can be fastened to a metal plate carrying the sample. Applying voltage to one leg of the tripod (or to the piezoelectric plate) causes the other tripod legs (or one or more of the metal feet) to move slightly. Both the direction and the magnitude of this movement can be precisely controlled. The probe is sharpened by applying a strong electric field; this dislodges the surface atoms of the tip until only a few (ideally, one) remain.

Differences between the STM and the SEM

The scanning tunneling microscope is an electron microscope with a resolution sufficient to resolve single atoms. The sharp tip in the STM is similar to that in the scanning electron microscope, but the differences in the two instruments are profound. In the SEM, electrons are extracted from the tip with a series of positively charged plates placed a few centimetres downstream from the tip. The electrons at the apex of the tip are confined to the region within the metal by a potential barrier. The attractive force from the positive charge on the plates is sufficient to permit the electrons to overcome the barrier and enter the vacuum as free particles. The apertures in the downstream plates form an electron lens that converts the diverging beam from the tip into a beam converging to a focus on the surface of the sample.

In the STM, the setup is much simpler. The plates that form the lens in the SEM are removed, and the tip is positioned close to the sample. The electrons move through the barrier in a way that is similar to the motion of electrons in a metal. In metals, electrons appear to be freely moving particles, but this is illusory. In reality, the electrons move from atom to atom by tunneling through the potential barrier between two atomic sites. In a typical case, with the atoms spaced five angstroms apart, there is a finite probability that the electron will penetrate the barrier and move to the adjacent atom. The electrons are in motion around the nucleus, and they approach the barrier with a frequency of 10^{17} per second. For each approach to the barrier, the probability of tunneling is 10^{-4}, and the electrons cross the barrier at the rate of 10^{13} per second. This high rate of transfer means that the motion is essentially continuous and tunneling can be ignored in metals.

Tunneling cannot be ignored in the STM; it is all-important. When the tip is moved close to the sample, the spacing between the tip and the surface is reduced to a value comparable to the spacing between neighbouring atoms in the lattice. In this circumstance, the tunneling electron can move either to the adjacent atoms in the lattice or to the atom on the tip of the probe. The tunneling current to the tip measures the density of electrons at the surface of the sample, and this information is displayed in the image. In semiconductors, such as silicon, the electron density reaches a maximum near the atomic sites. The density maxima appear as bright spots in the image, and these define the spatial distribution of atoms. In metals, on the other hand, the electronic charge is uniformly distributed over the entire surface. The tunneling current image should show a uniform background, but this is not the case. The interaction between tip and sample perturbs the electron density to the extent that the tunneling current is slightly increased when the tip is positioned directly above a surface atom. The periodic array of atoms is clearly visible in the images of materials such as gold, platinum, silver, nickel, and copper.

APPLICATIONS

Several surfaces have been studied with the STM. The arrangement of individual atoms on the metal surfaces of gold, platinum, nickel, and copper have all been accurately documented (Figure 7). The absorption and diffusion of different species such as oxygen and the epitaxial growth of gold on gold, silver on gold, and nickel on gold also have been examined in detail.

The surfaces of silicon have been studied more extensively than those of any other material. The surfaces are

Surface reconstruction

prepared by being heated in vacuum to temperatures so high that the atoms there rearrange their positions in a process called "surface reconstruction." The reconstruction of the silicon surface designated (111) has been studied in minute detail. Such a surface reconstructs into an intricate and complex pattern known as the "Takayanagi" 7×7 structure. The position, the chemical reactivity, and the electronic configuration of each atomic site on the 7×7 surface has been measured with the STM. The reconstruction of the silicon surface designated (100) is more simple. The surface atoms form pairs, or dimers, that fit into rows that extend across the entire silicon surface.

The initial stages in the formation of interfaces between silicon and metal layers have been the subject of numerous STM studies. The atomic structure of these modified surfaces has been catalogued for such metals as gallium, indium, aluminum, gold, and silver.

The internal structure and organized behaviour of molecules deposited on graphite and gold substrates are easily imaged in the STM. The study of alkane molecules and the molecules of liquid crystals constitutes much of the definitive work with the STM. Biological molecules are attracting attention, and definitive studies of these molecules should be forthcoming.

"Vacuum tunneling" of electrons from tip to sample can take place even though the environment in the region surrounding the tip is not a vacuum but is filled with molecules of gas or liquids. With a tip-sample spacing as small as five angstroms, there is little room for molecules—even though they may exist in the surrounding atmosphere. The STM can operate in ambient atmosphere as well as in high vacuum. Indeed, it has been operated in air, in water, in insulating fluids, and in the ionic solutions used in electrochemistry. It is much more convenient than ultrahigh-vacuum instruments. When a high-vacuum environment is employed, its purpose is not to improve the performance of the STM but rather to ensure the cleanliness of the sample surface.

The STM can be cooled to temperatures less than 4 K—the temperature of liquid helium. It can be heated above 500° C (973 K). The low temperature is used to investigate the properties of superconducting materials, while the high temperature is employed to study the rapid diffusion of atoms across the surface of metals and their corrosion.

The STM is used primarily for imaging, but there are many other modalities that have been explored. The strong electric field between tip and sample has been utilized to move atoms along the sample surface. It has been used to enhance the etching rates in various gases. In one instance, a voltage of four volts was applied; the field at the tip was strong enough to remove atoms from the tip and deposit them on the substrate. This procedure has been employed with a gold tip to fabricate small gold islands or clusters on the substrate with several hundred atoms of gold in each cluster. These so-called nanostructures are used to pattern the surface with a scale that is unprecedented. (C.F.Q.)

Development of the microscope

THE SIMPLE MICROSCOPE

Earliest microscopes

The earliest simple microscopes used drops of water captured in a small hole to function as a magnifying lens. It is not clear when crude glass lenses first began to be employed, but by the 17th century Antonie van Leeuwenhoek, a Dutch scientist, had developed techniques for making good-quality ground lenses for simple microscopes. These were limited in magnifying power and were used primarily for botanical studies.

THE COMPOUND MICROSCOPE

The compound microscope, using an objective and an eyepiece, was first described in the 16th century, but all drawings of the period indicate very impractical arrangements of lenses. The first useful compound microscope was constructed in the Netherlands sometime between 1590 and 1608. Three spectacle makers—Hans Jansen, his son Zacharias, and Hans Lippershey—have each received credit for the invention. This early microscope was limited by the use of very simple lenses, and the resolution was limited by blurring due to spherical aberration and chromatic aberration.

Further development of the compound microscope in the 17th and 18th centuries occurred primarily in England and Italy, albeit along slightly different paths. Many Italian instruments were designed for the examination of opaque objects by use of reflected light. The Italian microscope designer Eustachio Divini introduced the idea of using two plano-convex lenses to form an eyepiece that permitted some aberration correction. Many mechanical innovations, including equipping body tubes with screw-thread focusing mechanisms and using spring stages to hold specimen slides, were developed by the Italian microscopists.

In England the 17th-century scientist Robert Hooke introduced several techniques for improving the quality of microscopes. His instruments began a trend in England toward the development of elegant devices, incorporating many mechanical advances. English optics, however, continued to be constructed of simple lenses that suffered from spherical aberration and chromatic aberration. The spherical aberration could be limited somewhat by placing a stop (a disk with a small central aperture) behind the lens; but the chromatic aberration, which was believed to be intrinsic to refracting lenses, remained uncorrected until 1733, when Chester Moor Hall, an amateur optician, found by trial and error that combining a convex crown glass lens with a concave lens made of new lead-containing flint glass corrected the problem. While the original invention was intended for making achromatic telescope lenses, several workers recognized the application to microscopes, and in 1774 Benjamin Martin used a set of achromats for a microscope objective. This led to major improvements in the quality of microscope images and to many new designs for microscope objectives. As a result, by 1820 there were many types of new achromatic microscopes on the market.

Introduction of achromatic lenses

The appearance of new varieties of optical glasses encouraged continued development of the microscope in the 19th century, and considerable improvements were made in understanding the geometric optics of image formation. The English scientist Joseph Jackson Lister in 1830 published a work describing a theoretical approach to the complete design of microscope objectives. In 1834 George Biddell Airy, an English astronomer, determined that the resolving power in telescopes was limited by the finite wavelength of light due to diffraction. In 1873 Ernst Abbe related this concept to the ability of the microscope to resolve fine periodic structure in microscopic objects. Thus was born the modern theory of the microscope, which included the effects of light interference in determining the limit of resolution of the microscope. Abbe correctly related the limit of optical resolution to the wavelength of light and the numerical aperture of the objective, and he explained the relation between the type of light illuminating the object in the microscope and the appearance of the image. Abbe also invented the oil-immersion objective, in which the resolution was improved by immersion of the object in a medium with a high refractive index.

OTHER TYPES OF MICROSCOPES

Constant improvements in the optics and mechanical features of microscopes continued through the early 20th century. In 1938 Frits Zernike constructed the first phase-contrast microscope. In phase-contrast microscopy, the principles of diffraction image formation are used to convert minute changes in the optical path through an object into visible contrast in the image. Previously, the structure of many biological specimens could be revealed only if they were stained with a coloured dye to enhance the contrast in the image. With the phase-contrast microscope, the staining step could be eliminated. This concept was extended in many ways for use in industrial and scientific measurements.

In the search for higher resolution, light of ever shorter wavelength was used to illuminate the object. Ultraviolet microscopy was developed in the early 20th century by the German scientists August Köhler and Moritz von Rohr. The discovery of the wavelength of the electron and its dependence upon the energy of the electron beam

Electron microscopy

by Louis de Broglie in 1924 launched an interest in the use of electron beams in microscopes. Rapid development of such devices through the 1930s by the Russian-born American electronic engineer Vladimir Zworykin led to a good understanding of electron optics and the extension of resolution to the angstrom level.

Other types of microscopy were developed in the period from 1960 to 1970. The scanning electron microscope opened new areas of investigation in medical and physical sciences by permitting the examination of a wide variety of objects. The concept of scanning was also applied to optical microscopes, making resolution in depth as well as lateral dimensions possible.

By 1980, microscopy had been extended to employ almost any physical process that had a wavelength and could form an image, including high-energy particle beams with very short wavelengths. Acoustic microscopes using ultrasound as the imaging process were first suggested in 1936 and were finally developed into practical devices in 1970. These microscopes permit the examination of objects in a manner complementary to optical microscopy and provide additional information about the fundamental structure of the objects.

The ultimate microscopy, that of individual atoms, became possible in 1981 with the invention of the scanning tunneling microscope by Binnig and Rohrer (see above *Scanning tunneling microscopes*). In this type of microscope, the image is obtained by recording the electron current induced in an extremely fine tip as it is passed over a surface. The image is built up on a video display and enhanced by image processing to show details smaller than an atomic dimension. The instrument is mechanically simple but electronically sophisticated.

Electronics dominates new developments in all areas of microscopy. Image processing and enhancement of the visibility of low-contrast specimens by computers and digital displays is now commonplace. The extension of these techniques to the automatic recognition of certain structures in biological and physical objects is a matter of significant current development. (R.R.Sh.)

Ancient Middle Eastern Arts and Architecture

The ancient history and art of the Middle East were subjects on which Western scholars remained in almost total ignorance until the end of the 18th century. Certainly, the standing monuments of Egypt had been observed and described by travelers of earlier generations, but their history and significance were not understood until the discovery of the Rosetta Stone in 1799 and the subsequent decipherment of Egyptian hieroglyphs. Where other countries were concerned, some sort of historical outline could be reconstructed from the writings of the Greek historian Herodotus and the Old Testament, but spectacular architectural remains at sites such as a Persepolis, in Iran, or Boğazköy, in Turkey, had rarely been visited, much less recorded. As for portable antiquities, it was said that the total of those representing the ancient civilization of Mesopotamia could be contained in a box three feet square.

Archaeological excavation began in the 1840s and systematic recording of monuments at about the same time. It is well to remember that the extensive knowledge of ancient Middle Eastern art and architecture now accumulated depends almost exclusively on these two forms of activity. It is also necessary to bear in mind that the chronological sequence of archaeological discoveries made in past years has tended to be in inverse relationship to their actual antiquity. This may help to explain the frequent changes of criteria by which Middle Eastern works of art have been judged and the consequently unreliable character of early commentaries on them. By the mid-20th century, scholars were in a better position to assess the overall contribution of these countries to the evolution of world civilization and the formative beginnings of creative art. They were able not only to evaluate the importance of regional developments but also to comprehend the pattern of their diffusion and interrelation. The evidence on which such judgments must be based is, in fact, still no more than a chance residue—microscopically small—of the vast body of artifacts, works of art, and literature accumulated by the ancient peoples to be considered.

The countries of the Middle East occupy a unique position in the early history of art and architecture in that so many basic conceptions and formulas that in later ages were taken for granted had their genesis in this region. When, for instance, the early inhabitants of Mesopotamia erected monumental buildings, carved statues, or engraved stelae (stone slabs or pillars used for commemorative purposes), they were creating precedents of complete originality no less remarkable than their invention of writing or their mastery of primary elements in philosophy and science. It was the prodigy of their initiative in devising such forms of expression that, in the space of a few centuries, assured the transition from the pedestrian cultures of prehistory to what is now called civilization.

All this took place about the beginning of the 3rd millennium BC, but the artistic brilliance of that era should not obscure the more modest accomplishments by which it had been foreshadowed during the preceding millennia. For at least 40 centuries, families all over the Middle East had inhabited small farming settlements, combining agriculture with stockbreeding and occasional hunting. The forms of their buildings were utilitarian, and (with the exception of one precocious group, at Çatalhüyük, in Anatolia) their approaches to art were restricted to personal ornament and the decoration of pottery or domestic implements. Even in this limited sphere, their aptitude, in those days, for artistic expression, like their economy and social organization, varied little from one country to another. Each occasionally manifested a spasmodic impulse toward innovation, but ensuing developments usually proved ephemeral; in no single country can one detect any continuous thread of progressive invention before the late 4th millennium BC.

When the great awakening did take place, its effects were at first restricted to the river valleys of Egypt and Mesopotamia, where people would soon live in cities ruled by dynasties of kings. Each of these two great centres of civilization developed its own traditional forms of artistic expression, the evolution of which persisted almost without interruption until superseded by the classical culture of Greece. Elsewhere in the Middle East—in Persia, Anatolia, the Levant—the transformation took place more slowly. The divisive effects of regional geography inhibited cultural cohesion, and historical circumstances impeded its continuity. Some scholars have considered the ancient art of these secondary countries as largely derivative and "peripheral" to the mainstream of Middle Eastern accomplishment. More recent discoveries, however, have begun to show that, in each case, factors such as environment and national temperament combined to produce aspects of stylistic originality.

Mesopotamian arts and architecture

Location of Mesopotamia

The name Mesopotamia has been used with varying connotations by ancient writers. If, for convenience, it is to be considered synonymous with the modern state of Iraq, it can be seen in terms of two fairly well-defined provinces: a flat alluvial plain in the south and, in the north, the uplands through which the country's twin rivers flow in their middle courses. This geographic division of the area is reflected in the history of its cultural development from the earliest times.

The first traces of settled communities are found in the northern region and date from the mid-6th millennium BC, a period that archaeologists associate with the transition from a Neolithic to a Chalcolithic age. It is of some importance that this period also corresponds to the earliest use of painted ornament on pottery vessels, since the designs used for this purpose are the most reliable criteria by which ethnological groupings and migratory movements can be distinguished. Archaeologically, such groupings are, for the most part, arbitrarily named after the site at which traces of them were first found, and the same names are sometimes attributed to the prehistoric periods during which they were predominant. Hence, Hassuna, Hassuna-Sāmarrā', and Halaf in northern Iraq are the names given to the first three periods during which known early settlements were successively occupied by peoples whose relations were apparently with Syria and Anatolia. The designs on their pottery, sometimes in more than one colour, usually consist of zones filled with "geometric" ornament in patterns reminiscent of woven fabrics. These designs are often adapted to the shape of the vessels with creditable artifice. Only in Hassuna-Sāmarrā' pottery do devices occasionally appear that consist of animal, bird, or even human figures, ingeniously stylized and aesthetically attractive. Such motifs, however, appear to be adopted from contemporary Iranian ceramics. The only other notable art form popular at this time is that of hominoid figurines of stone or clay, associated with primitive religious cults; however, their formal idiosyncrasies vary greatly from group to group, and the meaning of their symbolism is unknown. Nor can they—or the pottery designs—be considered as ancestral to Mesopotamian art of historical times, the antecedents of which must be sought in southern Iraq.

Here, in the delta, the earliest phase of prehistory is associated with the name Ubaid I; and, since this phase has a parallel in Susiana, north of the Iranian frontier, the first settlers in both areas may have a common origin. Among these settlers, according to some scholars, was the germ of Sumerian genius, but this is not indisputably authenticated until the end of the 4th millennium. By 3100 BC, however, the presence of the Sumerians is finally proved by the invention of writing as a vehicle for their own language. From then onward, successive phases in the evolution of Sumerian art can satisfactorily be studied.

Three factors may be recognized as contributing to the character of Mesopotamian art and architecture. One is the sociopolitical organization of the Sumerian city-states and of the kingdoms and empires that succeeded them. From the earliest times, cities were fortified by and adorned with public buildings; irrigation systems were organized and jealously protected; armies were efficiently equipped and troops trained in concerted action; victories were celebrated and treaties ratified. Because interstate warfare or foreign conquests were primary preoccupations of Mesopotamian rulers, it is understandable that in most periods a certain class of artworks was dedicated simply to the glorification of their military prowess.

The role of religion

A second and even more important factor, however, is the major role played by organized religion in Mesopotamian affairs of state. Particularly in Sumerian times, the municipal and economic organization of a city was the responsibility of the temple, with its hierarchical priesthood in which was vested an authority almost equal to that of the ruler and his advisory council of elders. Accordingly, in the early days of Sumer and Babylonia, architectural attention was paid primarily to religious buildings, and all sculpture served religious purposes. The elaboration and adornment of palaces was an innovation of Assyrian times (see below *Assyrian period*).

The third factor that contributed to the character of Mesopotamian art is the influence of the natural environment. The practical limitations imposed upon both artist and architect by the geology and climate of southern Iraq are immediately apparent. Since no stone or wood was available in the alluvial plain, sculptors were dependent on scarce imported material or compelled to use such substitutes as terra-cotta (baked clay). Architecture also was profoundly affected, first, by the restriction of building material to brickwork and, second, by problems of roof construction, only partially solved by the contrivance of brick vaulting, in the 2nd millennium BC. For the Assyrians, in the north, good-quality stone was plentiful, but the cost of quarrying and transport, combined with an obstinate conservatism, caused it to be regarded as a luxury material and its use to be confined to sculptured ornament and conspicuous architectural features.

An equally apparent, if more abstract, association between Mesopotamian art and environment can be detected when the intellectual climate engendered by the latter is understood. In a country where summer and winter temperatures reach thermometric extremes, where agriculture depends exclusively on the artificial distribution of river water and contends precariously with the timing of seasonal floods, where the herdsman is afflicted by the depredations of wild beasts and the cultivator by the menace of poisonous insects—in such a country, the inhabitants must have felt themselves in perpetual conflict with hostile and potentially destructive elements in nature. All this confrontation and frustration is reflected in the melancholy undertones of their religious beliefs, particularly those of the Sumerians, for whom success and prosperity came to be identified with the principle of fertility and thus could only be attained by the appeasement of capricious deities. Such convictions are inherent in the fabric of their complicated mythology, which lends itself easily to expression in pictorial form and provides the predominant subject of almost all Sumerian art. Furthermore, since their mythical traditions and religious beliefs persisted for many centuries after the demise of the Sumerians themselves, they provided the basic imagery of almost all Mesopotamian art.

SUMERIAN PERIOD

Architecture. The beginnings of monumental architecture in Mesopotamia are usually considered to have been contemporary with the founding of the Sumerian cities and the invention of writing, in about 3100 BC. Conscious attempts at architectural design during this so-called Protoliterate period (*c.* 3400–*c.* 2900 BC) are recognizable in the construction of religious buildings. There is, however, one temple, at Abū Shahrayn (ancient Eridu), that is no more than a final rebuilding of a shrine the original foundation of which dates back to the beginning of the 4th millennium; the continuity of design has been thought by some to confirm the presence of the Sumerians throughout the temple's history. Already, in the Ubaid period (*c.* 5200–*c.* 3500 BC), this temple anticipated most of the architectural characteristics of the typical Protoliterate Sumerian platform temple. It is built of mud brick on a raised plinth (platform base) of the same material, and its walls are ornamented on their outside surfaces with alternating buttresses (supports) and recesses. Tripartite in form, its long central sanctuary is flanked on two sides by subsidiary chambers, provided with an altar at one end and a freestanding offering table at the other. Typical temples of the Protoliterate period—both the platform type and the type built at ground level—are, however, much more elaborate both in planning and ornament. Interior wall ornament often consists of a patterned mosaic of terra-cotta cones sunk into the wall, their exposed ends dipped in bright colours or sheathed in bronze. An open hall at the Sumerian city of Uruk (biblical Erech; modern Tall al-Warkā', Iraq) contains freestanding and attached brick columns that have been brilliantly decorated in this way. Alternatively, the internal-wall faces of a platform temple could be ornamented with mural paintings depicting mythical scenes, such as at 'Uqair.

The two forms of temple—the platform variety and that built at ground level—persisted throughout the early dynasties of Sumerian history (*c.* 2900–*c.* 2400 BC). It is known that two of the platform temples originally stood within walled enclosures, oval in shape and containing, in addition to the temple, accommodation for priests. But the raised shrines themselves are lost, and their appearance can be judged only from facade ornaments discovered at Tall al-'Ubayd (Figure 1). These devices, which were intended to relieve the monotony of sun-dried brick or mud plaster, include a huge copper-sheathed lintel, with animal figures modeled partly in the round; wooden columns sheathed in a patterned mosaic of coloured stone or shell; and bands of copper-sheathed bulls and lions, modeled in relief but with projecting heads. The planning of ground-level temples continued to elaborate on a single theme: a rectangular sanctuary, entered on the cross axis, with altar, offering table, and pedestals for votive statuary (statues used for vicarious worship or intercession).

Considerably less is known about palaces or other secular buildings at this time. Circular brick columns and austerely simplified facades have been found at Kish (modern Tall al-Uhaimer, Iraq). Flat roofs, supported on palm trunks, must be assumed, although some knowledge of corbeled vaulting (a technique of spanning an opening like an arch by having successive cones of masonry project farther inward as they rise on each side off the gap)—and even of dome construction—is suggested by tombs at Ur, where a little stone was available.

The corbel vault

Sculpture. Practically all Sumerian sculpture served as adornment or ritual equipment for the temples. No clearly identifiable cult statues of gods or goddesses have yet been found. Many of the extant figures in stone are votive statues, as indicated by the phrases used in the inscriptions that they often bear: "It offers prayers," or "Statue, say to my king (god). . . ." Male statues stand or sit with hands clasped in an attitude of prayer. They are often naked above the waist and wear a woolen skirt curiously woven in a pattern that suggests overlapping petals (commonly described by the Greek word *kaunakes,* meaning "thick cloak"). A togalike garment sometimes covers one shoulder. Men generally wear long hair and a heavy beard, both often trimmed in corrugations and painted black. The eyes and eyebrows are emphasized with coloured inlay. The female coiffure varies considerably but predominantly consists of a heavy coil arranged vertically from ear to ear and a chignon behind. The hair is sometimes concealed by a headdress of folded linen. Ritual nakedness is confined to priests.

It has been thought that the rarity of stone in Mesopotamia contributed to the primary stylistic distinction between Sumerian and Egyptian sculpture. The Egyptians quarried their own stone in prismatic blocks, and one can see that, even in their freestanding statues, strength of design is attained by the retention of geometric unity. By contrast, in Sumer, stone must have been imported from remote sources, often in the form of miscellaneous boulders, the amorphous character of which seems to have been retained by the statues into which they were transformed.

Beyond this general characteristic of Sumerian sculpture, two successive styles have been distinguished in the middle and late subdivisions of the Early Dynastic period. One very notable group of figures, from Tall al-Asmar, Iraq (ancient Eshnunna), dating from the first of these phases, shows a geometric simplification of forms that, to modern taste, is ingenious and aesthetically acceptable (Figure 2). Statues characteristic of the second phase, on the other hand, though technically more competently carved, show aspirations to naturalism that are sometimes overly ambitious. In this second style, some scholars see evidence of occasional attempts at portraiture. Yet, in spite of minor variations, all these figures adhere to the single formula of presenting the conventional characteristics of Sumerian physiognomy. Their provenance is not confined to the Sumerian cities in the south. An important group of statues is derived from the ancient capital of Mari, on the middle Euphrates, where the population is known to have been racially different from the Sumerians. In the Mari statues there also appears to have been no deviation from the sculptural formula; they are distinguished only by technical peculiarities in the carving.

Deprived of stone, Sumerian sculptors exploited alternative materials. Fine examples of metal casting have been found, some of them suggesting knowledge of the cire perdue (lost-wax) process, and copper statues more than half life-size are known to have existed. In metalwork, however, the ingenuity of Sumerian artists is perhaps best judged from their contrivance of composite figures. The earliest and one of the finest examples of such figures—and of Sumerian sculpture as a whole—comes from a Protoliterate level of excavation at Tall al-Warkā'. It is the limestone face of a life-size statue (Iraqi Museum, Bagh-

dad), the remainder of which must have been composed of other materials; the method of attachment is visible on the surviving face. Devices of this sort were brought to perfection by craftsmen of the Early Dynastic period, the finest examples of whose work are to be seen among the treasures from the royal tombs at Ur: a bull's head decorating a harp, composed of wood or bitumen covered with gold and wearing a lapis lazuli beard (British Museum); a rampant he-goat in gold and lapis, supported by a golden tree (Figure 3; University Museum, Philadelphia); the composite headdresses of court ladies (British Museum, Iraqi Museum, and University Museum); or, more simply, the miniature figure of a wild ass, cast in electrum (a natural yellow alloy of gold and silver) and mounted on a bronze rein ring (British Museum). The inlay and enrichment of wooden objects reaches its peak in this period, as may be seen in the so-called standard or double-sided panel from Ur (British Museum), on which elaborate scenes of peace and war are depicted in a delicate inlay of shell and semiprecious stones (Figure 4). The refinement of craftsmanship in metal is also apparent in the famous wig-helmet of gold (Iraqi Museum), belonging to a Sumerian prince, and in weapons, implements, and utensils.

Relief carving in stone was a medium of expression popular with the Sumerians and first appears in a rather crude form in Protoliterate times. In the final phase of the Early Dynastic period, its style became conventional. The most common form of relief sculpture was that of stone plaques, 1 foot (30 centimetres) or more square, pierced in the centre for attachment to the walls of a temple, with scenes depicted in several registers (horizontal rows). The subjects usually seem to be commemorative of specific events, such as feasts or building activities, but representation is highly standardized, so that almost identical plaques have been found at sites as much as 500 miles (800 kilometres) apart. Fragments of more ambitious commemorative stelae have also been recovered; the Stele of Vultures (Louvre Museum) from Telloh, Iraq (ancient Lagash), is one example. Although it commemorates a military victory, it has a religious content. The most important figure is that of a patron deity, emphasized by its size, rather than that of the king. The formal massing of figures suggests the beginnings of mastery in design, and a formula has been devised for mutiplying identical figures, such as chariot horses.

Cylinder seals

In a somewhat different category are the cylinder seals so widely utilized at this time. Used for the same purposes as the more familiar stamp seal and likewise engraved in negative (intaglio), the cylinder-shaped seal was rolled over wet clay on which it left an impression in relief. Delicately carved with miniature designs on a variety of stones or shell, cylinder seals rank as one of the higher forms of Sumerian art.

Prominent among their subjects is the complicated imagery of Sumerian mythology and religious ritual. Still only partially understood, their skillful adaptation to linear designs can at least be easily appreciated. Some of the finest cylinder seals date from the Protoliterate period (Figure 5, top). After a slight deterioration in the first Early Dynastic period, when brocade patterns or files of running animals were preferred (Figure 5, bottom), mythical scenes returned. Conflicts are depicted between wild beasts and protecting demigods or hybrid figures, associated by some scholars with the Sumerian epic of Gilgamesh. The

monotony of animated motifs is occasionally relieved by the introduction of an inscription.

AKKADIAN PERIOD

Sargon of Akkad's (reigned *c.* 2334–*c.* 2279 BC) unification of the Sumerian city-states and creation of a first Mesopotamian empire profoundly affected the art of his people, as well as their language and political thought. The increasingly large proportion of Semitic elements in the population were in the ascendancy, and their personal loyalty to Sargon and his successors replaced the regional patriotism of the old cities. The new conception of kingship thus engendered is reflected in artworks of secular grandeur, unprecedented in the god-fearing world of the Sumerians.

Architecture. One would indeed expect a similar change to be apparent in the character of contemporary architecture, and the fact that this is not so may be due to the paucity of excavated examples. It is known that the Sargonid dynasty had a hand in the reconstruction and extension of many Sumerian temples (for example, at Nippur) and that they built palaces with practical amenities (Tall al-Asmar) and powerful fortresses on their lines of imperial communication (Tell Brak, or Tall Bīrāk at-Taḥtānī, Syria). The ruins of their buildings, however, are insufficient to suggest either changes in architectural style or structural innovations.

Sculpture. Two notable heads of Akkadian statues have survived: one in bronze and the other of stone. The bronze head of a king (Figure 6), wearing the wig-helmet of the old Sumerian rulers, is probably Sargon himself (Iraqi Museum). Though lacking its inlaid eyes and slightly damaged elsewhere, this head is rightly considered one of the great masterpieces of ancient art. The Akkadian head (Iraqi Museum) in stone, from Bismāyah, Iraq (ancient Adab), suggests that portraiture in materials other than bronze had also progressed.

Relief sculpture

Where relief sculpture is concerned, an even greater accomplishment is evident in the famous Naram-Sin (Sargon's grandson) stela (Louvre), on which a pattern of figures is ingeniously designed to express the abstract idea of conquest (Figure 7). Other stelae and the rock reliefs (which by their geographic situation bear witness to the extent of Akkadian conquest) show the carving of the period to be in the hands of less competent artists. Yet two striking fragments in the Iraqi Museum, which were found in the region of An-Nāṣiriyah, Iraq, once more provide evidence of the improvement in design and craftsmanship that had taken place since the days of the Sumerian dynasties. One of the fragments shows a procession of naked war prisoners, in which the anatomic details are well observed but skillfully subordinated to the rhythmical pattern required by the subject.

Some compensation for the paucity of surviving Akkadian sculptures is to be found in the varied and plentiful repertoire of contemporary cylinder seals. The Akkadian seal cutter's craft reached a standard of perfection virtually unrivaled in later times. Where the aim of his Sumerian predecessor had been to produce an uninterrupted, closely woven design, the Akkadian seal cutter's own preference was for clarity in the arrangement of a number of carefully spaced figures.

The Akkadian dynasty ended in disaster when the river valley was overrun by the mountain tribes of northern Iran. Of all the Mesopotamian cities, only Lagash appears somehow to have remained aloof from the conflict and, under its famous governor Gudea, to have successfully maintained the continuity of the Mesopotamian cultural tradition. In particular, the sculpture dating from this short interregnum (*c.* 2100 BC) seems to represent some sort of posthumous flowering of Sumerian genius (Figure 8, left). The well-known group of statues of the governor and other notables, discovered at the end of the 19th century, long remained the only criterion by which Sumerian art could be judged, and examples in the Louvre and British Museum are still greatly admired. The hard stone, usually diorite, is carved with obvious mastery and brought to a fine finish. Details are cleverly stylized, but the musculature is carefully studied, and the high quality of the carving makes the use of inlay unnecessary. The powerful impression of serene authority that these statues convey justifies their inclusion among the finest products of ancient Middle Eastern art.

SUMERIAN REVIVAL

The short historical interlude represented by the Gudea sculptures was followed by a full-scale Sumerian revival, one that lasted for four centuries and culminated in the unification of the whole country under the rule of Ḥammurabi in the early 18th century BC. Dominated first by the powerful 3rd dynasty of Ur and later by the rival states of Isin and Larsa, the peoples of ancient Sumer reverted to their pre-Akkadian cultural traditions. On their northern frontiers the Sumerian culture was extended to increasingly prosperous younger city-states, such as Mari, Ashur, and Eshnunna, located on the middle courses of the Tigris and Euphrates rivers.

In all these cities, both old and new, the period is

Advances in architecture

notable for the advances made in architectural planning and the large-scale reconstruction of ancient buildings. In the south the early promise of Sumerian architecture had reached fulfillment, first in the great ziggurats, or stepped towers, rising above their walled temple enclosures at such cities as Ur, Eridu, Kish, Uruk, and Nippur. These huge structures, with their summit sanctuaries, the appearance of which can only be guessed at, were faced with kiln-baked brick, paneled and recessed to break the monotony of their colossal facades, and were strengthened with bitumen and reinforced with twisted reeds. Tradition associates the ziggurat at Borsippa (modern Birs Nimrūd, Iraq), near Babylon, with the biblical Tower of Babel. Surrounding temples at ground level were also much elaborated. The basic plan consisted of a tower-flanked entry, central court, antecella (or inner vestibule), and sanctuary, all arranged on a single axis; however, in the larger examples this plan could be expanded by means of communicating courtyards. Facades were often elaborately decorated with panels of pilasters (recessed columns) or engaged half columns, skillfully modeled in mud-brick. At Ur, kiln-baked brick was again used to construct corbeled vaulting over huge subterranean tomb chambers, entered through funerary chapels at ground level. Here, too, there are temple-palaces, the complicated planning of which is seldom self-explanatory.

Better examples of residential palaces are found in the newer cities of the north, especially Mari, where a vast building with more than 200 rooms was constructed by a ruler named Zimrilim (*c.* 1779–*c.* 1761). In this palace is found the standard reception unit common to all Babylonian palaces: a rectangular throne room that is entered by a central doorway from a square court of honour; and behind it a great hall, in this case apparently serving some religious purpose. There also is an immense outer courtyard, overlooked by a raised audience chamber, and, in the remotest corner of the building, a heavily protected residential suite. In some of the main chambers, mural paintings depicting ritual scenes and processions have been preserved.

The sculpture of this period is perhaps best represented by some well-preserved statues, also from the Mari palace (Figure 8, right). Their style owes much to the preceding Gudea period in the south, but they lack the authentic stamp of Sumerian design and workmanship. The same may be said of the few surviving pieces from the reign of Hammurabi (*c.* 1792–*c.* 1750), whose conquests ended the epoch—for example, the relief at the head of the stela in the Louvre on which his law code is inscribed.

ASSYRIAN PERIOD

Architecture. Ashur, a small Sumerian city-state on the middle Euphrates, began to gain political prominence during the pre-Hammurabi period discussed above. During the latter half of the 2nd millennium BC, the frontiers of Assyria were extended to include the greater part of northern Mesopotamia, and, in the city of Ashur itself, excavations have revealed the fortifications and public buildings constructed or rebuilt by a long line of Assyrian kings. The character of these buildings suggests a logical development of Old Babylonian architecture. There are certain innovations, such as the incorporation of small twin ziggurats in the design of a single temple, while in the temples themselves the sanctuary was lengthened on its main axis, and the altar itself was withdrawn into a deep recess. For the rest, the absence of ornament and the multiplication of buttressed facades with crenellated battlements tend to monotony.

Other forms of art are inconspicuous, except perhaps the contemporary cylinder seals, which show an interest in animal forms that anticipates the relief carving of a later phase of Mesopotamian civilization. Sometimes known as Middle Assyrian, this later period corresponds to the occupation of southern Mesopotamia by the Kassites and to the Mitanni kingdom on the north Syrian frontier, neither of which contributed greatly to the total development of ancient Middle Eastern art.

The fuller manifestation of Assyrian art and architecture is not seen until the 9th century BC, when Ashurnasirpal II transferred his capital from Ashur to Nimrūd (ancient

Assyrian palaces

Kalakh; biblical Calah). The rise of Assyria to imperial power during this century and those that followed gave increased vitality to Mesopotamian architecture. The vast palaces brought to light in the 19th century emphasize the new interest in secular building and reflect the ostentatious grandeur of the Assyrian kings. Like the temples of earlier days, they are usually artificially raised up on a platform level with the tops of the city walls, astride which they often stand. Their gates are flanked by colossal portal sculptures in stone, and their internal chambers are decorated with pictorial reliefs carved on upright stone slabs, or orthostats. In addition to the 9th-century structure at Nimrūd, palace platforms have been exposed at Khorsabad (ancient Dur Sharrukin), where Sargon II established a short-lived capital of his own in the late 8th century BC, and at Nineveh, which was rebuilt in the 7th century, first by Sargon's son Sennacherib and then by his grandson Esarhaddon. On the platforms at both Nineveh and Nimrūd, palaces and temples were multiplied by successive kings.

The platform at Khorsabad is occupied by a single royal residence, associated with a group of three modest temples and a small ziggurat. Similar buildings occupy a walled citadel at the foot of the platform, thus completing a complex that has been thoroughly excavated and provides the most informative example of typical contemporary architecture (Figure 9). Sargon's palace itself, like that of Zimrilim 1,000 years earlier (see above *Sumerian revival*), is planned, first, around a gigantic open courtyard accessible to the public and, second, around an inner court of honour. From the latter the great throne room is entered through triple doorways, around which, in common with the main outer entrance to the palace, are concentrated a fine array of portal sculptures. The throne room has an adjoining stairway leading to a flat roof and a suite of living apartments behind. Other state rooms, conventionally planned, open onto an open terrace facing the mountains beyond. All the principal internal chambers are decorated with reliefs, except for the throne room itself, where mural painting seems to have been preferred. The individual purpose and function of the innumerable administrative and domestic offices must remain largely conjectural.

Sculpture. Any history of late Assyrian art must be concerned primarily with relief carving. Some statues in the round have been found, but the comparative ineptitude of the majority of them suggests that this form of expression did not come naturally to Assyrian sculptors. Portal sculptures, which many would consider the most characteristic Assyrian art form, are not statues in the round but "double-aspect" reliefs (that is, they are meant to be seen from either the front or the side), apparently derived from a Hittite invention of the 14th century BC. These impressive guardian figures—usually human-headed bulls or lions—decorate the arched gateways and are sometimes supplemented by others set at right angles on the adjoining facades, their heads facing sideways. Each is composed from a single block of stone weighing up to 30 tons, roughly shaped in the quarry and then carved in situ.

Orthostat reliefs

Less spectacular orthostat reliefs form a continuous frieze of ornament around the bases of interior wall faces. There is evidence that they were placed in position before the walls that they decorate had been completed. Their carving in situ could thus be executed in full daylight. This form of architectural ornament dates from the first quarter of the 9th century BC and seems to have been a genuine Assyrian innovation. The earliest slabs, from the 9th-century palaces of Ashurnasirpal II and his son Shalmaneser III at Nimrūd, are about seven feet (two metres) high, with the design arranged in two superimposed registers separated by a band of cuneiform inscription. In those from later buildings, such as Sargon II's palace at Khorsabad, the individual sculptured figures reach a height of nine feet.

The subjects of the designs on these reliefs are rarely related in any way to religion. Superstitious symbols do occasionally appear in the form of benevolent winged beings, or genies, but the primary purpose of the picture is the glorification of the king himself, either by scenes of ceremonial homage or by extended pictorial narratives of his achievements. The most popular theme, giving rise to numerous variations, involves detailed scenes of military conquest and the ruthless suppression of revolt. These are often arranged episodically to represent successive events in the progress of a single campaign: the Assyrian army prepares for war; led by the king, it crosses difficult country on the way to attack a walled city; the city is taken, burnt, and demolished; the enemy leaders are punished with conspicuous brutality; and, finally, the victory is celebrated. Scenes such as these are distinguished above all by their stylistic vitality and fanciful detail. Animals as well as men are carefully observed and beautifully drawn. The principles of perspective as later defined by the Greeks are unknown, but attention is given to the relationship of figures in space and to devices for suggesting comparative distance.

At Khorsabad, late in the 8th century BC, some notable stylistic changes are perceptible. The lively carving of narrative and historical subjects has been replaced by more tedious symbols of pomp and ceremony. In keeping with

the winged bulls and genies of the portal sculptures, stiffly arranged files of courtiers, officials, and servants stand immobilized in the routine of ceremonial homage. The monotony of the figures is occasionally relieved by the sparing use of coloured pigment on the stone.

In the 7th-century palaces of Sennacherib and Ashurbanipal at Nineveh, the reliefs suggest a reaction in favour of narrative and violent activity. The slabs are covered to their full height by complicated battle scenes in which the progress of the fighting is suggested by episodic repetition. Types of landscape are depicted schematically, and significant episodes or individuals are identified by a short inscription, without impairing the overall rhythm of the design.

Hunting scenes

In the intervals between their military campaigns, Assyrian kings appear to have been much preoccupied with hunting, and scenes from the chase provided an alternative subject for the reliefs. Lions hunted with spears from a light chariot and herds of wild asses (onagers) or gazelles are subjects that stimulated the imagination and sensibility of the Assyrian artist (Figure 10).

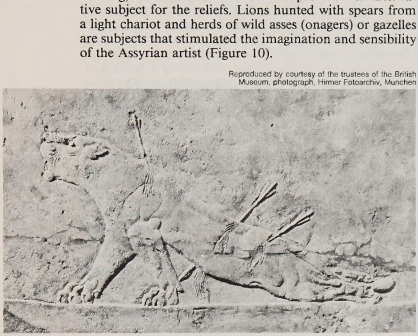

Figure 10: "Dying Lioness," detail of an alabaster mural relief from the North Palace of Ashurbanipal, Nineveh, Assyrian period, *c.* 650 BC. In the British Museum.

A contrast to these descriptive carvings is provided by the formal monumentality of the Assyrian rock reliefs, secular or religious devices carved on vertical rock faces in localities such as Bavian and Maltai to commemorate historical events that took place there.

The Assyrian talent for relief ornament was not confined to sculpture in stone. First seen during the reign of Shalmaneser III (858–824 BC) are striking examples of relief modeling in bronze. The huge wooden gates of a minor palace at Imgur-Enlil (Balawat), near Nimrūd, were decorated with horizontal bands of metal, 11 inches (28 centimetres) high, each modeled by a repoussé process (relief hammered out from behind), with a double register of narrative scenes. Their subjects are much the same as the stone reliefs, but even greater ingenuity has been used in adapting the designs to so confined a space.

Relief modeling in bronze

Painting and decorative arts. When greater economy of labour and material was necessary, mural paintings were substituted for slab reliefs. At the time of Tiglath-pileser III (744–727 BC), a country palace at Til Barsip (modern Tall al-Ahmar) was decorated in this way, with the conventional motifs of relief designs rather clumsily adapted to this very different medium. A few years later, such paintings were extensively used to decorate both wall faces and ceilings in Sargon II's palace buildings at Khorsabad. One magnificent panel of formalized ornament has been reconstructed. It is painted in primary colours on a white ground.

There is evidence that the Assyrian palaces were well equipped with furniture. The wooden components have perished, but the ivory ornaments with which the furniture was enriched have survived in great quantities. Of these "Assyrian ivories"—relief panels, inlays, and other forms of ornament—only a small proportion can be attributed to indigenous workmanship. The remainder represent either loot from the cities of Syria and Phoenicia or the work of craftsmen imported from those regions. The carving is often technically superb, and the enrichment of the ivory with gold, semiprecious stones, or coloured paste by cloisonné or champlevé processes (whereby the applied decoration is outlined by raised metal strips or fills depressed areas of the surface that have been cut out to receive it) gives increased elegance. The designs, however, are for the most part a pastiche of misunderstood Egyptian symbolism and are often less attractive than the purely Assyrian devices.

Assyrian ivories

NEO-BABYLONIAN PERIOD

During the half century following the fall of Nineveh, in 612 BC, there was a final flowering of Mesopotamian culture in southern Iraq under the last dynasty of Babylonian kings. During the reigns of Nabopolassar (625–605 BC) and his son Nebuchadrezzar II (604–562 BC), there was widespread building activity. Temples and ziggurats were repaired or rebuilt in almost all the old dynastic cities, while Babylon itself was enormously enlarged and surrounded by a double enceinte, or line of fortification, consisting of towered and moated fortress walls. Inside the city the most grandiose effect was obtained by the disposal of public buildings along a wide processional way, leading through the centre of the town to the temple and ziggurat of its patron god, Marduk. Where the street passed through the inner-city wall, the facades of the famous Ishtar Gate (Pergamon Museum, Berlin) and those facing the adjoining street were ornamented in brightly glazed brickwork, with huge figures of bulls, lions, and dragons modeled in relief. This form of decoration—a costly process, since each of the bricks composing the figures had to be separately cast—provided a solution for the problem of embellishing mud-brick facades. It appears again in the court of honour of Nebuchadrezzar's palace, using a more sophisticated design that suggests familiarity with Greek ornament. For the rest, there are few innovations in the planning of either palaces or temples during the Neo-Babylonian period. Also (strangely enough, in view of the prolonged excavations that took place at this site), examples of contemporary art are limited almost exclusively to cylinder seals and terra-cotta figurines of unpretentious design.

Syro-Palestinian arts and architecture

The countries bordering the Mediterranean between the Sinai Peninsula and the Nur Dağları (Amanus Mountains), to which the names Palestine and Syria are often loosely applied, had in fact no geographic integrity or clear historical definition. The interior of Syria and its extension beyond the Euphrates have in the past always been separated ethnographically, and sometimes politically, from the coastal cities of the Levant, the associations of which were with Cilicia and the trade routes of Palestine. In early historical times both Syria and Palestine, however, were continuously dominated by one or other of the great imperial powers—Egyptian, Mesopotamian, or Hittite. This situation was in no way conducive to the coherent development of indigenous culture; consequently, the individual contribution of these countries to the total accomplishment of ancient Middle Eastern art is of secondary importance.

An exception to this generalization must be made where prehistory is concerned, however. An archaeological sounding at Jericho, which carried back the history of settled communities far beyond the earliest finds made in the Tigris valley, uncovered a small, symmetrically planned religious building (dating from approximately 7000 BC); this should perhaps be regarded as the earliest attempt at formal architecture. In a setting only a century or so later, a strange collection of human heads was found, their features competently modeled in plaster, sometimes over the bone of actual skulls.

Jericho

Early in the 2nd millennium BC, the Levant and its coastal cities became a dependency of Egypt. Local rulers imported Egyptian works of art, which afforded some stimulation to regional craftsmanship. The tombs of the

rulers—at Byblos, for instance—were furnished with objects of fine craftsmanship in gold, ivory, ebony, and obsidian. The objects that were made locally can easily be distinguished from those imported from Egypt by the comparative ineptitude of their ornament. Egyptian motifs were generally adopted as elements in decorative design, but they were copied without precision and without regard for their meaning; the results, therefore, were of very uneven quality. The aesthetic failings of partly or wholly derivative ornamental styles characterized Levantine art for many centuries to come.

More obvious signs of regional individuality are apparent in the development of Syrian architecture at this period. It is perhaps best seen in the smaller cities of the interior, which were less subject to Egyptian influence. Two palaces at Alalakh (modern Tell Açana, Tur.), in the plain of Antioch, built, respectively, in the 15th and 13th centuries BC, show some characteristically Syrian features. Wooden-pillared porticoes at the entry to reception suites mark the development of a standard palace unit, known as a *bit hilani*, generally adopted some centuries later by the Syro-Hittites (see below *Anatolian arts and architecture: Hittite period*). Basalt orthostats, as yet unsculptured, anticipated those of the Neo-Assyrian palaces; and mural paintings, like those at Mari, decorated the chambers of an upper story in the Cretan manner. The earlier palace produced a single stone head that illustrates the contemporary Syrian sculpture style at its best. The remaining examples are crude.

During the early centuries of the 1st millennium BC, a strip of the Levant coast, from Ṭarṭūs (Syria) to somewhere south of Mount Carmel, became the homeland of a Canaanite people known as Phoenicians. As a result of archaeological excavations, something is known of their architecture as well as that of the contemporary Israelites in Palestine. Much information has been obtained about their walled cities and the development of their fortifications from the 18th century BC onward. It appears that by the time of King Solomon, in the 10th century BC, such military architecture had been standardized, for at three cities—Hazor, Megiddo, and Gezer—walls and gates alike are almost identical. Walls are of the casemate type (parallel walls with a space between) with internal chambers, and gateways are elaborate, with flanking towers and an approach through several transverse chambers. In the 9th century BC the invention of a more effective battering ram necessitated replacement of casemate walls by more solid structures.

Canaanite temples

The rather scanty remains of Canaanite temples have also been found at Hazor and elsewhere. They consisted of a courtyard, main hall, and sanctuary, all on a single axis, with occasional side chambers. The Hazor building showed a feature corresponding to the biblical description of the "brazen pillars" on either side of the central doorway of Solomon's Temple, which had been built by Phoenician craftsmen in the 10th century BC.

Two forms of Phoenician and Syrian craftsmanship take a high place in the repertoire of ancient Middle Eastern art: the carving and decoration of ivory, and the repoussé ornament of ceremonial bowls and other bronze objects. Some of the finest examples in both categories are to be found among the vast assemblage of material imported or appropriated by the Late Assyrian kings and found in their palaces, particularly at Nimrūd (Figure 11). Ivory carving has a long history in Syria and Palestine, as is shown by the well-known ivories from Megiddo, some of which are dated as early as the 14th century BC. So much study has been devoted to their design, especially to its non-Egyptian content and the original contribution of regional craftsmanship, that some scholars think it possible to distinguish purely Syrian designs from those of the Phoenician workshops.

Pre-Islāmic Arabian arts and architecture

The pre-Islāmic history of the great Arabian subcontinent is primarily that of a nomadic people. By the second half of the 20th century, traces of their art and architecture had been found only in the long-settled agrarian provinces of the south and the maritime trading centres facing the Arabian Sea. For the most part, these sites fall within the frontiers of the state known until 1990 as Yemen (Aden). In ancient times the prosperity of these provinces, with their harbour towns and caravan routes, depended entirely upon trade. Merchandise from Africa, India, and the Persian Gulf, together with frankincense and myrrh (for which Arabia was famous), were carried northward to Egypt and the Mediterranean, greatly enriching the cities and tribes through whose territory they passed. The history of the several kingdoms into which Arabia was divided—Saba' (Sheba), Qatabān, Ḥimyar, and others—is now known, and their cities, long inaccessible to archaeologists, are being systematically explored.

Influences on early Arabian art

It is not surprising that the style and character of both architecture and sculpture suggest a complicated synthesis of influences, first from Egypt or Mesopotamia and later from the classical culture of the Mediterranean. In public buildings—predominantly temples dedicated to deities of an Arabian pantheon—there is a long-standing tradition of fine ashlar masonry (of hewn or squared stone) and sculptured ornament. Sculpture is also represented by a striking variety of carved memorial stelae and freestanding votive statues, often carved in alabaster. These are notable for their crude but distinctive style of portraiture or symbolism. In sculptured friezes, some Arabian motifs are recognizable—for instance, the alternation between bucrania (ox heads adorned with ribbons or garlands) and ibex (wild goat) heads.

Anatolian arts and architecture

Anatolia is the name that is currently applied to the whole Asian territory of modern Turkey. Its western half is a broad peninsula connecting the continent of Asia with Europe. Because the country lacks geographic unity, its component regions being widely differentiated in climate and economy, early students of antiquity doubted the probability of its ever having acquired an overall cultural identity and considered its contributions to ancient art to have been provincial and intermittent. Archaeological research in more recent years, however, revealed in Anatolia a deep-seated aboriginal culture productive of ideas that are reflected in the art of the peninsula throughout its history.

Written history in Anatolia commences with the introduction of cuneiform writing (composed of wedge-shaped characters) by Assyrian merchants resident at Kanesh (Kültepe) and elsewhere in the 19th and 18th centuries BC. A conventional terminology is used in reference to the previous ages, knowledge of which is entirely dependent

on the results of archaeological excavations. The earliest of these periods, the chronology of which is still imprecisely defined, are the Neolithic and the Chalcolithic. An Early Bronze Age takes up the greater part of the 3rd millennium BC. During the Middle Bronze Age the central Anatolian principalities with whom the Assyrian merchants were in contact were amalgamated in the Hittite old kingdom (*c.* 1700–*c.* 1500 BC), and in the Late Bronze Age they made up the homeland of the Hittite empire (*c.* 1400–*c.* 1190 BC). The seven centuries that followed are loosely referred to as the Iron Age.

PRE-HITTITE PERIOD

Neolithic and Chalcolithic periods. Anatolian excavations have done much to illuminate the genesis of visual arts in the earliest settled communities. In a Neolithic setting, at Çatalhüyük in the Konya plain, a township covering more than 15 acres (6 hectares) and dating from the 7th millennium BC was found. The houses, already built of sun-dried brick, were contiguous, each having several rectangular rooms similarly planned and accessible only by a wooden ladder from a flat roof. These interconnected roofs provided space for the communal life of the inhabitants. Religious shrines were elaborately ornamented with animal heads or horns, either real or imitated in plaster. Walls were decorated with coloured murals, repeatedly repainted after replastering. The subjects of the paintings were ritual hunting scenes or obscure occult imagery, both themes recalling those of Paleolithic cave paintings. Sculpture in bone or stone was fashioned with remarkable skill, either as ornament or as cult effigy.

Hacılar

At Hacılar, a Chalcolithic site near Burdur, Tur., village houses were entered at ground level; their standard plan shows the first evidence of conscious architectural symmetry. Much in evidence among the contents of these houses is pottery painted with extremely decorative designs. The same ornament was applied to anthropomorphic jars and stylized human idols found in graves. A higher standard of modeling, however, was attained in unpainted clay figurines—steatopygous females, some seated or reclining, others holding a child or tame animal.

At Hacılar some provision was made for communal defense by the strengthening of contiguous buildings on the periphery of the settlement. In a 5th-millennium level at Mersin, in Cilicia, there is a purposefully planned military fortress, with slit windows in its protective wall, a towered gateway, and standardized accommodation for the garrison.

Early Bronze Age. In the Early Bronze Age the further development of military architecture is best illustrated at Troy, where parts of a fortress were uncovered. The most convincingly reconstructed plan dates from the second phase of the Early Bronze Age (*c.* 2700–*c.* 2500 BC). It shows a polygonal enclosure, hardly 300 feet in diameter, surrounded by heavy mud-brick walls on a stone substructure. There is a single gateway, with strongly built flanking towers and gate chambers, guarding the approach through a narrow sloping corridor. Most prominent within the enclosure is a large public building thought to be an assembly hall, built to the so-called megaron plan, which two millennia later was to dictate the form of a Greek temple. Approached through an open portico, the building consists of a megaron—a wide rectangular hall with an enormous central hearth. Near it is a second, less substantially constructed building that is thought to have been the residential palace, since hoards of gold ornaments and other precious objects were discovered buried beneath it; the archaeologist Heinrich Schliemann named these objects Priam's Treasure.

At Beycesultan, buildings that were almost certainly religious shrines were uncovered—a find of some interest, since temples are virtually unknown in Anatolia at this period. Rectangular shrine chambers seemed to be arranged in pairs, with ritual installations recalling the Horns of Consecration and Tree, or Pillar, cults of Minoan Crete. A palace building at the same site, dating from the Middle Bronze Age (*c.* 1750 BC), had reception rooms at first-floor level, also in the Minoan manner. In common with most other Bronze Age buildings in Anatolia, its walls were composed of a brick-filled timber framework on stone foundations. The private houses of this period at Beycesultan were all built on the megaron plan.

The art of the Anatolian Early Bronze Age is best represented by metalwork from royal tombs at Alaca Hüyük, in the bend of the Halys River (modern Kızıl River), and from two minor sites in Pontus—Horoztepe and Mahmatlar. At Alaca Hüyük, in particular, members of a ruling family were buried among the paraphernalia of funerary ritual, accompanied by their personal possessions: weapons, ornaments, toilet articles, domestic vessels, and utensils (made of gold, silver, and bronze). One dagger has a crescent-shaped handle and a blade of iron—a metal known to have had many times the value of gold at this time—and among the ornaments there is a fine gold-filigree (openwork made with metal wire) diadem. Equally striking was the variety of objects associated with the funerary ritual: figures of animals (such as stags), finely wrought in bronze and inlaid with silver, and strange openwork grills of bronze, sometimes adorned with animals. These objects were probably mounted at the heads of poles supporting a catafalque or canopy. There are also freestanding metal figurines, one of bronze with boots and breasts enriched with silver.

Metalwork from Alaca Hüyük

From these luxury objects found at Alaca Hüyük, together with those found at Troy and elsewhere, scholars have concluded that processes known to the Anatolian metalsmiths of the Early Bronze Age included casting by cire perdue, hammering or repoussé work, sweating or soldering, granulation (decoration consisting of tiny spheres of gold soldered onto a background), filigree, and cloisonné inlay. Carnelian, jasper, nephrite, obsidian, and meerschaum were all used for ornament.

Middle Bronze Age. Objects from the houses of the Kültepe merchants, representing the art of the Middle Bronze Age, are somewhat less impressive. Rhytons (a type of drinking vessel) and theriomorphic (having an animal form) vessels in painted terra-cotta show imaginative modeling, and local deities appear in the form of small statuettes and molded reliefs. It is, however, in the designs of contemporary cylinder seals that the art and religious concepts of the indigenous peoples are fully illustrated for the first time. Here is the iconography of the Anatolian gods, complete with their sacred furniture, ritual attributes, and appropriate animals.

HITTITE PERIOD

The Hittite old kingdom, with its capital city, Hattusa (modern Boğazköy), in the Halys bend, was one of several states into which Anatolia was divided during the second quarter of the 2nd millennium BC. Its finest monuments date from the imperial period that followed. The capital city, strategically placed astride a rocky gorge, has an inner enclosure, rising up to a high citadel rock (Büyükkale). Greatly extended in imperial times, the outer city has a four-mile circuit of powerful fortifications. The double walls, with their defensive towers and substructure of cyclopean masonry (large irregular blocks without mortar), stand upon a stone-faced rampart of earth, itself protected by a stone apron wall. The corbeled arches of its gates are flanked by portal sculptures—lions or sphinxes—anticipating those of the Late Assyrian palaces. Carved on the stone doorjamb of one arch is a famous relief of a warrior wearing the characteristically Hittite short kilt and conical helmet.

Elsewhere in the city there are four buildings recognizable as temples, the largest of which has been fully excavated. It is a huge building, surrounded by ranges of store chambers, planned around a wide courtyard with pillared colonnades and a small freestanding shrine in one corner. These features and the isolated position of the main sanctuary have no parallel in the temples of Mesopotamia or Syria.

Hittite sculpture

Modern knowledge of Hittite sculpture is derived, first, from the portal sculptures of Hattusa itself and, second, from rock sculptures, including those decorating the remarkable shrine called Yazılıkaya, some distance outside the town. Here, deep clefts in the limestone, open to the sky, form a setting for the cult; the reliefs are carved

on the vertical faces of the rock. One of the recesses, or chambers, is decorated with a pageant of deities, some standing on their appropriate cult animal or identified by a hieroglyphic inscription. These figures are carved with only average proficiency, and some of the iconography is borrowed from the Hurrians, with whom the Hittite royal family had intermarried. The figures in the second, or inner, sanctuary, however, are carved with an artistry inspired by religious fervour. The figure of a young king (Tudhaliyas IV) in the protective embrace of a god is hardly less impressive than the symbolism of a huge dagger thrust into the rock before him. The rock reliefs of this period elsewhere in Anatolia—Sirkeli, Gâvur Kalesi, and Fraktin, for example—are mainly of archaeological interest. They are inferior in carving to contemporary reliefs and to those of the Iron Age, of which there is a fine example at İvriz Harabesi in the Taurus Mountains, showing a local ruler of the 8th century BC paying homage to a fertility god.

Monuments such as that at İvriz Harabesi represent a curious aftermath of Hittite history. In about 1190 BC the empire was destroyed and the Hittites driven from their homeland on the Anatolian plateau by the Phrygians, but in the 10th–8th centuries they reappeared as part occupants of small city-states such as Milid (modern Arslantepe-Malatya), Sam'al (modern Zincirli), and Carchemish, in the Taurus or north Syria, where they shared political authority with indigenous Aramaeans and other peoples. During this Syro-Hittite period, their art and architecture was of a hybrid and rather inferior character much influenced by Assyria, to which the Hittites frequently became subject, and also by Phoenicia and Egypt. Conspicuous in their buildings are the sculptured orthostats that line the bases of the walls, often of coarse, black basalt awkwardly alternating with white limestone. Columns are of wood, with bases and capitals of stone, and monolithic statues, more than life-size, are a common feature. Fortifications are still an important aspect of their cities. Those at Zincirli enclose a circular town, a half mile in diameter, with a high-walled citadel in the centre, containing a complex of palaces. Like all Syrian palaces, these incorporate one or more *bit hilani* units, consisting of a columned portico, a long reception room, with an adjoining staircase to the roof, and a varying number of retiring rooms (see above *Syro-Palestinian arts and architecture*). A striking example of these *bit hilani* is the Kaparu Palace at Tall Ḥalaf, near the source of the Khābūr River. The almost barbaric array of sculpture shows the city to have been predominantly Aramaean.

URARTU

Eastern Anatolia during the 9th–8th centuries BC was occupied by the state of Urartu, at first a minor kingdom centred on Lake Van but later extended to include parts of what are now Armenia, Iranian Azerbaijan, and Kurdistan in northern Iraq. Entrenched in a mountainous country, well organized with provincial capitals and a network of small fortress cities, it resisted aggression from the Assyrians in the south. Urartian culture was based upon that of Mesopotamia, but some scholars consider its architecture

to be superior to that of the Assyrians, for the monotonous mud-brick facades of the southern plains and valleys are here replaced by a pattern of crenellated stone towers and buttresses adapted to the natural beauty of a rocky landscape. The excavation of two fortress cities, Karmirblur and Arin Berd, in Armenia, together with many others in Anatolia itself, has also revealed some unique features of Urartian architecture, including a standard form of temple: a square, towerlike building anticipating the temple-towers of Achaemenian times in Persia (Figure 12).

Urartu was renowned for its craftsmanship in bronze casting, examples of which reached Europe by way of Phrygia (Figure 12). Mural painting was practiced with some proficiency, but the drawing is weak, and the designs add little to the repertoire of Assyrian motifs, from which they are largely copied.

PHRYGIA

Plans dating from the Phrygian occupation of the Anatolian plateau (*c.* 1200 BC) have been recovered of small, fortified towns overlying the ruins of older Hittite cities. The Phrygian capital was at Gordium on the Sakarya (Sangarius) River, where excavations have revealed public buildings of the megaron type and the bastions of an impressive city gate. The rock-cut monuments of this period (Figure 13, right), concentrated around a Phrygian cult centre to the southeast of Eskişehir, include the Midas Monument: a tomb chamber framed in a relief depicting the gabled facade of a building. Ornament suggested by the sculptor has been explained by the discovery at other Phrygian sites of architectural terra-cottas: glazed tiles or panels, with human and animal figures (Figure 13, left). The contents of a royal tumulus (an artificial hillock or mound over a grave) burial at Gordium testify to the competence of Phrygian craftsmanship in other materials, including glass.

Iranian arts and architecture

Any reservation about attributing to Iran primary status among the countries contributing to the art of the ancient Middle East must be associated with the discontinuity of its early history and the comparatively incomplete state of its archaeological exploration. Nevertheless, it is clear that Iranian art maintained a distinctive identity from prehistoric times onward; thus, characteristics seen in designs on painted pottery of the 4th millennium BC can also be recognized, for instance, in the sculpture of the Achaemenian Persians. One of these characteristics—manifest in bronze casting and stone carving as well as in painted ornament—is the predominance of decoration over representation. Such purely Iranian predilections seem, surprisingly, to have survived the historical hiatus in the 2nd and 3rd millennia BC, during which the more culturally advanced regions of the country were so profoundly influenced by the ideas and artistic formulas of neighbouring Mesopotamia. During the better-documented years of the 1st millennium, they again survived, side-by-side with the innovations imposed by Greek and other foreign craftsmen, and were later in fact reciprocally transmitted to Europe.

EARLY IRANIAN PERIOD

The most artistically important, though not the most ancient, prehistoric painted pottery of Iran is derived from Susiana. The stylized shapes of animals and birds are used, their curves and contrasting angularities skillfully adapted to the sensitive shapes of the clay vessels in a manner that implies a long history of evolutionary experiment. The simplified silhouettes, which once must have appeared as individual figures, are linked together in a repetitive frieze to form a band of enrichment or to articulate some plastic feature. Nothing of this sort is to be seen in the contemporary Ubaid pottery of southern Mesopotamia, although the two cultures show a parallel progression.

In the succeeding Protoliterate period, each culture produced an independent form of pictographic writing. In Iran, this development took place in Elam, a region bordering on southern and central Mesopotamia. The Elamite use of pictographs was short-lived, however, and for a long time no further attempt was made to develop a written language. Modern knowledge of Elamite history during the centuries that followed thus depends exclusively on references in Mesopotamian literature, occasioned by the perpetual contacts between the two countries. Trade was on a large scale, and even the wars that so frequently interrupted it supplied the Elamites with Mesopotamian goods, including works of art that could serve as a pattern for Iranian artists. The stelae of Naram-Sin and Hammurabi were among major works brought as loot to

Influence of Mesopotamian art

the Elamite capital at Susa, where they have since been found. It is thus understandable that the native products of Elamite artists in the 3rd millennium BC—statues, reliefs, and smaller objects, such as cylinder seals—followed the conventions current in Mesopotamia. One interesting exception is a type of carved steatite bowl, at first thought to be an Elamite product but since found at sites as far apart as Mari on the Euphrates and Mohenjo-daro in the Indus valley, where it originated, thus emphasizing the part played by Susa in transcontinental trade.

During the late 2nd millennium BC, Elam experienced a period of great prosperity and political stability under a line of powerful rulers. The character of Elamite architecture at this time was revealed by the discovery and excavation of a vast temple complex at Choghā-Zanbīl (Dur Untash) in the Susa area. It was built by King Untash-Gal (*c.* 1265–*c.* 1245 BC) to fulfill the functions, first, of a holy shrine and centre of pilgrimage and, second, of a mausoleum for his family. Its central feature is a remarkably well-preserved ziggurat, 345 feet square and originally 144 feet high, built for the most part of baked bricks each weighing about 40 pounds (18 kilograms). Apart from the fact that it has been reconstructed with four receding stages and a summit temple, the structure of the ziggurat has little in common with that of Mesopotamian ziggurats. As described by one scholar,

> gates in the centre of each face led to diverging staircases up to the first stage, except on the southwest face, where a triple diverging staircase also led up to the second and higher stages.

Gates to the main stairways were flanked by glazed terracotta guardian animals—bulls or griffins. The paved area adjoining the ziggurat had a surrounding wall with imposing gateways. A similar outer wall enclosed a number of subsidiary temples, their dedication indicated by cuneiform inscriptions in the Elamite language. The ornamental sculptures from this complex were predominantly of glazed terra-cotta. A more striking example of contemporary Elamite sculpture is the life-size bronze statue of Queen Napirasu from Susa (now in the Louvre).

MEDIAN PERIOD

Much less is known about the northwestern part of modern Iran during the 2nd millennium BC, but from about 1000 BC onward it acquired a new importance. The southward migration of Indo-European peoples many centuries earlier, which had brought the Hittites to Anatolia and the Kassites to Babylon, was now followed by a new wave of peoples. Referred to as "Iranian," these peoples included both the Persians and the Medes. At first they were little more than a loose confederation of tribes, occupying a wide area of Iran south of the Caspian Sea. In settling there they had bypassed the eastern provinces of Urartu and the prosperous country called Mannai, south of Lake Urmia, also avoiding contact with mountain tribes of Luristan. In the 8th and 7th centuries BC, however, the weakening of Urartu and Mannai by Assyrian conquests, followed by a Scythian invasion and the final collapse of Elam, made all of western Iran accessible, and the foundations of Median empire were laid by Cyaxares.

With this complicated infusion of new elements and influences, it is hardly surprising that the Iranian art of this period shows a rich synthesis of novel characteristics. Its most conspicuous surviving products are derived from four principal sources: an excavation at Hasanlu, which was probably the capital of the Mannaeans; a chance-found treasure from Ziwiye (Ziwiyeh) in Iranian Kurdistan; tomb finds at Marlik, near Kazvin; and excavated graves in Luristan.

Principal sources

The Mannaean capital had a powerfully walled citadel, built between 1000 and 800 BC, and within it an enormous palace or temple, consisting of two-story buildings around a partially roofed courtyard. It had been destroyed by fire, and interest in its architecture, which should be considerable, has been eclipsed by the beauty of some objects recovered from the burnt debris. One was a silver cup decorated with electrum figures in two registers; there are chariots and soldiers above and, below, a lion and a horse opposed heraldically between archers. Even more remarkable was a bowl of solid gold (Archaeological Museum, Tehrān), elaborately figured with repoussé ornament, the religious or heroic imagery of which is largely incomprehensible (Figure 14). Though it shows no Assyrian influence, the associations of its linear style are with the West, and some links with Hurrian mythology have been detected in the design.

The hilltop fortress at Ziwiye falls within the territory of the Mannaean state, but the famous treasure found there dates from its later history (7th century BC). The marvelously designed objects making up the treasure include an elaborate pectoral (breast) ornament, a bracelet with lions' heads, a similarly adorned torque (rigid necklace), a ram's head rhyton, daggers, and enrichment for furniture—all of gold. As would be expected at this period, they show a variety of styles, sometimes combined in a single design, and carry suggestions of influence from Assyria, Syria, and even Egypt. The collection is thought by some to have been the property of a Scythian chief who temporarily ruled Mannai.

Dated to a period contemporary with the foundation of the Hasanlu citadel, though removed from it geographically, are the royal tombs found at Marlik. The tombs contained gold and silver vessels, comparable in design to those found at Hasanlu, and ingeniously grotesque animal figures in terra-cotta.

The Luristan bronzes

The Luristan bronzes include objects basically homogeneous in style but varying considerably in date and excavated from burial grounds in the eastern Zagros Mountains (Figure 15). There appear to have been more than 400 of these burial grounds, each comprising about 200 graves, so that the number of ornamental bronze objects reaching museums and private collections must have been very great. The burials appear to cover a long period of time; but two main groups have been distinguished, belonging, respectively, to the latter half of the 2nd millennium BC and to the Iron Age from 1000 BC onward. In the second period, particularly, there was a continual movement of Indo-European horsemen migrating from the north—a fact that helps to explain the character of the bronzes themselves, for they are nomads' gear. These portable goods and chattels of wandering tribes must have been produced by the settled craftsmen in the towns and villages of Iran for the nomads who passed through. Chariot or harness fittings are predominant: they include rein rings, bits, and ornaments, as well as weapons and various types of talismans. All suggest an indigenous school of craftsmanship catering to a changing clientele whose tastes and requirements varied with their origin. In the earlier group some very ancient Mesopotamian motifs are seen—rein rings, for instance, resembling those from the Ur tombs—but these have been explained as the belated use, in the 2nd millennium, of devices long superseded within Sumer itself.

ACHAEMENIAN PERIOD

There can be little doubt that, during the first half of the 8th century, when the Medes ruled northwestern Iran from their capital at Ecbatana (modern Hamadan), they developed some characteristic forms of architecture. This has been confirmed, for instance, by the discovery of a magnificent brick fortress at Nush-e Jan in that area. The evolution of a style capable of expressing the full genius of Iranian invention, however, fell to the lot of their Persian successors and fortunately is better documented by material remains.

Arrival of the Persians

The Persians first appear in history early in the mid-9th century BC as the occupants of a small state in Parsumash and Anshan, to the southeast of Susiana, ruled by a dynasty of kings to which its founder, Achaemenes, gave his name. Dependent first upon Elam and later subject to the Medes, the Persian state became more powerful in the 6th century, and in 550 BC, after defeating the Median armies, its fifth king, Cyrus II the Great, became ruler of all Iran. The empire that his further conquests created extended from Anatolia and Mesopotamia to the frontiers of India.

For Cyrus and his successors this access of temporal power and authority called for expression in the embellishment of their cities and the creation of an appropriately magnificent setting for their everyday lives. For an unsophisticated and hitherto nomadic people, this was an unprecedented requirement. Inspiration was at first sought in the existing formulas of Mesopotamia, Elam, Urartu, and Media, but from the beginning the matrix of the new style was the deep-seated artistic aptitude of the Iranians themselves. The marvels of Achaemenian art were conceived with native—and extraordinary—ingenuity. This continued to be the case even after the large-scale importation of Greek craftsmen in the time of Darius I the Great (reigned 522–486 BC).

Architecture. The earliest stages in the evolution of Achaemenian architecture are to be seen in the rather scanty remains of Cyrus' capital city at Pasargadae, north of Persepolis. The layout retained the character of a nomadic encampment: widely separated buildings—including gatehouse, residential palace, and audience hall—standing in a vast park, surrounded by a wall 13 feet thick. The audience hall provides the earliest example of a formula in design that was to become a criterion of the Achaemenian architecture: a columned hall with corner towers and external colonnades, called by the Persians an apadana. Other features are the Tomb of Cyrus, a gabled stone building on a stepped plinth, and a Zoroastrian fire temple (Zendan), a towerlike structure with a plan recalling that of the standard Urartian temple. Replicas of the Zendan were built later at Naqsh-e Rostam and elsewhere. Also at Pasargadae, the workmanship of Greek stonemasons was already recognizable, but their full contribution to the new Achaemenian style of architecture is better seen at Persepolis, to which Darius transferred the state capital in 518 BC.

The apadana

Achaemenian palaces are built on rock terraces leveled to receive them. The terrace at Persepolis measures approximately 1,600 by 1,000 feet and is more than 43 feet high, with traces of a high enclosure wall of mud brick around its outer edge and a magnificent stairway approach at its northeast corner. The palace buildings themselves, started by Darius in 518 BC and completed during the following half century by Xerxes I and Artaxerxes I, are rather closely grouped together, with little consideration for the overall composition (Figure 16). They are decorated, for the most part externally, with portal sculptures and long ranges of relief carving. Apart from the ornamental facades of the stairways by which the buildings are approached, sculpture is confined to the decoration of doors or windows. These stone-built features, together with a few internal columns, are all that have survived.

In the absence of the mud-brick walls themselves, it is

difficult to gain a true impression of the terrace's original appearance. Most characteristic of these Persian palaces is the proliferation of columns and the tendency to plan them around a square central chamber. In the main gatehouse, with its guardian bulls and bull-men, the square appears as an independent unit. Facing it at a higher level is the largest building of all, the great Apadana (hall) of Darius. It is 272 feet square and is said to have accommodated 10,000 people. The four corner towers presumably contained guardrooms and stairs. The sculptured stairway by which it was reached bears the famous relief of the tribute bearers (Figure 17). Next comes the Throne Hall, or Hall of a Hundred Columns. It has a portico on the north side with 16 pillars and guardian bulls built into the tower walls at either end. Seven sculptured windows in the north wall are balanced by corresponding niches elsewhere, and the reveals, or jambs, of the doors also are decorated with reliefs. Again approached by an ornamental stairway, a "tripylon" unit between these main buildings leads to others only tentatively identified. The plan of the building, called the Harlem by archaeologists, is to some extent self-explanatory. The character of the Treasury is indicated by security precautions in its planning. In this building the columns were of wood, heavily plastered and painted in bright colours. Elsewhere, columns are fluted in the Greek manner, while the more elaborate capitals and bases have a floral treatment that, like much other Achaemenian ornament, is half Greek and half Egyptian. The most notable form of capital and one peculiar to Achaemenian design is the "double-figure" impost (an upper addition to the capital), taking the form of paired bulls, bull-men, or dragons. Some of these features reappear in the contemporary palace at Susa. Also from this source are figured panels of molded and glazed brick (now in the Louvre), reminiscent of Nebuchadrezzar's Babylon.

Relief Sculpture

Sculpture. Relief sculpture is by far the most striking manifestation of Achaemenian art. Adopted as the basis of the new style was the straightforward technique of the Assyrians, with its engraved detail and lack of modeling. The employment of Ionian sculptors resulted in a complete break with this tradition, and the full plastic rendering of human or animal figures became the rule. A compromise between the aesthetic sensibility of the Greek sculptors and the disciplined precision of the Iranian tradition in metalwork produced a stylistic synthesis of unrivaled elegance.

Compared with the spirit and variety of the Assyrian narrative scenes, the subjects chosen for the Persian designs may at times appear monotonous. This may be partly explained, however, by the disparity in their architectural functions: the reliefs no longer appeared as interior decoration but were effectively used to give visual emphasis to prominent features of external facades where the bright colours applied to them profited from the sunshine. Well-known Achaemenian rock reliefs, such as those of the royal tombs at Naqsh-e Rostam, near Persepolis, and the relief with a famous inscription of Darius I at Bisitūn (historically Behistun), on the road to Hamadan, are primarily of archaeological interest. Of greater artistic importance are the many surviving examples of Achaemenian metalsmiths' work, which continued to draw extensively on the native tradition of Iranian design. The Oxus Treasure (now in the British Museum) includes outstanding and characteristic examples of Achaemenian metalwork (Figure 18).

SELEUCID PERIOD

The two centuries during which the Middle East and countries beyond were ruled by Alexander the Great (336–323 BC) and his Seleucid successors (312 BC–64 BC) are poorly represented in the realm of art and architecture. Everywhere in the Middle East, local artists were subject to strong Western influence, and Western craftsmen adapted their taste to that of a Greek or Hellenistic aristocracy. If there was a Greco-Iranian style, it had little to distinguish it from Greco-Mesopotamian or, for that matter, Greco-Indian art. Architecture of about 200 BC is represented by two "Greek" temples, at Kangāvar and Khurha, in Iran, in which classical orders (Doric, Ionic, and Corinthian) are handled with so little understanding that they can hardly be called Hellenistic. There are, however, isolated examples of contemporary sculpture from eastern sites to which this term could be more justifiably applied. Bronze statuettes from Nahāvand, a fine bronze head from Shami in the Bakhtiari, the marble fragments from Susa, and a striking alabaster statue from Babylon (all now in the Louvre) acquire added interest from their provenances.

PARTHIAN PERIOD

The Parthians were a nomadic people originating in the steppe country between the Caspian and Aral seas. The dynasty of Parthian kings that was to displace the Seleucid rulers of western Asia was founded in about 250 BC. One hundred years later, their conquests extended as far as Mesopotamia, and the frontier of Europe was withdrawn to the Euphrates. For another four centuries the further

extension of the Parthian empire was resisted with varying degrees of success by the armies of Rome.

In Iran and Mesopotamia, this long era of Parthian occupation is poorly represented by newly built towns, but there are a few notable examples. One was Ctesiphon, originally a Parthian military camp facing Seleucia, the older capital city on the other side of the Tigris River. Another was Hatra, a fortress city in the Al-Jazīrah desert between the Tigris and Euphrates rivers; and a third was Gūr-Fīrūzābād, south of Shīrāz. All these show the approximately circular plan of military tradition. The palaces, sometimes built of good ashlar masonry, and even the private houses are distinguished by a feature later characteristic of Islāmic architecture: the iwan, or three-sided hall, the fourth side of which is replaced by an open archway. At Hatra and in a Parthian palace at Ashur, the iwans multiplied in number, and the adjoining facades are decorated with engaged columns, singly or in tiers, corresponding approximately to the orders of classical architecture.

Parthian palaces

Hatra is by far the best preserved and the most informative example of a Parthian city. It has an inner and an outer city wall, the former built of ashlar masonry, and a temenos (temple enclosure) enclosing the principal sacred buildings. The great central group, built during the 2nd and 1st centuries BC and still standing with many of its vaulted chambers intact, includes the Shamash temple, a characteristic Iranian sanctuary with a square central chamber, ambulatory, and outer wall incorporating a staircase to the roof. Comparable buildings have been found as far afield as Taxila in the Indus valley. Excavations by Iraqi archaeologists have revealed temples dedicated to Al-Lāt and Shahiro, who, with Shamash, make up a Hatran trinity.

In the 1st and 2nd centuries AD Hatra was ruled by a dynasty of Arab princes whose written language was Aramaic. Iraqi excavations have yielded a great wealth of sculptures dating from this period, including portrait statues of the princes and their families. This material has thrown new light on the whole subject of Parthian art, which depended formerly on such isolated survivals as the magnificent bronze statue from Shami, in the old Elamite homeland. Rock reliefs at Tang-e Sarwak, Bīsitūn, and elsewhere reveal one salient characteristic of Parthian design—that is, the preference for "frontality" or, as one scholar describes it, "the tendency for the figures to ignore one another and to face the spectator with an unblinking stare." Frontality also is characteristic of the Romano-Syrian sculptures of Palmyra and later passed into the fabric of Byzantine art.

PETRA AND PALMYRA

Two cities, strategically placed in Jordan and eastern Syria, respectively, were at times associated with Parthian history and have left monuments suggesting a compromise between Roman and Middle Eastern art. Both were caravan cities, and each in turn acquired wealth and importance from its position at the junction of arterial trade routes. Petra, in biblical Edom, was ruled by Nabataean kings from late in the 2nd century BC until 106 AD, when it became a Roman colony. Its subsequent decline was due in part to the temporary ascendancy of Palmyra, on the western fringe of the Syrian desert, whose remarkable queen Zenobia ruled a miniature empire until she was defeated by the Romans in AD 272.

The significance of Petra in the history of ancient Middle Eastern art is difficult to assess, since its art is in large part restricted to the design of rock-cut tombs or temples. Imitation building facades carved on cliff faces surround the tomb and temple entrances. Their most distinctively Oriental characteristic is the baroque effect obtained by ingenious contortions of classical Roman formulas. The dramatic beauty of their natural setting and the chromatic peculiarity of the stone from which they were hewn are assets that have enhanced their reputation. Stripped of these, their interest is primarily academic.

The architecture of Palmyra is more conventionally Roman, but it is freely associated with sculpture, and many bas-relief carvings decorate the tombs of rich merchants and other notables. Parthian influence is to be seen in their style, particularly in the frontality of the human figures.

SĀSĀNIAN PERIOD

The last great Iranian dynasty to rule in the Middle East before the advent of Islām has left a heritage of ruined buildings and sculpture that are of increasing interest to those seeking the origins and antecedents of Western art. It has been said of Sāsānian art that, essentially Iranian in character, "it was receptive of foreign influences, but adapted them to the traditions of its native land, and as the art of a world empire, it spread into far distant countries."

A town called Gūr (modern Fīrūzābād) was built by the founder of the dynasty, Ardashīr I (reigned AD 224–241), with the circular plan characteristic of earlier times. A contrast is immediately seen at Bishāpūr, where Ardashīr's son Shāpūr I adopted the "grid" planning then popular in Greek cities. Building materials varied from country to country. The Sāsānian palace at Ctesiphon was built (probably in the 4th century AD) of baked brick (Figure 19). The facades on either side of its famous vaulted iwan hall (82 feet wide and 121 feet high) have blind arcading with freely simplified classical detail. A reconstruction of the palace at Gūr, built of rubble and plaster, shows a similar main facade, with cupolas (rounded vaults) over square chambers behind. Of the same material is Shāpūr I's palace at Bishāpūr, where the great hall, with its central cupola, has four iwans making a cruciform (in the form of a cross) plan. In buildings of this sort, the stucco facing of the walls was decorated with incised or painted ornament.

There were also mosaic pavements, in which portraits of individuals were shown three-quarters face, the frontality of Parthian design apparently having been abandoned.

The most important and revealing examples of Sāsānian sculpture are the rock reliefs scattered over the territory of the empire; there are more than 30 in Iran alone. Their style and content reveal a facet of art history that can do much to clarify the interaction of Eastern and Western ideas at this time. The scenes generally depicted are investitures, triumphs, the defeat of enemies, and other occasions in the life of royalty. Perhaps the two most striking designs in the whole series, each of them characteristic yet differently conceived, are the Investiture of Ardashīr I at Naqsh-e Rostam (Figure 20) and the Royal Hunt relief at Tāq-e Bostān. In the first the king and his god, both mounted on horseback, are sculptured in high relief in the Roman manner but are antithetically arranged to create a typically Iranian heraldic composition. In the second the two central figures are framed in a surrounding panorama of incidental detail, perhaps inspired by similar designs in mural painting. These and other examples reveal Western influence—for instance, in the molding of drapery of the body or the Achaemenian arrangement of subordinate figures in horizontal registers. Yet, unlike Achaemenian sculpture, there is no narrative intention in these reliefs. Their static celebration of a single event, investing it with a timeless significance, is the central accomplishment of this form of Sāsānian art. (S.H.F.L.)

Ancient Middle Eastern Religions

The religious beliefs, attitudes, and practices developed in the ancient Middle East (extending geographically from Iran to Egypt and from Anatolia and the Aegean Sea to the Arabian Peninsula and temporally from about 3000 to 330 BC, when Alexander the Great conquered much of the area) have had an enduring influence on Western civilization. While this article treats only those religions of Middle Eastern antiquity that have not survived to modern times, special attention is given in the introduction to their role as antecedents of the major Western religions (*i.e.*, Judaism, Christianity, and Islām), all of which originated in the region. For full treatment of these "inheritors" of the Middle Eastern tradition, including also the surviving Zoroastrianism and Parsiism, see under the names of the individual religions.

THE CULTURAL CONTEXT

General considerations

The ancient Middle East constituted an ecumene. The term ecumene comes from the Greek word *oikoumenē*, which means the inhabited world and designates a distinct cultural-historical community. The material effects of the commercial and cultural interconnections that permeated the component regions of the ancient Middle Eastern ecumene are richly supplied by archaeological excavations, which provide evidence of the spread of architectural, ceramic, metallurgical, and other products of ancient Middle Eastern man's industry. Manufacturing and services tended to be monopolized by professional guilds, including religious personnel specializing in sacrifices, oracles, divination, and other kinds of priestcraft. The mobility of such guilds throughout the entire area helps to explain the spread of specific religious ideas and techniques over great distances. Just as guild potters spread ceramic forms and methods, so also guild priests spread their religious concepts and practices from the Indian Ocean to the Aegean Sea, and from the Nile River to Central Asia. The Greek poet Homer, in the *Odyssey*, noted the mobility of guildsmen, mentioning religious personnel as well as architects, physicians, and minstrels. Guild priests called *kohanim* were found at ancient Ugarit on the Mediterranean coast of northern Syria as well as in Israel. Moreover, Mycenaean Greek (late Bronze Age) methods of sacrifice are similar to the Hebraic methods, which are preserved in many countries to this day in the traditional techniques of Jewish ritual slaughter.

Religious guilds

The "archaeological revolution." The decipherment of Mesopotamian and Egyptian literatures in the 19th century opened new vistas of ancient Middle Eastern history. Hitherto, scholarly knowledge had been limited to the contents of classical Hebrew, Greek, and Latin literatures. Explorations and excavations in the Middle East yielded not only texts but also an abundance of ancient art objects, artifacts of daily life, and architecture and thus have revolutionized scholarly knowledge of the ancient Middle East, including its religions. A ziggurat excavated at Babylon illustrates the form of the biblical Tower of Babel. The prototype of the biblical story of the Deluge has turned up in the Gilgamesh epic. A fragment (dating from about 1400 BC) of that Babylonian epic has been found at Megiddo in Israel, showing that the Mesopotamian version was current in Palestine before the Hebrews, under Joshua, conquered the land about 1200 BC. A previously little-known people, the Hittites, are, because of archaeological discoveries, now recognized as a major power of antiquity with a rich legacy of religious texts, especially rituals.

The earliest and certainly the most fundamental ancient Middle Eastern civilization—the Sumerian—had vanished without a reference in the literatures of the world. Sumerology is now an important field of investigation. Biblical studies have been revolutionized by the tablets (1400–1200 BC) found from 1929 onward at Ugarit. It has be-

come extremely difficult to keep abreast of the continually growing body of material, and very few scholars today feel secure enough to venture beyond limited areas.

Literary sources of knowledge of ancient Middle Eastern religion. Classical literature remains an important source for ancient Middle Eastern religion. The Roman historian Livy wrote many descriptions of religious rites of the ancient Middle East. The Roman poet Virgil's *Aeneid* and *Eclogues* reflect Egyptian, Semitic, and Anatolian, as well as Greek, antecedents. The Greek biographer Plutarch's *De Iside et Osiride* ("Concerning Isis and Osiris") is still the best description of the Egyptian myth of Isis and Osiris and of the cult of the dead. The Greek satirist Lucian's *De Dea Syra* ("Concerning the Syrian Goddess") is of enduring value for an understanding of Canaanite religion. The writings of Herodotus, the 5th-century-BC Greek historian, remain an indispensable source for the cultural history and religion of the ancient Middle East. And owing to the discovery of texts from Ugarit, the Homeric epic of the Greeks is now firmly linked to Middle Eastern literature.

The Old Testament as a source of knowledge

The Hebrew Bible is still the most important single source for knowledge of the ancient Middle East, reflecting life from Egypt to Iran, and from the Bronze Age beginnings to the Hellenistic Age. There is very little in the Old Testament that does not follow the types of religious literatures in the older Middle East: psalms, hymns, laws, rituals, prophecy, wisdom literature, and other types. Sometimes parts of the Bible are related in detail to specific outside sources. The Egyptian *Wisdom of Amenemope,* first published in modern times in 1923, for example, parallels Proverbs 22:17–24:22 so closely that it effectively opened up the field of the comparative study of ancient Middle Eastern wisdom literature.

Middle Eastern worldviews and basic religious thought

THE CONCEPT OF THE SACRED

All of the ancient Middle Eastern people saw the agency of the gods in every aspect of life and nature. Everything on earth was regarded as a reflex of its prototype in the divine or sacred sphere, such as in the biblical description of the creation of man "in the image of God"; God was viewed as the primary reality of the universe, and human beings were seen as the reflection of that reality. In Egypt, Thoth was the scribe in the pantheon. Mortal scribes were viewed as the human reflections of Thoth, and "the beak of the Ibis (*i.e.,* Thoth) is the finger of the Scribe" (*Wisdom of Amenemope,* ch. XV, 17:7).

The ancient Middle Eastern people believed that the universe resulted from the injecting of order (cosmos) into chaotic primordial beings or matter, followed by divine acts of creation. Genesis 1:1–3 says that when God began to create the heavens and the earth, the "earth was without form and void, and darkness was upon the face of the deep; and the Spirit of God was moving over the face of the waters. And God said, 'Let there be light'; and there was light." Thus darkness (*i.e.,* evil) was preexistent. Moreover, the deep (*tehom* in Hebrew) is the same as the primordial dragon called Tiamat (cognate to the Hebrew *tehom*) in the Babylonian epic of creation. The first act of creation is God's evoking light (*i.e.,* the forces of good) by fiat. Accordingly, God is not responsible for the forces of evil, which were there before he embarked on the creative process. Proceeding by fiat he separated the water-containing earth from the water-containing heaven, confined the earth's waters to the bodies of water (leaving the rest as dry land), created the various species of vegetation, the heavenly bodies, the animal kingdom, and finally man, who is to rule over the earth. All this takes six days, after which God rests on the seventh, so that the Sabbath crowns the epic of creation and imposes the obligation to observe the sabbath in keeping with the principle of *imitatio Dei* (the imitation of God).

The *Enuma elish*

The Babylonian creation epic (*Enuma elish,* "When on High") states that at first there existed only the male (Apsu) and female (Tiamat) gods of the deep. They raised a family of gods that were so unruly that Apsu resolved to destroy them. Rebellion and chaos ensued. Among the deities was Marduk, the god of Babylon. Since the main version of the epic of creation is the Babylonian, Marduk occupies the role of Creator. (In the Assyrian version, Ashur is important.) Tiamat, who had embarked on a course of destruction, was slain by Marduk, who cut her in two and used her carcass to create the universe. Out of half her body he fashioned the sky containing the heavenly bodies to mark the periods of time. The epic culminates in the glorification of Marduk and the establishment of his order. The *Enuma elish* was read on the Akitu, or New Year festival, at Babylon, to reestablish order, in accordance with sympathetic transference principles, by reciting Marduk's creation. The function of the Akitu is thus to rejuvenate society for the new year.

VIEWS OF MAN AND SOCIETY

The lack of hard-and-fast barriers between gods and men left room for hybridizing. The aristocracy, in particular, claimed some divine form of ancestry. Gilgamesh, a mortal king who ruled Uruk in Mesopotamia, was, according to the Gilgamesh epic, born of the goddess Ninsun, even as among the Greeks Achilles was accepted as the son of the goddess Thetis. Sometimes kings claimed to have two divine parents. King Keret, whose epic was found at Ugarit, claimed to be the son of El, the head of the pantheon, and of Asherah, El's wife. Every Egyptian pharaoh was hailed as "the son of Re" (the sun god). This does not, however, imply the absence of a human father. The concept was one of paternity at two levels; qualitative superiority emanated from the notion of divine paternity, but one's position in society came from the human husband of one's mother. Odysseus "the Zeus-begotten son of Laertes" (*Iliad* 10:144) was a hero because Zeus presumably impregnated his mother; but he was also king of Ithaca because his mother's husband was King Laertes of Ithaca. In this regard the birth and station of Christ differ only in that Mary was a virgin when she was divinely impregnated. Though the divine component of Christ is due to his divine paternity, his position as king of the Jews comes not from his heavenly Father but from Mary's husband, Joseph, who was descended from King David (Matthew 1).

In the ancient Middle Eastern worldview, gods could become mortal, and men could become gods. Utnapishtim, the hero of the Babylonian Flood story, was deified together with his wife by the fiat of the great god Enlil: "Hitherto Utnapishtim has been but human; henceforth Utnapishtim and his wife shall be like us gods" (Gilgamesh epic 11:193–194). In the Hebrew Bible, God so loved Enoch (Genesis 5:24) and Elijah (2 Kings 2:11) that he carried them aloft to heaven as immortals. But these were special cases, and in antiquity they set no precedent for common folk. Kings enjoyed deification regularly in Egypt, though in some other traditions only upon dying. The Hittite monarch Hattusilis III refers to his father's death as "when my father Mursilis became a god" (*Apology of Hattusilis,* line 22).

Purpose of man

From the ancient Middle Eastern point of view, man was created to serve the gods, and he does so in the hope that

the gods appreciate it and will reward him for it. The gods need food and drink and depend on men to supply them. After the Flood the biblical Noah won God's goodwill, for "the Lord smelled the pleasing odor" (Genesis 8:21) of the tasty flesh and fowl offered up to him. Noah was following a long tradition, for Utnapishtim (Gilgamesh epic 11:155–161) had, after the Flood, offered sacrifices and libations to the gods who "crowded like flies" as they "smelled the sweet savor." Though gods depend on man, man also depends on the gods, and therefore service to the deities must be maintained for the welfare of the state, even as the family and the individual must do what the gods expect of them for domestic and personal welfare.

Everything on earth reflects a divine prototype, and all human affairs are divinely ordered and scrutinized. Gods may even build the cities destined to be their cultic centres and in which they are to reside, at least part of the time. The Greek god Poseidon built the walls of Troy, according to the *Iliad* (21:446–447). At Ugarit, Baal's temple was designed and built by Kothar-wa-Hasis, the god of arts and crafts. The Israelite King David gave his son Solomon plans for the Temple drawn up by Yahweh's (the Lord's) own hand (1 Chronicles 28:19).

National policy went hand in hand with theology. Ashur was the national deity of Assyria; the kings of Assyria were in theory his chief executive officers. Thus Sennacherib, king of Assyria, in undertaking a military campaign, recorded that he did so not on his own initiative but in conformity with Ashur's will: "In my second campaign, Ashur my Lord impelled me." When the Hebrews and Ammonites had a border dispute, Jephthah told the Ammonites: "Will you not possess what Chemosh your god gives you to possess? And all that the Lord our God has dispossessed before us, we will possess" (Judges 11:24). There was no such thing as secular policy in the ancient Middle East.

Since the king was the human agent of the god, he was exalted above other men. In Israel, the king was chosen by God to rule his people. God's representative was a priest or prophet who consecrated the king by anointing his head with oil. But the king of Israel was not divine, neither while on the throne nor after death.

The divinity of kings evoked certain fictions. By sucking the breasts of goddesses, crown princes imbibed a source of divinity. The baby pharaoh sucking the breasts of Isis (who was perhaps in real life represented by her high priestess) is a common motif in Egyptian art. In Mesopotamia, it was not the usual practice for kings to claim divinity, but now and then it cropped up. Naram-Sin (23rd century BC) prefixed the sign for divinity before his name and was officially a god. The same usage is attested among kings of the 3rd dynasty of Ur (*c.* 2112 BC–2004 BC).

VIEWS OF BASIC VALUES AND ENDS OF HUMAN LIFE

Ethical emphases

The good life was one lived in accord with the regulations of one's god. In the realm of ethics and morals there was more international uniformity than there was in taboo and ritual. Honesty and kindness were universally recognized as good, theft and murder as bad. Wisdom literature tended to stress the same virtues and to condemn the same vices, regardless of the region and cult. It remained for the prophets of Israel to single out uncompromising virtue as the overriding consideration in the good life required by God. The most important factor in that system was "social justice," whereby the weak was always protected in conflicts of interest with the strong. This had an important place in what may be called "international religion"—*i.e.,* that governing relations between men from different areas belonging to different cults. That level of religion, called "fear of the gods," is tested when the strong man confronts the weak. The strong man who injures the weak lacks the fear of the gods; the strong man who helps the weak has the fear of the gods. This was religion transcending all the regional cults, and it came into play when strangers abroad were at the mercy of the local inhabitants. Odysseus in a foreign land wanted to know if the people there feared the gods or were lawless so that no stranger was safe (*Odyssey* 9:176). Abraham, too, was concerned in Philistia lest the inhabitants might kill him because there was no "fear of God(s)" (Genesis 20:11). Men of all nations and all cults knew that only among god-fearing men was there decency or safety.

There was another common trend in international religion. No matter how polytheistic a cult may have been, it left a place for the god shared by all peoples. Theos, "God" (not merely "a god"), is in Homer; *pa netjer,* "the God," occurs in Egyptian exactly like Elohim, "(the) God," in Hebrew. Nebuchadrezzar II, the 7th–6th-century-BC Babylonian king, made Zedekiah, the Judaean king, swear by Elohim (2 Chronicles 36:13), the God of the universe for Babylonians and Hebrews alike. Similarly, when the Hebrews spoke of truth uttered by Pharaoh Necho, which fell on the deaf ears of the Judaean King Josiah, the text (2 Chronicles 35:21) states that Elohim, "God," had spoken through the mouth of the pharaoh.

In Egyptian religion (followed by Judaism, Christianity, and Islām), the concept of a happy afterlife depending on one's ethical and moral record in this world was developed. Vignettes in the various Egyptian books of the dead show the deceased's heart being weighed against the feather of truth in the balances before the scribe god Thoth, who records the text. When the Bible speaks of God as "who tests the heart and the kidneys" (Psalms 7:9; Jeremiah 11:20 and 20:12) it refers to the same concept.

MYTHS AS THE BASIC MODE OF RELIGIOUS THOUGHT

Purpose of myths

Myths were developed to account for the cosmos. How did the gods bring heavens, earth, plants, beasts, and human beings into existence? What is the divine origin of human institutions and of the ecumene? What divine process is responsible for prosperity or failure? To explain such basic questions, etiological (origin or causal) myths were developed. For example, the attraction between man and woman (and the consequent institution of marriage) is explained by the myth that primeval man was one creature, subsequently divided into two parts, male and female, which are attracted to one another to regain their pristine unity. Aristophanes expresses this theory of sexual attraction in Plato's *Symposium.* Genesis relates the same theory in the familiar myth that a rib, taken out of Adam, was fashioned into Eve; and precisely because woman was taken out of man, man forsakes his father and mother to cleave unto his wife so that they become one flesh.

Myths are often invoked in magic (which, unlike religion, aims at compelling, instead of imploring, the gods). To banish evil from the life of a client, the magician may invoke the cosmic myth whereby the forces of good triumph over the forces of evil. Evil is depicted on a seal of the Akkad period (late 3rd millennium BC) in Mesopotamia as a seven-headed monster whose heads are being successively killed by good anthropomorphic (human-form) beings. At Ugarit, in mythological poems of the late Bronze Age, the good gods Baal and Anath slay the wicked Leviathan of the Seven Heads, providing the precedent for the victory of good over evil. The Hebrews also nurtured this myth whereby God slays the many-headed Leviathan (Psalms 74:14) and will do so again at the end of days, to quell evil and establish good for all eternity (Isaiah 27:1).

ASSOCIATION OF RELIGION WITH THE ARTS AND SCIENCES

Religion in the ancient Middle East was associated with both the arts and the sciences, though in the literature of the area it is difficult to disentangle the secular from the sacred. Hymns, at one level, and omen or ritual texts, at another level, are clearly religious. Yet it would be difficult to categorize the Gilgamesh epic of Mesopotamia or the Homeric epics of Greece as definitely either secular or religious. They deal with human events or worldly problems, but the gods are constantly on hand. The same may be said for two Ugaritic epics, the epic of Keret and the epic of Daniel and Aqhat, which date from the late Bronze Age. This also holds for the patriarchal narratives in the biblical book of Genesis about Abraham, Isaac, and Jacob, in which God and his messengers play the same kind of role in human affairs as do the gods in the Homeric or Ugaritic epics.

Religion had close ties with science as well as with literature and art. Astronomy, mathematics, and time

reckoning are sciences in which the ancient Middle East made great strides at an early date, long before 3000 BC. Heavenly bodies were at the same time both deities and personified numbers. The planet Venus was the "star" that the Assyrians and Babylonians called Ishtar, which was at the same time both the goddess Ishtar and the deified number 15. The Moon was not only Earth's satellite but also the lunar deity Sin and the deified number 30. The most perfect number was one, for by advancing from zero to one men believed they proceeded from nonexistence to existence. Moreover, all other whole numbers were regarded as multiples of one, representative of the Creator, the Prime Mover, of the universe. The Egyptians called Re "the one One"; the Babylonians identified the divine "One" with Anu, the god of heaven. When the Hebrew prophet Zechariah (14:9) proclaimed "on that day the Lord will be one and his name One," he indicated that the Hebrews, like their neighbours, reckoned with sacred numbers and saw in the number one a symbol of the Creator. Biblical monotheism, therefore, has more than one dimension, including not only the monotheistic principle that there is one God and none beside him but also the mathematical principle of the primacy of "one" and its deification as the Prime Mover.

Significance of the number one

THE ROLE OF MAGIC

The loftier trends of ancient Middle Eastern religion did not as a rule threaten to eliminate magic. White, or protective, magic was never seriously discouraged. Black, or destructive, magic was frowned on by organized society, regardless of whether the official religion was monotheistic or polytheistic, because black magic makes its victims unfit for functioning productively in society. Section II of the Babylonian king Hammurabi's (Hammurapi's) code punishes witchcraft (as well as false accusations of witchcraft) with the death penalty. Moreover, all organized religion tended to oppose magic that circumvented the official clergy. King Saul of Israel had characteristically banned sorcery, driving it underground. Yet when he wanted guidance from the dead prophet Samuel, Saul consulted the Witch of Endor, who was practicing her art illegally (1 Samuel 28:6–25). She was able to call up the spirit of the prophet from the underworld, which, incidentally, illustrates one of the reasons why society opposes spiritualism. The witch, by claiming to bring the greatest authorities of the past onto the current scene, threatens the authority of the establishment.

The Letters to the Dead of pharaonic Egypt were written by living persons to the dead in order to achieve practical results, in keeping with the pragmatic, down-to-earth nature of the ancient Egyptians. It was unquestioningly assumed that the dead continued to exert influence on the living. Difficulties experienced by widows, widowers, and other survivors were attributed to the malevolence or negligence of the ungrateful dead who failed to defend their dear ones in the land of the living.

The letters were most often inscribed on ceramic vessels but were sometimes written on papyrus, linen, or even on a stela. They were deposited in tombs, not necessarily those of the persons addressed. It was believed that all burials were part of one interconnected system and that the mail would be delivered to the deceased addressee as long as it was posted anywhere in this network.

The writers sometimes remind the deceased addressee of the water and offerings they have brought to the tomb. Occasionally they threaten to discontinue such services if the deceased persists in refusing to help them. A frequent grievance is that malevolent persons (often relatives) are defrauding the rightful heirs of the deceased person's estate. The writer may even vow to take legal action against the dead in the divine court of the West (*i.e.*, of the realm of the dead).

One of the letters, known as the Leiden Papyrus, is particularly interesting because of the light it sheds on Egyptian life as well as on the relations between the living and the dead. The author is a widower who has been in a bad state since his wife's death. He is convinced that his misfortunes are due to his late wife's ill will. In the letter he reminds her that he was a model husband and threatens to testify against her in the court of the West. He goes on to say that he was a young and busy officer in the pharaoh's service at the time he married her. In spite of the pressures of his important duties, he writes, he stood by his wife and did not abandon her. He even made the soldiers under his command defer to her and render service to her. Moreover, he refrained from having affairs with other women. Before his wife's death he was assigned a mission to the wild south, on which he could not take her. Nevertheless, he provided for all her needs and gave nothing to other women. When she fell ill he engaged a skillful physician who gave her the best possible care. While death was overcoming her, he virtually abstained from eating and drinking for eight months. When he finally returned home to Memphis, he gave her a first-class funeral, complete with a shroud of the finest Upper-Egyptian linen. At the time of the letter, three years have passed since the wife's death. During this time he has lived alone and remained faithful to his departed wife. Yet in spite of this flawless record, she has been afflicting him and behaving like one who does not know the difference between right and wrong. He has therefore decided to prosecute her. In closing the letter he reaffirms his fidelity, declaring that he has not touched any of the female members of the household.

Religious practices and institutions

NATURE: THE FRAMEWORK OF IDEAS AND PRACTICES

Fertility of agriculture, of edible animals, and of the human population was a paramount factor in the life and religion of the ancient Middle East. The forms that the fertility rites assumed varied from region to region, depending on climate and geography. Rain and dew were all-important in Canaan but of little significance in Egypt. In both areas water was crucial, but the source of the life-giving water was entirely different. The agricultural year varied in the two regions. In Egypt the year was divided into three seasons: inundation, sowing, and harvest. In Canaan there were two seasons: the winter, characterized by rainfall, and the summer, characterized by dew. The

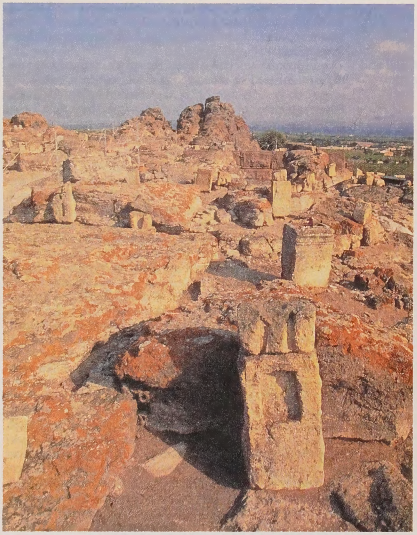
year was punctuated by different agricultural activities, as is indicated in the Gezer Calendar, in which all 12 months are accounted for as times of profitable agricultural activity, with harvests in the rainless summer as well as in the green winter. Anxiety was caused by the uncertainty of rain in the rainy season and of dew in its season. All of the regions of the ancient Middle East schematized the blessing of good years and the threat of bad years in terms of seven-year cycles. A Mesopotamian text illustrating this is the Gilgamesh epic (8:101–113), in which the slaying of the hero Gilgamesh would initiate seven lean years. At Ugarit the slaying of the hero Aqhat evokes a curse depriving the land of rain and dew for seven (or, climactically, eight) years. The seven lean and seven fat years in the biblical story of Joseph in Egypt reflect the same system. In Egypt, of course, rain and dew are out of the picture; instead, generous Nile risings mean prosperity; inadequate risings in the season of inundation spells misery. A text of the Ptolemaic period (4th–1st century BC), purporting to record events of the Pyramid age, tells of seven lean years in the reign of Djoser (3rd dynasty; *i.e., c.* 2650–*c.* 2575 BC). The pharaoh appealed to the gods, who responded by restoring an abundant flow of the Nile.



The population desired the normal pattern of times and seasons, so that "seedtime and harvest, cold and heat, summer and winter, day and night, shall not cease" (Genesis 8:22). But since the seasonal pattern is not dependable, the need for order evoked a system of cycles, notably the sabbatical, or seven-year, cycle. The sabbatical year was the seventh year, and the jubilee year followed seven sabbatical cycles. This was a pervasive system in the ancient Middle East. A Ugaritic liturgical text specially designed for this phenomenon aims at terminating a sabbatical cycle of privation and ushering in one of fertility by celebrating the birth and triumphal entrance of the deities Shahar ("Dawn") and Shalim ("Dusk"), whose advent brings an abundance of food and wine.

Fertility rites

It was only natural that fertility rites should include sexual myths that were acted out dramatically. The Ugaritic text just alluded to describes El, the head of the pantheon, copulating with two human women. This has echoes in Hosea and Ezekiel where God, as in the Canaanite literary tradition, is referred to as having a love affair with two women, symbolizing Judah and Israel. The Hebrews, however, eventually eliminated sex from their official theology as well as from their religious practices. Up to the time of King Josiah's reform (621 BC) there was a women's cult of Asherah (under *qedeshim* auspices [consecrated for fertility practices], according to 2 Kings 23:7) in the Jerusalem Temple, alongside the male cult of Yahweh. Asherah's devotees considered her the chief wife of Yahweh, even as she was the wife of El, head of the Canaanite pantheon, for in the Bible El is identified with Yahweh. But Josiah eliminated the cult of Asherah, and official Judaism has since then left no place for other gods, which meant the elimination of every goddess. Popular religion, to be sure, persisted in the female fertility principle until the destruction of the Temple in 586 BC. In Judaean excavations Astarte figurines were found in private homes down to that time. Further purification of the Hebrew religion, which was intensified by the catastrophe of 586, put an end to the practice of pagan fertility rites, including the use of goddess figurines. Without goddesses there could be no sexual activity in the pantheon, and thus Judaism has developed without a divine mother figure.

The ancient Middle East made a place for homosexuality and bestiality in its myths and rites. In the Asherah cult the *qedeshim* priests had a reputation for homosexual practices, even as the *qedeshot* priestesses for prostitution. Israel eventually banned both the *qedeshim* and *qedeshot,* while in Ugarit the *qedeshim* and *kohanim* were priestly guilds in equally good standing. Baal is portrayed in Ugaritic mythology as impregnating a heifer to sire the young bull god. The biblical book of Leviticus (18:22–27) bans homosexuality and bestiality expressly because the Canaanite population had been practicing those rites, which the Hebrews rejected as abominations.

Phoenician/Punic sites include an area called the *tophet* that contains large numbers of infant burials. One explanation of the *tophet* is that it reflects a major aspect of a fertility cult in which the first-born child belonged to the deity. The deity rewarded the parents who had sacrificed their child with future fertility. In the Hebrew Bible, just as the firstfruits of the harvest belong to God, so do the first-born of the people and their domestic animals (Exodus 13:1, 12–13, 15).

The actual cases in the literature do not always specify infant sacrifice. The Bible describes how King Mesha of Moab sacrificed his crown prince to avert a military disaster (2 Kings 3:27). King Ahaz of Judah sacrificed his son in pagan fashion (2 Kings 16:3). King Manasseh of Judah sacrificed his sons by fire (2 Chronicles 33:6), filling Jerusalem with innocent blood.

The Jewish practice of redeeming a first-born son at the age of one month (Numbers 18:16–17) appears to be a milder substitute for the practice of child sacrifice. Another alternative to sacrificing a child was to dedicate it to the service of God. Hannah, by fulfilling her vow to ded-

icate her first-born, Samuel, to God's service (1 Samuel 1:27–28) was rewarded by the birth of five other children whom she and her husband could keep for themselves (1 Samuel 2:20–21).

Ritual and myth

According to ancient views, the myth came first, and the rite imitated or reenacted it. This sequence, however, is not necessarily the order in which religion develops. Rites can be very tenacious, and when the origin of a rite has been forgotten, a myth has often been invented to explain it.

TYPES OF RELIGIOUS ORGANIZATION AND AUTHORITY

Religion occurs at different levels of society: personal, familial, local, national, and international. At the personal and international extremes there is need for but little organization. And yet in religion, as the people of the ancient Middle East saw it, there was a progression from one stage to the next. In the early myths of Genesis, God and Noah have direct personal relations. This leads to a covenant between God and all who went out of the ark: birds and beasts as well as mankind (Genesis 9:9–10). Through the sons of Noah and their descendants, who form the nations of the world (Genesis 10), there is a theoretical progress to international religion. This scheme of the relations between God and mankind, from the personal to the universal level, mirrors the historical record of religion. Judaism (followed later by Christianity and Islām) traces "the Religion" back to Abraham, who had personal and direct relations with God, as was customary in the ancient Middle Eastern milieu. Abraham's intimacy with God is similar to the intimacy between Odysseus and the Greek goddess Athena. The next step is a covenant between a particular deity and a particular person, binding the two together in a contractual relationship for all eternity from generation to generation. Such covenants were not rare; the Hittite King Hattusilis III made such a covenant with Ishtar. Abraham's covenant is unique simply because it was the only one destined to last in history.

The descendants of able men who established a dynasty or tradition would worship the God of their father, or fathers, and adhere to the original covenant. Genesis 31 portrays Jacob and Laban swearing by their respective ancestral gods: Jacob by the god(s) of Abraham and Laban by the god(s) of Nahor. Once a group expanded into a federation of clans or tribes, religious organization became necessary. A central shrine (such as the one at Shiloh in Israel) for amphictyonic (religious confederational) pilgrimage festivals required a professional priesthood and other religious personnel to take care of sacrifices, give oracular guidance, interpret dreams and omens, as well as to provide instruction. In an amphictyony of 12 tribes, each tribe could render federal service for religious and secular purposes, one month each year. A special tribe (such as the Levites in Israel, or the Magians in Iran) could be dedicated full-time to cultic duties.

Professional priesthood

A greater degree of centralization and organization of the cult would generally follow from the establishment of a powerful state. The cult of Marduk of Babylon spread in importance and influence because Babylon became the capital of a powerful kingdom in the time of Hammurabi (18th century BC) and of a mighty empire during the reign of Nebuchadrezzar (604–562 BC). The Egyptian cult of Amon-Re not only became powerful but took on the form of a universal religion as a result of the military and political triumphs of the rulers of Thebes, particularly during the reign of Thutmose III (1479–26 BC). Under Solomon, Jerusalem became the centre of a great commercial empire. The Temple of Solomon and its God, the God of Israel, were catapulted into an international prominence that was quite different from the national status that marked the extent of Hebraic religion previously. The new internationalism of Israel's involvements paved the way for the universality of the views of the prophets. The God of Israel was subsequently concerned with all mankind and not merely with one people in one small land. This ultimately meant the transformation of biblical religion from the cult of a single people to a more subtle, spiritual movement that required different organization and different personnel. The priesthood became defunct with the destruction of Herod's Temple and the cessation of sacrifices in AD 70. The new religious leaders (rabbis) were rather teachers and spiritual guides who were united by dedication to the same scripture. The spread of the devotees over the face of the earth meant that they were now divided into regional groups, serving under different sovereigns, and the individual Jewish communities were organized independently, each with its own house of worship.

Laws of purity

There were various devices for holding an ethnic-religious group together even though it might be fragmentized into scattered communities. Laws of purity, especially those pertaining to diet, kept different groups apart. Each normally respected the other's rules, but the fact that each group had different taboos kept them from breaking bread together and mingling socially. They could do business with each other in the marketplace, but they could not fraternize in each other's homes. Above all, laws of purity were deterrents to intermarriage, the major factor that breaks up religious communities and encourages homogenization.

A SURVEY OF ANCIENT MIDDLE EASTERN RELIGIONS

Mesopotamian religions

The term Mesopotamian religions serves generally to designate the religious beliefs and practices of the Sumerians and Akkadians, who inhabited ancient Mesopotamia (modern Iraq) in the millennia before the Christian era. These beliefs and practices form a single stream of tradition. Sumerian in origin, it was added to and subtly modified by the Akkadians (Semites who emigrated into Mesopotamia from the west at the end of the 4th millennium BC), whose own beliefs were in large measure assimilated to, and integrated with, those of their new environment. For historical background, see MESOPOTAMIA, THE HISTORY OF ANCIENT.

As the only available intellectual framework that could provide a comprehensive understanding of the forces governing existence and also guidance for right conduct in life, religion ineluctably conditioned all aspects of ancient Mesopotamian civilization. It yielded the forms in which that civilization's social, economic, legal, political, and military institutions were, and are, to be understood, and it provided the significant symbols for poetry and art. In many ways it even influenced peoples and cultures outside Mesopotamia, such as the Elamites to the east, the Hurrians and Hittites to the north, and the Aramaeans and Israelites to the west.

HISTORICAL DEVELOPMENT

Cultural background. Human occupation of Mesopotamia—"the land between the rivers" (*i.e.*, the Tigris and Euphrates)—seems to reach back farthest in time in the north (Assyria), where the earliest settlers built their small villages some time around 6000 BC. The prehistoric cultural stages of Ḥassūna-Sāmarrā' and Ḥalaf (named after the sites of archaeological excavations) succeeded each other here before there is evidence of settlement in the south (the area that was later called Sumer). There, the earliest settlements, such as Eridu, appear to have been founded around 5000 BC, in the late Ḥalaf period. From then on the cultures of the north and south move through a succession of major archaeological periods that in their southern forms are known as Ubaid, Warka, Protoliterate (during which writing was invented), and Early Dynastic, at the end of which—shortly after 3000 BC—recorded history begins. The historical periods of the 3rd millennium are, in order: Akkad, Gutium, 3rd dynasty of Ur; those of the 2nd millennium: Isin-Larsa, Old Babylonian, Kassite, and Middle Babylonian; and those of the 1st millen-

nium: Assyrian, Neo-Babylonian, Achaemenian, Seleucid, and Parthian.

Politically, an early division of the country into small independent city-states, loosely organized in a league with the centre in Nippur, was followed by a unification by force under King Lugalzagesi (*c.* 2375–2350 BC) of Uruk, just before the Akkadian period. The unification was maintained by his successors, the kings of Akkad, who built it into an empire, and—after a brief interruption by Gutian invaders—by Utuhegal (*c.* 2116–*c.* 2110) of Uruk and the rulers of the 3rd dynasty of Ur (*c.* 2112–*c.* 2004 BC). When Ur fell, around 2000 BC, the country again divided into smaller units, with the cities Isin and Larsa vying for hegemony. Eventually Babylon established a lasting national state in the south, while Ashur dominated a similar rival state, Assyria, in the north. From the middle of the 1st millennium onward, Assyria built an empire comprising, for a short time, all of the ancient Middle East. This political and administrative achievement remained essentially intact under the following Neo-Babylonian and Persian kings down to Alexander's conquest (331 BC).

Stages of religious development. The religious development—as indeed that of the Mesopotamian culture generally—was not significantly influenced by the movements of the various peoples into and within the area—the Sumerians, Akkadians, Gutians, Kassites, Hurrians, and Aramaeans (or Chaldeans). Rather it forms a uniform, consistent, and coherent Mesopotamian tradition changing in response to its own internal needs of insights and expression. It is possible to discern a basic substratum involving worship of the forces in nature—often visualized in nonhuman forms—especially those that were of immediate import to basic economic pursuits. Many of these figures belong to the type of the "dying god" (a fertility deity displaying death and regeneration characteristics) but show variant traits according to whether they are powers of fertility worshiped by marsh men, orchard growers, herders, or farmers. This stage may be tentatively dated back to the 4th millennium BC and even earlier. A second stage, characterized by a view of the gods as human in shape and organized in a polity of a primitive democratic cast in which each deity had his or her special offices and functions, overlaid and conditioned the religious forms and characteristics of the earlier stage during the 3rd millennium BC. Lastly, a third stage, characterized by a growing emphasis on personal religion involving concepts of sin and forgiveness and by a change of the earlier democratic divine polity into an absolute monarchical structure dominated by the god of the national state—to the point of pious abstention from all human initiative, in absolute faith and reliance on divine intervention—characterizes the 2nd and 1st millennia BC. As a result of this development, since the ancient Mesopotamians were intensely conservative in religious matters and unwilling to discard anything of a hallowed past, the religious data of any period, and particularly those of the later periods, are a condensed version of earlier millennia that must be carefully analyzed and placed in proper perspective before it can be evaluated.

THE LITERARY LEGACY: MYTH AND EPIC

Present knowledge of ancient Mesopotamian religion rests almost exclusively on archaeological evidence recovered from the ruined city-mounds of Mesopotamia during the last century or so. Of greatest significance is the literary evidence, texts written in cuneiform (wedge-shaped) script on tablets made of clay or, for monumental purposes, on stone. Central, of course, are the specifically religious texts comprising god lists, myths, hymns, laments, prayers, rituals, omen texts, incantations, and other forms; however, since religion permeated the culture, giving form and meaning to all aspects of it, any written text, any work of art, or any of its material remains are directly or indirectly related to the religion and may further scholarly knowledge of it.

Importance of archaeological discoveries

Among the archaeological finds that have particularly helped to throw light on religion are the important discoveries of inscribed tablets with Sumerian texts in copies of Old Babylonian date (*c.* 1800–*c.* 1600 BC) at Nippur and Ur, the Sumerian and Akkadian texts of the 2nd and 1st millennia from Ashur and Sultantepe, and particularly the all-important library of the Assyrian king Ashurbanipal (reigned 668–627 BC) from Nineveh. Of nonliterary remains, the great temples and temple towers (ziggurats) excavated at almost all major sites—*e.g.*, Eridu, Ur, Nippur, Babylon, Ashur, Kalakh (biblical Calah), Nineveh—as well as numerous works of art from various periods, are important sources of information. The Uruk Vase, with its representation of the rite of the sacred marriage, the Naram-Sin stela (inscribed commemorative pillar), the Ur-Nammu stela, and the stela with the Code of Hammurabi (Babylonian king, 18th century BC), which shows at its top the royal lawgiver before the sun god Shamash, the divine guardian of justice, are important works of art that may be singled out. Other important sources are the representations on cylinder seals and on boundary stones (*kudurrus*), both of which provide rich materials for religious iconography in certain periods.

In working with, and seeking to interpret, these varied sources two difficulties stand out: the incompleteness of the data and the remoteness of the ancients from modern man, not only in time but also in experience and in ways of thought. Thus, for all periods before the 3rd millennium, scholars must rely on scarce, nonliterary data only, and, even though writing appears shortly before that millennium, it is only in its latter half that written data become numerous enough and readily understandable enough to be of significant help. It is generally necessary, therefore, to interpret the scarce data of the older periods in the light of survivals and of what is known from later periods, an undertaking that calls for critical acumen if anachronisms are to be avoided. Also, for the later periods, the evidence flows unevenly, with perhaps the middle of the 2nd millennium the least well-documented and hence least-known age.

As for the difficulties raised by differences in the ways of thinking between modern man and the ancients, they are of the kind that one always meets in trying to understand something unfamiliar and strange. A contemporary inquirer must keep his accustomed values and modes of thought in suspension and seek rather the inner coherence and structure of the data with which he deals, in order to enter sympathetically into the world out of which they came, just as one does, for example, in entering the sometimes intensely private world of a poem, or, on a slightly different level, in learning the new, unexpected

meanings and overtones of the words and phrases of a foreign language.

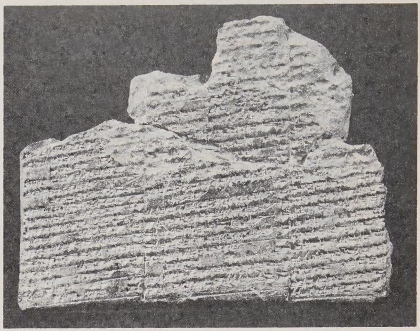
Sumerian literature. Mesopotamian literature originated with the Sumerians, whose earliest known written records are from the middle of the 4th millennium BC. It constitutes the oldest known literature in the world; moreover, inner criteria indicate that a long oral-literary tradition preceded, and probably coexisted with, the setting down of its songs and stories in writing. It may be assumed, further, that this oral literature developed the genres of the core literature. The handbook genres, however, in spite of occasional inclusions of oral formula—*e.g.,* legal or medical—may generally be assumed to have been devised after writing had been invented, as a response to the remarkable possibilities that writing offered for amassing and organizing data.

Functions of Mesopotamian religious literature

The purpose underlying the core literature and its oral prototypes would seem to have been as much magical as aesthetic, or merely entertaining, in origin. In magic, words create and call into being what they state. The more vivid and expressive the words are, the more they are believed to be efficacious—so by its expressiveness literature forms a natural vehicle of such creativity. In ancient Mesopotamia its main purpose appears to have been the enhancement of what was seen as beneficial. With the sole exception of wisdom literature, the core genres are panegyric in nature (*i.e.,* they praise something or someone), and the magical power and use of praise is to instill, call up, or activate the virtues presented in the praise.

That praise is of the essence of hymns, for instance, is shown by the fact that over and over again the encomiast, the official praiser, whose task it was to sing these hymns, closed with the standing phrase: "O [the name of a deity or human hero], thy praise is sweet." The same phrase is common also at the end of myths and epics, two further praise genres that also belonged in the repertoire of the encomiast. They praise not only in description but also in narrative, by recounting acts of valour done by the hero, thus sustaining and enhancing his power to do such deeds, according to the magical view.

In time, possibly quite early, the magical aspect of literature must have tended to fade from people's consciousness, yielding to more nearly aesthetic attitudes that viewed the praise hymns as expressions of allegiance and loyalties and accepted the narrative genres of myth and epic for the enjoyment of the story and the values expressed, poetic and otherwise.



Hymns, myths, and epics all were believed to sustain existing powers and virtues by means of praise, but laments were understood to praise blessings and powers lost, originally seeking to hold on to and recall them magically, through the power in the expression of intense longing for them and the vivid representation of them. The lamentation genre was the province of a separate professional, the elegist. It contained dirges for the dying gods of the fertility cults and laments for temples and cities that had been destroyed and desecrated. The laments for temples—which, as far as is known, go back no earlier than to the 3rd dynasty of Ur—were used to recall the beauties of the lost temple as a kind of inducement to persuade the god and the owner of the temple to restore it.

Penitential psalms lament private illnesses and misfortunes and seek to evoke the pity of the deity addressed and thus to gain divine aid. The genre apparently is late in date, most likely Old Babylonian (*c.* 19th century BC), and in it the element of magic has, to all intents and purposes, disappeared.

The core genres of Mesopotamian literature were developed by the Sumerians apparently as oral compositions.

The significance of writing

Writing, which is first attested at the middle of the 4th millennium BC, was in its origins predominantly logographic (*i.e.,* each word or morpheme was represented by a single graph or symbol) and long remained a highly imperfect means of rendering the spoken word. Even as late as the beginning of the Early Dynastic III period in southern Mesopotamia, in the early 3rd millennium, the preserved written literary texts have the character of mnemonic (memory) aids only and seem to presuppose that the reader has prior oral knowledge of the text.

As writing developed more and more precision during the 3rd millennium BC, more oral compositions seem to have been put into writing. With the 3rd dynasty of Ur a considerable body of literature had come into being and was being added to by a generation of highly gifted authors. Fortunately for its survival, this literature became part of the curriculum in the Sumerian scribal schools. It was studied and copied by student after student so that an abundance of copies, reaching a peak in Old Babylonian times, duplicated and supplemented each other as witnesses to the text of the major works. Fifty or more copies or fragments of copies of a single composition may support a modern edition, and many thousands more copies probably lie unread, still buried in the earth.

Myths. The genre of myths in ancient Mesopotamian literature centres on praises that recount and celebrate great deeds. The doers of the deeds (creative or otherwise decisive acts), and thus the subjects of the praises, are the gods. In the oldest myths, the Sumerian, these acts tend to have particular rather than universal relevance, which is understandable since they deal with the power and acts of a particular god with a particular sphere of influence in the cosmos. An example of such myths is the myth of "Dumuzi's Death," which relates how Dumuzi (Producer of Sound Offspring), the power in the fertility of spring, dreamed of his own death at the hands of a group of deputies from the netherworld and how he tried to hide himself but was betrayed by his friend after his sister had resisted all attempts to make her reveal where he was.

"Dumuzi's Death"

A similar, very complex myth, "Inanna's Descent," relates how the goddess Inanna (Lady of the Date Clusters) set her heart on ruling the netherworld and tried to depose her older sister, the queen of the netherworld, Ereshkigal (Lady of the Greater Earth). Her attempt failed, and she was killed and changed into a piece of rotting meat in the netherworld. It took all the ingenuity of Enki (Lord of Sweet Waters in the Earth) to bring Inanna back to life, and even then she was released only on condition that she furnish a substitute to take her place. On her return, finding her young husband Dumuzi feasting instead of mourning for her, Inanna was seized with jealousy and designated him as that substitute. Dumuzi tried to flee the posse of deputies who had accompanied Inanna, and with the help of the sun god Utu (Sun), who changed Dumuzi's shape, he managed to escape, was recaptured, escaped again, and so on, until he was finally taken to the netherworld. The fly told his little sister Geshtinanna where he was, and she went in search of him. The myth ends with Inanna rewarding the fly and decreeing that Dumuzi and his little sister could alternate as her substitute, each of them spending half a year in the netherworld, the other half above with the living.

A third myth built over the motif of journeying to the netherworld is the myth of "The Engendering of the Moongod and his Brothers," which tells how Enlil (Lord Wind), when still a youngster, came upon young Ninlil (goddess of grain) as she—eager to be with child and disobeying her mother—was bathing in a canal where he would see her. He lay with her in spite of her pretending to protest and thus engendered the moon god Suen. For this offense Enlil was banished from Nippur and took the road to the netherworld. Ninlil, carrying his child, followed him. On the way Enlil took the shape first of the Nippur gatekeeper, then of the man of the river of the netherworld, and lastly of the ferryman of the river of the netherworld. In each such disguise Enlil persuaded Ninlil to let him lie with her to engender a son who might take Suen's place in the netherworld and leave him free for the world above. Thus three further deities, all underworld figures, were engendered: Meslamtaea (He Who Comes Out of the Meslam Temple), Ninazu (Water Sprinkler [?]), and Ennugi (the God Who Returns Not). The myth ends with a paean to Enlil as a source of abundance and to his divine word, which always comes true.

Most likely all of these myths have backgrounds in fertility cults and concern the disappearance of nature's fertility with the onset of the dry season or with the underground storage of food.

As Enlil is celebrated for engendering other gods that embody other powers in nature, so also was Enki in the myth of "Enki and Ninhursag," in which myth Enki lay down with Ninhursag (Lady of the Stony Ground) on the island of Dilmun (modern Bahrain), which had been allotted to them. At that time all was new and fresh, inchoate, not yet set in its present mold. There Enki provided water for the future city of Dilmun, lay with Ninhursag, and left her. She gave birth to a daughter, Ninshar (Lady Herb), on whom Enki in turn engendered the spider Uttu, goddess of spinning and weaving. Ninhursag warned Uttu against Enki, but he, proffering marriage gifts, persuaded her to open the door to him. After Enki had abandoned Uttu, Ninhursag found her and removed Enki's semen from her body. From the semen seven plants sprouted forth. These plants Enki later saw and ate and so became pregnant from his own semen. Unable as a male to give birth, he fell fatally ill, until Ninhursag relented and—as birth goddess—placed him in her vulva and helped him to give birth to seven daughters, whom Enki then happily married off to various gods. The story is probably to be seen as a bit of broad humour.

Not only the birth of gods but also the birth, or creation, of man is treated in the myths. The myth of "Enki and Ninmah" relates how the gods originally had to toil for their food, dig irrigation canals, and perform other menial tasks until, in their distress, they complained to Enki's mother, Nammu, who took the complaints to Enki. Enki remembered the engendering clay of the Apsu (*i.e.*, the fresh underground waters that fathered him), and from this clay, with the help of the womb goddesses and eight midwife goddesses led by Ninmah (another name for Ninhursag), he had his mother become pregnant with and give birth to man so that he could relieve the gods of their toil. At the celebration of the birth, however, Enki and Ninmah both drank too much beer and began to quarrel. Ninmah boasted that she could impair man's shape at will, and Enki countered that he could temper even the worst that she might do. So she made seven freaks, for each of which Enki found a place in society and a living. He then challenged her to alleviate the mischief he could do, but the creature he fashioned—a prematurely aborted fetus—was beyond help. The moral drawn by Enki was that both male and female contribute to the birth of a happy child. The aborted fetus lacked the contribution of the birth goddess in the womb.

The ordering, rather than the creation, of the world is the subject of another myth about Enki, called "Enki and World Order." Beginning with long praises and self-praises of Enki, it tells how he blessed Nippur (Sumer), Ur, Meluhha (Ethiopia), and Dilmun (Bahrain) and gave them their characteristics, after which he turned his attention to the Euphrates and Tigris rivers, to the marshes, the sea, and the rains, and then to instituting one facet after another of the economic life of Sumer: agriculture, housebuilding, herding, and so forth. The story ends with a complaint by Enki's granddaughter Inanna that she has not been given her due share of offices, at which he patiently pointed to various offices she had in fact been given and kindly added a few more.

Another myth about the world order but dealing with it from a very different point of view concerns Enlil's son, the rain god Ninurta, called from its opening word *Lugal-e* ("O King"). This myth begins with a description of the young king, Ninurta, sitting at home in Nippur when, through his general, reports reach him of a new power that has arisen in the mountains to challenge him—*i.e.*, Azag, son of Anu (Sky) and Ki (Earth), who has been chosen king by the plants and is raiding the cities with his warriors, the stones. Ninurta sets out in his boat to give battle, and a fierce engagement ensues, in which Azag is killed. Afterward Ninurta reorganizes his newly won territory, builds a stone barrier, the near mountain ranges or foothills (the *hursag*), and gathers the waters that used to go up into the mountains and directs them into the Tigris to flood it and provide plentiful irrigation water from Sumer. The *hursag* he presents as a gift to his mother, who had come to visit him, naming her Ninhursag (Lady of the *hursag*). Lastly he sits in judgment on the stones who had formed the Azag's army. Some of them, who had shown special ill will toward him, he curses, and others he trusts and gives high office in his administration. These judgments give the stones their present characteristics so that, for example, the flint is condemned to break before the much softer horn, as it indeed does when the horn is pressed against it to flake it. Noteworthy also is the way in which order in the universe, the yearly flood and other seasonal events, is seen—consonantly with Ninurta's role as "king" and leader in war—under the pattern of a reorganization of conquered territories.

Other myths about Ninurta are *An-gim dim-ma* and a myth of his contest with Enki. The first of these tells how Ninurta, on returning from battle to Nippur, was met by Enlil's page Nusku, who ordered him to cease his warlike clamour and not scare Enlil and the other gods. After long speeches of self-praise by Ninurta, further addresses to him calmed him and made him enter his temple gently. The second tale relates how he conquered the Thunderbird Ansud with Enki's help but missed the powers it had stolen from him, and how, resentful at this, he plotted against Enki but was outsmarted and trapped. Another Sumerian myth, the "Eridu Genesis," tells of the creation of man and animals, of the building of the first cities, and of the flood.

Epics. The genre of epics appears generally to be younger in origin than that of myths and apparently was linked—in subject matter and values—to the emergence of monarchy at the middle of the Early Dynastic period. The works that have survived seem, however, all to be of later date. A single short Sumerian epic tale, "Gilgamesh and Agga of Kish," is told in the style of primary epic. It deals with Gilgamesh's successful rebellion against his

overlord and former benefactor, Agga of Kish. More in the style of romantic epic are the stories of "Enmerkar and the Lord of Aratta," "Enmerkar and Ensuhkeshdanna," and the "Lugalbanda epic," all of which have as heroes rulers of the 1st dynasty of Uruk (*c.* 3500 BC) and deal with wars between that city and the fabulous city of Aratta in the eastern highlands. Gilgamesh, also of that dynasty, figures as the hero of a variety of short tales; some, such as "Gilgamesh and Huwawa" and "Gilgamesh and the Bull of Heaven," are in romantic epic style, and others, such as "The Death of Gilgamesh" and "Gilgamesh, Enkidu and the Netherworld," concern the inescapable fact of death and the character of afterlife.

Akkadian literature. The first centuries of the 2nd millennium BC witnessed the demise of Sumerian as a spoken language and its replacement by Akkadian. Because of its role as bearer of Sumerian culture, as the language of religion, literature, and many arts, however, Sumerian (much as Latin in the Middle Ages) continued to be taught and spoken in the scribal schools throughout the 2nd and 1st millennia BC. New compositions were even composed in Sumerian. As time passed these grew more and more corrupt in grammar.

Akkadian, when it supplanted Sumerian as the spoken language of Mesopotamia, was not without its own literary tradition. Writing, to judge from Akkadian orthographic peculiarities, was very early borrowed from the Sumerians. By Old Babylonian times (*c.* 19th century BC), the literature in Akkadian, partly under the influence of Sumerian models and Sumerian literary themes, had developed myths and epics of its own, among them the superb Old Babylonian Gilgamesh epic (dealing with the problem of death; see below *Epics*) as well as hymns, disputation texts (evaluations of elements of the cosmos and society), penitential psalms, and not a few independent new handbook genres—*e.g.,* omina, rituals, laws and legal phrasebooks (often translated from Sumerian), mathematical texts, and grammatical texts. There was a significant amount of translation from Sumerian; translations include incantation series such as the *Utukke limnuti* ("The Evil Spirits"), laments for destroyed temples, penitential psalms, and others. The prestige of Sumerian as a literary language, however, is indicated by the fact that translations were rarely, if ever, allowed to supersede the original Sumerian text. The Sumerian text was kept with an interlinear translation to form a bilingual work.

The continued study and copying of literature in the schools, both Sumerian and Akkadian, by the middle of the 2nd millennium led to a remarkable effort of standardizing, or canonizing. Texts of the same genre were collected, often under royal auspices and with royal support, and were then sifted and finally edited in series that from then on were recognized as the canonical form. Authoritative texts were established for incantations, laments, omina, medical texts, lexical texts, and others. In myths and epics, such major and lengthy compositions as the Akkadian creation story *Enuma elish,* the Erra myth, the myth of Nergal and Ereshkigal, the Etana legend, the Gilgamesh epic, and the Tukulti-Ninurta epic were reworked or re-created.

Canonization of Mesopotamian religious literature

Of special interest are philosophical compositions, such as the Akkadian *Ludlul bel nemeqi,* "Let me praise the expert," and theodicies (justification of divine ways) that deal with the problem of the just sufferer, similar to the biblical Job. They constitute a high point in the genre of wisdom literature. From the 1st millennium BC the rise of factual historical chronicles and a spate of political and religious polemical writings reflecting the rivalry between Assyria and Babylonia deserve mention. Very late in the millennium, the first astronomical texts appeared.

Myths. The Akkadian myths are in many ways dependent on Sumerian materials, but they show an originality and a broader scope in their treatment of the earlier Sumerian concepts and forms; they address themselves more often to existence as a whole. Fairly close to Sumerian prototypes is an Akkadian version of the myth of "Inanna's Descent." An Old Babylonian myth about the Thunderbird Ansud, who stole the tablets of fates and was conquered by Ninurta, who was guided by Enki's counsel, is probably closely related to the Sumerian story of Ninurta's contest with Enki.

Also important is an Old Babylonian "Myth of Atrahasis," which, in motif, shows a relationship with the account of the creation of man to relieve the gods of toil in the "Enki and Ninmah" myth, and with a Sumerian account of the Flood in the "Eridu Genesis." The Atrahasis myth, however, treats these themes with noticeable originality and remarkable depth. It relates, first, how the gods originally had to toil for a living, how they rebelled and went on strike, how Enki suggested that one of their number—the god We, apparently the ringleader who "had the idea"—be killed and mankind created from clay mixed with his flesh and blood, so that the toil of the gods could be laid on man and the gods left to go free. But after Enki and the birth goddess Nintur (another name for Ninmah) had created man, man multiplied at such a rate that the din he made kept Enlil sleepless. At first Enlil had Namtar, the god of death, cause a plague to diminish mankind's numbers, but the wise Atrahasis, at the advice of Enki, had man concentrate all worship and offerings on Namtar. Namtar, embarrassed at hurting people who showed such love and affection for him, stayed his hand. Next Enlil had Adad, the god of rains, hold back the rains and thus cause a famine, but, because of the same stratagem, Adad was embarrassed and released the rains. After this, Enlil planned a famine by divine group action that would not be vulnerable as the earlier actions by individual gods had been. Anu and Adad were to guard the heavens, he himself earth, and Enki the waters underground and the sea so that no gift of nature could come through to man. The ensuing famine was terrible. By the seventh year one house consumed the other and people began eating their own children. At that point Enki—accidentally he main-

tained—let through a wealth of fish from the sea and so saved man. With this, however, Enlil's patience was at an end and he thought of the Flood as a means to get rid of humanity once and for all. Enki, however, warned Atrahasis and had him build a boat in which he saved himself, his family, and all animals. After the flood had abated and the ship was grounded, Atrahasis sacrificed, and the hungry gods, much chastened, gathered around the offering. Only Enlil was unrelenting until Enki upbraided him for killing innocent and guilty alike and—there is a gap in the text—suggested other means to keep human numbers down. In consultation with the birth goddess Nintur, Enki then developed a scheme of birth control by inventing the barren woman, the demon Pashittu who kills children at birth, and the various classes of priestesses to whom giving birth was taboo.

The role of Atrahasis as the hero of the Flood

The myth uses the motif of the protest of the gods against their hard toil and the creation of man to relieve it, which was depicted earlier in the Sumerian myth of "Enki and Ninmah," and also the motif of the Flood, which occurred in the "Eridu Genesis." The import of these motifs here is, however, new: they bring out the basic precariousness of man's existence; man's usefulness to the gods will not protect him unless he takes care not to annoy them, however innocently. He must stay within bounds; there are limits set for his self-expression.

A far more trustful and committed attitude toward the powers that rule existence finds expression in the seemingly slightly later Babylonian creation story, *Enuma elish,* which may be dated to the later part of the 1st dynasty of Babylon (*c.* 1894–*c.* 1595 BC). Babylon's archenemy at that time was the Sealand, which controlled Nippur and the country south of it—the ancestral country of Sumerian civilization. This lends political point to the battle of Marduk (thunder and rain deity), the god of Babylon, with the Sea, Tiamat; it also accounts for the odd, almost complete silence about Enlil of Nippur in the tale.

The origin of the gods

The myth tells how in the beginning there was nothing but Apsu, the sweet waters underground, and Tiamat, the sea, mingling their waters together. In these waters the first gods came into being, and generation followed generation. The gods represented energy and activity and thus differed markedly from Apsu and Tiamat, who stood for rest and inertia. True to their nature the gods gathered to dance, and in so doing, surging back and forth, they disturbed the insides of Tiamat. Finally, Apsu's patience was at an end, and he thought of doing away with the gods, but Tiamat, as a true mother, demurred at destroying her own offspring. Apsu, however, did not swerve from his decision, and he was encouraged in this by his page Mummu, "the original (watery) form." When the youngest of the gods, the clever Ea (Sumerian Enki), heard about the planned attack he forestalled it by means of a powerful spell with which he poured slumber on Apsu, killed him, and built his temple over him. He seized Mummu and held him captive by a nose rope.

In the temple thus built the hero of the myth, Marduk, was born. From the first he was the darling of his grandfather, the god of heaven, Anu, who engendered the four winds for him to play with. As they blew and churned up waves, the disturbing of Tiamat—and of a faction of the gods who shared her desire for rest—became more and more unbearable. At last these gods succeeded in rousing her to resistance, and she created a mighty army with a spearhead of monsters to destroy the gods. She placed her consort Kingu ("Task[?]") at the head of it and gave him absolute powers.

When news of these developments reached the gods there was consternation. Ea was sent to make Tiamat desist, and then Anu, but to no avail. Finally Anshar, god of the horizon and king of the gods, thought of young Marduk. Marduk proved willing to fight Tiamat but demanded absolute authority. Accordingly, a messenger was sent to the oldest of the gods, Lahmu and Lahamu ("Silt[?]"), to call the gods to assembly, and in the assembly the gods conferred absolute authority on Marduk, tested it by seeing whether his word of command alone could destroy a constellation and then again make it whole, hailed him king, and set him on the road of "security and obedience," a formula of allegiance that based his power and authority on the pressing need for protection of the moment.

In the ensuing encounter with Tiamat's forces Kingu and his army lost heart when they saw Marduk. Only Tiamat stood her ground, seeking first to throw him off his guard by flattery about his quick rise to leadership, but Marduk angrily denounced her and the older generation: "The sons (had to) withdraw (for) the fathers were acting treacherously, and (now) you, who gave birth to them, bear malice to the offspring." At this Tiamat, furious, attacked, but Marduk loosed the winds against her, pierced her heart with an arrow, and killed her. Kingu and the gods who had sided with her he took captive.

Having thus won a lasting victory for his suzerain, King Anshar, he gave thought to what he might do further. Cleaving the carcass of Tiamat, he raised half of her to form heaven, ordered the constellations, the calendar, the movements of Sun and Moon, and, keeping control of atmospheric phenomena for himself, made the Earth out of the other half of her, arranging its mountains and rivers. Having organized the various administrative tasks, he put their supervision in Ea's hands; to Anu he gave the tablets of fate he had taken from Kingu. His prisoners he paraded in triumphal procession before his fathers, and as a monument to his victory he set up images of Tiamat's monsters at the gate of his parental home. The gods were overjoyed to see him; Anshar rushed toward him and Marduk formally announced to him the state of security he had achieved. He then bathed, dressed, and seated himself on his throne, with the spear "Security and Obedience," named from his mandate, at his side. By now, however, the situation had subtly altered. The old fear and urgent need for protection was gone, but in its stead had come a promise held out by Marduk's organizational powers; so when the gods reaffirmed their allegiance to him as king they used a new formula: "benefits and obedience." From then on Marduk would take care of their sanctuaries and they, in turn, would obey him.

The building of Babylon

Marduk then announced his intention of building a city for himself, Babylon, with room for the gods when they come there for assembly. His fathers suggested that they move to Babylon themselves to be with him and help in the administration of the world he had created. Next, he pardoned the gods who had sided with Tiamat and had been captured, charging them with the building tasks. Grateful for their lives, they prostrated themselves before him, hailed him as king, and promised to do the building.

Pleased with their willingness, Marduk magnanimously wanted to relieve them even from this chore and planned to create man to do the toil for them. At the advice of his father Ea, he then had them indict Kingu as instigator of the rebellion. Kingu was duly sentenced and executed, and from his blood Ea created man. Then Marduk divided the gods into a celestial and a terrestrial group, assigned them their tasks in the cosmos, and allotted them their stipends. Thus freed from all burdens, the gods wanted to show their gratitude to Marduk, and as a token they took, of their own free will, for one last time, spade in hand to build Babylon and Marduk's temple Esagila. In the new temple the gods then assembled and distributed the celestial and terrestrial offices. The "great gods" went into session and permanently appointed the "seven gods of destinies," or better "of the decrees," who would formulate in final form the decrees enacted by the assembly. Marduk then presented his weapons, and Anu adopted the bow as his daughter and gave it a seat among the gods. Lastly, Marduk was enthroned, and after the gods had prostrated themselves before him they bound themselves by oath—touching their throats with oil and water—and formally gave him kingship, appointing him permanently lord of the gods of heaven and earth. After this they solemnly named his 50 names expressive of his power and achievements. The myth ends with a plea that it be handed on from father to son and told to future rulers, that they may heed Marduk: it is the song of Marduk who bound Tiamat and assumed the kingship.

The motifs from which this myth is built up are in large measure known from elsewhere. The initial generation of the gods is a variant form of the genealogy of Anu in

the great god list *An: Anum.* The threat to annihilate the disturbers of sleep are known from the Atrahasis and the Sumerian Flood traditions. The battle of Marduk with Tiamat seems to stem from western myths of a battle between the thunder god and the sea. The organization of the universe after victory recalls the organization of conquered territory in *Lugal-e.* The killing of a rebel god to create man to take over the gods' toil is found in the Atrahasis myth and—without the rebel aspect—in a bilingual creation myth found in Assur. New and original, however, is the way in which they have all been grouped and made dependent on the figure of the young king. The political form of the monarchy is seen as embracing the universe; it was the prowess of a young king that overcame the forces of inertia; it was his organizational genius that created and organized all; and it is he that—like his counterpart on earth, the human king—grants benefits in return for obedience.

The value of the monarchy

The high value set on the monarchy as a guarantor of security and order in the *Enuma elish* can hardly have seemed obvious in Babylonia in the first troubled years of Assyrian rule in the second quarter of the 1st millennium BC. From this period (*c.* 700 BC) comes a myth usually called the Erra epic, which reads almost like a polemic against *Enuma elish.* It tells how the god of affray and indiscriminate slaughter, Erra, persuaded Marduk to turn over the rule of the world to him while Marduk was having his royal insignia cleaned, and how Erra, true to his nature, used his powers to institute indiscriminate rioting and slaughter. Royal power here stands no longer for security and order but for the opposite: license to kill and destroy.

Two other Akkadian myths may be mentioned—both probably dating from the middle of the 2nd millennium—the myth of the "Dynasty of Dunnum" and the myth of "Nergal and Ereshkigal." The first of these tells of succeeding divine generations ruling in Dunnum, the son usually killing his father and marrying, sometimes his mother, sometimes his sister, until—according to a reconstruction of the broken text—more acceptable mores came into vogue with the last generation of gods, Enlil and Ninurta. This myth, as has been mentioned, underlies the Greek poet Hesiod's *Theogony.* The myth of Nergal and Ereshkigal relates the unorthodox way in which the god Nergal became the husband of Ereshkigal and king of the netherworld.

Epics. The quick rise of Sargon, the founder of the dynasty of Akkad (*c.* 2334–*c.* 2154 BC), from obscurity to fame and his victory over Lugalzagesi of Uruk form the theme of several epic tales. The sudden eclipse of the Akkadian empire long after Naram-Sin, which was wrongly attributed to that ruler's presumed pride and the gods' retaliation, is the theme of "The Fall of Akkad." Akkadian epic tradition continues and gives focus to the Sumerian tales of Gilgamesh.

The Gilgamesh epic

The Akkadian epic of Gilgamesh seems to have been composed in Old Babylonian times but was reworked by a certain Sin-leqe-unnini later in the 1st millennium BC. It tells how Gilgamesh, the young ruler of Uruk, drives his subjects so hard that they appeal to the gods for relief. The gods create a wild man, Enkidu, who at first lives with the animals in the desert but is lured away from them and becomes Gilgamesh's friend. Together they vanquish the terrifying Huwawa, set by Enlil to guard the cedar forest in the West, and, when on their return the goddess of Uruk, Ishtar, falls in love with Gilgamesh, is jilted by him, and sends the dread "bull of heaven" to kill him, he and Enkidu manage to kill the bull. At this point, however, their fortunes change. Enlil, angered at the killing of Huwawa, causes Enkidu to fall ill and die, and Gilgamesh, inconsolable at the death of his friend and terrified at the realization that he himself must someday die, sets out to find eternal life.

After many adventures he reaches his ancestor Utnapishtim, to whom the gods have granted eternal life, but his case proves to be a unique one and so of no help to Gilgamesh. Utnapishtim was rewarded for having saved human and animal life at the time of the great Flood. Eventually, just as Gilgamesh is ready to return home, he is told about a plant that rejuvenates and makes old men children again. Gilgamesh finds it and begins his return journey. But, as the day is warm, when he passes an inviting pool he leaves his clothes and the plant on the shore and goes in for a swim. A serpent smells the plant, comes out of its hole, and eats it. Thus Gilgamesh's quest comes to naught. Eternal life is beyond man's grasp. The Gilgamesh epic is perhaps the most moving work in ancient Mesopotamian literature, with its sharp contrast of values: the warrior's disdain of death and danger, which informs the early parts of the epic, and the haunting fear that drives Gilgamesh in the later parts.

Other Akkadian epics that deserve to be mentioned are the Etana epic, which tells how Etana, the first king, was carried up to heaven on the back of an eagle to obtain the plant of birth so that his son could be born. Also important are the epic tales about Sargon of Akkad, one of which, the birth legend, tells of his abandonment in a casket on the river by his mother—much as the Bible tells that Moses was abandoned—and his discovery by an orchardman, who raised him as his son. Another Sargon tale is "The King of Battle," which tells about conquests in Asia Minor to protect foreign trade. Naram-Sin is the central figure in another tale dealing with that king's pride and also relating the destructive invasions by barbarous foes. A late flowering of primary epic is the Assyrian Tukulti-Ninurta (reigned 1243–07 BC) epic that deals with that king's wars with Babylonia.

THE MESOPOTAMIAN WORLDVIEW AS EXPRESSED IN MYTH

The more completely a given culture is embraced, the more natural will its basic tenets seem to the people involved. The most fundamental of its presuppositions are not even likely to rise into awareness and be consciously held but are tacitly taken for granted. It takes a degree of cultural decline, of the loosening of the culture's grip on thought and action, before its most basic structural lines can be recognized and, if need be, challenged. Since culture, the total pattern within which man lives and acts, is thus not likely to be conceived of consciously and as a whole until it begins to lose its obvious and natural character, it is understandable that those myths of a culture that may be termed existential—in the sense that they articulate human existence as a whole in terms of the culture and show its basic structure—are rarely encountered until comparatively late in the history of a culture. Before that occurs, it is, rather, the particular aspects and facets of existence that are apt to claim attention.

In ancient Mesopotamia the oldest known materials, the Sumerian myths, have relatively little to say about creation; scholars must, for the most part, turn to the introductions of tales and disputations to infer how things were believed to be in the beginning. Thus, a story about the hero Gilgamesh refers in its introductory lines to the times "after heaven had been moved away from earth, after earth had been separated from heaven." The same notion that heaven and earth were once close together occurs also in a bilingual Sumero-Akkadian text from Ashur about the creation of man. The actual act of separating them is credited to the storm god Enlil of Nippur in the introduction to a third tale that deals with the creation of the first hoe. From similar passing remarks scholars have inferred that the gods, before man came into being, had to labour hard at the heavy works of irrigation agriculture and dug out the beds of the Tigris and the Euphrates.

Cosmogony and cosmology. Though the "Eridu Genesis" may have come close to treating existence as a whole, a true cosmogonic and cosmological myth that deals centrally with the origins, structuring, and functional principles of the cosmos does not actually appear until Old Babylonian times, when Mesopotamian culture was entering a millennium and a half of doubts about the moral character of world government and even of divine power itself. Yet, the statement is a positive one, almost to the point of defiance. *Enuma elish* tells of a beginning when all was a watery chaos and only the sea, Tiamat, and the sweet waters under ground, Apsu, mingled their waters together. Mummu, the personified original watery form, served as Apsu's page. In their midst the gods were

born. The first pair, Lahmu and Lahamu, represented the powers in silt; the next, Anshar and Kishar, those in the horizon. They engendered the god of heaven, Anu, and he in turn the god of the flowing sweet waters, Ea.

An: Anum

This tradition is known in a more complete form from an ancient list of gods called *An: Anum.* There, after a different beginning, Lahmu and Lahamu give rise to Duri and Dari, "the time-cycle"; and these in turn give rise to Enshar and Ninshar, "Lord and Lady Circle." Enshar and Ninshar engender the concrete circle of the horizon, Anshar and Kishar, probably conceived as silt deposited along the edge of the universe. Next was the horizon of the greater heaven and earth, and then—omitting an intrusive line—heaven and earth, probably conceived as two juxtaposed flat disks formed from silt deposited inward from the horizons.

Enuma elish truncates these materials and violates their inner logic considerably. Though they are clearly cosmogonic and assume that the cosmic elements and the powers informing them come into being together, *Enuma elish* seeks to utilize them for a pure theogony (account of the origin of the gods). The creation of the actual cosmos is dealt with much later. Also, the introduction of Mummu, the personified "original form," which in the circumstances can only be that of water, may have led to the omission of Ki, "Earth," who—as nonwatery—did not fit in.

The gods, who in *Enuma elish* come into being within Apsu and Tiamat, are viewed as dynamic creatures, who contrast strikingly with the older generation. Apsu and Tiamat stand for inertia and rest. This contrast leads to a series of conflicts in which first Apsu is killed by Ea; then Tiamat, who was roused later to attack the gods, is killed by Ea's son Marduk. It is Marduk, the hero of the story, who creates the extant universe out of the body of Tiamat. He cuts her, like a dried fish, in two, making one-half of her into heaven—appointing there Sun, Moon, and stars to execute their prescribed motions—and the other half into the Earth. He pierces her eyes to let the Tigris and Euphrates flow forth, and then, heaping mountains on her body in the east, he makes the various tributaries of the Tigris flow out from her breasts. The remainder of the story deals with Marduk's organization of the cosmos, his creation of man, and his assigning to the gods their various cosmic offices and tasks. The cosmos is viewed as structured as, and functioning as, a benevolent absolute monarchy.

The gods and demons. The gods were, as mentioned previously, organized in a polity of a primitive democratic cast. They constituted, as it were, a landed nobility, each god owning and working an estate—his temple and its lands—and controlling the city in which it was located. On the national level they attended the general assembly of the gods, which was the highest authority in the cosmos, to vote on matters of national import such as, for example, election or deposition of kings. The major gods also served on the national level as officers having charge of cosmic offices. Thus, for example, Utu, the sun god, was the judge of the gods, in charge of justice and righteousness generally.

Hierarchy of the gods

Highest in the pantheon—and presiding in the divine assembly—ranked An (Akkadian Anu), god of heaven, who was responsible for the calendar and the seasons as they were indicated by their appropriate stars. Next came Enlil of Nippur, god of winds and of agriculture, creator of the hoe. Enlil executed the verdicts of the divine assembly. Equal in rank to An and Enlil was the goddess Ninhursag (also known as Nintur and Ninmah), goddess of stony ground: the near mountain ranges in the east and the stony desert in the west with its wildlife—wild asses, gazelles, wild goats, etc. She was also the goddess of birth. With these was joined—seemingly secondarily—Enki (Ea), god of the sweet waters of rivers and marshes; he was the cleverest of the gods and a great troubleshooter, often appealed to by both gods and men. Enlil's sons were the moon god Nanna or Sin; the god of thunderstorms, floods, and the plough, Ninurta; and the underworld figures Meslamtaea, Ninazu, and Ennugi. Sin's sons were the sun god and judge of the gods, Utu (the Akkadian Shamash); the rain god Ishkur (the Akkadian Adad); and his daughter, the goddess of war, love, and morning and evening star, Inanna (the Akkadian Ishtar). Inanna's ill-fated young husband was the herder god Dumuzi (the Akkadian Tammuz). The dread netherworld was ruled by the goddess Ereshkigal and her husband Nergal, a figure closely related to Meslamtaea and Ninurta. Earlier tradition mentions Ninazu as her husband.

Demons played little or no role in the myths or lists of the Mesopotamian pantheon. Their domain was that of incantations. Mostly, they were depicted as outlaws; the demoness Lamashtu, for instance, was hurled from heaven by her father An because of her wickedness. The demons attacked man by causing all kinds of diseases and were, as a rule, viewed as wind and storm beings. Consonant with the classical view of the universe as a cosmic state, it was possible for a person to go to the law courts against the demons—*i.e.,* to seek recourse before Utu and obtain judgments against them. Various rituals for such procedures are known.

Man: his origin, nature, and destiny. Two different notions about man's origin seem to have been current in ancient Mesopotamian religions. Brief mentions in Sumerian texts indicate that the first men grew from the earth in the manner of grass and herbs. One of these texts, the "Myth of the Creation of the Hoe," adds a few details: Enlil removed heaven from earth in order to make room for seeds to come up, and after he had created the hoe he used it to break the hard crust of earth in Uzumua ("the flesh-grower"), a place in the Temple of Inanna in Nippur. Here, out of the hole made by Enlil's hoe, man grew forth.

The other notion presented the view that man was created from select "ingredients" by Enki, or by Enki and his mother Nammu, or by Enki and the birth goddess called variously Ninhursag, Nintur, and Ninmah. In the myth of "Enki and Ninmah" recounted above, Enki had man sired by the "engendering clay of the Apsu"—*i.e.,* of the waters underground—and borne by Nammu. The Akkadian tradition, as represented by the "Myth of Atrahasis," had Enki advise that a god—presumably a rebel—be killed and that the birth goddess Nintur mix his flesh and blood with clay. This was done, after which 14 womb goddesses gestated the mixture and gave birth to 7 human pairs. A similar—probably derived—form of this motif is found in *Enuma elish,* in which Enki (Ea) alone fashioned man out of the blood of the slain rebel leader Kingu. The creation of man from the blood shed by two slain gods is yet another version of the motif that appears in a bilingual myth from Ashur.

The divine and earthly nature of man

Man's nature, then, is part clay (earthly) and part god (divine). The divine aspect, however, is not that of a living god but rather that of a slain, powerless divinity. The Atrahasis story relates that the *etemmu* (ghost) of the slain god was left in man's flesh and thus became part of man. It is this originally divine part of man, his *etemmu,* that was believed to survive at his death and to give him a shadowy afterlife in the netherworld. No other trace of a notion of divine essence in man is discernible; in fact, man by himself was viewed as being utterly powerless to act effectively or to succeed in anything. For anything he might wish to do or achieve, man needed the help of a personal god or goddess, some deity in the pantheon who for one reason or other had taken an interest in him and helped and protected him, for "Without his personal god a man eats not."

About man's destiny all sources agree. However man may have come into being, he was meant to toil in order to provide food, clothing, housing, and service for the gods, so that they, relieved of all manual labour, could live the life of a governing upper class, a landed nobility. In the scheme of existence man was thus never an end, always just a means.

INSTITUTIONS AND PRACTICES

City-state and national state. In early dynastic times, probably as far back as historians can trace its history, Mesopotamia was divided into small units, the so-called city-states, consisting of a major city with its surrounding lands. The ruler of the city—usually entitled *ensi*—was

also in charge of the temple of the city god. The spouse of the *ensi* had charge of the temple of the city goddess, and the children of the *ensi* administered the temples of the deities who were regarded as children of the city god and the city goddesses. After the foundation of larger political units, such as leagues or empires, contributions were made to a central temple of the political unit, such as the temple of Enlil at Nippur in the Nippur league. On the other hand, however, the king or other central ruler might also contribute to the shrines of local cults. When, in the 2nd and 1st millennia, Babylonia and Assyria emerged as national states, their kings had responsibility for the national cult, and each monarch supervised the administration of all temples in his domain.

The purpose of man in relation to the gods

Cult. In the cultic practices, humans fulfilled their destiny: to take care of the gods' material needs. They therefore provided the gods with houses (the temples) that were richly supplied with lands, which people cultivated for them. In the temple the god was present in—but not bounded by—a statue made of precious wood overlaid with gold. For this statue the temple kitchen staff prepared daily meals from victuals grown or raised on the temple's fields, in its orchards, in its sheepfolds, cattle pens, and game preserves, brought in by its fishermen, or delivered by farmers owing it as a temple tax. The statue was also clad in costly raiment, bathed, and escorted to bed in the bedchamber of the god, often on top of the temple tower, or ziggurat. To see to all of this the god had a corps of house servants—*i.e.,* priests trained as cooks, bakers, waiters, and bathers, or as encomiasts (singers of praise) and musicians to make the god's meals festive, or as elegists to soothe him in times of stress and grief. Diversions from the daily routine were the great monthly festivals and also a number of special occasions. Such special occasions might be a sudden need to go through the elaborate ritual for purifying the king when he was threatened by the evils implied in an eclipse of the Moon, or in extreme cases there might be a call for the ritual installation of a substitute king to take upon himself the dangers threatening, and various other nonperiodic rituals.

Partly regular, partly impromptu, were the occasions for audiences with the god in which the king or other worshipers presented their petitions and prayers accompanied by appropriate offerings. These were mostly edibles, but not infrequently the costly containers in which they were presented, stone vases, golden boat-shaped vessels, etc., testified to the ardour of the givers. Appropriate gifts other than edibles were also acceptable—among them cylinder seals for the god's use, superhuman in size, and weapons for him, such as maceheads, also outsize.

To the cult, but as private rather than as part of the temple cult, may be counted also the burial ritual, concerning which, unfortunately, little is known. In outgoing Early Dynastic times in Girsu two modes of burial were current. One was ordinary burial in a cemetery; the nature of the other called laying the body "in the reeds of Enki," is not understood. It may have denoted the floating of the body down the river into the canebrakes. Elegists and other funerary personnel were in attendance and conducted the laments seeking to give full expression to the grief of the bereaved and propitiate the spirit of the dead. In later times burial in a family vault under the dwelling house was frequent.

Sacred times. During most of the 2nd millennium each major city had its own calendar. The months were named from local religious festivals celebrated in the month in question. Only by the 2nd millennium did the Nippur calendar attain general acceptance. The nature of the festivals in these various sacred calendars sometimes reflected the cycle of agricultural activities, such as celebrating the ritual hitching up of the plows and, later in the year, their unhitching, or rites of sowing, harvesting, and other activities. The sacred calendar of Girsu at the end of the Early Dynastic period is rich in its accounting of festivals. During some of these festival periods the queen traveled through her domain to present funerary offerings of barley, malt, and other agricultural products to the gods and to the spirits of deceased charismatic human administrators.

The cycles of festivals celebrating the marriage and early death of Dumuzi and similar fertility figures in spring were structured according to the backgrounds of the various communities of farmers, herders, or date growers. The sacred wedding—sometimes a fertility rite, sometimes a harvest festival with overtones of thanksgiving—was performed as a drama: the ruler and a high priestess took on the identity of the two deities and so ensured that their highly desirable union actually took place. In many communities the lament for the dead god took the form of a procession out into the desert to find the slain god in his gutted fold, a pilgrimage to the accompaniment of harps and heart-rending laments for the god.

New Year Festival

Of major importance in later times was the New Year Festival, or Akitu, celebrated in a special temple out in the fields. Originally an agricultural festival connected with sowing and harvest, it became the proper occasion for the crowning and investiture of a new king. In Babylon it came to celebrate the sun god Marduk's victory over Tiamat, the goddess of the watery deep. Besides the yearly festivals there were also monthly festivals at new moon, the 7th, the 15th, and the 28th of the month. The last—when the moon was invisible and thought to be dead—had a distinctly funereal character.

Administration. Supreme responsibility for the correct carrying out of the cult, on which the welfare of the country depended, was entrusted to the city ruler, or, when the country was united, the king. The city ruler and the king were, however, far more than administrators; they also were charismatic figures imparting their individual magic into their rule, thus creating welfare and fertility. In certain periods the king was deified; throughout the 3rd millennium, he became, in ritual action, the god Dumuzi in the rite of the sacred marriage and thus ensured fertility for his land. All the rulers of the 3rd dynasty of Ur (*c.* 2112–*c.* 2004 BC) and most of the rulers of the dynasty of Isin (*c.* 2020–*c.* 1800 BC) were treated as embodiments of the dying god Damu and invoked in the ritual laments for him. As a vessel of sacred power the king was surrounded by strict ritual to protect that power, and he had to undergo elaborate rituals of purification if the power became threatened.

The individual temples were usually administered by officials called *sangas* ("bishops"), who headed staffs of accountants, overseers of agricultural and industrial works on the temple estate, and *gudus* (priests), who looked after the god as house servants. Among the priestesses the highest-ranking was termed *en* (Akkadian *entu*). They were usually princesses of royal blood and were considered the human spouses of the gods they served, participating as brides in the rites of the sacred marriage. Other ranks of priestesses are known, most of them to be considered orders of nuns. The best-known are the votaries of the sun god, who lived in a cloister (*gagûm*) in Sippar. Whether, besides nuns, there were also priestesses devoted to sacred prostitution is a moot question; what is clear is that prostitutes were under the special protection of the goddess Inanna (Ishtar).

Sacred places. Mesopotamian worshipers might worship in open-air sanctuaries, chapels in private houses, or small separate chapels located in the residential quarters of town, but the sacred place par excellence was the temple. Archaeology has traced the temple back to the earliest periods of settlement, and though the very early temple plans still pose many unsolved problems, it is clear that from the Early Dynastic period onward the temple was what the Sumerian (*e*) and Akkadian (*bîtum*) terms for it indicate; *i.e.,* the temple was the god's house or dwelling. In its more elaborate form such a temple would be built on a series of irregular artificial platforms, one on top of the other; by the 3rd dynasty of Ur, near the end of the 3rd millennium, these became squared off to form a ziggurat. On the lowest of these platforms a heavy wall—first oval, later rectangular—enclosed storerooms, the temple kitchen, workshops, and other such rooms. On the highest level, approached by a stairway, were the god's living quarters centred in the cella, a rectangular room with an entrance door in the long wall near one corner. The god's place was on a podium in a niche at the short wall farthest from the entrance; benches with statues of worshipers ran

The structure and function of the temple

along both long walls, and a hearth in the middle of the floor served for heating. Low pillars in front of the god's seat seem to have served as stoppers for a hanging that shielded him from profane eyes. Here, or in a connecting room, would be the god's table, bed, and bathtub.

At a later time in Babylonia the dimensions of the cella with its adjoining rooms were greatly enlarged so that it became an open court surrounded by rooms. Only the section separated by the hanging remained roofed and became a new cella, entered from the middle of its long side and with the god in his niche in the wall directly opposite. The development in Assyria took a slightly different course. There, the original door in the long side moved around the corner to the short side opposite the god, creating a rectangular cella entered from the end wall.

The function of the temple, as of all of the other sacred places in ancient Mesopotamia, was primarily to ensure the god's presence and to provide a place where he could be approached. The providing of housing, food, and service for the god achieved the first of these purposes. His presence was also assured by a suitable embodiment—the cult statue, and, for certain rites, the body of the ruler. To achieve the second purpose, greeting gifts, praise hymns as introduction to petitions, and other actions were used to induce the god to receive the petitioner and to listen to, and accept, his prayers.

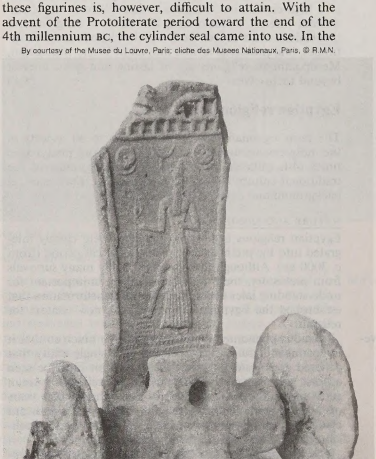
In view of the magnitude of the establishment provided for the gods and the extent of lands belonging to them and cultivated for them—partly by temple personnel, partly by members of the community holding temple land in some form of tenure—it was unavoidable that temples should vie in economic importance with similar large private estates or with estates belonging to the crown. This importance, one may surmise, would lie largely in the element of stability that an efficiently run major estate provided for the community. With its capacity for producing large storable surpluses that could be used to offset bad years and with its facilities for production—such as its weaveries—the temple estates could absorb and utilize elements of the population, such as widows, waifs, captives, and others, who otherwise would have perished or become a menace to the community in one way or other. The economic importance of the temple primarily was local. The amount of foreign trade carried on by them apparently was small. The power behind foreign trade seems rather to have been the king.

The magical arts. In the ancient Mesopotamian view, gods and humans shared one world. The gods lived among men on their great estates (the temples), ruled, upheld law and order for humans, and fought their wars. In general, knowing and carrying out the will of the gods was not a matter for doubt: they wanted the practice of their cult performed faultlessly and work on their estates done willingly and well, and they disapproved, in greater or lesser degree, of breaches of the moral and legal order. On occasion, however, humans might well be uncertain: did a god want his temple rebuilt or did he not? In all such cases and others like them, the Mesopotamians sought direct answers from the gods through divination, or, conversely, the gods might take the initiative and convey specific wishes through dreams, signs, or portents.

Belief in divination and astrology

There were many forms of divination. Of interest to students of biblical prophecy is recent evidence that prophets and prophetesses were active at the court of Mari on the Euphrates in Old Babylonian times (*c.* 1800–*c.* 1600 BC). In Mesopotamia as a whole, however, the forms of divination most frequently used seem to have been incubation—sleeping in the temple in the hope that the god would send an enlightening dream—and hepatoscopy—examining the entrails, particularly the liver, of a lamb or kid sacrificed for a divinatory purpose, to read what the god had "written" there by interpreting variations in form and shape. In the 2nd and 1st millennia large and detailed handbooks in hepatoscopy were composed for consultation by the diviners. Though divination in historical times was regularly presented in terms of ascertaining the divine will, there are internal indications in the materials suggesting that it was originally less theologically elaborated. Apparently it was a mere attempt to read the future from "symptoms" in the present, much as a physician recognizes the onset of a disease. This is particularly evident in that branch of divination that deals with unusual happenings believed to be ominous. Thus, if a desert plant sprouted in a city—indicating that desert essence was about to take over—it was considered an indication that the city would be laid waste.

Related to the observation of unusual happenings in society or nature, but far more systematized, was astrology. The movements and appearance of the Sun, the Moon, and the planets were believed to yield information about future events affecting the nation or, in some cases, the fate of individuals. Horoscopes, predicting the character and fate of a person on the basis of the constellation of the stars at his birth, are known to have been constructed in the late 1st millennium, but the art may conceivably be older.



Belief in witchcraft

Witchcraft was apparently at all times considered a crime punishable by death. Frequently, however, it probably was difficult to identify the witch in individual cases, or even to be sure that a given evil was the result of witchcraft rather than of other causes. In such cases, the expert in white magic, the *āšipu* or *mašmašu*, was able to help both in diagnosing the cause of the evil and in performing the appropriate rituals and incantation to fight it off. In earlier times the activities of the magicians seem generally to have been directed against the lawless demons who attacked humans and caused all kinds of diseases. In the later half of the 2nd, and all through the 1st millennium, however, the fear of man-made evils grew, and witchcraft vied with the demons as the chief source of all ills.

RELIGIOUS ART AND ICONOGRAPHY

The earliest periods in Mesopotamia have yielded figurines of clay or stone, some of which may represent gods or demons; certainty of interpretation in regard to these figurines is, however, difficult to attain. With the advent of the Protoliterate period toward the end of the 4th millennium BC, the cylinder seal came into use. In the

designs on these seals—often, it would seem, copies from monumental wall paintings now lost—ritual scenes and divine figures, recognizable from what is known about them in historical times, make their first appearance. To this period also belongs the magnificent Uruk Vase, with its representation of the sacred marriage rite. Until the early centuries of the 2nd millennium the cylinder seal remains one of the most prolific sources of religious motifs and representations of divine figures, but larger reliefs, wall paintings, and sculpture in the round greatly add to modern historians' understanding of who and what is rendered. In the 2nd and 1st millennia, the humble categories of clay plaques and clay figurines often contained representations of deities, and the numerous sculptured boundary stones (*kudurrus*) furnish representations of symbols and emblems of gods, at times identified by labels in cuneiform. To the 1st millennium belong also the magnificent colossal statues of protective genies (spirits) in the shape of lions or human-headed bulls that guarded the entrances to Assyrian palaces, and also, on the gates of Nebuchadrezzar's (d. 562 BC) Babylon, the reliefs in glazed tile of lions and dragons that served the same purpose.

CONCLUSION

A religious development covering four millennia such as one finds in ancient Mesopotamian religions is obviously of interest in and of itself. The tendencies that lead from a central concern with salvation from famine to a concern with salvation from attack, and finally to salvation from a sense of personal guilt, with the attendant deepening and enriching of the concept of the divine, invites close study. So also do the many moving and profound expressions of religious faith in the hymns, laments, and prayers of these religions. As one of the earliest religious systems in history to structure, and be itself structured by, the complexities of a high civilization, Mesopotamian religions are of significant interest to historians, historians of religion, and theologians. As a source from which religious insights, attitudes, and problems flowed into all of Western tradition, Mesopotamian religions are of lasting and great interest beyond themselves. (T.J.)

Egyptian religion

The term Egyptian religion here refers to all aspects of the indigenous religion of ancient Egypt from predynastic times (4th millennium BC) to the disappearance of the traditional culture in the first centuries AD. For historical background and detailed dates, see EGYPT.

NATURE AND SIGNIFICANCE

Egyptian religious beliefs and practices were closely integrated into Egyptian society of the historical period (from *c.* 3000 BC). Although there were probably many survivals from prehistory, these may be relatively unimportant for understanding later times, because the transformation that established the Egyptian state created a new context for religion.

Pervasiveness of religion

Religious phenomena were pervasive, so much so that it is not meaningful to view religion as a single entity that cohered as a system. Nevertheless, religion must be seen against a background of potentially nonreligious human activities and values. During its more than 3,000 years of development, Egyptian religion underwent significant changes of emphasis and practice, but in all periods religion had a clear consistency in character and style.

It is inappropriate to define religion narrowly, as consisting only in the cult of the gods and in human piety. Religious behaviour encompassed contact with the dead, practices such as divination and oracles, and magic, which mostly exploited divine instruments and associations.

There were two essential foci of public religion: the king and the gods. Both are among the most characteristic features of Egyptian civilization. The king had a unique status between humanity and the gods, partook in the world of the gods, and constructed great, religiously motivated funerary monuments for his afterlife. Egyptian gods are renowned for their wide variety of forms, including animal forms and mixed forms with an animal head on a human body. The most important deities were the sun god, who had several names and aspects and was associated with many supernatural beings in a solar cycle modeled on the alternation of night and day, and Osiris, the god of the dead and ruler of the underworld. With his consort Isis, Osiris became dominant in many contexts during the 1st millennium BC, when solar worship was in relative decline.

The Egyptians conceived of the cosmos as including the gods and the present world—whose centre was of course Egypt—and as being surrounded by the realm of disorder, from which order had arisen and to which it would finally revert. Disorder had to be kept at bay. The task of the king as the protagonist of human society was to retain the benevolence of the gods in maintaining order against disorder. This ultimately pessimistic view of the cosmos was associated principally with the sun god and the solar cycle. It formed a powerful legitimation of king and elite in their task of preserving order.

Despite this pessimism, the official presentation of the cosmos on the monuments was positive and optimistic, showing the king and the gods in perpetual reciprocity and harmony. This implied contrast reaffirmed the fragile order. The restricted character of the monuments was also fundamental to a system of decorum that defined what could be shown, in what way it could be shown, and in what context. Decorum and the affirmation of order reinforced each other.

These beliefs are known from monuments and documents created by and for the king and the small elite. The beliefs and practices of the rest of the people are poorly known. While there is no reason to believe that there was a radical opposition between the beliefs of the elite and of others, this possibility cannot be ruled out.

SOURCES AND LIMITATIONS OF ANCIENT AND MODERN KNOWLEDGE

The only extensive contemporaneous descriptions of ancient Egyptian culture from the outside were made by Classical Greek and Roman writers. Their works include many important observations about Egyptian religion, which particularly interested the writers and which until late antiquity was not fundamentally different in type from their own religions. Herodotus (5th century BC) remarked that the Egyptians were the most religious of people, and the comment is apt because popular religious practices proliferated in the 1st millennium BC. Other significant Classical sources include Plutarch's essay on Isis and Osiris (1st century AD), which gives the only known connected narrative of their myth, and writings of Apuleius (2nd century AD) and others about the Isis cult as it spread in the Greco-Roman world.

In other respects, ancient Egypt has been recovered archaeologically. Excavation and the recording of buildings have produced a great range of material, from large monuments to small objects and texts on perishable papyrus. Egyptian monuments are almost unique in the amount of inscription they bear; vast numbers of texts and representations with religious content are preserved, especially from the later 2nd and 1st millennia BC. Much of this material is religious or has religious implications. This dominance may be misleading, partly because many monuments were in the desert where they are well preserved and partly because the lavishing of great resources on religious monuments for the king and the gods need not mean that people's lives were dominated by religion.

In addition to favouring large monuments and the elite, the archaeological record has other important biases. The formal cults of major deities and the realm of the dead are far better known than everyday religious activities, particularly those occurring in towns and villages, very few of which have been excavated. The absence of material deriving from the religious practice of most people in itself constitutes evidence, suggesting both the inequality of society and the possibility, confirmed by other strands of evidence, that many people's religious life did not focus on official cult places and major temples.

Official works of art

Many official works of art present standard conceptions of the divine world and of the king's role in this world and in caring for the gods. Much religious evidence is at the

same time artistic, and the production of works of art was a vital prestige concern of king and elite. Religious activities and rituals are less well known than this formalized artistic presentation of religious conceptions. The status of personal religion in the context of official cults is poorly understood.

Official forms were idealizing, and the untoward, which is everywhere an important focus of religion, was excluded almost entirely from them. The world of the monuments is that of Egypt alone, even though the Egyptians had normal, sometimes reciprocal, relations with other peoples. Decorum affected what was shown. Thus, the king was almost always depicted as the person offering to the gods, although temple rituals were performed by priests. Scenes of offering and of the gods conferring benefits on the king may not depict specific rituals, while the equal form in which king and gods are depicted bears no direct relation to real cult actions, which were performed on small cult images kept inside shrines.

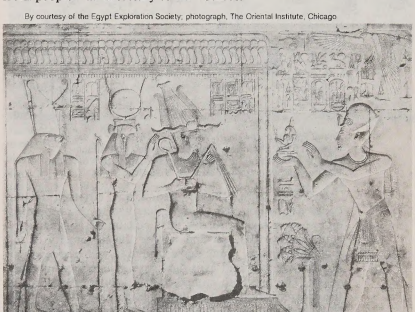
An additional limitation is that knowledge of many central concerns was restricted. The king was stated to be alone in knowing aspects of the solar cycle. Knowledge of some religious texts was reserved to initiates, who would benefit from them both in this life and in the next. Magic evoked the power of the exotic and esoteric. Evidence for some restricted material is preserved, but it is not known who had access to it, while in other cases the restricted knowledge is only alluded to and is now inaccessible.

Death and the next world dominate both the archaeological record and popular modern conceptions of Egyptian religion. This dominance is determined to a great extent by the landscape of the country, since tombs were placed if possible in the desert. Vast resources were expended on creating prestigious burial places for absolute rulers or wealthy officials. Tombs contained elaborate grave goods (mostly plundered soon after deposition), representations of "daily life," or less commonly of religious subjects, and some texts that were intended to help the deceased attain the next world and prosper there. The texts came increasingly to be inscribed on coffins and stone sarcophagi or deposited in burials on papyrus. Some royal tombs included long passages from religious texts, many of them drawn from nonmortuary contexts and hence more broadly valuable as source material.

One crucial area where religion extended beyond narrow bounds was in the ethical instructions, which became the principal genre of Egyptian literature. These are known from the Middle Kingdom (*c.* 1900–1600 BC) to the Roman period (1st century AD). As with other sources, the later texts are more overtly religious, but all show inextricable connections between proper conduct, the order of the world, and the gods.

KING, COSMOS, AND SOCIETY

The king was the centre of human society, the guarantor of order for the gods, the recipient of god-given benefits including life itself, and the benevolent ruler of the world for humanity. He was ultimately responsible for the cults of the dead, both for his predecessors in office and for the dead in general. His dominance in religion corresponded to his central political role: from late predynastic times (*c.* 3100 BC), state organization was based on kingship and on the service of officials for the king. For humanity, the king had a superhuman role, being a manifestation of a god or of various deities on earth.



The king's titles and divine status

The king's principal original title, the Horus name, proclaimed that he was an aspect of the chief god Horus, a sky god who was depicted as a falcon. Other identifications were added to this one, notably "Son of Re (the sun god)" and "Perfect God," both introduced in the 4th dynasty (*c.* 2575–2465 BC), when the great pyramids were constructed. The epithet "Son of Re" placed the king in a close but dependent relation with the leading figure in the pantheon. "Perfect God" (often rendered "Good God") indicated that the king had the status of a minor deity, for which he was "perfected" through accession to his office; it restricted the extent of his divinity and separated him from full deities.

In his intermediate position between humanity and the gods, the king could receive the most extravagant divine adulation and was in some ways more prominent than any single god. In death he aspired to full divinity but could not escape the human context. Although royal funerary monuments differed in type from other tombs and were vastly larger, they too were pillaged and vandalized, and few royal mortuary cults were long-lasting. Some kings, notably Amenhotep III (1390–53 BC), Ramses II (1279–13 BC), and several of the Ptolemies, sought deification during their own lifetimes, while others, such as Amenemhet III (1818–*c.* 1770 BC), became minor gods after their deaths, but these developments show how restricted royal divinity was. The divinized king coexisted with his mortal self, and as many nonroyal individuals as kings became deified after death.

The gods, the king, humanity, and the dead existed together in the cosmos, which the creator god had brought into being from the preexistent chaos. All living beings, except perhaps the creator, would die at the end of time. The sun god became aged and needed to be rejuvenated and reborn daily. The ordered cosmos was surrounded by and shot through with disorder, which had to be kept at bay. Disorder menaced most strongly at such times of transition as the passage from one year to the next or the death of a king. Thus, the king's role in maintaining order was cosmic and not merely social. His exaction of service from people was necessary to the cosmos.

King Seti I offering a figure of *ma'at* to Osiris, Isis, and Horus; relief in the temple of King Seti I, Abydos, early 13th century BC.

Ma'at

The concept of *ma'at* ("order") was fundamental in Egyptian thought. The king's role was to set *ma'at* in place of *izfet* ("disorder"). *Ma'at* was crucial in human life and embraced notions of reciprocity, justice, truth, and moderation. *Ma'at* was personified as a goddess and the creator's daughter and received a cult of her own. In the cult of other deities, the king's offering of *ma'at* to a deity (see illustration) encapsulated the relationship between humanity, the king, and the gods: as the representative of humanity, he returned to the gods the order that came from them and of which they were themselves part. *Ma'at* extended into the world of the dead: in the weighing of the heart after death, shown on papyri deposited in burials (see illustration), the person's heart occupies one side of the scales and a representation of *ma'at* the other. The meaning of this image is deepened in the accompanying text, which asserts that the deceased behaved correctly on earth and did not overstep the boundaries of order, declaring that he or she did not "know that which is not"—that is, things that were outside the created and ordered world.

This role of *ma'at* in human life created a continuity between religion, political action, and elite morality. Over the centuries, private religion and morality drew apart from state concerns, paralleling a gradual separation of king and temple. It cannot be known whether religion and

morality were as closely integrated for the people as they were for the elite, or even how fully the elite subscribed to these beliefs. Nonetheless, the integration of cosmos, king, and *ma'at* remained fundamental.

THE GODS

Egyptian religion was polytheistic. The gods who inhabited the bounded and ultimately perishable cosmos varied in nature and capacity. The word *netjer* ("god") described a much wider range of beings than the deities of monotheistic religions, including what might be termed demons. As is almost necessary in polytheism, gods were neither all-powerful nor all-knowing. Their power was immeasurably greater than that of human beings, and they had the ability to live almost indefinitely, to survive fatal wounds, to be in more than one place at once, to affect people in visible and invisible ways, and so forth.

The judgment of the dead. While Osiris, the ruler of the dead, watches from his throne, the jackal-headed god Anubis weighs the heart of the deceased against the figure of *ma'at*. Funerary papyrus from Thebes, *c.* 1025 BC.

Most gods were generally benevolent, but their favour could not be counted on, and they had to be propitiated and encouraged to inhabit their cult images so that they could receive the cult and further the reciprocity of divine and human. Some deities, notably such goddesses as Neith, Sekhmet, and Mut, had strongly ambivalent characters. The god Seth embodied the disordered aspects of the ordered world, and in the 1st millennium BC he came to be seen as an enemy who had to be eliminated (but would remain present).

The characters of the gods were not neatly defined. Most had a principal association, such as that of Re with the sun or that of the goddess Hathor with women, but there was much overlap, especially among the leading deities. In general, the more closely circumscribed a deity's character, the less powerful that deity was. All the main gods acquired the characteristics of creator gods. A single figure could have many names: among those of the sun god, the most important were Khepri (the morning form), Re-Harakhty, and Atum (the old, evening form). There were three principal "social" categories of deity: gods, goddesses, and youthful deities, mostly male.

Cult centres

Gods had regional associations, corresponding to their chief cult places. The sun god's cult place was Heliopolis, Ptah's was Memphis, and Amon's was Thebes. These were not necessarily their original cult places. The principal cult of Khnum, the creator god who formed people from clay like a potter, was Elephantine, and he was the lord of the nearby First Cataract. His cult is not attested there before the New Kingdom, however, even though he was important from the 1st dynasty (*c.* 2925–2775 BC). The main earlier sanctuary there belonged to the goddess Satet, who became Khnum's companion. Similarly, Mut, the partner of Amon at Thebes, seems to have originated elsewhere.

Deities had principal manifestations, and most were associated with one or more species of animal. For gods the most important forms were the falcon and bull, and for goddesses the cow, cobra, vulture, and lioness. Rams were widespread, while some manifestations were as modest as the millipede of the god Sepa. Some gods were very strongly linked to particular animals, as Sebek was with the crocodile and Khepri with the scarab beetle. Thoth had two animals, the ibis and the baboon. Some animal cults were only partly integrated with specific gods, notably the Ram of Mendes in the Delta and the Apis and Mnevis bulls at Memphis and Heliopolis, respectively. Animals could express aspects of a deity's nature: some goddesses were lionesses in their fiercer aspect but were cats when mild.

These variable forms relate to aspects of the person that were common to gods and people. The most significant of these were the *ka*, which was the vital essence of a person that was transmitted from one generation to the next, the *ba*, which granted freedom of movement and the ability to take on different forms, principally in the next world, and the *akh*, the transfigured spirit of a person in the next world.

The chief form in which gods were represented was human, and many deities had only human form. Among these deities were very ancient figures such as the fertility god Min and the creator and craftsman Ptah. The cosmic gods Shu, of the air and sky, and Geb, of the earth, had human form, as did Osiris, Isis, and Nephthys, deities who provided a model of human society. In temple reliefs the gods were depicted in human form, which was central to decorum. Gods having animal manifestations were therefore shown with a human body and the head of their animal. The opposite convention, a human head and an animal body, was used for the king, who was shown as a sphinx with a lion's body. Sphinxes could receive other heads, notably those of rams and falcons, associating the form with Amon and Re-Harakhty. Demons were represented in more extravagant forms and combinations; these became common in the 1st millennium BC. Together with the cult of animals, they were mocked by Greek and Roman writers.

Minor deities

Apart from major deities—gods who received a cult or had a significant cosmic role—there were important minor figures. Several of these marginal beings had grotesque forms and variable names. The most prominent were Bes, a helpful figure with dwarf form and a masklike face, associated especially with women and children, and Taurt, a goddess with similar associations whose physical form combined features of a hippopotamus and a crocodile. Among demons, the most important figure was Apopis, shown as a colossal snake, who was the enemy of the sun god in his daily cycle through the cosmos. Apopis existed outside the ordered realm; he had to be defeated daily, but, since he did not belong to the sphere of existence, he could not be destroyed.

Groupings of deities. The number of deities was large and was not fixed. New ones appeared and some ceased to be worshiped. Deities were grouped in various ways. The most ancient known grouping is the ennead, which is probably attested from the 3rd dynasty (*c.* 2650–2575 BC). Enneads were groups of nine deities, nine being the "plural" of three (in Egypt the number three symbolized plurality in general); not all enneads consisted of nine gods.

The principal ennead was the Great Ennead of Heliopolis. This was headed by the sun god and creator Re or Re-Atum, followed by Shu and Tefnut, deities of air and moisture; Geb and Nut, who represented earth and sky; and Osiris, Isis, Seth, and Nephthys. This ordering incorporated a myth of creation, to which was joined the myth of Osiris, whose deeds and attributes ranged from the founding of civilization to kinship, kingship, and succession to office. The ennead excluded the successor figure, Horus son of Osiris, who is essential to the meaning of the myth. Thus, the ennead has the appearance of a grouping that brought together existing religious conceptions but was rather arbitrary and inflexible, perhaps because of the significance of the number nine.

Other numerical ordering schemas included the Ogdoad (group of eight gods) of Hermopolis, which embodied the inchoate world before creation and consisted of four pairs of male and female deities with abstract names such as Darkness, Absence, and Endlessness. Here, too, the number was significant in itself, because at least six different

pairs of names are known although eight deities are listed in any occurrence. The major god Amon, whose name can mean "He who is hidden," was often one of the ogdoad with his female counterpart, Amaunet.

The most common grouping, principally in the New Kingdom and later, was the triad. The archetypal triad of Osiris, Isis, and Horus exhibits the normal pattern of a god and a goddess with a youthful deity, usually male. Most local centres came to have triads, the second and third members of which might be devised for the sake of form. Thus, one triad worshiped in the Greco-Roman-period temple at Kawm Umbū (Kôm Ombo) consisted of Haroeris (the "elder Horus"), the goddess Tsenetnofret ("the perfect companion"), and the youthful god Pnebtawy ("the lord of the two lands"). The last name, which is an epithet of kings, is revealing, because youthful gods had many attributes of kings. As this case indicates, triads resemble a minimal nuclear family, but deities were rarely spouses. The notion of plurality and the bringing together of the essential types of deity may have been as important to the triads as the family analogy.

Syncretism

Another important ordering of deities was syncretism, a term with a special meaning for Egyptian religion. Two or more names of gods were often combined to form a composite identity; many combinations included the name of Re. Prominent examples are Amon-Re, a fusion of Amon and Re, and Osiris-Apis, a fusion of Osiris with the Apis Bull. Although composite forms such as Amon-Re became the principal identities of some gods, the separate deities continued to exist, and sometimes, as in the case of Re, to receive a cult. In part, these syncretisms expressed the idea of Amon in his aspect as Re; they were thus analogous to the multiple manifestations of individual deities. Through syncretism many major deities came to resemble one another more closely.

Myth. Myths are poorly known. Religious discourse was recorded in hymns, rituals, temple scenes, and specialized texts, but rarely in narrative, which only slowly became a common written genre and never had the highest literary prestige. In addition, much religious activity focused on constant reiteration or repetition rather than on development. A central example of this tendency is the presentation of the cycle of the sun god through the sky and the underworld, which was an analogy for the creation, maturity, decay, and regeneration of an individual life and of the cosmos. This is strikingly presented in the underworld books. These pictorial and textual compositions, which probably imparted secret knowledge, were inscribed in the tombs of New Kingdom kings. They describe the solar cycle in great detail, including hundreds of names of demons and of deities and other beings who accompanied the sun god in his barque on his journey through night and day. The texts are in the present tense and form a description and a series of tableaux rather than a narrative.

The fact that mythical narratives are rare does not imply that myths or narratives did not exist. There is reason to think that some myths underlay features of enneads and therefore originated by the Early Dynastic period (*c.* 3000 BC). Mythical narratives preserved from the New Kingdom and later include episodes of the rule of the sun god on earth, tales of the childhood of Horus in the delta marshes, and stories with themes similar to the Osiris myth but with differently named protagonists. The rule of the sun god was followed by his withdrawal into the sky, leaving people on earth. The withdrawal was motivated by his age and by the lack of tranquility in the world. One narrative recounts how Isis obtained a magical substance from Re's senile dribbling and fashioned from it a snake that bit him; to make her still the agony of the snakebite, he finally revealed to her the secret of his "true" name. A myth with varied realizations recounts how Re grew weary of humanity's recalcitrance and dispatched his daughter or "Eye" to destroy them. Regretting his action later, he arranged to have the bloodthirsty goddess tricked into drunkenness by spreading beer tinted the colour of blood over the land. This myth provides an explanation for the world's imperfection and the inaccessibility of the gods. In Greco-Roman times it was widespread in Lower Nubia, where it seems to have been related to the winter retreat of the sun to the Southern Hemisphere and its return in the spring.

THE CULT

Most cults centred on the daily tending and worship of an image of a deity and were analogous to the pattern of human life. The shrine containing the image was opened at dawn, and then the deity was purified, greeted and praised, clothed, and fed. There were several further services, and the image was finally returned to its shrine for the night. Apart from this activity, which took place within the temple and was performed by a small group of priests, there were numerous festivals, at which the shrine and image were taken out from the sanctuary on a portable barque, becoming visible to the people and often visiting other temples. Thus, the daily cult was a state concern, whose function was to maintain reciprocity between the human and the divine, largely in isolation from the people. This reciprocity was fundamental because deities and humanity together sustained the cosmos. If the gods were not satisfied, they might cease to inhabit their images and retreat to their other abode, the sky. Temples were constructed as microcosms whose purity and wholeness symbolized the proper order of the larger world outside.

The priesthood

The priesthood became increasingly important. In early periods there seem to have been no full-time professional priests; people could hold part-time high priestly offices, or they could have humbler positions on a rotating basis, performing duties for one month in four. The chief officiant may have been a professional. While performing their duties, priests submitted to rules of purity and abstinence. One result of this system was that more people were involved in the cult and had access to the temple than would have been the case if there had been a permanent staff. Although most priestly positions were for men, women were involved in the cult of the goddess Hathor, and in the New Kingdom and later many women held the title of "chantress" of a deity (perhaps often a courtesy title); they were principally involved in musical cult performances.

Festivals allowed more direct interaction between people and the gods. Questions were often asked of a deity, and a response might be given by a forward or backward movement of the barque carried on the priests' shoulders. Oracles, of which this was one form, were invoked by the king to obtain sanction for his plans, including military campaigns abroad and important appointments. Although evidence is sparse, consultation with deities may have been part of religious interaction in all periods and for all levels of society.

Apart from this interaction between deities and individual people or groups, festivals were times of communal celebration, and often of the public reenactment of myths such as the death and vindication of Osiris at Abydos or the defeat of Seth by Horus at Idfū. They had both a personal and a general social role in the spectrum of religious practice.

Nonetheless, the main audience for the most important festivals of the principal gods of state held in capital cities may have been the ruling elite rather than the people as a whole. In the New Kingdom these cities were remodeled as vast cosmic stages for the enactment of royal-divine relations and rituals.

PIETY, PRACTICAL RELIGION, AND MAGIC

Despite the importance of temples and their architectural dominance, the evidence for cult does not point to mass participation in temple religion. The archaeological material may be misleading, because in addition to major temples there were many local sanctuaries that may have responded more directly to the concerns and needs of those who lived around them. From some periods numerous votive offerings are preserved from a few temples. Among these are Early Dynastic and Old Kingdom provincial temples, but the fullest evidence is from New Kingdom temples of Hathor at Thebes and several frontier sites, and from the Late and Ptolemaic periods (664–30 BC).

Although votive offerings show that significant numbers

of people brought gifts to temples, it is difficult to gauge the social status of donors, whose intentions are seldom indicated, probably in part for reasons of decorum. Two likely motives are disinterested pious donation for the deity, and offering in the hope of obtaining a specific benefit. Many New Kingdom offerings to Hathor relate to human fertility and thus belong to the second of these categories. Late period bronze statuettes are often inscribed with a formula requesting that the deity represented should "give life" to the donor, without stating a specific need. These may be more generally pious donations, among which can also be counted nonroyal dedications of small parcels of land to temples. These donations are recorded on stelae from the New Kingdom onward. They parallel the massive royal endowments to temples of land and other resources, which resulted in their becoming very powerful economic and political institutions.

Animal cults

Apart from the donation of offerings to conventional cult temples, there was a vast Late period expansion in animal cults. These might be more or less closely related to major deities. They involved a variety of practices centring on the mummification and burial of animals. The principal bull cults, which gave important oracles, focused on a single animal kept in a special shrine. The burial of an Apis bull was a major occasion involving vast expenditure. Some animals, such as the sacred ibis (connected with Thoth) were kept, and buried, in millions. The dedication of a burial seems to have counted as a pious act. The best-known area for these cults and associated practices is the necropolis of northern Ṣaqqārah, which served the city of Memphis. Numerous species were buried there, and people visited the area to consult oracles and to spend the night in a temple area and receive a healing dream. A few people resided permanently in the animal necropolis in a state akin to monastic seclusion.

There are two further important groups of evidence for pious and reciprocal relations between people and gods. One is proper names of all periods, the majority of which are meaningful utterances with religious content. For example, names state that deities "show favour" to or "love" a child or its parents. From the end of the New Kingdom (*c.* 1100 BC), names commonly refer to consultation of oracles during pregnancy, alluding to a different mode of human-divine relations. The second source is a group of late New Kingdom inscriptions recounting episodes of affliction that led to people's perceiving that they had wronged a god. These texts, which provide evidence of direct pious relations, are often thought to show a transformation of religious attitudes in that period, but allusions to similar relations in Middle Kingdom texts suggest that the change was as much in what was written down as in basic attitudes.

Piety was one of many modes of religious action and relations. Much of religion concerned attempts to comprehend and respond to the unpredictable and the unfortunate. The activities involved often took place away from temples and are little known. In later periods, there was an increasing concentration of religious practice around temples; for earlier times evidence is sparse. The essential questions people asked, as in many religious traditions, were why something had happened and why it had happened to them, what would be an appropriate response, what agency they should turn to, and what might happen in the future. To obtain answers to these questions, people turned to oracles and to other forms of divination, such as consulting seers or calendars of lucky and unlucky days. From the New Kingdom and later, questions to oracles are preserved, often on such mundane matters as whether someone should cultivate a particular field in a given year. These cannot have been presented only at festivals, and priests must have addressed oracular questions to gods within their sanctuaries. Oracles of gods also played an important part in dispute settlement and litigation in some communities.

A vital focus of questioning was the world of the dead. The recently deceased might exert influence on the living for good or for bad. Offerings to the dead, which were required by custom, were intended, among other purposes, to make them well disposed. People occasionally deposited with their offerings a letter telling the deceased of their problems and asking for assistance. A few of these letters are complaints to the deceased person, alleging that he or she is afflicting the writer. This written communication with the dead was confined to the very few literate members of the population, but it was probably part of a more widespread oral practice. Some tombs of prominent people acquired minor cults that may have originated in frequent successful recourse to them for assistance.

Letters to the dead

Offerings to the dead generally did not continue long after burial, and most tombs were robbed within a generation or so. Thus relations with dead kin probably focused on the recently deceased. Nonetheless, the dead were respected and feared more widely. The attitudes attested are almost uniformly negative. The dead were held accountable for much misfortune, both on a local and domestic level and in the broader context of the state. People were also concerned that, when they died, those in the next world would oppose their entry to it as newcomers who might oust the less recently dead. These attitudes show that, among many possible modes of existence after death, an important conception was one in which the dead remained near the living and could return and disturb them. Such beliefs are rare in the official mortuary literature.

A prominent aspect of practical religion was magic. There is no meaningful distinction between Egyptian religion and magic. Magic was a force present in the world from the beginning of creation and was personified as the god Heka, who received a cult in some regions. Magic could be invoked by using appropriate means and was generally positive, being valuable for counteracting misfortune and in seeking to achieve ends for which unseen help was necessary. Magic also formed part of the official cult. It could, however, be used for antisocial purposes as well as benign ones. There is a vast range of evidence for magical practice, from amulets to elaborate texts. Much magic from the Greco-Roman period mixed Egyptian and foreign materials and invoked new and exotic beings. Preserved magical texts record elite magic rather than general practice. Prominent among magical practitioners, both in folklore and, probably, in real life, were "lector priests," the officiants in temple cults who had privileged access to written texts. Most of the vast corpus of funerary texts was magical in character.

THE WORLD OF THE DEAD

The majority of evidence from ancient Egypt comes from funerary monuments and burials of royalty, of the elite, and for the Late period of animals; relatively little is known of the mortuary practices of the mass of the population. Reasons for this dominance of the tomb include both the desert location of burials and the use of mortuary structures for display among the living. Alongside the fear of the dead, there was a moral community between the living and the dead, so that the dead were an essential part of society, especially in the 3rd and 2nd millennia BC.

The basic purpose of mortuary preparation was to ensure a safe and successful passage into the hereafter. Belief in an afterlife and a passage to it is evident in predynastic burials, which are oriented to the west, the domain of the dead, and which include pottery grave goods as well as personal possessions of the deceased. The most striking development of later mortuary practice was mummification, which was related to a belief that the body must continue intact for the deceased to live in the next world. Mummification evolved gradually from the Old Kingdom to the early 1st millennium BC, after which it declined. It was too elaborate and costly ever to be available to the majority.

Mummification

This decline of mortuary practice was part of the more general shift in the focus of religious life toward the temples and toward more communal forms. It has been suggested tentatively that belief in the afterlife became less strong in the 1st millennium BC. Whether or not this is true, it is clear that in various periods some people voiced skepticism about the existence of a blessed afterlife and the necessity for mortuary provision, but the provision nevertheless continued to the end.

It was thought that the next world might be located in

the area around the tomb (and consequently near the living); on the "perfect ways of the West," as it is expressed in Old Kingdom invocations; among the stars or in the celestial regions with the sun god; or in the underworld, the domain of Osiris. One prominent notion was of the "Elysian Fields," where the deceased could enjoy an ideal agricultural existence in a marshy land of plenty. The journey to the next world was fraught with obstacles. It could be imagined as a passage by ferry past a succession of portals, or through an "Island of Fire." One crucial test was the judgment after death, a subject often depicted from the New Kingdom onward. The date of origin of this belief is uncertain, but it was probably no later than the late Old Kingdom. The related text, Chapter 125 of the Book of the Dead, responded magically to the dangers of the judgment, which assessed the deceased's conformity with *ma'at*. Those who failed the judgment would "die a second time" and would be cast outside the ordered cosmos. In the demotic story of Setna (3rd century BC), this notion of moral retribution acquired overtones similar to those of the Christian judgment after death.

INFLUENCE ON OTHER RELIGIONS

Egyptian culture, of which religion was an integral part, was influential in Nubia as early as predynastic times, and in Syria in the 3rd millennium BC. During the New Kingdom, Egypt was very receptive to cults from the Middle East, while Egyptian medical and magical expertise were highly regarded among the Hittites, Assyrians, and Babylonians. The chief periods of Egyptian influence were, however, the 1st millennium BC and the Roman period. Egypt was an important centre of the Jewish diaspora starting in the 6th century BC, and Egyptian literature influenced the Hebrew Bible. With Greek rule there was significant cultural interchange between Egyptians and Greeks. Notable among Egyptian cults that spread abroad were those of Isis, which reached much of the Roman world as a mystery religion, and of Sarapis, a god whose name probably derives from Osiris-Apis, who was worshiped widely in a non-Egyptian iconography and cultural milieu. With Isis went Osiris and Horus the child, but Isis was the dominant figure. Many Egyptian monuments were imported to Rome to provide a setting for the principal Isis temple in the 1st century AD.

The cults of Isis and Sarapis

The cult of Isis was probably influential on another level. The myth of Osiris shows some analogies with the Gospel story and, in the figure of Isis, with the role of the Virgin Mary. The iconography of the Virgin and Child has evident affinities with that of Isis and the infant Horus. Thus, one aspect of Egyptian religion may have contributed to the background of early Christianity, probably through the cultural centre of Alexandria. Egypt also was an influential setting for other religious and philosophical developments of late antiquity such as Gnosticism, Manicheism, Hermetism, and Neoplatonism, some of which show traces of traditional Egyptian beliefs. Some of these religions became important in the intellectual culture of the Renaissance. Finally, Christian monasticism seems to have originated in Egypt and could look back to a range of native practices, among which were seclusion in temple precincts and the celibacy of certain priestesses. Within Egypt, there are many survivals from earlier times in popular Christianity and Islām. (J.R.Ba.)

Syrian and Palestinian religions

The religions of Syria and Palestine between 3000 and 300 BC are usually defined by the languages of those who practiced them: *e.g.*, Amorite, Hurrian, Ugaritic, Phoenician, Aramaic, and Moabite. The term "Canaanite" is often used broadly to cover a number of these, as well as the religion of early periods and areas from which there are no written sources. Knowledge of the religions of these groups is very uneven; it usually consists of mere glimpses of one or another aspect. Only from the city-state of Ugarit (14th–13th centuries BC) is there a wide range of religious expression. For historical background on the region, see the articles ISRAEL, JORDAN, LEBANON, PALESTINE, and SYRIA.

NATURE AND SIGNIFICANCE

Internally, the landscape of Syria and Palestine is broken into many different regions. In consequence, the population was generally divided among many polities, each of which had its own official religion. Externally, Syria-Palestine formed a land bridge between the great civilizations of Mesopotamia and Egypt and faced westward across the Mediterranean Sea toward the cultures of the Aegean. Syria and Palestine were subject to influences from these cultures and in their turn contributed to them. As a result, the official religions of the area were often syncretistic and sometimes cosmopolitan. Particular cults and myths were carried westward and adopted by the Egyptians of the New Kingdom (1539–1075 BC), by the Greeks and their antecedents, and later by the Romans. Despite their many different outer forms, and the individual stamp given them by the various political powers, the religions of Syria and Palestine appear to have been typologically similar. Out of them, however, emerged the ultimately quite distinctive religion of Israel, from which in turn Judaism, Christianity, and, less directly, Islām were formed.

The evidence available is primarily the product of the small, wealthy, ruling elites of these societies. It bears witness primarily to their religion, giving only indirect testimony to the beliefs or practices of the vast majority of the population. This official religion is polytheistic, the anthropomorphic gods as a whole being referred to as an extended family, or an assembly, or by other collective terms. Most earlier sources come from more cosmopolitan contexts and reflect that fact in their attention to a variety of gods. The sources from the 1st millennium suggest a greater concentration on a few gods or indeed on one supreme god.

Some divine names appear through most of the period from 3000 to 300 BC. In other cases, different names appear in different periods and in different regions or languages, and often titles are used instead of names. Consequently, it is sometimes not possible to determine to what extent new names have been assigned to gods whose cult is continuous across these boundaries and to what extent different gods may lie behind the same title. In general it appear that a few types prevailed and persisted over the centuries.

The most pervasive type was the storm god (Hadad, Baal, Teshub), who was associated with rain, thunder, and lightning—and thus with fertility and war. Another type was a more patriarchal creator god, bearing the simple name El ("God"). The major female deities appear to have been of either the belligerent type (Anath, Astarte) or the matriarchal type (Asherah). These often, but not always, served as the respective consorts of the two male types. Also prominent throughout the period were a solar and a lunar deity.

Types of deities

Consistent with the sources of documentation, the monarch emerges as a significant medium between god and people, acting on the people's behalf in the cult of the god and on the god's behalf in the care of the people. The cult was generally practiced in a "house" of the god, where a professional priesthood attended to the daily needs of the god, represented in effigy.

The most recurrent concerns in the written sources are (1) the good relations between monarch and god and the well-being of the monarch and his family (alive and deceased), on which the order of society depended, and (2) the natural conditions—rainfall, sunshine, fertility of soil, flocks, and herds—on which most people depended directly for survival and on which the agrarian economy as a whole depended.

SOURCES OF MODERN KNOWLEDGE

Until the late 19th century most of the information about pre-Hellenistic Syria and Palestine came from the Hebrew Bible and from various Greek and Latin sources.

While the Hebrew Bible was largely completed by 300 BC, its attitude toward contemporary religions of the area was generally quite hostile, so that its references to these religions may not only devalue them but also exaggerate or distort various aspects of them. On the other hand, Israelite religion was itself an outgrowth of, as well as a

reaction to, the religions of its neighbours, so that many features of Israelite religion found in the Hebrew Bible exemplify the religions of the larger area. The only sure guide to making such discriminations is the knowledge gained from indigenous documents.

Greek and Latin sources may be less hostile, but they are also much later, from the Roman period. While they may be more reliable in their description of the contemporary character of the religions of the area, that character may have been significantly different after several centuries of Hellenism from what it had been even in the middle of the preceding millennium. Notable among the Greek and Latin sources are *De Dea Syra* ("About the Syrian Goddess") from the 2nd century AD, attributed to Lucian of Samosata, and the section of Eusebius of Caesarea's *Praeparatio evangelica* ("Preparation for the Gospel"; 4th century AD) that cites extracts from a history of Phoenicia by Philo of Byblos (*c.* AD 100); Philo himself claimed to be translating the work of an early Phoenician priest, Sanchuniathon. While indigenous sources now confirm isolated elements of this allegedly early description of Phoenician religion, its distortions also have become more demonstrable. Philo's history is in fact an attempt to recount early Phoenician history by constructing a systematic chronological sequence of events out of the various local traditions of his time and interpreting the latter euhemeristically—that is, by treating gods and myths as representative of historical individuals and events.

Beginning in the late 18th century, the finds of early explorers of the area and subsequently of archaeologists engaged in more systematic excavation have produced a rapidly increasing number of firsthand sources. Successive generations of epigraphers and philologists have deciphered the texts and attained an increasingly sophisticated understanding of the languages. Unfortunately, the texts that are best understood tend to be formulaic and yield only the most external kinds of information about the religion, while the more distinctive texts, which seem more interesting and promise to be more revealing, are usually more difficult to penetrate.

Cuneiform archives from various 2nd-millennium sites and from the 3rd millennium at Ebla in northwestern Syria provide some documentation of the religion. The most abundant documentation comes from the 14th- and 13th-century remains of the city of Ugarit (modern Ras Shamra), on the Mediterranean coast of Syria. This includes the only native examples of extended religious narrative. It also comprises the widest range of genres, including myths, legends, liturgical texts, god lists, omens, and correspondence.

Ugarit

From the 1st millennium come scores of Phoenician inscriptions, both from the Phoenician coast and from other areas of the eastern Mediterranean; neo-Hittite hieroglyphic inscriptions and Aramaic inscriptions from northern Syria, almost all from the 9th and 8th centuries; and Moabite, Ammonite, and Hebrew inscriptions. These are very limited in genre, and relatively few are more than a few lines long.

Uninscribed materials from excavated sites throughout Syria and Palestine supplement the picture: they include the foundations of temples, temple furnishings, figurines, images of gods and their emblems, and scenes of gods, myths, and religious activities on reliefs and seals. However, criteria for identifying religious materials have not always been carefully considered, nor has discriminating attention been given to the question of the reflection of religious life in material remains in general. It is often difficult to correlate with confidence written and unwritten materials.

In spite of these new and ever-growing sources of knowledge, the resulting picture is still very irregular. While there is an unparalleled variety of sources, covering a century and a half, from the large cosmopolitan city of Ugarit, other written materials give a much more limited picture. For many periods, areas, and topics there are no written remains. Descriptions of the religion of any one period or area (with the exception of Ugarit) are extremely limited and superficial. Generalizations about the religions of Syria and Palestine may well prove to have significant exceptions as some of these gaps are filled by new discoveries.

INSTITUTIONS AND PRACTICES

The temple typically occupied a dominating site in the city along with the palace. Like the palace, it had political, administrative, and economic functions, as well as its distinctive religious functions. The temple, or the temple and palace together, were often raised and/or walled off in a separate precinct or acropolis. The temple was the "house" of the god—often so in both name and form. It was also a storehouse for the god's treasures and hence sometimes particularly thickly walled. The temple staff played a leading role in the life of the city.

In the early 3rd millennium the temples were built on the same plan as houses: a rectangle with the entrance on one of the long sides, with a small altar or a niche for the cult statue opposite the entrance. Sometimes there were benches around the three uninterrupted walls. An outer court contained the main altar, where the larger community could participate in worship. At the beginning of the 2nd millennium the house of the god was extended by the expansion of the niche into an additional room ("cella") and of the entrance into a porch—the form later used by the Phoenician architects of Solomon's Temple in Jerusalem. There were also outdoor shrines, such as the "high place" at Gezer (near modern Ramla, Israel) with its row of standing stones and monumental stone basin (and surviving charred animal remains). Over the centuries there was an increasing variety of forms at different sites. At particular sites, however, the plans of temples often remained virtually identical, even after previous superstructures had been destroyed.

Temple architecture

Israel Exploration Society—Hazor Expedition

Standing stones and seated deity from the high place at Hazor, dating from the 13th century BC.

Typical temple furniture included the cult statue, standing stones, bowls and their stands, altars, and benches around the walls. Hazor, in the Jordan Valley north of the Sea of Galilee, has yielded a 13th-century statue of a male deity on a bull-shaped base. In another temple a set of cultic objects, also from the 13th century, was found behind a stone slab: a seated male figure and a group of standing stones, the central one of which has engraved on it a vertical pair of arms with hands outstretched toward a disk and crescent.

The palace too might have a chapel. The palace at Mari, on the Euphrates in eastern Syria, housed a statue of a goddess holding a vase from which she dispensed flowing ("living") water; the water was channeled through the statue to the vase. Wall paintings in the palace depict the same image, as well as scenes of the king being presented to a god and making offerings to a god.

A common religious object, not confined to sacred places, is the "Astarte" figurine, depicting a nude woman, often with exaggerated breasts and genitalia, and sometimes holding a child. This was perhaps a fetish representing the mother goddess and used to stimulate conception, childbirth, or lactation.

The temple was staffed by cultic personnel (priests) under a "chief of priests," and by practitioners of the various other skills required by the functions of the temple. These included singers and other musicians, diviners, scribes, and other specialists, depending on the size of the temple. The temple staff was sustained by some of the sacrifices, by supplies from the estates of the temple or palace, or by direct contributions imposed on the surrounding population. Its essential religious function was the care of the cult statue, the offering of sacrifices, and the performance of other rituals for the welfare of god, monarch, and community.

Typically the monarch and sometimes other members of the royal family played a leading role in the most significant cultic acts and festivals. A king of Sidon refers to himself as "priest of Astarte." One text from a town near Ugarit concerns a sacrifice by the queen.

In tombs formed from subterranean caves beneath the western palace of Ebla during the second quarter of the 2nd millennium, skeletal remains and treasures suggest a cult of deceased monarchs. From Mari and Ugarit researchers have learned of a significant cult of former rulers (called "Healers" at Ugarit)—from putative or mythical figures to the most recently deceased—who supported the reigning monarch with divine blessings. The monarch's expectations of life after death are expressed in an inscription on an 8th-century monumental effigy of the god Hadad from Zincirli (ancient Sam'al) in south-central Turkey. King Panammu directs that his future heir, when making sacrifice to Hadad, pray that Panammu's soul may eat and drink with the god. Phoenician kings of Sidon later refer to a resting place with the Healers, and the same word is used by the Israelites to refer to all the dead.

Sacrifice

People attempted to influence the gods through animal sacrifices, petitions, and vows (promises of gifts contingent on the deity's response to a request for help). Sacrifice was central to the cult. Domestic animals were the main victims—cattle, sheep, and goats—and also birds. There is clear evidence for two types of sacrifice: simple gifts and whole burned offerings. There also is scattered evidence of human sacrifice, probably limited to situations of unusual extremity (contrast the account of the sacrifice of his eldest son by the king of Moab in 2 Kings 3:26–27 with the more abundant evidence of child sacrifice from Carthage and other Phoenician colonies in the west.)

The will of the gods was discovered in various ways. Use of the Mesopotamian technique of liver divination (hepatoscopy) is evidenced by the discovery of clay liver models (sometimes inscribed with omens) at such sites as Ugarit and Hazor, as well as by abundant written testimony at sites closer to Mesopotamia, such as Mari. Ugarit also had a list of omens based on abnormal births. King Idrimi of Alalakh refers to divining by observation of the flight of released birds.

The correspondence from Mari abundantly testifies to the institution of prophecy—spontaneous pronouncements by cult personnel and occasionally others, delivering messages from the deity. By this means the deity disclosed his or her wishes or gave divine warnings or promises to the king. The Aramaean king Zakir records that he appealed to his god in desperation during a siege and that the god answered him through prophets with promises of deliverance—obviously fulfilled, since the king makes so much of this in his inscription. According to the Egyptian "Report of Wen-Amun," a young man of Byblos went into a trance and resolved a diplomatic deadlock by announcing that the Egyptian envoy whom the local king had refused to see had indeed been sent by the Egyptian god Amun. Biblical narratives portray similar prophetic phenomena in Israel. The gods also revealed themselves through dreams, which again were carefully reported to the monarch by his officers at Mari.

According to later classical sources a central focus of Syrian religion was the rituals surrounding the myth of the dying god. The myth, according to these sources, variously draws on other Middle Eastern or Egyptian traditions but essentially tells of the deity's death and subsequent sojourn in the underworld and of an accommodation reached between the queen of the underworld and the goddess associated with the god that allows him to return to earth for six months of the year. Associated rituals include the sacrifice of a male pig, mourning for the dead god in a funeral procession, cultivating "gardens" in small pots and baskets, and a threshing rite.

GODS, MYTHOLOGY, AND WORLDVIEW

There are significant differences between the divine names used in personal names, those of literary myths and epics, and those of more official pantheons, as found in cultic and political texts.

Personal names

Personal names are probably the most conservative of these sources. Some of the deities referred to in personal names are not mentioned in other contemporary sources. They may also preserve the memory of old family or clan cults. The piety expressed in personal names shows that people often saw themselves (or their children) as related to a god especially by kin or service. At Ugarit the god was variously conceived as father, mother, brother, sister, mistress, king, or judge, and the person named could be the son, daughter, offspring, servant, boy, or man of the god. The names also refer to individuals as the "gift" or "beloved" of the god. In personal names the relationship between an individual and a god is more important than the particular deity's role in traditional mythology or the official cult.

The projection of anthropomorphic features onto the gods and the need to explain things—from specific rituals to the nature of the world—led to the telling of stories about the gods. The written versions of such myths and epics often preserve older traditions and may figure as their chief divine actors gods other than those prominent in the current official pantheon. The only source of such native Syro-Palestinian religious literature is 14th-century Ugarit.

In the Ugaritic myths, El is depicted as a bearded old man, kindly and wise. In the legend of King Keret (or Kirta; *k-r-t*), El is the sole benefactor of Keret in that king's various sufferings: he responds to Keret's misery at his lack of a family by appearing to him in a dream and giving him detailed directions for getting a certain princess as his wife. When Keret has successfully followed these directions, El appears at his wedding and pronounces a blessing, promising them many children. After the children are born, Keret becomes sick because of failure to fulfill a vow. No mortal or deity is able to help him until finally El again intervenes and creates a creature for the specific task of healing him. No sooner has Keret recovered and resumed his duties than he faces another crisis—his son proposes to take over from him—but the sequel (a third intervention by El?) has not been preserved. In the text El is called "the Father of humankind." He is the patriarch of the gods, the final power and authority, though he does not always act decisively and he is not always treated with due respect. As the creator god, "the Creator of Creatures" (though no creation myth has been

preserved) and the king of the gods, he is the owner and chief executive of the world. Even the forces of chaos, Yamm and Mot ("Sea" and "Death"), are his beloved children. El is called "the Bull" and is represented iconographically by a bull. His consort is Elat, usually known as Asherah, the "Progenitress of the Gods." She is also called simply Qudshu, "Holiness." Asherah is associated with the sea and with serpents.

Baal (Hadad) is regularly denominated "the son of Dagan," although Dagan (biblical Dagon) does not appear as an actor in the mythological texts. Baal also bears the titles "Rider of the Clouds," "Almighty," and "Lord of the Earth." He is the god of the thunderstorm, the most vigorous and aggressive of the gods, the one on whom mortals most immediately depend. Baal resides on Mount Zaphon, north of Ugarit, and is usually depicted holding a thunderbolt. He is the protagonist of a cycle of myths from Ugarit. These tell of a challenge from Yamm ("Sea"), to which Baal responds. Armed with magical weapons made by the craftsman god, Kothar, Baal manages to overcome Yamm. Another major episode is instigated by Baal's lack of a house. With the assistance of Asherah and Anath, Baal gets El's approval to build a house; Kothar accomplishes the construction; and Baal celebrates by inviting the gods to a feast. The other major story concerns Baal's relations with Mot ("Death"), whom he initially defies, but to whom he eventually succumbs. The attempt to find a god adequate to assume Baal's role fails. Anath disposes of Mot, and then El learns in a dream that Baal is again alive. Mot also reappears, and he and Baal fight until the sun goddess warns Mot of the consequences. There is apparently a final definition of their respective spheres of influence.

The Baal cycle

After Baal is swallowed up by Mot, his sister Anath, called "the Maiden," longs for him like a mother. She finds Baal and buries him. She then defeats Mot and disposes of his body as if it were grain, grinding him up and scattering him over land and sea. Elsewhere in the text Anath refers to her victories over various monstrous enemies in single combat, and she is depicted in scenes of bloody slaughter. She is the "villain" of the tale of Aqhat, also from Ugarit. In this story the gods grant the childless Danel a son, Aqhat, on whom Danel confers a bow made by the craftsman god, Kothar. Anath offers Aqhat riches and immortality in exchange for the bow, but Aqhat refuses her offers. After bullying El into letting her have her way with Aqhat, she proceeds, with the aid of her henchman Yutpan, to have Aqhat killed. Danel performs various rites to try to remove the consequent blight on the land, until he is informed of his son's murder. He then seeks his remains and buries him, curses the towns closest to the site of the murder, and mourns for seven years, after which he gives his blessing to his daughter's proposed mission to avenge Aqhat's death. She sets out and comes to the camp of Yutpan, where the two of them start drinking—at which point the preserved portion of the tale ends. Anath is often associated with Athtart (later Hebrew Ashtoreth, Greek Astarte). Both are renowned for their beauty, and both are closely associated with Baal.

Another group of gods play important subordinate roles in the myths. The sun goddess, Shapash, "Light of the Gods," helps Anath in her retrieval of the dead Baal and intervenes in the final conflict between Baal and Mot. The craftsman god, known as both Kothar ("Skilled") and Hasis ("Clever"), makes the weapons with which Baal disposes of Yamm and builds the palace for Baal. He is the source of Aqhat's bow, coveted by Anath. The Kathirat are goddesses of marriage and pregnancy, who appear before the conception of Aqhat and in a brief myth about the marriage of Yarikh ("Moon") and his Mesopotamian consort Nikkal. Shahar and Shalim are the gods of dawn and dusk, whose conception and birth are recounted in a liturgical myth.

While the great cycle of narratives about Baal from Ugarit in its present form is clearly a literary work rather than a myth, it is doubtlessly composed of religiously significant mythic material. It depicts the prevailing order of things as the result of struggles among the gods—successive bids for power in which Yamm and Mot are confined to their present bounds and Baal and Anath (associated with fertility and military prowess, respectively) prevail. Having descended into the underworld and survived Death, Baal embodies the assertiveness and continuity of life.

It is the official documents of religious practice—god lists, sacrificial lists, and temple rituals, as well as the inscribed monuments—that disclose most directly the gods favoured by the authorities of the time. While virtually all the gods of the myths are Semitic in name, the gods of the cult are much more diverse. This official pantheon presumably included the gods of leading families within this cosmopolitan state and the gods of allied neighbouring states.

The religion of Ebla

At 3rd-millennium Ebla the most important god was Dagan, "Lord of Gods" and "Lord of the Land." Other gods of Ebla included El, Resheph, the storm god, Ishtar, Athtart, Chemosh, and the sun goddess. The gods of the city included several referred to by their Sumerian names. The great rivers of northern Syria were also deified, so that their local names remain unknown. Personal or family gods were referred to as "the god of my father" and "the god of the ruler."

In the early 2nd millennium the great goddess, Ishtar, was widely portrayed in contemporary northern Syria as both warrior and fertility goddess. A standing stone from Ebla depicts her in a winged shrine, standing on a bull. Dagan was also popular—there are references to the local Dagan of various towns: Dagan of Terqa, Dagan of Tuttul, and so on. The royal establishments of Mari and Ugarit owed special allegiance to a deity called "The Lady of the Palace."

The Indo-European gods Varuṇa, Mitra, and Indra were recognized in the kingdom of Mitanni in northeastern Syria, where a Hurrian population was ruled by an Indo-Aryan aristocracy in the third quarter of the 2nd millennium. Little is known of the religion of the Hurrians beyond the names and general character of their chief gods: Teshub, a storm god, and his consort Hepat; their son, Sharruma, also a storm god; the goddess Shaushka,

identified with the Mesopotamian Ishtar; and Kushukh and Shimegi, lunar and solar deities, respectively. Hurrian mythology is known only through Hittite versions (see below *Religions of Asia Minor: Religions of the Hittites, Hattians, and Hurrians*.)

King Idrimi of Alalakh designates himself "servant of the storm god; of Hepat; and of Ishtar, the Lady of Alalakh, my lady." He acknowledges his dependence on the storm god in his adventures and concludes his autobiographical inscription by invoking deified Heaven and Earth, the gods of heaven and earth, the storm god "the lord of heaven and earth," and the great gods. Thus an individual king of the mid-2nd millennium pays tribute specifically to the storm god and then to the two major goddesses of his world, and he acknowledges the rest by means of collectives.

The documentation at Ugarit attests to a more explicit and specific comprehensiveness. Several god lists have been recovered from Ugarit. The most "official" one, which has survived in two Ugaritic copies and one Akkadian translation, consists of 33 items, beginning with a generalized ancestral deity, Ilib, "God of the Father." (One version prefixes the "God of [Mount] Zaphon"—presumably the deity of the mountain north of Ugarit, which is later referred to directly as a god.) Then comes El, followed by Dagan, Baal of Zaphon, and six other Baals. (El, Ilib, or Baal of Ugarit variously come at the head of other god lists.) There follows a small group of gods and goddesses bracketed by Earth-and-Heaven and Mountains-and-Valleys, including the Kathirat, Yarikh, Mount Zaphon, Kothar, and Athtar. Then comes a group of major goddesses, led by Asherah, Anath, and Shapash and concluding with Athtart. The list ends with another group beginning with "the gods who are Baal's auxiliaries," and including the assembly of the gods. This group includes Resheph, Yamm, and Shalim.

Figurines from throughout the area and from a period of many centuries represent an enthroned couple (corresponding to El and Asherah) and a belligerent pair (corresponding to Baal and Anath or Athtart). These figurines are probably replicas of life-size (or larger-than-life) cult images. In any case, they attest to the ongoing official significance of these four types of deity under whatever names.

Developments in the 1st millennium

In the 1st millennium the written documentation shrinks to formulaic inscriptions, very occasionally developed into more expressive literary miniatures. Gods are often referred to in these texts by titles or by new names, so that it is often difficult to ascertain their relationship to the deities of the 2nd millennium, or indeed to determine their individuality in relation to one another. It appears that there was a tendency in this millennium to concentrate all divine power in one deity, as has been noted of Mesopotamia and as is most obviously and extremely the case in Israel.

The storm god, Hadad, appears as the chief god of the Aramaeans in northern Syria in the 9th and 8th centuries. The moon god (under the name Sahar) also is prominent in this area. Some rulers speak of their own dynastic deity. A king who owes his position to the Assyrian emperor refers to the latter and the dynastic deity equally as "my master."

It is clear that several different deities are referred to by the form Baal-X ("Lord of X"). Hadad is probably represented by Baal-Shamen ("Lord of the Heavens"). El appeared under the tile Baal-Hammon—rarely on the mainland, but abundantly in the Phoenician colonies of Africa; under this name he becomes the chief deity of Carthage. In the Phoenician heartland the supreme goddess of Byblos—presumably Asherah—is called simply Baalat Gubl ("the Lady of Byblos"). Anath becomes much less visible during the 1st millennium than at Ugarit. Athtart (Astarte), on the other hand, becomes more prominent. At Sidon, as earlier at Ugarit, she is referred to as "the Name of Baal," perhaps indicating that she was called upon as a mediator with the supreme Baal (Hadad). Alongside other long-familiar deities such as Resheph and Shamash appeared certain new names, including Eshmun (especially at Sidon), Melqart ("king of the [underworld] city"; especially at Tyre), and, of course, Yahweh (in Israel—but also represented at least in personal names at Hamath and Larnaca). According to the Hebrew Bible, Asherah and Astarte were both worshiped in Israel during the first half of the millennium, and Hebrew inscriptions attest to a pairing of Yahweh and Asherah.

Chemosh, known from Ebla and Ugarit, reappears as the national god of Moab. King Mesha of Moab interprets Israel's occupation of his country as a consequence of Chemosh's anger with his land. He claims that, at Chemosh's direction, he reconquered land occupied by Israel, and he attributes his success to Chemosh. He reports that he dedicated the Israelite inhabitants to Chemosh by slaughter and says that Chemosh will henceforth dwell in these territories. This is recorded on the Moabite Stone (now in the Louvre, Paris) a stela that commemorates these events and Mesha's building of a sanctuary for Chemosh in gratitude. The formal identity of these expressions and this kind of religious interpretation of events with those found in some of Israel's literature encourages the surmise that they may also have been shared by the Ammonites with respect to their national god, Milcom.

Philistine religion

The Philistines, traditionally believed to have originated in Crete, were one group of the Sea Peoples that moved from the Aegean Sea to the southeastern Mediterranean. They settled in southeastern Palestine after being repulsed by the Egyptians. Their religion, while it retains some Aegean and Egyptian elements from the Philistines' origins and route of migration, appears largely indistinguishable from Canaanite religion in general. The Bible refers to the gods of the Philistines by the familiar Canaanite names Dagon, Baalzebub, and Ashtart. The name of Asherah has been found inscribed on storage jars in a cultic room at Ekron. (S.B.P.)

Arabian religions

The description of the religions of Arabia given here comprises the polytheistic beliefs and practices that existed before the rise of Islām in the 7th century AD in Arabia, in the broad sense of the term, including the confines of the Syrian desert. The religion of Palmyra, which belongs to the Aramaic sphere, is excluded from this account. The monotheistic religions that had already spread in Arabia before the arrival of Islām are also mentioned briefly. For historical background, see ARABIA.

NATURE AND SIGNIFICANCE

In the polytheistic religions of Arabia most of the gods were originally associated with heavenly bodies, to which were ascribed powers of fecundity, protection, or revenge against enemies. Aside from a few deities common to various populations, the pantheons show a marked local particularism. But many religious practices were in general use. The study of these practices is instructive in view of their similarities with those of the biblical world and also with those of the world of Islām, for, while firmly repudiating the idolatry of the pre-Islāmic period, which it calls the "Age of Ignorance" (Jāhiliyah), Islām has nevertheless taken over, in a refined form, some of its practices.

SOURCES OF MODERN KNOWLEDGE

Knowledge of pre-Islāmic Arabia rests mainly on original archaeological and epigraphic data from the region itself. Countless pre-Islāmic sites are scattered over the whole Arabian Peninsula: ancient lines of circles of raised stones, cairns, graveyards, and so on. In addition there are more recent constructions such as fortified towns and ruins of temples and irrigation systems. Many rock faces are covered with incised drawings. The oldest drawings, barely visible under a dark patina, date back to several millennia BC and provide evidence, for instance, of an ancient cult for the bull and the ostrich. These ancient drawings also depict queer ritual scenes that refer to a still obscure mythology. More explicit and much later (at least no earlier than the end of the 2nd millennium BC) are tens of thousands of alphabetic rock graffiti in ancient Arabian dialects, written in related local alphabets. These graffiti were clustered predominantly along the natural routes

followed by nomads and caravaneers, as well as less numerous monumental inscriptions from the sites formerly occupied by a sedentary population.

The written graffiti are short inscriptions scratched on the rock. The author gives his name and his patronymic and/or his tribal affiliation and genealogy. Short messages, such as a description of an incident, a sad evocation of a dead relative, or an invocation to a god, may follow. Thanks to their considerable number, such texts, which may be rather insignificant in themselves, provide valuable information on the gods and their attributes and on their worshipers.

Monumental inscriptions

The monumental inscriptions are much more elaborate and meaningful, both because they belong to the complex institutions of a sedentary culture and because they appear in an archaeological context. They are carefully engraved, so that the state of evolution of the script allows them to be dated approximately, even when no explicit date is given. They are utilitarian in character and are usually concerned with the construction of buildings, the dedication of objects to a god, or arrangements relating to irrigation. They may also describe military campaigns. So far only traces of a true religious literature have been recovered. But several specimens of a hitherto unknown type of document, excavated since 1970 in Yemen, contradict the unilateral character of the inscriptions. These are records from private archives (personal letters, contracts, and so on), finely engraved in a cursive writing on small wooden sticks. Iconographic documents such as statues and reliefs, seals, and coins also reveal aspects of the religion.

Yet another source is the Muslim tradition. Next to the pre-Islāmic poetry, belatedly put into writing, it comprises the Qur'ān, the sacred book of the Muslims transmitted by its Prophet Muḥammad, which takes a stand against idolatry. Historical traditions have been transmitted by early Muslim annalists and geographers; more specific data on the ancient folklore and religion appear, for instance, in "The Book of the Idols" (*Kitāb al-Aṣnām*), by the Iraqi genealogist Ibn al-Kalbī (8th–9th century AD), and in "The Crown" (*al-Iklīl*), by the Yemeni encyclopaedist and geographer al-Hamdānī (9th–10th century AD), which describes the pre-Islāmic antiquities of Yemen.

External sources are scanty: Arabia has remained little known to its neighbours. From the 9th to the 7th century BC Assyrian kings report their campaigns against North Arabian kings (or queens) and tribes and occasionally name their gods. The annals of Sargon for the year 718 BC and those of his son Sennacherib name two successive sovereigns of Saba' who sent them a "tribute" of aromatics. The Book of Kings of the Bible describes the legendary visit in Jerusalem of a queen of Sheba, bringing presents of gold and frankincense, during the reign of Solomon (10th century BC). In the middle of the 6th century BC the Neo-Babylonian king Nabu-na'id (Nabonidus) conquered the oasis of Taymā' in the Hejaz (Al-Ḥijāz). He boasts of having settled populations from Babylonia there and in neighbouring oases such as Dedān, Khaybar, and Yathrib (Medina), which are known to have been inhabited since ancient times by Jewish populations. It is quite probable that Jews of the Babylonian Exile were among those forced settlers and initiated at that time the Jewish presence in Arabia.

Some classical authors, from Herodotus (5th century BC) to Claudius Ptolemy (2nd century AD), provide information on the religion of the Arabs and on the geography of the Arabian Peninsula. Several Byzantine authors report conflicts between Jews and Christians in Yemen in the 6th century AD.

For many subsequent centuries Arabia remained practically closed to European penetration. Important discoveries of monuments and inscriptions occurred only from about the middle of the 19th century. It was only after World War II, and indeed mostly since the late 1970s, that major archaeological surveys and excavations began in various parts of the peninsula.

THE HISTORICAL SETTING

South Arabia. From the middle of the 2nd millennium BC a sedentary agrarian civilization developed in Yemen in the oases along the edge of the desert. The people of this civilization had gradually mastered techniques enabling them to accumulate water from seasonal mountain rivers and distribute it into extensive irrigation systems. At the end of the 8th century appeared the oldest monumental inscriptions so far recorded, displayed on the walls of buildings. A total of about 8,000 such texts, whole or fragmentary, which correspond to 13 centuries of South Arabian history, have been discovered.

The main South Arabian kingdoms

The texts from the 6th century BC mention the main South Arabian kingdoms, which were spaced out from the northwest to the southeast in the oases along the edge of the desert. There were successively Ma'īn, the kingdom of the Minaeans; Saba', the most important, with its capital, Mārib; Qatabān and Awsān (both located in the area of former Aden Territory [Yemen]); and finally Ḥaḍramawt (the eastern part of the former Aden Protectorate), extending inland from and along the coast of the Gulf of Aden toward Oman; its capital was Shabwa. The coastal area of Ḥaḍramawt was the nearly exclusive biotope of the wild tree from which was extracted the best kind of frankincense, which was the most precious aromatic in the Middle East used for the cult of the gods and of the dead. Along with other aromatics, frankincense was carried inland northwestward on the caravan route through Yemen to a place north of Yemen, where the route bifurcated, running through the oases of the Hejaz (on the Red Sea coast of the Arabian Peninsula) toward Egypt and Syria, and through Qaryat al-Fa'w on the caravan route to central Arabia toward the Persian Gulf and Mesopotamia. Minaean merchants, established in Dedān in the Hejaz and in Qaryat al-Fa'w, were in control of that trade. During the following centuries Saba' struggled with Qatabān for hegemony. About the beginning of the Common era the rise of overseas trade between Egypt and India disrupted the political and economic balance in South Arabia and resulted in a period of general conflict. At the end of the 3rd century AD, Saba', which had meanwhile conquered Ma'īn, Qatabān, and finally Ḥaḍramawt, was in turn conquered, with the whole of South Arabia, by Ḥimyar, a little kingdom that had risen in the southwestern corner of Yemen. This political unification hastened the decay of the overly diversified polytheistic beliefs. After about AD 350 monotheistic invocations to *Raḥmānān*, "the Merciful" (an epithet of Aramaic origin used for God by both Jews and Christians), or to the "Lord of Heaven and Earth," take the place of former polytheistic formulas and dedications. These early monotheistic texts probably emanated from Jewish immigrants from the oases of the Hejaz, although Christianity had already been introduced in South Arabia by Byzantine and Syrian missionaries.

About AD 523 Yūsuf As'ar Yath'ar (nicknamed Dhū Nuwās by the Muslim tradition), a Ḥimyarite king of Jewish faith, persecuted and killed numerous monophysite Christians in Najrān on the northern frontier of Yemen. He also killed Byzantine merchants elsewhere in his kingdom. Outraged by the massacre and pressed by the Christian world to intervene, the Negus of Ethiopia gathered a fleet and landed with troops in Yemen. Having killed the Ḥimyarite king in battle, the Negus appointed an indigenous Christian as his viceroy and sailed back home. Somewhat later Abraha, a former Ethiopian general, took power. The Muslim tradition credits him with a fruitless military expedition with elephants (alluded to in the title, "the Elephant," of chapter 105 of the Qur'ān), directed in 570 against Mecca and its polytheistic shrine. About the end of the 6th century the famous Mārib dam finally collapsed after several major dam bursts. This was a symptom rather than the cause of the long decline of the South Arabian culture, which had led to the emigration northward of several Yemeni tribes. About 572 South Arabia came under Persian occupation. This lasted until 628, when the local satrap in charge embraced Islām, thus opening his province to the new faith and to the Islāmic culture.

North and central Arabia. There are various populations to consider, differing in their languages and systems of writing, in their pantheons, and above all in their ways of life. Sedentary populations of merchants and farmers were settled in towns and oases, which were centres of

developed civil and religious institutions. In sharp contrast with them were the breeders of sheep and goats—semi-nomads living in precarious shelters in the vicinity of sedentary settlements—and true nomads: camel breeders and caravaneers, capable of crossing the desert, moving with their herds over great distances toward seasonal pastures, and living under tents. Their places of worship were rocky high places; portable idols followed the peregrinations of the tribe.

Among the oases or towns of which the local gods are known appears in the first place the oasis of Dūmat al-Jandal, halfway between the Sinai and Babylon; the Assyrian king Esarhaddon names its gods (see below). In the North Arabian oasis of Taymā', stelae written in Aramaic and dated to the 5th century BC name the local deities. In the 5th century BC, the oasis of Dedān (al-'Ulā) was the capital of a short-lived Dedānite kingdom; then, from the 4th century to the 1st century BC, it was the capital of the kingdom of Liḥyān, which for nearly two centuries was home to a colony of Minaean tradesmen from South Arabia. Dedān and the neighbouring site of Al-Ḥijr (Ḥegrā') were occupied from the north in about 25 BC by the Nabataean kingdom.

The Nabataeans

The Nabataeans were originally a nomadic tribe from the land of Madiān in the northern Ḥejaz who settled in North Arabia, the Negev, and southern Jordan as far north as the Dead Sea, from which they extracted bitumen. Their capital, Petra, north of the Gulf of Aqaba, is historically attested from the beginning of the 4th century BC. In spite of their Arab origin, they used an Aramaic dialect as their written language. At the time of their greatest wealth and power, under Aretas IV (8 BC–40 AD), their territory extended from Al-Ḥijr in the south, northward past Petra, along the northern route east of the Jordan River as far as the Ḥawrān region south of Damascus. The Nabataean territory—except for its southern part—was incorporated into the Roman Provincia Arabia in AD 106. The last dated Nabataean text dates from AD 356.

The so-called "Thamūdic" graffiti are named after Thamūd, one of several Arabian tribes named in the Assyrian annals. Thamūdaeans are named about AD 169 in a Greek inscription on a Nabataean temple in the northeastern Ḥejaz, and in a 5th-century Byzantine source, as members of a cameleer corps on the northeastern Egyptian frontier. The Muslim tradition wrongly ascribes to the Thamūd the Nabataean tombs carved in the rock in Al-Ḥijr. The name "Thamūdic" was first given to a type of alphabetic graffiti found in the region of Taymā', because what may be mentions of the tribal name Thamūd occur in some of these texts. Later the name was incorrectly applied to various types of graffiti found throughout Arabia, dating from the 4th century BC to the 3rd or 4th century AD.

The Ṣafaitic graffiti (1st century BC to the 4th century AD) are so called because they belong to a type first discovered in 1857 in the basaltic desert of Ṣafā', southwest of Damascus. Many thousands of such texts, scattered over an area including eastern Syria and Jordan and northern and northeastern Saudi Arabia, have so far been collected and in part published.

From the disruption of the Arabian sphere in the 3rd and 4th centuries, owing in part to the penetration of Christianity and to the emigration of south and central Arabian tribes toward Syria and lower Iraq, emerged during the 4th and 5th centuries some buffer states, vassals of the Byzantine and Persian empires and of the Ḥimyarite kingdom. The Ghassānids were settled in Syria, the Lakhmids in Al-Ḥīrah on the Euphrates, and the Kindites in central Arabia. In the 5th and 6th centuries they were closely involved in the hostilities between Byzantium and Persia.

PRE-ISLĀMIC DEITIES

South Arabia. The astral basis of the South Arabian pantheon emerges from such divine names as Shams ("Sun") and Rub' ("Moon-Quarter"). The epithets "Mother of 'Athtar," "Mother of [the] goddesses," "Daughters of [the god] Il" allude to still-obscure theogonic myths.

The name of the Venus god 'Athtar corresponds to that of the Mesopotamian goddess Ishtar (Venus). Hawbas, a goddess, was his consort (but seems to have been locally a masculine deity). As head of the South Arabian pantheon, 'Athtar had superseded the ancient supreme Semitic god Il or El, whose name survives nearly exclusively in theophoric names. 'Athtar was a god of the thunderstorm, dispensing natural irrigation in the form of rain. When qualified as Sharīqān, "the Eastern One" (possibly a reference to Venus as the Morning Star), he was invoked as an avenger against enemies.

National deities

Next to 'Athtar, who was worshiped throughout South Arabia, each kingdom had its own national god, of whom the nation called itself the "progeny" (*wld*). In Saba' the national god was Almaqah (or Ilmuqah), a protector of artificial irrigation, lord of the temple of the Sabaean federation of tribes, near the capital Ma'rib. Until recently Almaqah was considered to be a moon god, under the influence of a now generally rejected conception of a South Arabian pantheon consisting of an exclusive triad: Father Moon, Mother Sun (the word "sun" is feminine in Arabic), and Son Venus. Recent studies underline that the symbols of the bull's head and the vine motif that are associated with him are solar and Dionysiac attributes and are more consistent with a sun god, a male consort of the sun goddess. In Ma'in the national god Wadd ("Love") originated from North Arabia and probably was a moon god: the magic formula *Wd'b*, "Wadd is [my?] father," written on amulets and buildings, is often accompanied by a crescent Moon with the small disk of Venus. In Ḥaḍramawt the national god Syn was also a sun god: the current identification with the Mesopotamian moon god Sin (Suen) raises phonetic objections, and the symbolic animal of Syn, shown on coins, was the eagle, a solar animal. In Qatabān the national god 'Amm, "paternal uncle," may have been a moon god. The sun goddess Shams was the national deity of the kingdom of Ḥimyar. She appears also, in a minor role, in Saba'. Other aspects of Shams are certainly concealed in some of the many and still obscure South Arabian female divine epithets.

Lesser deities

Among various lesser or local deities, the nature and even the sex of many of whom remain unknown, the better-documented are listed here. In Qatabān, Anbay and Ḥawkam are invoked together as (the gods) "of command and decision(?)." The name Anbay is related to that of the Babylonian god Nabu, while Ḥawkam derives from the root meaning "to be wise." They probably represent twin aspects (as Evening and Morning Star?) of Babylonian Nabu-Mercury, the god of fate and science and the spokesman of the gods. In Ḥaḍramawt, Ḥawl was probably a moon god; his name apparently alludes to the lunar cycle. Some tribes worshiped their own "patron" (*shym*). Ta'lab was the patron of Sum'ay, a Sabaean federation of tribes. In Ma'īn, Nikraḥ was a healer patron; his shrine, located on a hillock in the middle of a large enclave marked by pillars, was an asylum for dying people and women in childbirth.

Among other North or central Arabian gods worshiped in South Arabia, Dhū-Samāwī ("the Heavenly One"), was presented by Bedouin tribes with votive statuettes of camels to ensure the well-being of their herds. Kāhil, the national god of the central Arabian kingdom of Qaḥṭān in Qaryat al-Fa'w, was assimilated there to Dhū-Samāwī. He was also known in South Arabia. Conversely, the Sabaean god 'Athtar Sharīqān appears in Qarya under the Arabic transcription *'Athar* [sic] *a(sh)-Sharīq*.

The South Arabian deities are usually evoked by a symbol, as, for instance, a bull's head, snake, or thunderbolt. Seldom (and later) do they appear in human form, inspired by late Hellenistic iconography: for example, seated Demeter with cornucopia, Dionysus-Sabazios, and the Dioscuri.

North Arabia. North Arabian gods are named for the first time in the annals of the 7th-century BC Assyrian king Esarhaddon, in which he reports having returned to the oasis of Adumatu (Dūmat al-Jandal) the idols previously confiscated as war booty by his father, Sennacherib. Among the gods named by Esarhaddon are 'Atarsamāin, 'Atarqurumā, Nukhay, and Ruldayu. Herodotus wrote that the Arabs worshiped as sole deities Alilat, whom he identifies with both Urania and Aphrodite, and Orotalt,

identified with Dionysus. Both accounts concur: Ruldayu and Orotalt are phonetic transcriptions of the same name, Ruḍā, a sun god often named in the Thamūdic inscriptions and in Ṣafaitic (in Ṣafaitic, Ruḍā eventually becomes a goddess). In the Nabataean kingdom the counterpart of Dionysus was the great god nicknamed dū-Sharā (Dusares), "the one of Sharā" from the name of the mountain overlooking Petra. This epithet replaced the secret name (probably Ruḍā) of that god, a rival to Shay' al-Qawm, "the Shepherd of the People," he "who drinks no wine, who builds no home," the patron of the nomads, represented as Lycurgus and also worshiped by the Liḥyānites. Nukhay, perhaps a solar god, was worshiped by the Thamūdaeans and Ṣafaites.

Al-Ilāt or Allāt ("the Goddess"), was known to all pantheons. She is a daughter or a consort, depending on the region, of al-Lāh or Allāh ("the God"), Lord of the Ka'bah in Mecca; he is also named in Thamūdic texts. Al-Ilāt formed a trio with the goddesses al-'Uzzā ("the Powerful") and Manāt (or Manawat, "Destiny"). Among the Nabataeans al-'Uzzā was assimilated to Venus and Aphrodite and was the consort of Kutbā' or al-Aktab ("the Scribe"; Mercury); among the Thamudaeans, however, she was assimilated to 'Attarsamay (or 'Attarsam). Manāt was depicted as Nemesis in the Nabataean iconography. The three goddesses were called the "Daughters of Allāh" in pre-Islāmic Mecca, and they are mentioned in the Qur'ān (53: 19–22). In South Arabia they are called the "Daughters of Il," and al-Ilāt and al-'Uzzā are mentioned in Sabaean inscriptions.

In Taymā', in the northern Hejaz, Aramaic inscriptions of the 2nd half of the 5th century BC mention the gods Ṣalm, Ashimā', and Shingalā'. Only the first name can be identified with the figure of a bull's head with a solar disk between the horns represented in the inscriptions. Ṣalm is also named in some Thamūdic graffiti with similar drawings, found in a rock sanctuary near Taymā'.

The secret name of the Liḥyānite god nicknamed dhū-Ghābat, "the One of the thicket," is unknown. Other Liḥyānite gods were han-Aktab, "the Scribe," and Ba'alshamīn, "the Lord of Heavens," and 'Aglibōn, a fertility bull god, both of whom were borrowed from Palmyra.

SANCTUARIES, CULTIC OBJECTS, AND RELIGIOUS PRACTICES AND INSTITUTIONS

The sanctuaries, sometimes carved in the rock on high places, consisted of a *ḥaram*, a sacred open-air enclosure, accessible only to unarmed and ritually clean people in ritual clothes. There the baetyl, a "raised stone," or a statue of the god, was worshiped. The Nabataeans originally represented their gods as baetyls on a podium, but later they gave them a human appearance.

Petra

Of the Nabataean high places that are carved from the rock, the best-known overlooks the site of Petra. On a summit measuring roughly 215 by 65 feet (65 by 20 metres) are carved a large triclinium for ritual meals, a podium with baetyls, a sacrificial altar, and a basin. The stone-built temples of the Nabataeans and South Arabians were more elaborate structures, consisting of a rectangular walled enclosure, near one end of which was a stone canopy or a closed cella or both, which contained the altar for sacrifices or the idol of the god. Other rooms and a cistern might be added. The Ka'bah in Mecca, which became the sacred shrine of the Muslims, has a similar structure: it is a closed cella (which was full of idols in pre-Islāmic times) in a walled enclosure, with a well. A baetyl, the Black Stone, is inserted in the wall of the Ka'bah; it is veiled by a cloth cover (the *kiswah*), reminiscent of the leather cover of the Ark of the Covenant. Numerous South Arabian temples have been surveyed. The temple of Almaqah in Mārib had an unusual shape, that of an ellipse with a major axis about 345 feet long, with a strong wall about 28 feet high, built of fine limestone ashlars. A small temple, in front of which were eight standing pillars, comprises a gallery supported by pillars around a rectangular court; it served as a peristyle to the main temple, in the wall of which it was inserted.

To the gods were offered, on appropriate altars, sacrifices of slaughtered animals, libations and fumigations of aromatics, votive objects, or persons dedicated to serve in the temple. A ritual slaughter of enemies in gratitude for a military victory is mentioned at the rock sanctuary of the sun goddess of Ḥimyar. Normally the dedicator of a sacrifice performed the slaughtering of the animal.

In addition to the northwestern Arabian *Kāhin*, "soothsayer," several kinds of priests and temple officials appear in Liḥyānite, Nabataean, and South Arabian inscriptions, but their respective functions are not clear. North Arabian queens and ancient Qatabānian rulers bore priestly titles. In Saba', some priests (*rshw*) of 'Athtar, recruited on a hereditary basis from three clans, took office in turn for seven years as eponyms (*kabir*) in charge of the collection of the tithe and of the rites aimed at obtaining rain.

A marble relief, the dedication or epitaph of a woman. The inscription, in South Arabian script of the 3rd century AD, reads as follows: "Image of Ghallat, daughter of Mufidat; may 'Athtar crush whomever breaks it." In the upper register a goddess plays a musical instrument; two women bring offerings. The arch above the scene is formed by the necks of twin dragons whose heads appear in the upper corners with a bunch of grapes; this is a symbol of immortality. The scene represents the other world. In the lower register a woman, probably Ghallat, reclines on a couch; her outstretched arm points toward the small representation of a gazelle or horse. A standing woman touches her head. This scene may be a representation of oneiromancy. In the British Museum.

The priests interpreted the oracles, which, throughout Arabia, were mostly obtained by cleromancy (*istiqsām*): the answer (positive, negative, expectative, and so on) to a question asked of the god was obtained by drawing lots from a batch of marked arrows or sticks. Many Sabaean texts mention the oracles, but only one inscription mentions arrows in connection with them. A bunch of sticks possibly used for that purpose was found in 1987 in a Sabaean temple. Among the many other forms of divination known from pre-Islāmic Arabia, only oneiromancy, or divination by means of dreams (possibly after incubation in the temple), is well attested in Sabaean texts.

Pilgrimages

Throughout pre-Islāmic Arabia, "truces of God" allowed people to attend in security the yearly pilgrimages to important shrines. The rites included purification and the wearing of ritual clothing, sexual abstinence, abstention from shedding blood, and circuits performed (*ṭawāf, dawār*) around the sacred object; they were concluded by the slaughter of animals, which were eaten in collective feasts. Today such practices still form the core of the Islāmic pilgrimage to Mecca. The classical, Nabataean, Liḥyānite, and Sabaean sources mention pilgrimages.

In South Arabia pilgrims were entertained in the temples on the proceeds of the tithe. The sanctuary of Jabal al-Lawdh, in al-Jawf of northern Yemen, consisted of two temples: the first, at the foot of the mountain, was connected to another one near the summit, some 3,000 feet higher up, by a 3.7-mile processional way. Open courtyards contained many rows of low masonry benches, more than 30 feet long, which were probably used for the ritual meals mentioned in the texts found at the site. Among the Nabataeans, sacral brotherhoods (*mrzḥ;* "thiasoi") held ritual meals in the temples or in burial rooms of the dead.

The sovereigns of Saba' performed a rite called "hunting the game of 'Athtar and the game of Kurūm." The gazelle was the symbol animal of 'Athtar, and Kurūm is now known to be a hypostasis or a consort of 'Athtar (this explains the name 'Atarqurumā of an idol in Dūmat al-Jandal, mentioned above). This rite was aimed at obtaining rain, and that is also the aim of a formal tribal ibex hunting still performed today in Ḥaḍramawt. *Istisqā'*, a collective rogation for rain with magical rites, in times of acute drought, is mentioned by the Muslim tradition and in two Sabaean texts. The rite is still part of the Islāmic ritual.

South Arabian texts confessing offenses against ritual cleanliness, along with data from classical sources and the Muslim tradition on pre-Islāmic customs, contribute to outline an ancient Arabian code of ritual cleanliness similar to that of the Leviticus and of Muslim jurisprudence, although some Islāmologists, unaware of the pre-Islāmic Arabian epigraphic material, have attributed the Muslim code on ritual cleanliness (*ṭahārah*) to a Jewish influence on early Islām in Medina.

Burials

The dead were buried under a mound of stones or in burial chambers carved from the rock. The Ṣafaite Bedouin used to add a stone, possibly bearing a written expression of grief, to the heap marking the grave of a friend or relative. Some excavated heaps have yielded dozens of such texts. An ancient Arab custom was to tie the mount of a dead warrior to the tomb of its master and leave it to die there. There is probably no relationship between this custom and the discovery, in 1985 in Ḥaḍramawt, of tombs of ritually beheaded kneeling camels. Collective burial chambers were carved in the rock underground or from cliffs in various parts of Arabia. Liḥyānite, Nabataean, and South Arabian inscriptions may mark the entrance, name the occupants and their respective share of ownership, and threaten any intruder or usurper. Surgically prepared mummies were discovered for the first time in 1983 in North Yemen, in burial chambers carved in a cliff. In the Nabataean capital, Petra, and in Madā'in Ṣaliḥ, the necropolis of their city of Al-Ḥijr, in the Hejaz, many dozens of rock burial chambers show a great variety of elaborate facades carved in high relief in the red sandstone. Religions of Asia Minor

This account covers the beliefs and practices of the ancient peoples and civilizations of Turkey and Soviet Armenia, including the Hittites, Hattians, Luwians, Hurrians, Assyrian colonists, Urartians, and Phrygians. For historical background, see TURKEY AND ANCIENT ANATOLIA.

SOURCES OF MODERN KNOWLEDGE

Until comparatively recent times, the pre-Christian religions of Asia Minor were known only through the works of classical writers. For the Greeks and Romans, Asia Minor was above all the home of the religion of Cybele, the Great Mother of the Gods, whose cult was centred in Phrygian Pessinus. A monument such as the colossal, but much weathered, figure of a Hittite goddess carved high up on the slopes of Mount Sipylus (near Manisa) was of necessity ascribed by the 2nd-century-AD Greek traveler and geographer Pausanias to the Mother of the Gods, since no other ancient Anatolian goddess was known to him.

During the 19th century many such pre-classical rock reliefs and inscribed monuments were reported by travelers, but it was the discovery of the royal Hittite archives at Boğazköy (ancient Hattusa) in 1907 that made available for the first time a mass of indigenous literary evidence for an Anatolian civilization belonging to the 2nd millennium BC, before the arrival of the Phrygians. Because of the discovery of these archives, written on clay tablets, the religion of the Hittites necessarily predominates in any account of the early religions of Asia Minor. Later Hittite history has been further clarified by the decipherment of the Hittite hieroglyphic inscriptions on monuments dating for the most part from the early centuries of the 1st millennium BC, after the downfall of Hattusa. For the same period, the cuneiform inscriptions of the kingdom of Urartu in the region of Lake Van contain some information on the religion of that area, though they are mostly concerned with other matters.

Boğazköy

The clay tablets of Assyrian commercial colonists found at Kültepe, Aliṣar, and Boğazköy belong to the period immediately preceding the rise of the kingdom of Hattusa, but they contain little information bearing on the life of the indigenous population. For all earlier periods, scholars are dependent on the inarticulate data of archaeology—isolated finds, the interpretation of which leaves a large element of uncertainty.

PREHISTORIC PERIODS

The earliest evidence of religious beliefs has come to light at the mound of Çatal Hüyük, to the south of modern Konya. Here in four seasons of excavations (1961–65), James Mellaart discovered remains of a Neolithic village of mud-brick houses, many of which could be identified as shrines. They are dated by radiocarbon to about 6500–5800 BC (calculated with a half-life of 5,730 years). Huge figures of goddesses in the posture of giving birth, leopards, and the heads of bulls and rams are modeled in high relief on the walls of some of these shrines. Others contain frescoes showing elaborate scenes such as the hunting of deer and aurochs, or vultures devouring headless human corpses. A series of stone and terra-cotta statuettes found in these shrines represent a female figure, sometimes accompanied by leopards and, from the earlier levels of excavation, a male either bearded and seated on a bull or youthful and riding a leopard. The main deity of these Neolithic people was evidently a goddess, a mistress of animals, with whom were associated both a son and a consort. Her character is vividly shown by a schist plaque carved to represent two scenes, a sacred marriage and a mother with child. The dead appear to have been excarnated in a mortuary outside the village by exposure to vultures, as shown in the painting, before being buried under the platforms in the houses.

Cults of goddesses

At Hacilar, near Lake Burdur, a somewhat later culture was unearthed by the same excavator, and here again were found statuettes of goddesses associated with felines; but, as in the later levels at Çatal Hüyük, the son or consort is absent.

Entirely different and far removed in time and place are the discoveries at Alaca Hüyük and Horoztepe in northern Anatolia. Here, dating from the latter half of the 3rd millennium BC (*c.* 2400–2200), were found royal tombs richly furnished with artifacts in bronze and precious metals. Beside the heads of skeletons lay female figurines; one such figure found in a grave at Horoztepe represents a mother nursing her child. Many of the objects found in these graves must have had ritual significance. At Horoztepe a bronze sistrum, or rattle, was found. But the outstanding feature of the graves at both sites is the occurrence of bronze standards, which may have been carried on poles. They are openwork objects of circular or occasionally rhomboid form and are adorned with figures of animals (bulls, stags, and, in one instance, felines), birds, flowers, and swastikas and other geometric patterns. Other standards, consisting of simple statuettes of stags or bulls, also occur.

The archaeological finds of central Anatolia follow immediately after the period of these royal tombs from the Pontic region. Kültepe, near Kayseri, became in the 19th century BC the centre of Assyrian trading outposts (*kārum*); but from the mound itself, from a level just prior to the foundation of the Assyrian colonies, have come a series of remarkable statuettes. The majority of these are abstract,

disk-shaped idols without limbs; many of them have two, three, or even four heads, and others bear on their chests small male figures in relief, in one case accompanied by a lion. There can be little doubt that here again is a representation of a divine family—a mother goddess with consort and child or children. From a level at Boğazköy contemporary with Kültepe comes a limestone mold of a "mistress of animals," a nude goddess standing on a pair of felines and holding aloft an animal in either hand. Molds for a pair of figures, a bearded god and a goddess—the god carries various weapons or emblems, the goddess in most instances holds a baby—have been found at several sites at a somewhat later level.

Though the Old Assyrian tablets are concerned exclusively with commercial matters, the seal impressions that they bear contain a new and elaborate system of religious symbolism (iconography) that later reached its maturity under the Hittites. Here a whole pantheon of deities, some recognizably Mesopotamian, others native Anatolian, are distinguished by such features as dress, attendant animals, weapons, actions, and attitudes. Among them are several weather gods, all associated with a bull, but distinguished in various ways; the weather is depicted in the form of rain falling above the god. A bull alone, carrying an enigmatic pyramid upon its back, sometimes surmounted by a bird, is a particularly common motif and probably symbolizes a weather god. Other deities are a war god holding various weapons, a hunting god holding a bird or hare, a god in a horse-drawn chariot, another in a wagon drawn by boars, a goddess enthroned and surrounded by animals, a nude goddess, and several composite beings. On many seals the deity—and especially the bull with the pyramid—is shown receiving ritual offerings.

Weather gods

RELIGIONS OF THE HITTITES, HATTIANS, AND HURRIANS

An interval of only a few decades separates the end of the Assyrian colony period from the earliest records of the kingdom of Hatti, and for the next five centuries (*c.* 1700–1200 BC) the history of Asia Minor is well documented. The texts reveal a country inhabited by a number of distinct peoples. The Hittites in the centre, the Luwians in the south and west, and the Palaians in the north were speakers of related Indo-European languages. In the southeast were the Hurrians, comparatively late arrivals from the region of Lake Urmia. The Hattians, whose language appears to have become extinct, were most probably the earliest inhabitants of the kingdom of Hatti itself.

Each of these nations had its own pantheon, and individual cult centres had their own names for deities. The result is a bewildering number of divine names, and even when a deity is denoted not by a name but by a logogram (sign or signs standing for a word) to indicate weather god, sun god, moon god, and so forth, it seems that the deity of each city was regarded by the Hittite theologians as a distinct personality. There are even special weather gods, such as the weather god of the lightning, the weather god of the clouds, the weather god of the rain, the weather god of the palace, the weather god of the royal person, the weather god of the sceptre, and the weather god of the army, each again conceived as a separate personality. To us these are simply manifestations or aspects of a single deity, and this is reflected to some extent in the iconography, the pattern of religious symbolism, in which, as in the preceding period, there is a well-defined and limited number of divine types. Often deities were represented by a symbol on clubs and other weapons. An example is the rock carving of a sword deity in Yazılıkaya (Inscribed Rock) near Boğazköy. A human head tops the hilt, which is carved in the form of four crouching lions.

Types of gods

The pantheon. The most widely worshiped deity of Hittite Anatolia was clearly the weather god, as befits a country dependent on rain for its fertility; and under the title "weather god of Hatti" he became the chief deity of the official pantheon, a great figure who bestowed kingship, brought victory in war, and probably represented the nation in its dealings with foreign powers. Thus the treaty with Egypt is said to be "for the purpose of making eternal the relations which the sun-god [of Egypt] and the weather-god [of Hatti] have established for the Land of Egypt and the Land of Hatti." His name in Luwian, and probably also in Hittite, was Tarhun (Tarhund); in Hattic he was called Taru, and in Hurrian, Teshub. He is associated with the sacred bull and appears on monuments either attended by a pair of divine bulls or driving over mountains in a chariot drawn by bulls. In the cult itself Tarhun might even be represented by a bull.

As Tarhun's spouse, the great goddess of the city of Arinna was exalted as patroness of the state. (Arinna has not been located, but it was situated somewhere in the heartland of the Hittite kingdom, within a day's journey of the capital.) Her name in Hattic was Wurusemu, but the Hittites worshiped her under the epithet Arinnitti. She is always called a sun goddess, and sun disks appear as emblems in her cult, but there are indications that she may originally have had chthonic, or underworld, characteristics. As "sun goddess of the earth" she might be identified with Lelwani, the ruler of the netherworld. The king and queen were her high priest and priestess.

The weather god of another city, Nerik, was regarded as the son of this supreme pair, and they had daughters named Mezzulla and Hulla and a granddaughter, Zintuhi. Telipinu was another son of the weather god and had similar attributes. He was a central figure in the Hittite myths.

There was also a male sun god, distinct from the sun goddess of Arinna, a special form of whom was the "sun god in the water," probably the sun as reflected in the waters of a lake. His name in Hittite was Istanu, borrowed from the Hattic Estan (Luwian Tiwat, Hurrian Shimegi). There was also a moon god (Hittite and Luwian Arma, Hurrian Kushukh), but he plays little part in the texts. In the iconography, the sun god was represented in the robes of the king, whose title was "My Sun"; the moon god was shown as a winged figure with a crescent on his helmet, sometimes standing on a lion. According to official theology there also existed a sun god or goddess of the underworld. In this place resided the Sun on its journey from west to east during the night.

Solar and lunar deities

The god of hunting appears frequently on Hittite monuments; he holds a bird and a hare, as on the Kültepe seals, and he stands on a stag, his sacred animal. From descriptions of the statues it appears that this is the deity denoted in the texts by the logogram KAL, to be read Kurunda or Tuwata, later Ruwata, Runda. The war god also appears, though his Hittite name is concealed behind the logogram ZABABA, the name of the Mesopotamian war god. His Hattic name was Wurunkatti, his Hurrian counterpart Hesui. His Hattic name meant "king of the land."

The Hittite goddess of love and war is similarly disguised under the logogram of the Babylonian ISHTAR; she was evidently much revered and was the special protectress of Hattusilis III. Her Hurrian name was Shaushka. As a warrior goddess she was represented as a winged figure standing on a lion with a peculiar robe gathered at the knees and accompanied by doves and two female attendants.

There was a mother goddess, Hannahanna "the grandmother," closely associated with birth, creation, and destiny, but the theologians appear to have regarded her as a minor deity.

It is impossible to enumerate the lesser deities, many of whom are mere names to us. Among them were many mountains, rivers, and springs, and the spirits of past kings and queens who had "become gods" at death. Demons are conspicuous by their absence; sickness and misfortune were ascribed either to sorcery or to divine retribution.

During the later years of the Hittite kingdom, the state cult came under strong Hurrian influence. The sun goddess of Arinna and the weather god of Nerik were identified with the Hurrian queen of the gods, Hebat, and her son, Sharruma; and at Yazılıkaya, where a rocky outcrop forming a natural open chamber was adorned with a series of 64 bas-reliefs that represented the national pantheon, every identifiable deity bears a Hurrian name written in Hittite hieroglyphs. The central group is recognizable as the family of the sun goddess, but she is named Hepatu, her son Sharruma. They both stand on felines, she, perhaps, on a lion or lioness, and he on a panther. The Hittites had here already begun a process of assimilation.

Influence of Hurrian religion

Gods and men. The gods were imagined to have their

own lives, though also needing the service of their worshipers, who in turn were dependent on the gods for their well-being. They lived in their temples, where they had to be fed, clothed, washed, and entertained. Part of their time, however, might be spent in heaven or in roaming the sea or the mountains. They might withdraw in anger and so cause life on Earth to wither and cease. One of the most characteristic rituals of the Hittites was the invocation by which a god who had absented himself was induced to return and attend to his duties by a combination of prayer and magic.

The relation between man and god resembled that between servant and master. "If a servant has committed an offence and confesses his guilt before his master, his master may do with him whatever he pleases; but because he has confessed his guilt . . . his master's spirit is appeased and he will not call that servant to account." Confession and expiation form the main theme of the extant royal prayers.

Divination. Divination, through which the cause of divine displeasure was ascertained, was mainly of three kinds: augury (divination by flight of birds), haruspicy (divination by examining the entrails of sacrificial animals), and an enigmatic procedure using tokens with symbolic names, arts said to be practiced respectively by the "bird-watcher," the seer, and the "old woman." The omens, as interpreted by these experts, were either favourable or unfavourable and would give a yes or no answer according to the sense of the question put to them. In this way, by a lengthy process of elimination, it was possible to determine the precise offence that required expiation. Haruspicy was a science inherited by the Hittites from the Babylonian seers. The other two methods of divination seem to have been indigenous to Asia Minor.

The cult. The Hittite records at Boğazköy give abundant evidence for a state religious cult. The king himself and all important state matters, including royal decrees and treaties, were placed under the protection of national deities.

Sacrifices and festivals

The proper conduct for temple personnel was laid down in a tablet of instructions that gives some insight into the organization of a temple. Divine vengeance is threatened against those who misappropriate food or drink brought for sacrifice, who admit unclean animals or unauthorized persons into the temples, who purloin vessels or implements belonging to the god, who fail to celebrate festivals at the proper time, and who desert their posts to spend the night with their wives.

Many extant texts consist of descriptions of festivals in which the king or queen is the chief officiant. These festivals were numerous, but their names are largely unintelligible. Many of them were seasonal. The preliminary details, such as the robing of the king and his entry into the temple, accompanied by various dignitaries and by musicians playing their instruments, differed little from one festival to another. Owing to the very large number of fragmentary texts, it has not yet been possible to discern special characteristics of the festivals. They invariably culminated in libations and frequently in a cultic meal. One such festival lasted 38 days and involved celebrations in a dozen different cities.

Burial customs. The tablets from Boğazköy have yielded much information about the burial practices of the Hittites. There was a burial ritual for a king or queen that lasted 13 days and in which the body was cremated and the fire extinguished with potable liquids. The bones were then dipped in oil or fat and wrapped in cloth. A feast followed their placement on a stool in a stone chamber. Although cremations were practiced, burial of the body in an earthen grave was not uncommon. In 1952 Kurt Bittel excavated two sites near Yazılıkaya, close to a natural rock outcrop. One site contained 72 burials, 50 of which were cremations. The other site contained only cremations, and the presence of some precious objects among them suggests that these might be burials of privileged persons.

Mythology. In Anatolia itself myth seems to have remained on a rather primitive level. Such myths are found embedded in magical or ritual texts, aimed at curing diseases, ensuring good fortune, and the like.

A particularly well-attested type of myth occurs in connection with the invocation of an absent god and tells how the god once disappeared and caused a blight on Earth, how he was sought and found, and eventually returned to restore life and vigour. In one such myth the weather god withdraws in anger and the search is conducted by the sun god (whose messenger is an eagle), the father of the weather god, his grandfather, and his grandmother Hannahanna. In another, it is Telipinu who is angry, and the gods who search are the sun god, the weather god, and Hannahanna, the grandfather being omitted. In both these versions, the missing god is found by a bee sent forth by Hannahanna. In another similar story, the sun god and Telipinu are both missing, not from anger, but because they have been seized by "Torpor," which has paralyzed nature. In yet another version, the weather god of Nerik is said to have gone down to the netherworld through a hole in the ground, apparently the hole from which the river Marassantiya (modern Kızıl Irmak) gushed forth, which suggests that this weather god may really have been a god of the underground waters.

"The Slaying of the Dragon"

Another myth, "The Slaying of the Dragon," connected with the Hattian city Nerik, was apparently recited at a great annual spring festival called Purulli. It tells how the weather god fought the dragon and was at first defeated, but subsequently, by means of a ruse (of which there are two quite distinct versions), succeeded in getting the better of him and killing him.

Other mythological tales of Hittite and Hattian deities existed, but they are too fragmentarily preserved to give any connected story.

The elaborate epic of the struggle against Ullikummi, and the *Theogony,* though written in Hittite, are Hurrian in origin and refer to Hurrian and even Mesopotamian deities. The *Theogony* tells of the struggle for kingship among the gods. Alalu, after holding the kingship for nine years, was defeated by Anu (the Babylonian sky god) and went down to the netherworld. Anu in his turn, after nine years, gave way to Kumarbi, a Hurrian god, and went up to heaven. Eventually the weather god Teshub was born, and though the god KAL apparently reigned for a period, and the end of the tale is lost, it is certain that Teshub was the final victor, for there are many allusions to the "former gods" who were banished to the netherworld by him. The conception itself derives from Babylonia.

The "Song of Ullikummi" tells of a plot by Kumarbi to depose Teshub from his supremacy by begetting a monstrous stone as champion. Ullikummi, the stone monster, grows in the sea, which reaches his waist, while his head touches the sky; he stands on the shoulder of Upelluri, an Atlas figure who carries heaven and earth. Teshub is warned of the danger and goes out to battle in his chariot drawn by bulls, but he fails and appeals for help to Ea (Babylonian god of wisdom). The latter orders the "former gods" to produce the ancient tool by which heaven and earth had once been cut apart (the only surviving hint of a Hittite creation myth), and with this he severs Ullikummi from the giant and so destroys his power. Again the end is lost, but it is certain that the final victory went to Teshub.

RELIGIONS OF SUCCESSOR STATES

When Hattusa fell, in about 1180 BC, the Luwians moved eastward and southward into Cappadocia, Cilicia, and North Syria. Here they formed a number of small successor kingdoms. Shortly afterward the Phrygians crossed the Bosporus from Thrace and occupied the centre of the Anatolian plateau, cutting off in the extreme southwest a remnant of the Luwian people, who became known as the Lycians and maintained their reverence for the Luwian gods Tarhun, Runda, Arma, and Santa into classical times.

The East Luwians, whose rulers used the Hittite hieroglyphic script to record their deeds, worshiped these same deities; but their chief goddess was Kubaba, who hardly appears in the archives of Hattusa except as the local goddess of Carchemish in Syria. Her prominence was due to political factors, for Carchemish was then the leading Hittite city.

Developments in iconography

The traditional Hittite iconography survived but was gradually permeated by Aramaic and Assyrian influences. Orthostats (stone slabs set at the base of a wall) from

Malatya on the Euphrates show Tarhun in his bull-drawn chariot receiving libations from a king dressed in his traditional robes, and there is a relief showing his battle with the dragon. At Carchemish was found a representation of the winged moon god with the sun god, both standing on a single lion. Kubaba appears enthroned, the throne resting on a lion. Runda (the Hittite Kurunda or KAL) is regularly symbolized by a stag's head or antler.

Urartu. In the far east of Anatolia, the Hurrian nation formed around Lake Van a new kingdom, which rose to considerable power, from about 900 to 600 BC. With few exceptions, the cuneiform inscriptions of this kingdom of Urartu are historical and reveal nothing of its religion, except the names of deities. The national god was Haldi, and he is associated with a weather god, Tesheba, a sun goddess, Shiwini (compare Hurrian Teshub and Shimegi), and a goddess, Bagbartu (or Bagmashtu). Haldi is represented standing on a lion, Tesheba on a bull, Shiwini holding a winged sun disk above her head. The cult was practiced not only in temples (one of which is shown in detail on an Assyrian relief) but also in front of rock-hewn niches in the form of gates through which the deity was probably believed to manifest himself.

The Phrygians. Little would be known of the religion of the Phrygians but for the fact that in 204 BC the Roman Senate, on the instructions of the priests, who had consulted the Sibylline books, had the sacred black stone of the Phrygian Mother goddess, Cybele, or Cybebe, transported from Pessinus, together with her priests, and installed in a temple on the Palatine. As a result, there is much information about the cult and its mythology, though it must be remembered that during 200 years of Persian rule Anatolia had been exposed to many alien influences from the east, which may have affected this cult.

The high priest of Cybele was given the name of Attis, and—at least in later times—she was attended by a band of fanatical devotees called *galli*, whose orgiastic dancing, at the climax of which they castrated themselves in their ecstasy, was notorious.

The cult myth of these rites told how Cybele (known at Pessinus as Agdistis, from Mount Agdos [or Mount Agdistis] in the vicinity) loved a beautiful youth named Attis. According to the earliest version, Attis was killed, as was the Syrian Adonis, by a boar. All later versions, however, refer to wild revelry and castration. Agdistis is a bisexual monster who is trapped by Bacchus and castrated; Attis is betrothed to a daughter of Midas (or Gallus, the king of Pessinus); the wedding guests are driven mad by Cybele, and first Midas, then Attis, castrates himself, the latter as he lies beneath a pine tree; in one version Attis is turned into a pine tree. A poem by Catullus describes how a young Greek wanderer named Attis was caught up in the revels and sacrificed his virility, only to be prostrated later with remorse. The "Phrygian rites" introduced into Rome by Claudius included the ceremonious felling of a pine tree to represent the dead youth and its transport in procession to the temple. Still later, the sacrifice of a bull and the belief in the resurrection of Attis were added to the cult.

How much of this myth belonged to the original cult of the Phrygian Mother goddess is questionable. Herodotus, in describing the celebration of the rites by the legendary Scythian sage Anacharsis, mentions only that he did so in a grove, that he carried a timbrel (a small hand drum or tambourine), and that he fastened images about his person. There is no suggestion of orgiastic rites.

In Asia Minor itself, the cult of Cybele is marked by carved rock facades with niches or by rock-hewn thrones, on which the statue would be set; in front of these, the rites were celebrated in the open air. Cybele was a goddess of the mountains, out of which she was believed to manifest herself to her devotees. Representations of the goddess show her in her niche, sometimes flanked by lions, draped in a long garment and wearing a high polos (cylindrical crown or headdress) or with bared breasts and flanked by musicians. Her name and her association with the lion cannot be separated from the Hittite Kubaba, whose cult had spread from Carchemish to the borders of Phrygia, but the process by which this matronly figure was transformed into the Mountain Mother of the Phrygians can only be surmised.

Representations of Cybele

The goddess Ma of Comana, despite her name (Mother), was regarded at least by the Romans as a deity distinct from Cybele and was identified with the war goddess Bellona. Her relationship to the ancient Hittite-Hurrian goddess Hebat of Kummanni (=Comana) remains obscure, for there is no evidence that the latter was a goddess of war.

The god Men, who appears on numerous monuments of the Hellenistic period, was an equestrian moon god, later identified with Attis and with the Thracian Sabazius. He is basically the Persian moon god Mao, as (Artemis) Anaitis is the Persian Anahita.

CONCLUSION

Asia Minor shows a remarkable continuity in its worship. From the Neolithic Period, for 6,000 years, the population venerated a divine pair, mother goddess and weather god, the former in association with the lion, the latter with the bull; a divine son, associated with the panther; and a god of hunting whose symbolic animal was the stag. To the ancients, for whom the essence of a thing lay in its name, this continuity was less obvious than it is today. The many names under which the deities were known at different times and places appear to us of less significance, in a religious sense, than the constancy of the types. (O.R.G.)

Ancient Iranian religions

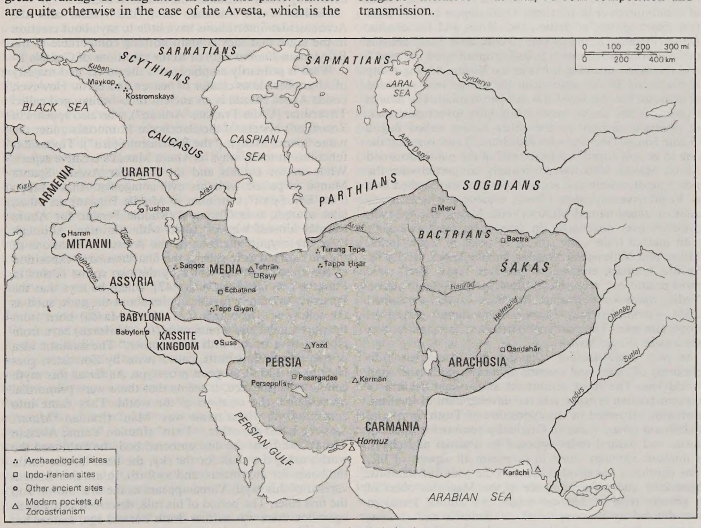
The religions of ancient Iran are the diverse beliefs and practices of a culturally and linguistically related group of peoples who inhabited the Iranian Plateau and its borderlands as well as areas of Central Asia from the Black Sea to Khotan (modern Ho-t'ien, China). The northern Iranians (referred to generally as Scythians [Saka] in classical sources), who occupied the steppes, differed significantly from the southern Iranians. In religion and culture both

the northern and southern Iranians had much in common with the ancient Indo-Aryans, although there was much borrowing from Mesopotamia as well, especially in western Iran. From at least the time of the rise of the Median empire, Iranian religion and culture has had a profound influence upon the Middle East, as also the Middle East upon Iran. This account will take the conquest of the Achaemenian Empire by Alexander the Great as a somewhat arbitrary date for the close of the period of ancient Iranian religion, even though these influences have continued through later history and some forms of Iranian religion have persisted to the present day. It will also treat ancient Iranian religion, insofar as possible, apart from Zoroastrianism. Unless otherwise indicated, all spellings of Iranian names and terms are given in reconstructed forms that often differ from the Avestan spellings of the Zoroastrian canon.

For a full account of that religion, see ZOROASTRIANISM AND PARSIISM. For historical background, see IRAN.

SOURCES OF KNOWLEDGE

Modern understanding of ancient Iranian religion is impeded by the limitations of the available sources, which are inevitably of two sorts: textual and material.



Textual sources are both indigenous and foreign, the latter being primarily Greek, although for purposes of historical reconstruction the ancient Indian Vedic literature is indispensable. The main problem with the Greek sources, the most important of which is Herodotus, is that the information they contain is not always very reliable, either because it is outright erroneous or because it is based on misunderstandings. The main indigenous sources are the Achaemenian royal inscriptions in the Old Persian language (with Akkadian, Elamite, and Aramaic translations) and the Avesta, the sacred scriptures of Zoroastrianism, in a language called Avestan. The royal inscriptions, especially those of Darius (522–486 BC) and his son Xerxes (486–465 BC), for the most part eloquent pieces of propaganda, are rich in references to religion. In addition to the information they contain, they have the great advantage of being fixed in time and place. Matters are quite otherwise in the case of the Avesta, which is the principal source of knowledge of ancient Iranian religions.

Indigenous sources

Like the Bible, the Avesta is a collection of a variety of texts composed over what appears to be a considerable span of time by different authors, which has endured editing and redaction at several points during the history of its development. The text that is now extant represents only a fragment of what remained in the 9th century of the late Sāsānian Avesta compiled under the direction of Khosrow I (AD 531–579). Summaries of the contents of the Sāsānian Avesta show that it was an enormous collection containing texts in Avestan as well as in—and predominantly so—Pahlavi, the language of Sāsānian Zoroastrianism. In spite of the relatively recent date of the existing Avesta, it contains matter of great antiquity, of which the *Gāthās* (or "Songs" of Zoroaster) and much of the *Yashts* are among the oldest. The *Gāthās* contain expressions of Zoroaster's religious vision which, in many ways, is a complicated reinterpretation of inherited Iranian religious ideas. The *Yashts* are collections of verses dedicated to the various deities. Most of the *Yashts*, though touched up with Zoroastrian terminology and ideas, have little to do with anything specifically Zoroastrian. The gods invoked are essentially the gods of pre-Zoroastrian Iran. Unfortunately, there is little agreement as to when Zoroaster lived, though most scholars agree that he lived some time between about 1200 and 600 BC. It does not seem possible to date the *Yashts* much more precisely, except to believe that their redaction (not necessarily composition) may have first taken place in the 5th century BC.

As mentioned above, the earliest religious texts of the closely related Indo-Aryans (principally the Rigveda) are indispensable for making historical reconstructions of the development of Iranian religion. The Rigveda, a collection of more than 1,000 hymns to various deities, can be dated to a period from approximately 1300 to 900 BC. Apart from the Achaemenian inscriptions, there is no secure evidence that religious compositions were reduced to writing until the late Arsacid or early Sāsānian periods. Thus, unlike the other religions of the Middle East, the Iranian religions had no written texts in the ancient period. All religious "literature" was oral, in both composition and transmission.

Material sources are much more limited and are, for the most part, restricted to western Iran. The remains of Achaemenian architecture and art, by far the most important of the material sources, provide abundant evidence of imperial articulation of religious symbols and show a thorough dependence on Middle Eastern precedents.

ORIGIN AND HISTORICAL DEVELOPMENT

During the second half of the 2nd millennium two groups of culturally and linguistically related peoples who called themselves "Arya" migrated from the steppes down into the Middle East, the Iranian Plateau, and the northwestern part of the Indian subcontinent. One group, the Indo-Aryans, settled in Anatolia and in India. The other, the Iranians, settled in greater Iran. These people were originally seminomadic pastoralists whose chief economic base was cattle, primarily bovines but also sheep and goats. They bred horses which they used for riding and pulling chariots in warfare and sport. It is not at all clear how rigidly their society was originally segmented. There were specialists in religious matters, and men who could afford horses and chariots were reckoned as warriors and leaders. By the Achaemenian period there developed a more rigid division of society into four basic classes: priests, nobles, farmers/herdsmen, and artisans. Society generally was patriarchal, and male dominance was strongly reflected in the religion. Like the ancient Israelites, as the Iranians occupied the land they became increasingly dependent upon agriculture and settled in villages and towns. During this process they were certainly influenced by the indigenous populations, of whose religion almost nothing is known, except by inference from elements of Iranian religion that have no reflex in the Veda or among other Indo-Europeans.

Owing to their common origin, Iranian and Indo-Aryan religions are very similar. From a comparative study of both groups, it is possible to reconstruct, in general features, the early forms of Iranian religion for which there is no direct documentation. The pantheon, similar to those of other Indo-European peoples, embraced a large number of deities, both female and, predominantly, male. Some of these were personifications of natural phenomena, others of social norms or institutions. There appear to have been two major groups of deities, the *daivas* and the *ahuras*. *Daiva* (literally "heavenly one"; Vedic *deva*, Latin *deus*) is derived from the common Indo-European word for "god," and this is the meaning it has in the Vedas. Among many Iranians and in Zoroastrianism the *daivas* were regarded as demons, but this belief was not pan-Iranian. The *ahuras* ("lords"; Vedic *asura*) were certain lofty sovereign deities, in contradistinction to the other deities called *bagha* (Vedic *bhaga*, "the one who distributes") and *yazata* ("the one to be worshiped"). At the head of the pantheon stood Ahura Mazdā, who was particularly connected with the principle of cosmic and social order and truth called *arta* in Vedic (Avestan *asha*). Closely associated with him was another *ahura* named Mithra (Vedic Mitra), the god who presided over covenants. In Iran there were two gods with martial traits quite similar to those of Vedic Indra, Mitra, and Vrthraghna. Among female deities the Earth, Spantā Aramati, and the sacred river, Ardvī Sūrā, were most prominent. A sacrificial ritual *yazna* (Avestan *yasna*, Vedic *yajña*) was performed in which fire and the sacred drink *hauma* (Avestan *haoma*, Vedic *soma*) played an important part. The principal officiant at the sacrifice was the *zautar* (Vedic *hotar*).

Daivas and *ahuras*

As with other ancient religions, the cosmological dichotomy of chaos and cosmos figured in both myth and worldview. The most prominent and unique feature of ancient Iranian religion was the development of dualism, primarily expressed in the opposition of Truth (*arta*) and Falsehood (*drug*, *drauga*). Originally confined to ideas of social and natural order opposed by disorder and chaos, a dualistic ideology came to permeate all aspects of life. The pantheon was divided between the gods and demons. Especially under the influence of the Magi, members of a priestly tribe of Median origin, the animal kingdom was divided up between beneficent animals and noxious creatures. Even in vocabulary there developed a system of "ahuric" and "daivic" words for such things as body parts: for example, the word *zasta* was used for the hand of a righteous person, and *gava* for the hand of an evil person. It is important to note that this was not a Gnostic system, like those that flourished in the Middle East during the early centuries of the Common era, as there was no myth of evil matter coming into being through the corruption and fall of a spiritual being.

Except for a mostly legendary line of eastern Iranian kings, the *kavis*, the last of whom was Zoroaster's patron Vishtāspa (Greek Hystapes), the only historical information on the relation of religion to political authority comes from the Achaemenian period in western Iran. The ideology of kingship was closely tied to the supreme deity, Ahura Mazdā, through whose will the kings ruled. The Achaemenian kings had to contend with the power of the Median priesthood, the Magi. Their origin is unclear, but according to classical sources they presided at all religious ceremonies where they chanted "theogonies." That they were deeply involved in politics is seen from the attempt of the magus Gaumāta to seize the throne upon the death of Cambyses II. Although Darius persecuted the Magi, they remained powerful and eventually became the official priesthood of the empire. They were probably responsible for articulating a thoroughly dualist ideology and contributing to Zoroastrianism its zealous preoccupation with ritual purity. In addition, they were famous throughout the ancient world as wonder-workers.

MYTHOLOGY AND COSMOLOGY

Since all the sources for Iranian myths, whether classical authors or indigenous texts, are post-Zoroastrian, it is often difficult to discern what elements of the myths are Zoroastrian innovations and what elements are inherited. It is particularly hard to resolve this problem owing to the nature of Zoroastrianism itself as a religion that has always drawn heavily on already existing ideas and that has accommodated itself to various forms of Iranian religions. As is the case with ancient religions generally, Iranian religions did not possess one unified collection of myth. What one finds are fragments of a wide variety of myths exhibiting many variations on common themes.

Creation of the cosmos. Both the Avesta and the Achaemenian inscriptions have little to say about creation in the sense that they contain nothing comparable to the Babylonian *Enuma elish* or to the traditions of Genesis 1–3. What is primarily emphasized is the power and majesty of Ahura Mazdā as creator of heaven and earth. However, beside Ahura Mazdā is an ancient Indo-Iranian god called Thvarshtar (Vedic Tvaṣṭar; "Artisan"), who also appears in Zoroaster's system of the Beneficent Immortals under the name Spanta Manyu ("the Beneficent Spirit"). Thvarshtar functions in many ways as Ahura Mazdā's creative aspect. While in the *Gāthās* and the Younger Avesta, Spanta Manyu is paired with his evil antagonist Ahra Manyu ("the Evil Spirit"; Ahriman in Middle Persian), in other, later sources, it is Ohrmazd (Middle Persian for Ahura Mazdā) himself who is paired with Ahriman. Although there are cryptic allusions in the Avesta to creations of the two antagonistic spirits, the first discursive exposition of the creation of the world by the two spirits occurs in Plutarch (*De Iside et Osiride* 47), where he says that the Persians "tell many mythical tales about the gods, such as the following. Oromazes (*i.e.*, Ahura Mazdā) born from the purest light, and Areimanios (*i.e.*, Ahriman) born from gloom, strive in war with one another." The dualistic idea of two primordial spirits, called twins by Zoroaster, goes back to an Indo-European prototype. As far as this myth can be reconstructed, it seems that there were primordial twins before the creation of the world. They came into conflict. One, whose name was "Man" (Iranian **Manu*, "man"), killed the other, "Twin" (Iranian Yama; Avestan Yima), and from the dismembered body he fashioned the world, using the skull for the sky, the flesh for the earth, the bones for mountains, and so forth. In another Iranian variant of this myth Yama appears as the first mortal and the first ruler. The period of his rule, described as a golden age when there was neither death nor old age, neither hot nor cold, and so on, comes to an end when falsehood enters Yama's speech. The royal Glory (Khvarnah) flees

The myth of primordial twins

from Yama and takes refuge in the cosmic sea. Yama is then overthrown by a serpentine tyrant named Azhi Dahāka ("Dahāka the Snake"), whose rule ushers in a period of drought, ruin, and chaos. In turn, Azhi Dahāka is defeated by the hero Thraitauna, who establishes the legendary line of kings called *kavis*.

Zoroaster seems to have been the first religious thinker to conceive an eschatological myth concerning a future saviour who will rescue the world from evil, an idea that has been greatly elaborated in Zoroastrianism. It may have been influential in the development of the concept of the Messiah in postexilic Judaism. Iranian religion also had a variant of the Noah's Ark myth. In this myth, Yama appears as the first herdsman and leader of humankind. After a long rule during which he has to enlarge the earth three times owing to overcrowding, Ahura Mazdā tells him that a great winter is coming and advises him to prepare for it by building a gigantic three-story barnlike structure (*vara*) to hold pairs of animals and seeds of plants. From the fragmentary version of the myth that has survived, it appears that the *vara* is actually a sort of paradise or island of the blessed, though this story originated as a pastoralist myth about the building of the first winter cattle station by the culture hero.

Cosmography. The Iranians conceived of the cosmos as a three-tiered structure consisting of the earth below, the atmosphere, and the stone vault of heaven above. Beyond the vault of heaven was the realm of the Endless Lights, and below the earth was the realm of darkness and chaos. The earth itself rested on the cosmic sea called Varu-Karta. In the centre of the earth was the cosmic mountain Harā, down which flowed the river Ardvi. The earth was divided into six continents surrounding the central continent, Khvaniratha, the locus of Aryāna Vaijah, the Aryan land (*i.e.*, Iran).

CULTIC PRACTICES, WORSHIP, AND FESTIVALS

In sharp contrast to the peoples of the Middle East, the Iranians did not make images of their deities, nor did they build temples to house them, preferring to worship in the open. Worship of the gods was performed primarily in the context of a central ritual called *yazna*, which corresponds in a great many details to the Vedic *yajña*. It is interesting to note that both rituals, though they have undergone some changes over the millennia, are still performed by Zoroastrians and Hindus in what must be the oldest continuously enacted ritual known. The plan of the *yazna*, as far as it can be reconstructed, was essentially that of a highly stylized festive meal offered to an honoured guest, the sacrificer being the host and the deity the guest. Although it is not known precisely when or how frequently the *yazna* was held (in Zoroastrianism it became a daily ritual), the reason for holding a *yazna* was to enter into communion with a divine being either for a specific purpose (to obtain offspring or a victory, and so on) or for general welfare, or as an expression of piety. As a ritual meal, the *yazna* followed the established rules of hospitality: the guest was sent an invitation; on his arrival from afar he was greeted, shown to a comfortable seat, given meat and a refreshing and invigorating drink, and entertained with song extolling his great deeds and virtues. Finally, the guest was expected to return the hospitality in the form of a gift.

The *yazna*

Of utmost importance was fire. In ancient Iran, fire was at once a highly sacred element and a deity. Thus, the word *ātar* denoted simultaneously "fire" and "Fire," every instance of fire being a manifestation of the deity. Since burned offerings were not made, the role of Ātar, like that of his Vedic counterpart Agni, was principally that of intermediary between heaven and earth, between humans and gods. Beyond the sphere of the *yazna*, fire was always treated with utmost care as a sacred element. Whether in the household hearth or, at a later period, in fire temples, the sacred fire had to be maintained with proper fuel, kept free from polluting agents, and above all never permitted to go out or be extinguished.

More important than the meat offering of an animal victim was the preparation of the divine drink *hauma* (Vedic *soma*). As with fire, *hauma* was regarded as both a sacred drink and as a powerful deity. Probably the greatest part of the *yazna* was devoted to the pressing of the *hauma*. Although there have been a number of proposals for the identification of the plant whose juices were extracted for the ritual drink, all have fallen short of absolute proof, and some, such as the toxic mushroom *Amanita muscaria*, are not worth consideration. In any case, an understanding of the religious meaning of *hauma* does not depend on a botanic identification. The word *hauma* itself derives from a verb "to press, extract" and thus literally means the thing that has been pressed out of the stems or stalks (*āsu*) of whatever plant was being used—*i.e.*, juice. In this process the stalks were first soaked in water, then pounded. In Zoroastrianism this has been done with a metal mortar and pestle, but originally the stalks were pounded between two pressing stones, a lower and an upper. The juice, described as yellow, was filtered and mixed with milk, to cut the bitter taste, and perhaps with water too. Since the resulting drink was consumed immediately, it is clear that it was not alcoholic but rather was a mind-altering drug. The *Yasht* to Hauma says, "All other intoxicants are accompanied by Wrath with the horrible club, but that intoxication which is Hauma's is accompanied by gladdening Truth (*arta*)." This brief statement can be amplified by the far more extensive descriptions of the Rigveda, where *soma* is not only offered to the gods but also taken by poets to enhance their insight and creative powers in their search for truth. Also, *hauma*, invoked for victory, was taken as a stimulant by warriors going into battle, and various heroes of Iranian myth and legend are remembered as primary practitioners of its cult.

The preparation of *hauma*

As mentioned above, a comfortable seat was provided for the god or gods invited to *yazna*. Originally this consisted of special grasses strewn on the ground in front of the altar. In Vedic terminology this seat was called the *barhiṣ* (Avestan *barzish*, "cushion"), while in Zoroastrianism a cognate word, Avestan *barəsman* (Iranian *barzman*), is used for a bundle of sticks—later thin metal rods—that is manipulated by the priest.

It is likely that from a very early period a priest, the *zaotar* (Vedic *hotar*), was required to properly carry out the *yasna*. The *zaotar* might be assisted by a number of other ritual specialists. With the priest or priests acting on behalf of the sacrificer, the god or gods were invoked through the intermediary of Fire. The sacred drink was prepared and the victim led up. When the god arrived he was seated on the *barzman* and given food (parts of the slaughtered victim) and drink, after which he was entertained with song. Finally, the host-sacrificer put in a request for a return gift: heroic sons, long life, health, or victory, for example. In a certain sense, then, the entire ritual followed the old Latin dictum *do ut des* ("I give so that you may give"), in providing a means of inducing the powerful deities to act with favour toward human beings. Yet it also made possible communion between the divine and human realms. Deities could also be addressed directly in prayer with the supplicant standing erect with upraised arms; prostration was unknown.

Of further importance is the song of praise directed to the divine guest. Much of the poetic portions of the Avesta and almost all of the Rigveda must be understood in this ritual context. That is to say, ancient Indo-Iranian poetry was religious in nature and specifically composed for those ritual occasions when the gods required songs of praise to make them well disposed to their worshipers. The obscurity of Zoroaster's *Gāthās* and of many Vedic hymns can best be understood when it is realized that the intended audience was not humans but rather the gods.

During the year there were various festivals, mostly relating to the agricultural and herding cycles. By far the most important was that of the New Year, which is still celebrated by Iranians with great festivity.

HUMAN NATURE

In the Zoroastrian formulation of the myth of creation, humans are created for the noble purpose of aiding in the repulsion of the Evil Spirit. Whether or not this concept is pre-Zoroastrian, it shows that in Iranian religion human nature was held to be essentially good, in the sense

that there was no myth about the baseness of the human condition such as that found in Babylonian mythology (for example, in the *Enuma elish*). Humans have free will and determine their own destinies as a result of their ethical choices.

Spiritual elements or Souls

In addition to the body (*tanū*), it was held that an individual consisted of a number of spiritual elements that loosely fall under the category of souls. These are (1) the animating force (*ahu*), (2) the breath of life (*vyāna*), (3) mind/spirit (*manah*), (4) the soul (*ruvan;* Avestan *urvan*), (5) the protective spirit (*fravarti;* Avestan *fravashi*), and (6) the spiritual double (*dainā;* Avestan *daēnā*). In Zoroastrianism, where belief in the day of judgment is central, it is the *ruvan* that is held accountable for a person's actions during life and that suffers reward or punishment in the life to come. At the time of judgment the *ruvan* encounters the *dainā,* which is an embodiment of the sum of its deeds during life, manifested as either a beautiful maiden or an ugly hag. Depending on how these deeds are weighed, the soul either crosses safely the Chinvat Bridge to the other world or falls into the abyss. The *fravarti* is a deity who acts as a protective spirit of each individual and is also an ancestor spirit; together all the *fravartis* form a warrior band, similar in some ways to the Vedic Maruts.

MAJOR DEITIES

Ahura Mazdā. Ahura Mazdā ("Wise Lord") was probably the chief god of the pre-Zoroastrian pantheon. In both the religion of Zoroaster and that of Darius and Xerxes, he was worshiped as the supreme god, almost to the exclusion of all others. First of all he is the creator of the universe and the one who establishes and maintains the cosmic and social order, *arta.* Darius proclaims him as "the great god . . . who created this earth, who created yonder heaven, who created man, who created happiness for man, who made Darius king." Throughout his inscriptions, Darius speaks not only of the source of the authority of the kingship as deriving from Ahura Mazdā, but also makes it clear that his own establishment of political stability over the chaos of rebellion and his maintenance of order through law imitates the divine model set by the Creator. Using the ancient Indo-European poetic device of interrogative discourse, Zoroaster asks, "Who is the original father of *arta*? Who established the paths of the sun and the stars? Who is it through whom the moon now waxes now wanes? Who supports the earth below and (keeps) the heavens (above) from falling down? Who yokes the two steeds to the wind and the clouds? . . . Who fashioned honoured Devotion together with Dominion? Who made . . . a son respectful of his father?"

In neither the Avesta nor the Achaemenian inscriptions is Ahura Mazdā identified with a natural phenomenon. Since, however, in the hymn to the goddess Rti (Reward), Ahura Mazdā is identified as her father and Spanta Aramati (Earth) as her mother, it is implied that he has taken over, to some extent, the role of the Indo-European Father Heaven (*Dieus Pater, Vedic Dyāus Pitar), who is mythologically paired with Mother Earth. Furthermore, the Greek historian Herodotus seems to have made this identification when he wrote, "Zeus, in their (the Persians') system, is the whole circle of the heavens." Other Greek sources commonly equate Zeus with Oromazes (Ahura Mazdā), because of Ahura Mazdā's position as father and chief god of the pantheon. As his name implies, he seems to have been sought by his worshipers for wisdom and insight, and, to judge by the intense experiences of Darius (whether or not his professions are genuine) and of Zoroaster, he was probably the object of a personal devotion that appears to have been lacking with other deities.

Identification of Zeus and Ahura Mazdā

Mithra. Beside Ahura Mazdā, Mithra is the most important deity of the ancient Iranian pantheon and may have even occupied a position of near equality with him. In the Achaemenian inscriptions Mithra, together with Anāhitā, is the only other deity specifically mentioned. Although the ancient pantheon contained an individual sun god, Hvar Khshaita, in the eastern Iranian traditions reflected in the Avesta, Mithra has a hint of connection with the sun, more specifically with the first rays of dawn as he drives forth in his chariot. In western Iran the identification was complete, and the name Mithra became a common word for "sun." In spite of his connection with the sun, Mithra functioned preeminently in the ethical sphere. The word *mithra* was a common noun that meant "covenant, contract, treaty" and, as such, Mithra was the god Covenant, the celestial deity who oversaw all solemn agreements that people made among themselves and who severely punished anyone who broke the terms of a covenant, whether it was between individuals or between countries or other sociopolitical entities. In his capacity to find out the covenant breaker, he is described as sleepless, ever-waking, having 1,000 ears, 10,000 eyes, and a wide outlook. He is portrayed as a great warrior brandishing his mace while driving in his chariot to battle, where he intervenes on behalf of those faithful to treaties by throwing the treaty-breakers (*mithra-drug*) into panic and defeat. As a sovereign deity, Mithra bore the standing epithet *varu-gavyūti,* meaning "one who (presides over) wide pasture lands"—*i.e.,* one who keeps under his protection (another of his epithets was *pāyu,* "protector") the territories of those who worship him and abide by their covenants. It should be mentioned that Mithra gave his name to a mystery religion, Mithraism, which was popular throughout the Roman Empire, but whose Iranian origins are difficult to trace.

Anāhiti. One of the longest Avestan *Yashts* is to the powerful goddess whose full name is given as Ardvī Sūrā Anāhitā, literally "the damp, strong, untainted." In fact, the long name seems to combine two originally separate names and, hence, two deities. First, Ardvī Sūrā is the Iranian name of the heavenly river goddess who in the Rigveda is called Sarasvatī. In this role, she brings fresh water to the earth, filling streams, rivers, and seas as she flows from Mount Hukarya to the Varu-Karta sea. Second, Anāhiti is a separate goddess of uncertain origin whose cult seems to have been popular originally in northeastern Iran. The name probably meant "untaintedness, purity (both moral and physical)." It is interesting that the Greek Anaitis (Ἀναΐτις) preserves the Old Iranian form of the name, while Anāhit(a), of the Avestan and Old Persian, shows a more recent linguistic form. Unlike any other Iranian deity, she is described in great detail in the *Yashts,* especially in respect to her clothing and ornamentation, to such an extent that one assumes a dressed cult image must be the source of the description. This is confirmed by the fact that Artaxerxes II mentions her. Then, too, the Babylonian historian Berosus reports that this king had many images of her made and distributed. Since the Iranians did not traditionally make images, it may be assumed that Anāhiti's cult borrowed heavily from Mesopotamian models. The Mesopotamian goddess Ishtar probably provided the clearest model, though the details of Anāhiti's dress, her beaver coat, for example—show significant differences. There were other striking similarities: Ishtar was the goddess of war and patroness of the palace, while the greater part of Anāhiti's *Yasht* is devoted to her martial traits and her patronage of Iranian heroes and legendary rulers (in post-Achaemenian Iran Anāhiti was intimately connected with kingship and the shah). In addition, both goddesses were important for fertility.

Influence of the Mesopotamian goddess Ishtar

Vrthraghna. The mighty deity of war Vrthraghna had martial traits in common with Mithra and with the Vedic war god Indra. In post-Achaemenian times he was syncretistically equated with Hercules and was a favourite deity of monarchs, some of whom took his name. The name Vrthraghna means "the smashing of resistance or obstruction," and in his capacity as the god who guaranteed his people the ability to overcome all enemy resistance, his name came to be understood in the general sense of "Victory." In connection with rulership and the granting of victory, he bore the epithet *bara-khvarnah,* "bearing the Glory." Like Mithra in his martial aspects, Vrthraghna represented an ideal type of warrior. For the earliest immigrants onto the Iranian Plateau he personified the aspirations of the Aryans seeking to win new territory from an entrenched indigenous population, while for later populations he became the divine manifestation of the will to world conquest.

Among all the deities Vrthraghna preeminently possesses

the power to undergo various transformations, both anthropomorphic and theriomorphic. Rich mythologies may have existed concerning these avatars, but only 10 forms have been recorded: the Wind (the god Vāyu), bull, stallion, rutting camel, wild boar, a 15-year-old man (15 was considered to be the ideal age), falcon, ram, goat, and hero. All have in common aggressive force and virility, while in some violence is conspicuous. Particularly graphic is the description of him as the "ferocious wild boar with sharp teeth and tusks, a boar that kills at one blow . . . who, overtaking his opponent . . . strikes (him) down with a toss of his head . . . until he smashes the vertebrae, the pillars of life, . . . (and) mixes on the ground the bones, hair, brains, and blood."

Rashnu. Like Mithra, with whom he was often associated, Rashnu was an ethical deity, the divine judge who ultimately presided over legal disputes among men. His name, derived from the same Indo-European verb, **reg* ("to be, make straight, direct, judge"), as are the German words for "judge," *Richter,* and "law," *Recht.* In particular, he appears to have been the god of oaths and ordeals administered during trials. In many ways he carried out the judicial functions of the Vedic god Varuṇa, who among other things, was the ultimate judge presiding over oaths, and who was frequently inseparable from the Vedic Mitra. While it remains unclear whether or not Ahura Mazdā exercised any judicial function, together Rashnu and Mithra seem to have acted in complementary areas of law: Mithra was concerned specifically with covenants of all sorts, while Rashnu had more general jurisdiction over legal matters, especially those of a criminal nature, in that he is invoked as the one who "best smite(s), who best destroy(s) the thief and the bandit at this trial."

Tishtrya and Tiri. Astral deities seem to have figured much more prominently in ancient Iranian religion than in Vedic religion, and this may well be attributed to the influence of Babylonian science on the Iranians, particularly the western groups. In the Avesta such stars and constellations as Ursa Major, the Pleiades, Vega, Fomalhaut, and the Milky Way are mentioned, but the most important astral deities seem to have been Tishtrya and Tiri. An entire *Yasht* is devoted to Tishtrya, who, for reasons that remain obscure, is identified with the star Sirius. Even though the heliacal rising of Sirius would have occurred at the season of drought, his principal myth involves a battle with a demonic star named Apausha ("Nonprosperity") over rainfall and water. In a combat that was reenacted in a yearly equestrian ritual, Tishtrya and Apausha, assuming the forms of a white stallion and a horse of horrible description, respectively, battle along the shores of the Varu-Karta sea. Initially Apausha is victorious, but after receiving worship Tishtrya conquers him, driving him away "along a path the length of a race course." At this point Tishtrya causes the cosmic sea to surge and boil, and then another star, Satavaisa (Fomalhaut), rises with the cloud-forming mists that are blown by the bold Wind in the form of "rain and clouds and hail to the dwelling and the settlements (and) to the seven continents." As one of the stars "who contains the seeds of waters" (*i.e.,* who cause rain), Tishtrya was also intimately connected with agriculture. He battled and defeated the shooting stars, identified as witches, especially one called "Bad Crop" (Duzhyāryā). In Zoroastrianism, Tishtrya was at some point, probably in late Achaemenian times, identified with the western Iranian astral deity, Tiri (Mercury in Sāsānian astronomy), about whom little is known save that a very important agricultural festival, the Tiragān, as well as the 4th month and the 13th day of the Zoroastrian calendar, bears his name. Syrian and Palestinian religions. PATRICK D. MILLER, JR., PAUL D. HANSON and S. DEAN MCBRIDE (eds.), *Ancient Israelite Religion* (1987), includes essays on Mari prophecy, on aspects of the religion of Ugarit, the Arameans, and the Phoenicians, and several on the religion of Israel in relation to its Canaanite environment. A more extensive survey of Phoenician religion with good illustrations may be found in SERGIO RIBICHINI,

"Beliefs and Religious Life," in SABATINO MOSCATI (ed.), *The Phoenicians* (1988), pp. 104–125. A good overview of Ugaritic religion with photographs of the major religious artifacts is ANDRÉ CAQUOT and MAURICE SZNYCER, *Ugaritic Religion* (1980). A comprehensive presentation of the various Semitic religions of the area and period is by HARTMUT GESE, "Die Religionen Altsyriens," in HARTMUT GESE, MARIA HÖFNER, and KURT RUDOLPH, *Die Religionen Altsyriens, Altarabiens, und der Mandäer* (1970), pp. 1–232. JAMES B. PRITCHARD, *The Ancient Near East in Pictures Relating to the Old Testament,* 2nd ed. (1969, reissued 1974), contains photographs of many important religious objects from throughout the period and area. A good article on the individual gods and myths of Ugarit and the Phoenicians may be found in MARVIN H. POPE and WOLFGANG RÖLLIG, "Syrien: Die Mythologie der Ugariten und Phönizien," in H.W. HAUSSIG (ed.), *Wörterbuch der Mythologie,* part 1, *Die alten Kulturvölker,* vol. 1, *Götter und Mythen im Vorderen Orient,* 2nd ed. (1983), pp. 217–312. HAROLD W. ATTRIDGE and ROBERT A. ODEN (trans.), *The Phoenician History* (1981), offers Philo of Byblos' Greek text, an English translation, and notes on that work. A more extensive commentary without translation is found in ALBERT I. BAUMGARTEN, *The Phoenician History of Philo of Byblos* (1981). A reconstruction of the early ritual basis of the dying god cult is offered by NOEL ROBERTSON, "The Ritual Background of the Dying God in Cyprus and Syro-Palestine," *Harvard Theological Review,* 75(2):313–59 (1982).

Arabian religions. A short survey of the history of ancient Arabia is given by A.K. IRVINE, "The Arabs and Ethiopians," in D.J. WISEMAN (ed.), *Peoples of Old Testament Times* (1973), pp. 287–311. South Arabia is covered by WALTER W. MÜLLER, "Outline of the History of Ancient Southern Arabia," in WERNER DAUM (ed.), *Yemen: 3000 Years of Art and Civilisation in Arabia Felix* (1987), pp. 49–54. J. WELLHAUSEN (comp.), *Reste altarabischen Heidentums,* 2nd ed. (1897), contains most of the Muslim data on the pagan folklore and religion. The epigraphic material is extensively used in the following studies, which are still valuable: G. RYCKMANS, "Les Religions arabes préislamiques," in *Histoire générale des religions,* vol. 2, pt. 1, pp. 201–228 (1960); and MARIA HÖFNER, "Die vorislamischen Religionen Arabiens," in HARTMUT GESE, MARIA HÖFNER, and KURT RUDOLPH, *Die Religionen Altsyriens, Altarabiens und der Mandäer,* pp. 233–402 (1970). A short but excellent survey of the ancient Arabian religion is given by A. CAQUOT, "Les Religions des Sémites occidentaux," in HENRI-CHARLES PUECH (ed.), *Histoire des Religions,* vol. 1 (1970), pp. 307–358, with North and South Arabia especially the focus of pp. 340–355. Several important works are by J. STARCKY: "Pétra et la Nabatène," in LOUIS PIROT *et al., Dictionnaire de la Bible, Supplément,* vol. 7 (1966), cols. 886–1017, with cols. 985–1017 focusing especially on religion, and a very short but more recent contribution, "La religion des Nabatéens," in *Inoubliable Petra: Le Royaume nabatéen aux confins du désert* (1980), pp. 66–70, an exhibition catalog. Two concise but up-to-date studies on ancient South Arabian religions may be found in JOSEPH CHELHOD *et al., L'Arabie du Sud: Histoire et civilisation,* vol. 1, *Le peuple yéménite et ses racines* (1984), both by A.F.L. BEESTON: "The Religions of Pre-Islamic Yemen," pp. 259–269, and "Judaism and Christianity in Pre-Islamic Yemen," pp. 271–278. Another such study is J. RYCKMANS, "The Old South Arabian Religion," in the work on Yemen ed. by Daum cited above, pp. 107–110.

Religions of Asia Minor. A. GÖTZE, *Kleinasien,* 2nd rev. ed. (1957, reprinted 1974), part of the series "Handbuch der Altertumswissenschaft," is a classic work covering all periods. EKREM AKURGAL and MAX HIRMER, *The Art of the Hittites* (1962), provides an excellent presentation of Hittite and pre-Hittite art and iconography. MAURICE VIEYRA, *Hittite Art, 2300–750 B.C.* (1955), is also useful. SETON LLOYD, *Early Highland Peoples of Anatolia* (1967), is a popular but excellent account of all periods, with many illustrations. Works on Hittite civilization and religion include O.R. GURNEY, "Hittite Kingship," in S.H. HOOKE (ed.), *Myth, Ritual, and Kingship: Essays on the Theory and Practice of Kingship in the Ancient Near East and in Israel* (1958), pp. 105–121, *The Hittites,* 2nd ed. rev. (1990), a general description, and *Some Aspects of Hittite Religion* (1977); and HANS G. GÜTERBOCK, "Hittite Religion," in V. FERM (ed.), *Forgotten Religions* (1950, reissued 1970), pp. 83–109, and "Hittite Mythology," in SAMUEL NOAH KRAMER (ed.), *Mythologies of the Ancient World* (1961, reprinted 1989), pp. 141–179. JAMES MELLAART, *Catal Hüyük* (1967), presents an illustrated account of the evidence from Catal Hüyük and Hacilar. FRANZ CUMONT, *The Oriental Religions in Roman Paganism* (1911, reprinted 1956), is a classic. A three-part study by E.N. LANE, "A Re-Study of the God Men," *Berytus,* 15:5–58 (1964), 17: 13–47 and 81–106 (1967–68), offers a valuable summary of work on Men and Cybele.

Iranian religions. ÉMILE BENVENISTE, *The Persian Religion According to the Chief Greek Texts* (1929), is the first effort to analyze the Greek texts. WILLIAM W. MALANDRA, *An Introduction to Ancient Iranian Religion* (1983), is an anthology of texts from the Avesta and the Achaemenian inscriptions with an introduction and extensive commentary. MARGARET COOL ROOT, *The King and Kingship in Achaemenid Art* (1979), provides a thorough and insightful analysis of the imperial use of visual symbols. M. SCHWARTZ, "The Religion of Achaemenian Iran," in ILYA GERSHEVITCH (ed.), *The Cambridge History of Iran,* vol. 2 (1985), pp. 664–697, is also informative. GEO WIDENGREN, *Die Religionen Irans* (1965), is a good handbook. A more up-to-date handbook is MARY BOYCE, *A History of Zoroastrianism* (1975–), which contains a rich bibliography and takes a different approach from that of Widengren.

Milan

Milan (Italian Milano) is a city of riches, both cultural and economic. This wealth derives from its long history as the political and commercial centre of Italy's richest agricultural region, the Po Basin. While it preserves a remarkable artistic and architectural heritage, contemporary Milan also is one of the world's leading centres of fashion and industrial design. The economic and financial centre of Italy and the headquarters of the country's most important publishing and media firms, Milan also forms the core of the country's largest metropolitan area and plays a prominent role in Italian intellectual and cultural life.

CHARACTER OF THE CITY

Fiscally, contemporary Milan is the richest city in Italy and one of the richest in Europe. When the Milanese proclaim their city the "moral capital" of Italy, they not only express the ancient regionalism typical of all Italy, but they refer to Milan's cultural and intellectual leadership and especially to its role as the motor of the country's extraordinary economic development in the 20th century. As Italy's economic heart—the headquarters of its most important banks and corporations, a leading international centre of fashion and design, and the capital of work, innovation, production, and efficiency—Milan has long claimed a kind of supremacy among Italian cities. In contrast, the Milanese see the country's political capital, Rome, as the parasitical capital of taxation, state spending, and party skullduggery. Milan's economic contributions far exceed, even on a statistical basis, those of all other Italian cities; however, since Italy's unification, the city has remained relatively politically insignificant. Yet its political subordination to Rome has not been a consequence of its physical distance from much of the rest of Italy, which makes it peripheral geographically, since many European capitals lie far from the centre of the country they rule.

Competition with Rome

Regardless, many of the most important political and cultural developments in Italy had their roots in Milan. Reformist socialism was born there, as was Fascism, and the Futurists were based in the city. During World War II, Milan claimed the title of "capital of the Resistance," and during Italy's postwar boom, known as the economic miracle, Milan was undoubtedly the "capital of the miracle." The student and workers' movements also flourished in Milan during and after 1968. With the city's transformation to a post-industrial centre in the 1980s and '90s, Italy's political centre of gravity shifted away from Rome and toward Milan, especially under the premierships of the Milanese Bettino Craxi (1983–87) and Silvio Berlusconi (1994). Culturally, the city has been home to many of Italy's leading architects, designers, visual artists, novelists, and filmmakers. Italy's most important publishing and media enterprises are based there. Milan has always had La Scala, the greatest opera house in the world, and some of the most important educational institutions in Europe, from Bocconi University to the Politecnico. Finally, Milan has two of the greatest football (soccer) teams in the world—AC Milan and Inter Milan—and one of its most imposing stadiums, San Siro.

Its extraordinary mix of intellectuals, designers, industrialists, and financiers enabled Milan to become an international centre of excellence for economic sectors from sports cars to fashion design. Over the years, this versatility and dynamism have combined with the characteristic *operosità* ("industriousness") of the Milanese. The old saying "Milan says and Milan does" has been adopted by the hundreds of thousands of migrants (first from within Italy—from both north and south—and, since the 1980s, from abroad) who have contributed to the success of the city. The integration of these migrants has never been easy, but Milan has always been willing to accept those who contribute to its rich and varied economic structure.

THE LANDSCAPE

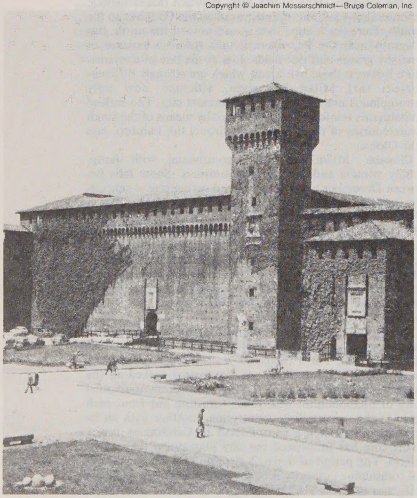
Site. Milan is set in the heart of the Po Basin of northern Italy, halfway across the immense plain spreading between the Ticino and Adda rivers. The site is 400 feet (122 metres) above sea level. To the north lies the great sweep of the southern flank of the Alps. Between this semicircle of mountains and the course traced by the Po River to the south, there lies a zone that is arid toward the north, but swampy near the Po, where it turns into an expanse of marshy groves and rice fields. It is at the line of demarcation between these two areas, which are strongly differentiated, that Milan has risen, although now only swamplands mark the site of the ancient city. The earliest inhabitants reinforced their defenses by means of the small watercourses of the Sèveso, the Nirone, the Lambro, and the Olona.

Climate. Milan's climate is continental, with damp, chilly winters and hot, humid summers. Snow falls between December and February, and springtime is generally rainy. In winter temperatures range between 30° and 50° F (−1° and 10° C) and in summer between 68° and 86° F (20° and 30° C). Characteristic of the Po Basin, the city is often shrouded in fog in winter, but this has decreased with the drainage of the rice fields to the south. The growth of an almost uninterrupted built-up area around the city has reduced local air circulation, and pollution from vehicular exhausts often covers the city in smog.

The city plan. Each period of historical crisis, advance, and consolidation has been reflected in the organic structure of Milan. For a thousand years the core of the city was located just southwest of the present cathedral, the Duomo, and was made up of the rectangular, four-gated city of Mediolanum, with roads thrusting out from each gate to the surrounding countryside, together with an irregular outer defense consolidated in Carolingian times. This core has influenced the city plan down to modern times. The period of dynastic struggle and the imposition of transalpine authority brought further changes. After the city was razed in 1162, an enlarged oval was constructed, the course of its outer walls still traceable in contemporary streets. Spanish domination brought the erection of still another outer ring resulting from the 16th-century

reconstructions. This, too, can be traced in contemporary boulevards. Within the city centre, the main focus of activity centred on the Castello Sforzesco, a product of the 15th-century dynastic struggles, reinforced by the Spanish in the following century; the Piazza Mercanti, the centre of medieval economic activity; and the great Piazza del Duomo, laid out before the cathedral in 1489. Castle, cathedral, and a newer commercial area centred on the Piazza Cordusio, representatives of the motivating forces in Milanese life, dominate the modern city centre.

Several times since the late 19th century city planners have laid down the basis of a more organic plan, bypassing the traditional radial street plan, so that new districts might have wide streets and avenues intersecting at right angles. The centres of the newer suburban areas—Bollate, Novate Milanese, Cusano Milanino, Cinisello Balsamo, Sesto San Giovanni, and even Monza (nine miles [15 kilometres] away to the northeast)—are linked to the core of the ancient city by major arteries. Entire industrial districts have developed, particularly in the north and northeast and in the south and southwest. Unfortunately, while the periphery has been amply developed, the central nucleus has not benefited from a similar transformation, and the narrowness of the streets and squares creates problems for modern traffic. Since the end of World War II, practically all industrial growth has been concentrated in peripheral areas of the city. Industrial progress has reached such a level that a third of Milan's population is in some way connected with industrial construction. Heavy industries are concentrated outside the city boundaries, around Sesto San Giovanni. Since 1950 the city centre has fared badly under the influence of industrialization, with many old streets and buildings replaced haphazardly by massive blocks and skyscrapers containing apartments and offices. The Pirelli Building (1955–59), near the Stazione Centrale ("Central Station"), and the Olivetti Building in Via Clerici are among the few modern structures of architectural note.



The basic plan

THE PEOPLE

Milan's population has shown a rapid increase since World War II. This increase has been due mainly to the flood of immigrants from the impoverished Italian south seeking improved conditions in the factories of the industrial north. Population pressure has resulted in the growth of slums and such shantytowns as Brianza, as well as in an expansion of the city itself. Milan has pressed outward into the surrounding countryside with renewed vigour, particularly to the northeast, toward Crescenzago, and to the south, toward Rogoredo and Vigentino. Milan's enormous urban expansion has contributed to its economic growth.

THE ECONOMY

Industry. Milan, the most important economic centre of Italy, owes this fact to its geographical position. It is located at the centre of the traffic routes of the Val Padana and lies on the borderline between the advanced agriculture of the fertile irrigated plains to the south and the limited agriculture of the north. In addition, it is backed by an impressive industrial development. Milan's rich and extremely populous surroundings, differing from those of other large Italian manufacturing centres, increase the city's economic importance and potential for expansion. An extensive network of road and rail communications spreads toward the outlying areas and particularly toward the north, giving the city an economic advantage that other Italian cities do not possess.

Industrial products

The mechanical industries predominate; the production of automobiles, airplanes, motorcycles, major electric appliances, railroad materials, and other metalworking accounts for almost half of the work force. Textile manufactures (cotton, hemp, silk, and artificial fibres) are situated in the province of Milan, while in the city itself manufactures of ready-made clothing and designer fashions predominate. Milan's fashion industry has achieved great commercial importance, and the city contains the salons of some of the world's best known designers. Chemical production is also considerable. Besides large quantities of medicinal products, dyes, soaps, and acids are also manufactured. Also noteworthy to the city economy are graphic arts and publishing, as well as food, wood, paper, and rubber products. Milan's position as the electronic media centre of Italy has been augmented by the rapid growth of high-technology industries, including data processing and telecommunications.

Commerce. Commercial activity in the city has also been stimulated by industrial development. The largest wholesale markets of Italy are in Milan. Of greatest importance are the export trades, which include artificial fibres, cotton and wool goods, chemical products, and machinery. This enormous economic complex has benefited from the efficiency of the city's banks and of its stock market, which is the largest in Italy. Milan is the principal centre of exchange in Italy; every April the city hosts the International Sample Trade Fair (in Italy called Fiera Campionaria de Milano), which ranks as one of the major trade exhibitions in Europe.

Transportation. In addition to being a centre of production and exchange, Milan is also a national focus of transportation. The state-run railroads are integrated within the city landscape by means of a carefully designed and executed plan. The vast Piazza della Repubblica, for example, which contains the Pirelli Building and other tall buildings, is located on land formerly occupied by a railway station. Trade goods are sent and received at the Stazione Lambrate-Ortica. Two other stations serve for the transportation of passengers, five more for various kinds of merchandise. The largest railway loading site is the Stazione Centrale. Transalpine tunnels and other mainline connections link Milan with all parts of Europe, and there are many nonstop trains to and from major cities. The road network converging upon Milan is also important, carrying, as it does, an unceasing flow of foreign and domestic tourists. Besides being the focus of a number of major highways, Milan is also the starting point for the famous scenic route known as the Autostrada del Sole, which traverses the spine of the lengthy Italian peninsula. The metropolitan transportation service operates an extensive system of bus, tramway, and subway routes throughout the metropolitan area.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. The city, technically the commune of Milan, capital of the province (*provincia*) of the same name and of the Lombardy Region (*regione*), is under the jurisdiction of the Republic of Italy. The government of the Italian state is composed of a central administration and of a peripheral or local administrative system, the latter having limited jurisdiction over a particular region. The most important division of the peripheral system is the prefecture (*prefettura*), at the head of which is the prefect, the highest authority of the executive power in the province of Milan. It supervises the activities of public administration. In its own area, the province performs the important functions of regulating health, sanitation, public works, welfare, education, agriculture, and commerce. The province of Milan, as all other Italian provinces, has a vice prefect, a counselor of prefecture, and an administrative and provincial assembly whose members, as well as its president, are selected by the prefect. The commune of Milan is administered by a council, chosen from a large assembly, and a mayor (*sindaco*). In the administrative elections of the communal council all electors registered in the province take part. The assembly and the mayor are elected by the communal council. The mayor is the head of the communal administration and represents the central government of the Republic of Italy. Mayoral responsibilities include performing marriage ceremonies, registering births and deaths, and maintaining safety and order on behalf of each citizen.

Regional innovations

The region and regional council, instituted in the early 1970s, are constituted as autonomous entities and have various prerogatives. Among these are the right to promulgate laws on matters related to the city so long as they do not infringe upon the national interest or the interest of other Italian regions. The regional authorities are the regional council, the assembly, and the president of the assembly. In the commune of Milan, the conciliation judge presides. The city is also divided into 20 zones, each of which has a council that can address matters of local concern.

Services. The central post office functions 24 hours per day. The city maintains a large, well-staffed streets and sanitation department, which endeavours to maintain both the cleanliness of the city and the health of its citizens. This task is made difficult, however, by overcrowding and poor housing conditions in some sectors. Health-care facilities are nonetheless generally good, and the city has a large network of publicly and privately run hospitals and clinics, as well as research facilities.

CULTURAL LIFE

The Duomo

The most striking of the monuments to be seen in contemporary Milan is the Duomo, a triumph of Gothic architecture; it is the third largest church of contemporary Europe, holding more than 20,000 people. Begun in 1386, it took five centuries to complete and rises over the area occupied at one time by the churches of Sta. Tecla and Sta. Maria Maggiore. The most imposing parts of the Duomo are its lateral aspects, its two top crosses, and the apse. In the latter, a powerful impression is made by the three immense Gothic windows of finely carved marble. The casing, of pink-tinged Italian marble, is to be found on all sides of the structure. At the lower level, it lends character to the small trilobate arches, capitals, and flowers; it also appears on the buttresses and, above them, runs along the crowning row of gigantic statues; above these, it covers the decorated water gutters and, finally, enhances the lacelike ornamental crest. The exterior of the cathedral is covered with a remarkable profusion of turrets, pinnacles, and more than 3,000 statues. Within are 52 pillars, each over 80 feet tall and more than 10 feet in diameter and bearing, instead of capitals, a crown of statues within their niches.

The most notable of the city's many palaces is the Palazzo di Brera, construction of which dates from 1651. Its architect, Francesco Maria Ricchino, infused the whole Milanese Baroque with his severe style. The Pinacoteca di Brera, one of the largest art galleries in Italy, contains a fine collection of north Italian painting. The building also contains the Biblioteca Nazionale Braidense, and its beautiful courtyard is dominated by Antonio Canova's statue of Napoleon. On the Corso Garibaldi stands S. Simpliciano, which according to tradition was founded in the 4th century by St. Ambrose. Its apse contains the 15th-century fresco "Coronation of the Virgin" by Ambrogio Bergognone. Other notable churches in the central area include S. Satiro, S. Eustorgio, S. Lorenzo Maggiore, and S. Babila. In Via Monte Napoleone, there are several handsome palaces, including the Bagatti-Valsecchi palaces. Leonardo da Vinci's fresco the "Last Supper," one of the most famous paintings of the Renaissance, is located in the former refectory of the Dominican monastery of Sta. Maria delle Grazie. Beyond the Piazza Cavour (which

contains a monument to the great Italian statesman for whom it is named as well as the imposing and ultra-modern Centro Svizzero ["Swiss Centre"]) lie the public gardens, in which the Museo Civico di Storia Naturale (Museum of Natural History) stands. One of its most interesting exhibits is the Turati ornithological collection. The former Villa Reale, now the Galleria d'Arte Moderna e Padiglione d'Arte Contemporanea, is also nearby.

Libraries and universities

The Biblioteca Ambrosiana (founded 1609) and the Biblioteca Comunale are also of significance. Other excellent libraries are found in the universities, the philological clubs of the Instituto Lombardo Accademia di Scienze e Lettere, as well as in the Donati Foundation. The Archivio di Stato also contain an imposing collection. Milan is the seat of three universities: the Università Cattolica del Sacro Cuore (1920), one of the best Roman Catholic schools in Italy; the state-run Università degli Studi (1923); and the Università Commerciale Luigi Bocconi (1902). Other institutions of higher education include the Instituto di Ingegneria Nucleare, Centro di Studi Nucleari Enrico Fermi and the Conservatorio di Musica Giuseppi Verdi.

Milan's Teatro alla Scala (popularly called La Scala), constructed 1776–78 by the leading Neoclassical architect Giuseppe Piermarini, is one of the great theatres of the world. (Piermarini, incidentally, designed the Corso di Porta Romana, the first paved street of modern Europe.) The city also contains several other theatres, including the Lirica, the Odeon, and the Stabile, which is the home of one of Italy's major theatrical companies. There are also numerous motion-picture houses.

Sections of a network of communication and transportation canals, the Navigli, constructed in the 16th century, remain, especially in the southern part of the city. In the summer a tour boat makes trips on the canals between Porta Ticinese and the Po, passing by country estates that were built from the 16th to the 19th century for Milanese nobles.

Milan is the leading sports centre of Italy. Many of the facilities are located in San Siro, on the northwestern edge of the city. The Palazzo dello Sport is a splendid example of recreational architecture. The Ippodromo del Gallopo, a large horse-racing arena, is one of the best in Europe. The Mirabello course is also excellent. In addition, San Siro has a fine association football (soccer) stadium, a civic arena, and numerous other fields for various sports, among which the modern Vigorelli, for cycling races, is well known. The Lago Idroscalo, an artificial lake next to Linate airport, is also a popular recreation area. The Grand Prix automobile-racing circuit at nearby Monza has an international reputation.

History

THE EARLY PERIOD

Foundation and early growth. The earliest settlement on the site of Milan was founded by the Gauls about the year 600 BC, and in ensuing centuries it became the capital of a Celtic tribe known as the Insubres. At the time of the Roman conquest, 222 BC, Mediolanum, as it was then called, was already one of the most powerful cities of the region on the Roman side of the Alps known as Cisalpine Gaul. Under the emperor Augustus, it became a part of the 11th region of Italy, acquiring increasing prestige and economic power until it became the second city of the Western Roman Empire behind Rome itself. In the 3rd century AD, following the partition of the empire instituted by the emperor Diocletian, it was assigned as residence and main administrative centre for one of the two emperors. The emperor Constantine the Great declared it the seat of the Vicar of Italy. In the year 452, Attila the Hun devastated the city, and in 539 the Goths destroyed it. The city, however, did not entirely perish as a result of these barbarian incursions, and by the second half of the 10th century city life was surging with renewed vigour. Under the Carolingians (the region was incorporated into the dominions of Charlemagne in 774), life in Milan showed increased vitality, particularly through the efforts of Archbishop Ansperto da Biassono, who rebuilt and strengthened the fallen walls of the city in the late 9th century. Under Ariberto da Antimiano (1018–45), the political power of the archbishopric reached its apogee. This assumption of temporal power by the archbishops, dating from about 1000, can be considered as the origin of the subsequent greatness of Milan.

Early settlement

Establishment of the commune

In 1045, however, as a result of tensions engendered by the authority of the archbishops and because of the increasing growth and stability of the city as a whole, Milan constituted itself as a commune (*comune*), with permanent and autonomous governmental structures. In the resultant struggle for primacy among the cities of Lombardy, Milan became involved in a series of long battles against its less prosperous neighbours—Pavia, Cremona, Como, and Lodi. In 1111 the Milanese razed Lodi, and, after a bitter struggle lasting from 1118 to 1127, Como was destroyed. This was the pretext for the intervention of Frederick I Barbarossa, who decided to bring Milan under the direct authority of the central imperial power of his Holy Roman Empire. The city held out until 1162, when it yielded after a nine-month siege. Its fortifications were then razed, and the destruction of the city was such that the Milanese were forced to seek refuge in the surrounding countryside. The war blazed on until 1183, the year of the Peace of Constance, although Milan, rebuilt in 1167 under the auspices of the newly founded Lombard League, succeeded in playing a major role in the defeat of the German forces of Barbarossa at the Battle of Legnano in 1176. Its privileges rewon, the city attained a splendid economic florescence over the next 100 years.

Feudal conflicts. In the early years of the 12th century, however, the new industrial classes, in particular the guilds of the woolens and armaments workers, increased constantly in power and influence. The feudal nature of the relationship between the archbishop and his allies meant that the archbishop had to make enormous concessions to the emergent social and political forces among the citizenry in order to reinforce his own party, diminishing thereby the financial privileges of the church. Following the worsening of the relationship with Frederick II of Swabia, the Milanese proclaimed Pagano della Torre, a member of a family emerging as leaders of the less feudal of the city's power groupings, as their protector. The city forces were nevertheless defeated by the Emperor in the Battle of Cortenuova (1237). In the shadow of the subsequent struggle between the Torriani family and another powerful Milanese family, the Visconti, the Signorial era was born. The Torrianis, leaders of the new popular forces, took the name of Guelfs; the Viscontis, followed by the aristocracy, headed the Ghibelline faction.

Dynastic struggles

In 1277 Ottone Visconti, archbishop of Milan, utterly defeated the enemy in the Battle of Desio. His nephew Matteo succeeded him, and, starting in 1311, Matteo and his heirs reigned as supreme lords of the city and of the surrounding state, replacing the political forms of the commune. Under this lordship, or *signoria,* the industrial and mercantile economy underwent rapid development, giving birth to further powerful coalitions of economic interests. But in 1450, Milan found itself besieged again. Francesco Sforza (1401–66), a ruthless and ambitious general, occupied the city and founded a new dynasty, basing his claim on his marriage to an illegitimate daughter of one of the Viscontis. A period of prosperity then began for Milan, based on the power of the Sforzas and the introduction of the silk industry. It was the golden period of the Italian Renaissance, typified by the splendour of the Sforza court.

The dynasty of the Sforzas, however, had but a short-lived enjoyment of power. In 1499 the Duchy of Milan fell into the hands of Louis XII, king of France, who was also a distant descendant of the Viscontis. In 1500 Ludovico Sforza (also called Il Moro) conquered the state but was defeated at Novara in the same year. The French continued to rule until 1513, at which point they were overthrown by Massimiliano Sforza, son of Il Moro, who had Swiss assistance. Francis I, successor to Louis XII, reconquered Milan in his renowned victory of Marignano (now Melegnano) in 1515. In accordance with the conditions of a peace treaty signed in 1529, Milan was once more returned to the Sforzas.

EVOLUTION OF THE MODERN CITY

In 1535 the incumbent duke died unexpectedly, and Milan and the entire Milanese state fell under the domination of the Habsburg emperor Charles V, who in 1540 invested his son—the future Philip II of Spain—with the duchy. Under Spanish rule—which was to last until 1706—the political and artistic elite of Milan rapidly succumbed. The dramatic period of dynastic struggle, which was also a period of economic growth, was to be replaced by a long period of economic stagnation and political decline associated with unimaginative foreign rule. In 1630 the city was struck by the great plague. This catastrophe was to be vividly portrayed by the local author Alessandro Manzoni (1785–1873) in his *I promessi sposi* (*The Betrothed*), a historical novel that is one of the finest artistic achievements of Italian and indeed European literature. The end of the desolation and squalor of the period of Spanish domination began with the outbreak, in 1701, of the War of the Spanish Succession. In September 1706 the city passed from Spanish to Austrian rule. Although the first half of the 18th century was marked by neglect and oppression, after the Treaty of Aix-la-Chapelle (1748), the new rulers, in collaboration with the wealthy commercial classes of Milan, fostered a half-century of enlightened, if despotic, growth. It is during this period that such figures as Cesare Beccaria, the outstanding criminologist and economist, and Pietro Verri, the gifted administrator and man of letters, were active. These and other members of a Milanese group known as the Società dei Pugni embraced the theoreticians of the French Revolution, in spite of Austrian censorship. Neoclassical architecture also flourished. When the republican army of France, with Napoleon Bonaparte at its head, entered Milan in 1796, it was greeted enthusiastically, particularly by the middle classes. In 1797 the constitution of a Cisalpine Republic was promulgated. In 1805 Milan became the capital of the Kingdom of Italy, under Napoleon, who was crowned in the city. A true awakening then occurred in the consciousness of the Milanese people, as their city prospered from its domination of most of the Italian peninsula.

The city under Napoleon

These hopes were dashed, however, by the invasion and reestablishment of Austrian authority that followed the collapse of the Napoleonic Empire in 1814. This alien control was to remain for nearly 50 years. Influenced by the new currents of Italian unity and nationalism known as the Risorgimento and smarting under the oppressive Austrian rule, the citizenry finally rose up in the "Cinque Giornate," the five days of March 18–22, 1848. In what has become one of the most celebrated episodes of the city's history, Milan was liberated from the Austrians for several months until the rebellion was finally suppressed. Although by Aug. 6, 1848, the brutal occupation forces of the aging Austrian commander Joseph Radetzky had taken firm control of Milan, resistance forces of the city continued their opposition to the invaders. Young men from Piedmont and Sardinia entered the city's army. It remained for the second War of Italian Independence to finally liberate Milan from foreign control, and a few days after the Battle of Magenta (June 4, 1859), the people of Milan witnessed the triumphant entry of Victor Emmanuel II, the Italian king of Piedmont and Sardinia. The city—by now in the throes of an industrial revolution emphasizing metal products—was incorporated into the new Italian state, maintaining itself in a position of prime importance in the national economy. (A.L./J.Fo.)

Restoration and revolution

At the turn of the 20th century, Milan was the centre of Italy's socialist mass trade union movement. It was also home to revolutionary socialist, anarchist, and nationalist movements. World War I gave a huge boost to Milan's heavy industry, but after the war, the city entered a period of instability. Fascism was born in Milan in 1919, and Benito Mussolini based his newspaper there. Fascism's national ascendancy was mirrored in Milan in 1922 when black-shirted squads occupied City Hall and effectively ended local democracy. Although Fascism never won over the Milanese working classes, it enjoyed strong support among the city's administrative, commercial, and business classes. Moreover, Fascism left its mark on Milan in a series of public projects, including the massive Law Courts, the imposing Central Station, and several broad boulevards.

During World War II, the city suffered grave damage from intensive Allied bombing. In 1943 the Germans occupied Milan, and partisans led sabotage campaigns that made the city the "capital of the Resistance." Partisans liberated the city before the Allies arrived in April 1945. Mussolini's dead body was famously displayed in Piazzale Loreto in Milan in the same month. The advent of the Cold War dashed the hopes of the city's left for radical change. A long economic boom during the 1950s and '60s brought prosperity for some but forced Milan's city government to address massive social problems such as the arrival of thousands of impoverished migrants from southern Italy and uncontrolled urban expansion. In 1968 Milan was at the centre of Italy's leftist student movement. In 1969 a bomb in a Milan bank killed 16 people. Although the authorities arrested thousands of leftists, the bombing had in fact been the work of neo-fascists trying to push the state to repress the left. Later, investigators discovered links between the bombers, the Italian secret services, and NATO agents. Ongoing terrorism and economic depression dominated the 1970s.

A second economic boom arrived in the 1980s, when the city's dominant Socialist Party embraced the new, postindustrial economy centred on finance, fashion, and design. However, the party's gloss and glitter concealed massive corruption. Beginning in 1992, Milanese judges, including Antonio Di Pietro, ordered the arrest of politicians and businessmen on charges of bribery. Milan became known as Tangentopoli ("Bribesville"). Within two years, the so-called "Clean Hands" investigations in Milan had destroyed Italy's patronage-based party structure, in which Milanese politicians had played a prominent and corrupt role. Milan's "moral capital" image was in tatters.

Out of the ruins of Tangentopoli came Silvio Berlusconi, who had become wealthy through building speculation in Milan and had purchased the AC Milan football team in 1986. The key to his success, however, was the creation of several hugely successful television and advertising companies. His Milanese base helped him form a new party in 1993—Forza Italia (Go Italy)—that retained a prominent role in Italian politics into the 21st century. Power, it seemed, was shifting away from Rome for the first time since World War I.

By the end of the 20th century, Milan had transformed from an industrial to a postindustrial powerhouse, thanks to a capable commercial and financial elite and a skilled workforce in fashion, design, and the media. The cheap labour of the more than 100,000 foreign immigrants who settled in and around Milan during the late 20th century also contributed to the city's prosperity. However, the city's glittering wealth masked persistent and largely unaddressed social and ecological problems. Milan entered the new millennium with one of the strongest urban economies in the world but without a clear vision of its future as a city. (J.Fo./Ed.)

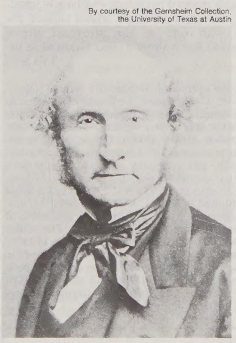
John Stuart Mill

John Stuart Mill was a British philosopher and economist, prominent as a publicist in the reforming age of the 19th century. He remains of lasting interest as a logician and an ethical theorist.



Early life and career. The eldest son of the British historian, economist, and philosopher James Mill, he was born on May 20, 1806, in his father's house in Pentonville, London. He was educated exclusively by his father, who was a strict disciplinarian. By his eighth year he had read in the original Greek Aesop's *Fables,* Xenophon's *Anabasis,* and the whole of the historian Herodotus. He was acquainted with the satirist Lucian, the historian of philosophy Diogenes Laërtius, the Athenian writer and educational theorist Isocrates, and six dialogues of Plato. He had also read a great deal of history in English. At the age of eight he started Latin, the geometry of Euclid, and algebra and began to teach the younger children of the family. His main reading was still history, but he went through all the Latin and Greek authors commonly read in the schools and universities and, by the age of 10 could read Plato and the Athenian statesman Demosthenes with ease. About the age of 12, he began a thorough study of Scholastic logic, at the same time reading Aristotle's logical treatises in the original. In the following year he was introduced to political economy and studied the work of the Scottish political economist and philosopher Adam Smith and that of the English economist David Ricardo.

While the training the younger Mill received has aroused amazement and criticism, its most important aspect was the close association it fostered with the strenuous character and vigorous intellect of his father. From his earliest days he spent much time in his father's study and habitually accompanied him on his walks. He thus inevitably acquired many of his father's speculative opinions and his father's way of defending them. But he did not receive the impress passively and mechanically. The duty of collecting and weighing evidence for himself was at every turn impressed upon the boy. His childhood was not unhappy, but it was a strain on his constitution and he suffered from the lack of natural, unforced development.

Effects of his education

From May 1820 until July 1821, Mill was in France with the family of Sir Samuel Bentham, brother of Jeremy Bentham, the English Utilitarian philosopher, economist, and theoretical jurist. Copious extracts from a diary kept at this time show how methodically he read and wrote, studied chemistry and botany, tackled advanced mathematical problems, and made notes on the scenery and the people and customs of the country. He also gained a thorough acquaintance with the French language. On his return in 1821 he added to his work the study of psychology and of Roman law, which he read with John Austin, his father having half decided on the bar as the best profession open to him. This intention, however, was abandoned, and in 1823, when he had just completed his 17th year, he entered the examiner's office of the India House. After a short probation he was promoted in 1828 to assistant examiner. For 20 years, from 1836 (when his father died) to 1856, Mill had charge of the British East India Company's relations with the Indian states, and in 1856 he became chief of the examiner's office.

Mill.

In 1822 Mill had read P.-E.-L. Dumont's exposition of Bentham's doctrines in the *Traités de Législation,* which made a lasting impression upon him. The impression was confirmed by the study of the English psychologists and also of two 18th-century French philosophers—Étienne Bonnot de Condillac, who was also a psychologist, and Claude-Adrien Helvétius, who was noted for his emphasis on physical sensations. Soon after, in 1822–23, Mill established among a few friends the Utilitarian Society, taking the word, as he tells us, from *Annals of the Parish,* a novel of Scottish country life by John Galt.

Two newspapers welcomed his contributions—*The Traveller,* edited by a friend of Bentham's, and *The Morning Chronicle,* edited by his father's friend John Black. One of his first efforts was a solid argument for freedom of discussion in a series of letters to the *Chronicle* on the prosecution of Richard Carlile, a 19th-century English radical and freethinker. Mill seized every chance for exposing departures from sound principle in Parliament and courts of justice. Another outlet was opened up for him (April 1824) with the founding of the *Westminster Review,* which was the organ of the philosophical radicals. In 1825 he began work on an edition of Bentham's *Rationale of Judicial Evidence* (5 vol., 1827). He took part eagerly in discussions with the many men of distinction who came to his father's house and engaged in set discussions at a reading society formed at the home of English historian George Grote in 1825 and in debates at the London Debating Society, formed in the same year.

Public life and writing. The *Autobiography* tells how in 1826 Mill's enthusiasm was checked by a misgiving as to the value of the ends that he had set before him. At the London Debating Society, where he first measured his strength in public conflict, he found himself looked upon with curiosity as a precocious phenomenon, a "made man," an intellectual machine set to grind certain tunes. The elder Mill, like Plato, would have put poets under ban as enemies of truth; he subordinated private to public affections; and Landor's maxims of "few acquaintances, fewer friends, no familiarities" had his cordial approval. The younger Mill now felt himself forced to abandon these doctrines. Too much in awe of his father to make him a confidant, he wrestled with his doubts in gloomy solitude. He emerged from the struggle with a more catholic view of human happiness, a delight in poetry for its own sake, a more placable attitude in controversy, a hatred of sectarianism, and an ambition no less noble and disinterested but moderated to practical possibilities. Gradually, the debates in the Debating Society attracted men with whom contact was invigorating and inspiring. Mill ceased to attend the society in 1829, but he carried away from it the conviction that a true system of political philosophy was

Beginning of his mature thought

> something much more complex and many-sided than he had previously had any idea of, and that its office was to supply, not a set of model institutions but principles from which the institutions suitable to any given circumstances might be deduced.

Mill's letters in *The Examiner* in the autumn of 1830, after a visit to Paris, where he made the acquaintance of the younger liberals, may be taken as marking his return to hopeful activity; and a series of articles on "The Spirit of the Age" appeared in the same paper in 1831. During the years 1832 and 1833 he contributed many essays to *Tait's Magazine, The Jurist,* and *The Monthly Repository.* In 1835 Sir William Molesworth founded *The London Review,* with Mill as editor. It was amalgamated with *The Westminster* (as *The London and Westminster Review*) in 1836, and Mill continued as editor (latterly as proprietor, also) until 1840. In and after 1840 he published several important articles in *The Edinburgh Review.* Some of the essays written for these journals were reprinted in the first two volumes (1859) of Mill's *Dissertations and Discussions* and give evidence of the increasing width of his interests. Among the more important are "Thoughts on Poetry and Its Varieties" (1833), "Writings of Alfred de Vigny" (1838), "Bentham" (1838), "Coleridge" (1840), "M. De Tocqueville on Democracy in America" (1840), "Michelet's History of France" (1844), and "Guizot's Essays and Lectures on History" (1845). The twin essays on Bentham and Coleridge show Mill's powers at their splendid best and indicate very clearly the new spirit that he tried to breathe into English radicalism.

Works on logic and political economy

During these years Mill also wrote his great systematic works on logic and on political economy. His reawakened enthusiasm for humanity had taken shape as an aspiration to supply an unimpeachable method of proof for conclusions in moral and social science; the French positivist philosopher Auguste Comte had some influence here, but the main inspiration undoubtedly came from the English scientist and mathematician Sir Isaac Newton, whose physics had already been accepted as a model of scientific exposition by such earlier British philosophers as John Locke, David Hume, Jeremy Bentham, and James Mill. But he was determined that the new logic should not simply oppose the old logic. In his *Westminster* review (of 1828) of Richard Whately's *Elements of Logic,* he was already defending the syllogism against the Scottish philosophers who had talked of superseding it by a supposed system of inductive logic. He required his inductive logic to "supplement and not supersede." For several years he searched in vain for the means of concatenation. Finally, in 1837, on reading William Whewell's *Philosophy of the Inductive Sciences* and rereading John F.W. Herschel's *Preliminary Discourse on the Study of Natural Philosophy,* Mill at last saw his way clear both to formulating the methods of scientific investigation and to joining the new logic onto the old as a supplement. *A System of Logic,* in two volumes, was published in 1843 (3rd–8th editions, introducing many changes, 1851–72). Book VI is his valiant attempt to formulate a logic of the human sciences—including history, psychology, and sociology—based on causal explanation conceived in Humean terms, a formulation that has lately come in for radical criticism.

Mill distinguished three stages in his development as a political economist. In 1844 he published the *Essays on Some Unsettled Questions of Political Economy,* which he had written several years earlier, and four out of five of these essays are solutions of perplexing technical problems—the distribution of the gains of international commerce, the influence of consumption on production, the definition of productive and unproductive labour, and the precise relations between profits and wages. Here for the most part Mill appears as the disciple of David Ricardo, striving after more precise statements and reaching forward to further consequences. In his second stage, originality and independence become more conspicuous as he struggles toward the standpoint from which he wrote his *Principles of Political Economy.* This was published in 1848 (2 vol.; 2nd and 3rd eds., with significant differences, 1849, 1852), and, at about the same time, Mill was advocating the creation of peasant proprietorships as a remedy for the distresses and disorder in Ireland. Thereafter, he made a more thorough study of Socialist writers. He was convinced that the social question was as important as the political question. He declined to accept property, devised originally to secure peace in a primitive society, as necessarily sacred in its existing developments in a quite different stage of society. He separated questions of production and distribution and could not rest satisfied with the distribution that condemned the labouring classes to a cramped and wretched existence, in many cases to starvation. He did not come to a Socialist solution, but he had the great merit of having considered afresh the foundations of society. This he called his third stage as a political economist, and he says that he was helped toward it by Mrs. Taylor (Harriet Hardy), who became his wife in 1851.

Activities during his married life

It is generally supposed that Mill writes with a lover's extravagance about Harriet's powers. He expressly says, indeed, that he owed none of his technical doctrine to her, that she influenced only his ideals of life for the individual and for society, and that the only work directly inspired by her is the essay on the "Enfranchisement of Women" (*Dissertations,* vol. 2). Nevertheless, Mill's relations with her have always been something of a puzzle.

During the seven years of his marriage Mill became increasingly absorbed in the work of the British East India Company and in consequence published less than at any other period of his life. In 1856 he became head of the examiner's office in the India House, and for two years, till the dissolution of the company in 1858, his official work kept him fully occupied. It fell to him as head of the office to write the defense of the company's government of India when the transfer of its powers was proposed. Mill opposed the transfer, and the documents in which he defended the company's administration are models of trenchant and dignified pleading. On the dissolution of the company, Mill was offered a seat in the new council but declined it and retired with a pension of £1,500. His retirement from official life was followed almost immediately by his wife's death at Avignon, France. He spent most of the rest of his life at a villa at Saint-Véran, near Avignon, returning to his house at Blackheath only for a short period in each year.

The later years. Mill sought relief by publishing a series of books on ethics and politics that he had meditated upon and partly written in collaboration with his wife. The essay *On Liberty* appeared in 1859 with a touching dedication to her and the *Thoughts on Parliamentary Reform* in the same year. In his *Considerations on Representative Government* (1861) he systematized opinions already put forward in many casual articles and essays. It has been remarked how Mill combined enthusiasm for democratic government with pessimism as to what democracy was likely to do; practically every discussion in these books exemplifies this. His *Utilitarianism* (in *Fraser's Magazine,* 1861; separate publication, 1863) was a closely reasoned attempt to answer objections to his ethical theory and to remove misconceptions about it. He was especially anxious to make it clear that he included in "utility" the pleasures of the imagination and the gratification of the higher emotions; and to make a place in his system for settled rules of conduct.

Mill also began to write again on the wider philosophical questions that had occupied him in the *Logic.* In 1865 he published both his *Examination of Sir William Hamilton's Philosophy* and his *Auguste Comte and Positivism,* but in both writings his motives were largely political. It was because he regarded the writings and sayings of Sir William Hamilton as the great fortress of intuitional philosophy in Great Britain that Mill undertook to counter his pretensions. In dealing with Comte, Mill distinguished sharply between Comte's earlier philosophical doctrine of Positivism and his later religion of humanity. The doctrine he commended (as he had frequently done previously) because he regarded it as a natural development of the outlook of George Berkeley and Hume; the religion he attacked because he saw in it merely another attempt to foist a priestly hierarchy upon suffering humanity. It is noticeable that Mill's language in these books is much closer to the language of Bentham and James Mill than it had been since his boyhood, and it was as an act of piety that in 1869 he republished his father's *Analysis of the Phenomena of the Human Mind* with additional illustrations and explanatory notes.

Mill in Parliament

While engaged in these years mainly with theoretical studies, Mill did not remit his interest in current politics. He supported the North in the U.S. Civil War, using all his strength to explain that the real issue at stake in the struggle was the abolition of slavery. In 1865 he stood as parliamentary candidate for Westminster, on conditions strictly in accordance with his principles. He would not canvass or pay agents to canvass for him, nor would he engage to attend to the local business of the constituency. He was with difficulty persuaded even to address a meeting of the electors but was elected. He took an active part in the debates preceding the passage of the 1867 Reform Bill, and helped to extort from the government several useful modifications of the bill, for the prevention of corrupt practices. The reform of land tenure in Ireland (see his *England and Ireland,* 1868, and his *Chapters and Speeches on the Irish Land Question,* 1870), the representation of women (see below), the reduction of the national debt, the reform of London government, and the abrogation of the Declaration of Paris (1856)—concerning the carriage of property at sea during the Crimean War—were among the topics on which he spoke. He took occasion more than once to enforce what he had often advocated, England's duty to intervene in foreign politics in support of freedom. As a speaker Mill was somewhat hesitating, but he showed great readiness in extemporaneous debate. Elected rector of St. Andrews University, he published his "Inaugural Address" in 1867.

Mill's subscription to the election expenses of the free-thinker and radical politician Charles Bradlaugh and his attack on the conduct of Gov. E.J. Eyre in Jamaica were perhaps the main causes of his defeat in the general parliamentary election of 1868. But his studied advocacy of unfamiliar projects of reform had made him unpopular with "moderate Liberals." He retired with a sense of relief to Avignon. His villa was filled with books and newspapers; the country round it furnished him with a variety of walks; he read, wrote, discussed, walked, botanized. He was extremely fond of music and was himself a fair pianist. His stepdaughter, Helen Taylor (died January 1907), was his constant companion after his wife's death. Mill was an enthusiastic botanist all his life and a frequent contributor of notes and short papers to the *Phytologist.* During his last journey to Avignon he was looking forward to seeing the spring flowers and completing a flora of the locality.

Mill did not relax his laborious habits or his ardent outlook on human affairs. The essays in the fourth volume of his *Dissertations* (1875; vol. 3 had appeared in 1867)—on endowments, on land, on labour, and on metaphysical and psychological questions—were written for the *Fortnightly Review* at intervals after his short parliamentary career. In 1867 he had been one of the founders, with Mrs. P.A. Taylor, Emily Davies, and others, of the first women's suffrage society, which developed into the National Union of Women's Suffrage Societies, and in 1869 he published *The Subjection of Women* (written 1861), the classical theoretical statement of the case for woman suffrage. His last public activity was concerned with the starting of the Land Tenure Reform Association, for which he wrote in *The Examiner* and made a public speech a few months before his death; the interception by the state of the unearned increment on land and the promotion of cooperative agriculture were the most striking features in his program, which he regarded as a timely compromise in view of the impending struggle between capital and labour in Europe. His *Autobiography* and *Three Essays on Religion* (1874) were published posthumously.

Mill died at Avignon on May 8, 1873. A bronze statue of him stands on the Thames embankment in London, and G.F. Watts's copy of his original portrait of Mill hangs in the National Gallery there.

Influence and significance. Mill was a man of extreme simplicity in his mode of life. The influence that his works exercised upon contemporary English thought can scarcely be overestimated, nor can there be any doubt about the value of the liberal and inquiring spirit with which he handled the great questions of his time. Beyond that, however, there has been considerable difference of opinion about the enduring merits of his philosophy. At first sight he is the most lucid of philosophers. Many people have spoken of the marvelous intelligibility of his writing. Usually, however, it is not long before doubts begin to creep in. Although the lucidity remains, its span is seen to be somewhat limited, and one sometimes has the uneasy feeling that he is being equally lucid on both sides of a question.

Oddly enough, however, this judgment has not led to any neglect of Mill. Little attention is now paid to Hamilton or to Whewell, but Mill's name continually crops up in philosophical discussions. This is partly due to the fact that Mill offers a body of doctrine and a set of technical terms on many subjects (notably on induction) that have proved extremely useful in the classroom. But a more important reason is that he has come to be regarded as a sort of personification of certain tendencies in philosophy that it is regarded as continually necessary to expound or expose because they make such a powerful appeal to serious minds. Thus he is or says he is a Utilitarian; yet nothing, it is pointed out, could tell more strongly against Utilitarianism than certain passages in his writings. Then again, he is said to be an Empiricist (although he says himself that he is not), and his theories of the syllogism and of mathematics are constantly used to demonstrate the fatal consequences of this way of thinking.

It is misleading to speak without qualification of Mill's Utilitarianism. Nor is it sufficient to add that Mill modified the Utilitarianism that he inherited from Bentham and from his father in one way and another in order to meet the criticisms that it encountered in Victorian times. He does, it is true, sometimes give that impression (as in his essay *Utilitarianism*); but elsewhere (as in his essay *On Liberty*) he scarcely attempts to conceal the fact that his premises are completely independent of Bentham's. Thus, contrary to the common belief, it appears to be very hazardous to characterize offhand the precise position of Mill on any major philosophical topic. He sometimes behaved with a reckless disregard of consequences more suitable to a Romantic than to a Utilitarian. He is thoroughly romantic, again, and thoroughly representative of his age in the eagerness with which he seeks out and endeavours to assimilate every last exotic line of thought which shows any signs of vitality. He himself claimed to be superior to most of his contemporaries in "ability and willingness to learn from everybody," and indeed, for all his father's careful schooling, there was never anybody less buttoned up against alien influences than Mill. In his writings there can be discerned traces of every wind of doctrine of the early 19th century.

MAJOR WORKS

POLITICS AND ECONOMICS: *Essays on Some Unsettled Questions in Political Economy* (1844); *Principles of Political Economy,* 2 vol. (1848; 2nd and 3rd eds. with important differences, 1849, 1852); *On Liberty* (1859); *Considerations on Representative Government* (1861); *Utilitarianism* (1863); *On The Subjection of Women* (1869).

PHILOSOPHY AND RELIGION: *A System of Logic* (1843); *Examination of Sir William Hamilton's Philosophy* (1865); *Auguste Comte and Positivism* (1865); *Three Essays on Religion* (1874).

OTHER WORKS: Essays on "Bentham" (1838) and "Coleridge" (1840) in *Dissertations and Discussions,* 4 vol. (1859–75), also reprinted together with an introduction by F.R. LEAVIS (1950); *Autobiography,* ed. by Helen Taylor (1873).

BIBLIOGRAPHY. The definitive edition of the *Collected Works* is that edited by JOHN M. ROBSON *et al.,* in 17 vol. (begun in 1963); each volume has a full introduction, notes, and indexes.

Biography: The standard biography is M.ST.J. PACKE, *The Life of John Stuart Mill* (1954, reissued 1970), a fascinating book (including a bibliography), with interpretations sometimes too colourful. Mill's own *Autobiography* has been edited several times, for example by JACK STILLINGER (1969). Stillinger has also edited *The Early Draft of John Stuart Mill's Autobiography* (1961), written in 1853–54, which includes a much more vivid and intimate account of Mill's relations with his father and mother; it suggests a more gloomy picture of his childhood than does the final version. (This is not a work that Mill was himself prepared to publish.) ALEXANDER BAIN, *John Stuart Mill: A Criticism with Personal Recollections* (1882, reprinted 1969), will never be superseded; an excellent, rambling account by Mill's closest philosophical disciple, it refers to many conversations and quotes from letters now lost. F.A. HAYEK (ed.),

John Stuart Mill and Harriet Taylor (1951, reprinted 1969), is full of details about the writing of Mill's works from the 1830s to 1858 (with gaps for times when they were meeting together); the painting of Harriet Taylor should not be missed. PEDRO SCHWARTZ, *The New Political Economy of J.S. Mill* (1972), is an intellectual biography; EUGENE R. AUGUST, *John Stuart Mill* (1975), is a biography for the general reader.

Comment and criticism: RICHARD P. ANSCHUTZ, *The Philosophy of J.S. Mill* (1953, reprinted 1969), a subtle and precise study presupposing a wide reading of the texts; KARL W. BRITTON, *John Stuart Mill: Life and Philosophy*, 2nd ed. (1969), an introductory book—sympathetic but critical; ÉLIE HALÉVY, *The Growth of Philosophic Radicalism* (1928; new ed., 1949, reissued 1972; originally published in French, 1901–04), the standard comprehensive account of the school in which Mill was brought up, with issues fully analyzed and discussed (including a bibliography); JOHN P. PLAMENATZ, *The English Utilitarians*, 2nd ed. (1958, reissued 1966), on the background and content of Mill's moral theory; JOHN M. ROBSON, *The Improvement of Mankind: The Social and Political Thought of John Stuart Mill* (1968), offering an account of Mill's life and of his mature views on morals, scientific method, politics, and sociology; MAURICE COWLING, *Mill and Liberalism* (1963), an eccentric account that imputes to Mill a strong strain of authoritarianism; DENNIS F. THOMPSON, *John Stuart Mill and Representative Government* (1976), an analysis of his *Considerations on Representative Government;* ALAN RYAN, *John Stuart Mill* (1970), an attempt to show that a single constant theory of inductivism underlies all Mill's writings; RICHARD HALLIDAY, *John Stuart Mill* (1976), arguing that behind Mill's eclecticism is a coherent pattern of thought; PETER WINCH, *The Idea of a Social Science*, ch. 3 (1958, reissued 1977), an attack on attempts to construct a causal science of human conduct; FRANCIS H. BRADLEY, *Ethical Studies*, 2nd ed. (1927, reissued 1962), in which the third essay is an attack on Mill's hedonism; G.E. MOORE, *Principia Ethica* (1903, reissued 1976), a very lively onslaught on Mill's Utilitarianism, often patently unfair; C.L. TEN, *Mill on Liberty* (1980), an interpretation of the conflict between his Utilitarianism and his liberalism; J.O. URMSON, "The Interpretation of the Moral Philosophy of J.S. Mill," *Philosophical Quarterly*, 3:33–39 (1953), on moral rules; NEY MACMINN, J.R. HAINDS, and J. MCCRIMMON (eds.), *Bibliography of the Published Writings of John Stuart Mill* (1945, reprinted 1970).

Milton

John Milton ranks second only to Shakespeare among English poets; his writings and his influence are a very important part of the history of English literature, culture, and libertarian thought. He is best known for *Paradise Lost,* which is generally regarded as the greatest epic poem in the English language. Milton's prose works, however, are also important as a valuable interpretation of the Puritan revolution, and they have their place in modern histories of political and religious thought.

Milton was born in London on Dec. 9, 1608. His grandfather, an Oxfordshire yeoman, had been a staunch Roman Catholic who had disinherited his son, the poet's father, for turning Protestant. John Milton, Sr., went to London, where he made his way to prominence and a comfortable fortune as a scrivener, or notary, and through the collateral business of private banking or moneylending. Milton was to pay repeated tributes to his father's generous concern with his education. Of his mother (d. 1637) Milton said only that she was well esteemed and known for her charities. He had an older sister, Anne, and a younger brother, Christopher, who became a lawyer.

Education and early poems. Milton was educated at St. Paul's School, London. The conventional date given for his admission is 1620, but it may have been as early as 1615. In addition to his regular schoolwork in Latin, Greek, and, later, Hebrew, the boy had instruction at home, perhaps partly in modern languages, from private tutors. Milton was a voracious student; he traced the initial cause of his later blindness to his having, from his 12th year, rarely quit his books before midnight. Along with a couple of Latin exercises that have survived, his earliest attempts at verse, made when he was 15, were rhymed paraphrases of Psalms 114 and 136. Milton's closest friend, at school and later, was Charles Diodati, the son of a prominent physician of Italian origin, who went from St. Paul's to Oxford.

Years at Cambridge

On April 9, 1625, Milton entered Christ's College, Cambridge; he received his Bachelor of Arts degree in March 1629 and his Master of Arts in July 1632. His experience at Cambridge can be partly gathered from his abundant Latin verse and his seven Latin prolusions (public speeches that were expected to display the speaker's learning and rhetorical and argumentative powers). Apparently in March 1626 he clashed in some way with his tutor and was suspended temporarily. On his return to the university he was assigned to another tutor and graduated at the normal time.

Milton's nickname at the university, "the Lady," was apparently bestowed because of his handsome and delicate features and a purity of mind and behaviour that disdained the diversions of his coarser fellows. During his seven years at Cambridge he seems to have moved from some unpopularity to general respect and, among dons and cultivated students, to high esteem. He did not love the scholastic logic that dominated the curriculum; then, as well as later, he denounced it as barren. In his last prolusion (*c.* 1631/32) he proclaimed the fervent creed and dream of a young Renaissance humanist who was at once a Christian and a Platonist. By Milton's own account, his early enthusiasm for the sensual poetry of Ovid and other Roman writers gave way to an appreciation of the idealism of Dante, Petrarch, and Edmund Spenser. He then moved on to Platonic philosophy and finally came to hold the mysticism of the biblical Book of Revelation in the highest esteem.

Meanwhile, Milton had been learning his craft and sometimes revealing his inner self in writing Latin verse. (Latin was then the standard language of the university world.) The young poet's sensuous instincts were revealed in these poems and were further displayed, along with his mastery of Italian, in six Italian pieces (1630?), with which his first English sonnet, "O Nightingale," may be linked.

Earliest extant English poems

Early in 1628 Milton wrote the first of his extant English poems (apart from the two psalms), "On the Death of a Fair Infant," an elegy, in the Elizabethan vein, on his baby niece, Anne Phillips. In part of an academic prolusion in English couplets ("At a Vacation Exercise," July 1628) he declared his devotion to his native language, a style free from eccentricity, and exalted themes concerning nature and humanity. And in the Latin "Elegy VI," addressed to Diodati in the Christmas season of 1629–30, he praised the light verse kindled by wine and love but turned from that to celebrate the ascetic purity of the heroic poet. The elegy ended with a reference to a poem he had just written, his first great poem in English, "On the Morning of Christ's Nativity." Such a poem, composed shortly after his 21st birthday, may be taken as a kind of announcement of his poetical coming of age and future direction, both in its religious theme and in its mastery of conception and form and image and rhythm. Probably in 1631 Milton wrote the companion poems "L'Allegro" and "Il Penseroso." Though less ambitious in theme than the "Nativity," they have their own complexity, concealed beneath a unique grace and charm. Milton had lately (1630) also written the lines "On Shakespeare," which were printed in the Shakespearean Second Folio, 1632.

Milton's scholarly and literary gifts had from childhood marked him out in the minds of his family and teachers for the ministry; in his later prose he said he had refused to "subscribe slave" in a church governed by prelacy, but the date of his negative decision is not known. As his academic career approached its end, the problem of an occupation came up, and the poem "Ad Patrem"—though some scholars link it with *Comus* (1634)—may well have been written in 1631–32. In "Ad Patrem" ("To Father"), with a mixture of filial gratitude, firmness, and confidence in poetry and himself, Milton assumes or urges that he should not be pushed into some basely lucrative profession by a father who has fostered his literary pursuits and is himself a devotee of the muses.

Horton period (1632–38). On taking his Master of Arts degree in July 1632, Milton retired to his father's house—until 1635 at Hammersmith, then at the country estate at Horton, near Windsor—and proceeded to give himself the liberal education Cambridge had not provided. It was in these years that he laid the foundation or set the direction of his liberal thinking. He sought to digest the mass of history, literature, and philosophy, to gain the "insight

Self-education

into all seemly and generous arts and affairs" needed by the citizen-poet who would be a leader and teacher.

Two short religious poems written at this time, "On Time" and "At a Solemn Musick" (1632–33?), are early renderings of the beatific vision that always kindled Milton's imagination. Both contrast the grossness of temporal life, the jarring discord of sin, with the eternity and harmony of heaven and good. The same contrast is sounded in the masque known as *Comus.* During 1630–34, perhaps in 1632, Milton had, at the invitation probably of the musician Henry Lawes, written *Arcades,* a miniature masque of Jonsonian courtliness. This presumably led to a request from Lawes for another masque. *Comus* was presented on Sept. 29, 1634, before John Egerton, earl of Bridgewater, at Ludlow Castle in Shropshire, in honour of his becoming lord president of Wales. The acted version of *Comus,* though somewhat shorter than the text familiar to readers, in length and elevated seriousness went far beyond the limits of the usual court masque, which emphasized lavish costumes, spectacle, music, and dancing. *Comus* is a masque against "masquing," contrasting a private heroism in chastity and virtue with the courtly round of revelry and pleasure. It was Milton's first dramatizing of his great theme, the conflict of good and evil.

The allegorical story in *Comus* centres on a virtuous Lady who becomes separated from her two brothers while traveling in the woods. The Lady encounters the evil sorcerer Comus, son of Bacchus and Circe, who imprisons her by magic in his palace. In debate the Lady rejects Comus' hedonistic philosophy and defends temperance and chastity. The chastity the Lady represents is not mere abstinence; it is a positive love of the good that is both Christian and Platonic. Comus, who is portrayed with a dramatic irony that anticipates the treatment of Satan in *Paradise Lost,* puts forth specious naturalistic arguments which the Lady answers first on the rational level; then, with a conscious change of tone, she rises to an impassioned religious affirmation of chastity, and the masque's epilogue celebrates the love of virtue.

Composition of "Lycidas"

If *Comus* is, in a way, a song of innocence, "Lycidas" (written in November 1637) is a song of experience—Milton's first attempt to justify the ways of God to himself and to men. His former fellow collegian, Edward King, was drowned in a shipwreck in the Irish Sea in August 1637, and Milton was asked to contribute to a volume of elegies; "Lycidas," signed "J.M.," appeared at the end of an undistinguished collection of pieces in Latin, Greek, and English (1638). The classical pastoral elegy had, from its Greek beginnings, proved its value as a dramatic vehicle for almost anything that a poet wished to say. Milton, working as usual within a venerable tradition, as usual recreated it. He had no reason to feel deep personal sorrow, but the drowning of a virtuous and promising young man, on the threshold of service as a clergyman, brought home the whole enigma of life and death, of the rightness of things in a world where such events could happen. What if his own talents—which during his years of study he had been nurturing—should be cut off? At the poem's end, divine justice and providence and the conditions of earthly life are vindicated not by reason but by the beatific vision of Lycidas' soul received into heaven. It is impossible to summarize the complexities and depths of the poem, its reverberating solidity of reference, its rich variety of pace and tone, the artistic control that dominates turbulent emotions and ends with the high serenity of victory won. "Lycidas" may be the greatest short poem in the English language.

Italian tour (1638–39). In May 1638, a year after his mother's death, Milton set off—with one servant—on a visit to Italy. He sojourned chiefly in Florence, Rome, and Naples. Milton and some of his early Latin poems were cordially welcomed among men of letters and patrons and their academies. This experience warmed his heart and nourished his self-confidence. (It should be remembered that at home he had very little literary acquaintance and, outside a small circle, no poetic reputation.) In Naples he was the guest of Giambattista Manso, marchese di Villa, who had been the patron of Torquato Tasso, and in Florence he made a call—later recorded in *Areopagitica*—on the aged astronomer Galileo Galilei, who was under house arrest because his views on the universe conflicted with the doctrine of the Roman Catholic church. Milton felt obliged to forgo a visit to Sicily and Greece because of news of mounting political tension in England, although he lingered some time longer in Italy. In August 1638 Milton's friend Diodati died. Milton had been informed of his loss while in Italy; on his way home he stopped to see Diodati's uncle, Giovanni Diodati, who was professor of theology at the University of Geneva.

Middle period (1641–60). Milton returned to England in July 1639, settled in a house in London, and prepared to take in pupils. He composed an elaborate pastoral elegy on Diodati, "Epitaphium Damonis" (*c.* 1640), which has commonly been ranked as his finest Latin poem, though as an elegy it is inferior to "Lycidas." Milton had returned to England with plans for an Arthurian epic; like other ambitious poets of the Renaissance, he hoped to write the great modern heroic poem. But he was also deeply anxious about the Puritan cause. In his denunciation of hireling clergy in "Lycidas," Milton had virtually declared his Puritan allegiance, and the years 1641–60 he gave almost wholly to pamphleteering in the cause of religious and civil liberty. There is an important personal passage in his fourth tract, *The Reason of Church-Government Urg'd Against Prelaty* (1642), that shows it was a heavy sacrifice to put aside his craving for poetic immortality and leave his cherished studies to "embark in a troubled sea of noises and hoarse disputes." And, as his work went on, he was sustained by the conviction that in his many and varied defenses of liberty he was, in another way, fulfilling his epic and patriotic aspirations. His first five pamphlets (1641–42) were contributions to the attack made on prelacy in the Anglican church by a group of Presbyterian divines (called, from their initials, the "Smectymnuus" group). The attack was directed chiefly against the church's episcopal hierarchy, *The Book of Common Prayer,* and ritual, as being a compromise with Rome. The group urged a return to the democratic simplicity and purity of the apostolic church. Milton's first tract was *Of Reformation Touching Church Discipline in England* (1641). This begins by assailing the Anglican service and ends with a vision of the new and grand Reformation. In a personal passage in his fourth pamphlet, *The Reason of Church-Government,* Milton explains his religious conception of poetry and the deferment of his great epic because of what he feels to be his public duty.

Allegiance to Puritanism

Notoriety came in 1643, with Milton's pamphlet *Doctrine and Discipline of Divorce* (enlarged edition 1644), which was followed by three more tracts in 1644 and 1645 on the same theme. His preoccupation with the subject of divorce was presumably hastened by his own marital disaster. In June(?) 1642, several months before the outbreak of the Civil Wars, Milton had married Mary Powell, the daughter of a royalist squire of Oxfordshire who owed money to his father. Success could hardly be predicted for the marriage of a scholar and poet of 33 to an uneducated girl half his age from a large, easygoing household. The young wife, visiting her family a little later, declined—doubtless with their backing—to return to her new husband's household. The shock must have been especially severe for a man who—as one may infer from the anguished cries that recur in the *Doctrine*—had approached marriage with high hopes and earnest prayers, and there was no release from such a tragic mistake. In the tracts Milton argued that the sole cause admitted for divorce—adultery—might be less valid than incompatibility and that the forced yoke of a loveless marriage was a crime against human dignity. For this he was attacked as a libertine by royalists and Presbyterians alike. In 1645 friends brought about a reunion between Milton and his wife, and in 1646, when the Powells had been ruined by the war, he took into his house, for nearly a year, the whole noisy family of 10. Three daughters, Anne, Mary, and Deborah, were born in 1646, 1648, and 1652. A son died in infancy. Mrs. Milton died a few days after Deborah's birth.

First marriage

In 1644 Milton published what are for modern readers his best-known pamphlets, *Of Education* and *Areopagit-*

ica. Of Education is one of the last in a long line of European expositions of Renaissance humanism. His aim was to mold boys into enlightened, cultivated, responsible citizens and leaders on the basis of the study of the ancient classics, in due subordination to the Bible and Christian teaching. But he also gave notable emphasis to science. *Areopagitica* is on the freedom of the press and was specifically written to protest an order issued by Parliament the previous year requiring government approval and licensing of all published books. Milton argues that to mandate licensing is to follow the example of the detested papacy. He defends the free circulation of ideas as essential to moral and intellectual development and reasserts above all his belief in the power of truth to triumph over falsehood through free inquiry and discussion. *Areopagitica* is now regarded as a classic plea on behalf of civil liberties and democratic values, but the tract seems to have had very little effect in its own time.

During the next four years Milton may have worked chiefly on his *The History of Britain* (1670). On Feb. 13, 1649, two weeks after the execution of Charles I, Milton's first political tract, *The Tenure of Kings and Magistrates,* appeared. In it he expounds the doctrine that power resides always in the people, who delegate it to a sovereign but may, if it is abused, resume it and depose or even execute the tyrant. A month later he was invited to become secretary for foreign languages to Cromwell's Council of State. Hitherto a detached observer, Milton, in spite of his private studies, was doubtless eager to have a hand in the workings of government. He was not on the policy-making level, but he had the easy command of Latin needed for foreign correspondence. Also, as a publicist of demonstrated sympathy with the revolution, he was expected to continue his defense of the cause against the multiplying attacks on the regicides.

Secretary for foreign languages to the Council of State

Milton's first effort in this line was *Eikonoklastes* (October 1649), one of a number of answers to *Eikon Basilike,* a book edited from the late king's papers by his chaplain, John Gauden. During 1651 Milton was censor and supervisory editor of the chief Commonwealth newspaper, *Mercurius Politicus,* edited by Marchamont Needham. In this year appeared his Latin *Defence of the People of England.* Charles II, in exile, had engaged Claudius Salmasius (Claude de Saumaise), the most eminent of classical scholars, to arraign the regicides (*Defensio Regia pro Carolo I,* 1649). Milton was less effective in legal argument than in discrediting Salmasius by personal abuse; like some other crusaders, he tended to see opponents as monstrous enemies of a sacred cause who must be destroyed by any means.

If he was, then and later, uplifted by the vanquishing of a renowned antagonist, he was inevitably and profoundly depressed by the loss of his eyesight; it had been failing for years, and blindness became complete in the winter of 1651–52. Milton was only 43, and the great poem was still unwritten. Blindness reduced his strictly secretarial duties, though he continued through 1659 as a translator of state letters.

Onset of blindness

The Second Defence of the People of England—also in Latin, since it was also addressed to Europe at large—was much more worthy of its subject and its author. In it he celebrated the achievements of the Commonwealth leaders (though he was bold enough to warn Cromwell against one-man rule). In 1659 two more tracts on church and state were published. In *A Treatise of Civil Power in Ecclesiastical Causes* Milton argued for religious freedom (except for Roman Catholics, since Catholicism had shown itself a danger to national security). In *Considerations Touching the Likeliest Means to Remove Hirelings out of the Church* he reasserted the ideal of a clergy of apostolic simplicity of life.

His last political pamphlet, *The Readie and Easie Way to Establish a Free Commonwealth,* was published in March 1660 and again, enlarged, in April. It was an act no less courageous than futile, since machinery was patently moving to bring back Charles II and install him as king (he made his triumphal entry on May 29). Milton's pamphlet is a cry of incredulity and despair from the last champion of "the good Old Cause." The glories of the Commonwealth, to which he himself had given 20 years and his eyesight, were being swept away by a nation of slaves "now choosing them a captain back for Egypt." The Restoration was the last and heaviest of Milton's many disillusionments.

The Restoration government executed the Commonwealth leader Sir Henry Vane the Younger and exhumed and hanged at Tyburn the bodies of Cromwell, Henry Ireton, and John Bradshaw. Milton himself, as a noted defender of the regicides, was in real danger. In the summer of 1660 a warrant was out for his arrest; he was kept in hiding by friends. In August the Act of Oblivion, granting pardon to most Commonwealth supporters, was passed. Milton was safe within its terms but was nevertheless taken into custody (and released on December 15). According to various early stories, his life was spared through the intercession either of the poet Andrew Marvell, who in 1657 had become a fellow secretary and was now a member of Parliament, or of the royalist playwright Sir William Davenant, whose life Milton had earlier been the means of saving. It may have been decided that the blind writer was now harmless and that token proceedings against him would be enough.

The large bulk of Milton's prose—which fills four times as many volumes as his poetry—is read only by scholars, but much of it is important for several reasons. In an age of great prose, Milton's, at its best, has an individual if often undisciplined greatness, and *Areopagitica* at least is a classic document. Moreover, as the record of Milton's growth (a leftward growth, in religion and politics) and of his dreams and disillusionments, his prose works are the essential introduction to *Paradise Lost, Paradise Regained,* and *Samson Agonistes,* providing a bridge between the radiant idealism of his youth and the much-tried faith and fortitude of his later years. In particular, his *A Treatise on Christian Doctrine* held a central place in his thoughts and labours. He seems to have finished it by about 1658–60 (it was first printed and translated by Charles Sumner in 1825). Its importance is that it expounds, with differences, the theological frame of *Paradise Lost.* Viewed in perspective, most of Milton's essential beliefs are those of traditional Christianity, but he does depart from orthodoxy on a few points, notably his denial of predestination. Brought up, like most Anglicans of his time, as a Calvinist, he regarded himself as one at least until 1644, but his final belief was in the Arminian doctrine—the salvation not of a predestined few but of all believers, who constitute the true elect. Milton above all insisted on humanity's rational freedom and responsible power of choice.

Estimate of the prose works

Sonnets and other poems (1642–58). Milton's early poems, in English, Latin, Greek, and Italian, were published at the beginning of 1646 (dated 1645). During the 20 years given to public affairs he was mostly cut off from poetry but did write 17 occasional sonnets, versified a number of psalms, and began the composition of *Paradise Lost.* Some of the sonnets are deeply personal: two on his blindness (1652–55) and one on the death in 1658, some months after childbirth, of his second wife, Katherine Woodcock, whom he had married in 1656.

The major sonnets have much poetical as well as autobiographical interest, and as a group they illustrate (with "Lycidas") both in texture and rhythm the beginnings of the grand style (*i.e.,* a literary style marked by a sustained and lofty dignity and sublimity) that was to have full scope in *Paradise Lost.* One is less conscious of sonnet structure and of rhymes than of a single massive unit that approaches a paragraph of Milton's blank verse.

Paradise Lost. By 1650 Milton had given up the idea of composing a British epic. Instead he chose what was considered the most momentous event, next to the life and death of Christ, in the world's history—the fall of mankind from grace. It is not known when *Paradise Lost* was actually begun. Guesses have centred on 1655–58. Clearly, the lines on the poet's having fallen on evil days, in the prelude to Book 7, were composed after the Restoration, and the whole may have been done pretty much in the order in which it stands. It was finished by 1665. The first edition of 1667 was in 10 books; this was reissued in 1668 and 1669, and in some of these issues

Composition of *Paradise Lost*

Milton added the prefatory note on his use of blank verse and "The Argument." In the second edition (1674), Books 7 and 10 were each split into two, making a total of 12 books. The arguments, which summarize the contents of each book and were formerly grouped together, were placed at the head of the respective books.

Paradise Lost is an epic poem written in blank verse—*i.e.,* unrhymed iambic pentameter verse. It tells the story of Satan's rebellion against God and his expulsion from heaven and the subsequent temptation and expulsion of Adam and Eve from the Garden of Eden. By Milton's time the Fall of Man had already received innumerable literary treatments, narrative and dramatic, so that the simple tale in Genesis and the more shadowy role of Satan in heaven, earth, and hell had acquired a good deal of interpretative and concrete embellishment. So the main motives and events of *Paradise Lost* had abundant literary precedent, though they were handled with powerful originality; Milton, like a Greek dramatist, was reworking a story familiar in outline to his audience. His story, moreover, gave him the advantage of immemorial belief and association in the minds of his earlier readers. This advantage no longer operates in the same way—although, for modern readers, the fable still possesses at least the immemorial and universal import of archetypal myth.

The story of the Fall of Man had little of the solidity and variety of character and action of the classical epics, however, and so Milton the classicist naturally borrowed much in the way of form and style and epic convention. While he was said to have known the Homeric poems by heart, his great classical model was Virgil's *Aeneid,* with which *Paradise Lost* has some inner as well as surface affinities.

Some Virgilian features of *Paradise Lost* are easily observable. Milton centres the magnificent first two books of his poem on the figure of Satan and his legions as they lie in hell. Virgil has a roll call of the Italian chiefs who gather to oppose Aeneas; Milton's roll call of the leaders of the fallen angels, in making them individuals, also becomes a survey of the spread of heathen idolatry over the Eastern world. The realistic power of the debate of the fallen angels in hell dwarfs all other epic councils. Epic accounts of Hades are combined, in Milton's pictures of hell, with Christian lore, but the lurid and dismal scenes and the physical and mental diversions of the fallen angels symbolize their spiritual death and futile striving. The wars of gods and Titans and giants in classical literature supply details for the war in heaven in *Paradise Lost,* which is a large metaphor for the anarchy of sin. And Odysseus' and Aeneas' retellings of past events become the archangel Raphael's account of Satan's revolt and war and the Son's creation of the world.

Much has been written about Milton's powerful characterization of Satan, who is one of the supreme figures in world literature. Satan has, on a superhuman scale, the strength, the courage, and the capacity for leadership that belong to the ancient epic hero, but these qualities are all perverted in being devoted to evil and self-aggrandizement. In his first grand speech to his lieutenant Beelzebub, Satan's defiance of God manifests his egoistic pride, his false conception of freedom, and his alienation from all good; and his other public harangues reinforce and amplify our sense of power that is religiously and morally corrupt and blind. Against the background of hell, Satan maintains the false magnificence of his "heroic" stature, but outside of hell he loses even that. In his soliloquy addressed to the Sun, he reveals, like Dr. Faustus or Macbeth, his despairing consciousness of his own evil and damnation, a consciousness that gives him potentially tragic dimensions. Thus Satan and his fellows are enveloped in dramatic irony because—though the corruption of man is achieved—they fight and scheme in ignorance of the unshakable power of God and goodness.

Dramatic irony in *Paradise Lost*

Adam and Eve are enveloped in a parallel kind of irony. The picture of the Garden of Eden is a symbolic rendering of Milton's vision of perfection, but it is presented when the reader accompanies Satan into the garden, so that idyllic innocence and happiness are seen only under the shadow of evil. Though the pair have had warnings, Eve is beguiled by an appeal to her vanity and ambition, by the hubristic dream of attaining godlike knowledge and power; and Adam allows his love for Eve to oversway his love for God. Both, far from attaining godlike knowledge, succumb to animal lust; yet, when grace and penitence begin to work in them, they have a strength beyond the reach of Satan. On the other hand, though there is promised redemption for the faithful, and though the poem is, logically, a divine comedy with a happy ending, Milton's panorama of human history gives little ground for hope on earth. Irony, profoundly compassionate irony, pervades the moving last lines which describe Adam and Eve as they depart from Eden—not now the majestic lords of creation but two frail human beings beginning life anew in the world of sin and sorrow and death, though "with Providence their guide" and the hope of achieving a "paradise within."

The more one reads *Paradise Lost* the more one recognizes Milton's powers of imagination and organization. Everywhere, on the largest or the smallest scale, in abstract idea or concrete act, theme and material are closely knit through parallel and contrast. The central conflict and contrast between good and evil are reflected and intensified in the contrasts between heaven and hell, light and darkness, order and chaos, love and hate, humility and pride, reason and passion. In the council in hell, Satan alone volunteers for the perilous journey to earth to bring about the Fall of Man; in the council in heaven, the Son alone volunteers to suffer on earth for man's salvation. Satan unlooses the destructive anarchy of war; the Son creates the world. Eve and Adam reenact the sin and fall of Satan. The boundless scene of *Paradise Lost* is indeed only a backdrop or magnified reflection of the drama that goes on in the hearts of the human protagonists, and, when they fall, the ideal world of eternal spring and eternal life becomes the world we live in.

To speak of the setting in more literal terms, Milton's imagination fills space so immense that the created universe—the Ptolemaic one—hangs from heaven like one of the smallest stars close to the Moon. Milton showed his awareness of the Copernican universe, but the Ptolemaic one had the advantages of traditional familiarity and of keeping earth and man at the focal centre. In his handling of vast space Milton's imagination and language work with a suggestive vagueness that is very different from the minute particularity of Dante's world. He is excited by the starry dance of the cosmic order and, likewise, by the fecundity of Eden, and his account of creation is alive with the sense of movement and growth. The poem is rich in its appeal to both the eye and the ear.

Milton's preface stresses the novelty and rightness of blank verse for a heroic poem, and his manipulation of rhythm and sound is of course one of his supreme achievements. The continuous flow of his long sentences and paragraphs is naturally unlike the dramatic blank verse of Shakespearean dialogue, and it builds up a continuous onward pressure. While the iambic pentameter line remains the norm, there may be extra syllables, and there is endless variety in the number, weight, and position of stresses. At the same time there is a secondary and still more fluid system of rhythmic units, which flow from the caesura in one line to the caesura in the next, resulting in an infinity of permutations and combinations. Milton's blank verse is never monotonous, and the pattern of sound is so wedded to the pattern of sense that each is essential to the other.

Milton's frequently Latinate syntax and diction have sometimes been censured, especially by modern poets and critics for whom colloquial speech and rhythm are the only acceptable medium. But Milton's means of achieving the elevation required by a lofty theme is intermixed with pure simplicity. His use of Latinate syntax or structure and his freedom in the placing of phrases and clauses greatly enlarge and enrich his range of emphasis and his use of economy, contrast, suspension, all the devices of forceful utterance—devices often really colloquial. Many other functional elements of the grand style can be noted: periphrasis, epic similes, geographic, historical, and mythological allusions, and so on.

Last major works. In *Paradise Lost* (Book 9) Milton had spoken of "patience and heroic martyrdom" as themes

Paradise Regained and *Samson Agonistes*

unsung, though nobler than martial prowess, and this "better fortitude" was celebrated in the epic poem *Paradise Regained* and the tragedy *Samson Agonistes* (published in the same volume in 1671). *Paradise Regained* is a natural sequel to *Paradise Lost:* Christ, the second Adam, wins back for man what the first Adam had lost. But Milton did not, as might have been expected, deal with the Crucifixion; instead, he showed Christ in the wilderness overcoming Satan the tempter, thereby proving his fitness for his ultimate trial and, in his human role, showing what humankind might achieve through strong integrity and humble obedience to the divine will. Although the poem has been found cold by the mass of readers and critics, it nevertheless has all the fire of Milton's religious and moral passion and his reverence for true heroism.

For some readers, the drama of *Samson Agonistes* is the most powerful and completely satisfying of Milton's major works. It is by far the greatest English drama on the Greek model and is known as a closet tragedy—*i.e.,* one more suited for reading than performance. The play deals with the final phase of Samson's life and recounts the story as told in the Book of Judges of the Old Testament. The action, up to the reported catastrophe, is wholly psychological; it is the process by which Samson, "eyeless in Gaza at the mill with slaves," moves from preoccupation with his misery and disgrace to selfless humility and renewed spiritual strength, so that he can once more feel himself God's chosen champion. He is granted a return of his old strength and pulls down the pillars that support the temple of the Philistine god Dagon (also spelled Dagan), crushing himself along with his captors. The drama must owe a great deal of its power to Milton's sense of kinship with his hero; he has been eyeless in London among a nation of slaves. But nowhere does the classical impersonality and restraint of Milton's art show so strongly; there is nothing in the drama that does not belong to the story of Samson. And Milton's classical style appears in a new phase, in a rugged, sinewy, colloquial texture, and in irregular rhythms of new expressiveness.

Altogether, if *Samson* was his last epic poem, it was a grand testament. Like Samson, Milton was able to conquer despair or to sublimate it in his last three great poems. These expressed not his earlier revolutionary faith in men and movements but a purified faith in God and the regenerative strength of the individual soul.

Last years (1658–74). The poet's final 16 years of life, during which these three works were finished or composed, were peaceful, although there were concrete troubles: a frugal domestic economy necessitated by greatly diminished resources; blindness and what was sometimes a more severe affliction, the pains of gout; and a degree of friction with his daughters, due probably to faults on both sides. Apart from the publication of books, the chief events of these years were Milton's marriage (1663) to a third wife, the young and amiable Elizabeth Minshull, who survived him, and the removal, during the plague of 1665, to a house (now a Milton museum) at Chalfont St. Giles, Buckinghamshire.

Last works

The publications of Milton's late years were *Paradise Lost* (1667), for which he received £10; textbooks of simplified Latin grammar (1669) and logic (1672); *The History of Britain* (1670); *Paradise Regained* and *Samson Agonistes* (1671); the second, enlarged edition of the *Poems* of 1645 (1673); the second, revised edition of *Paradise Lost* (1674); and *Epistolae Familiares* with the *Prolusiones Oratoriae* (1674). *A Brief History of Moscovia* appeared in 1682. A Latin dictionary on which Milton had long worked was completed by others and published in 1693. Edward Phillips translated *Letters of State* (1694). Milton's great epic poems were, of course, composed in his head, especially at night, as famous allusions in *Paradise Lost* indicate; when he was ready "to be milked," he would dictate, often with one leg flung over the arm of his chair. The taking of dictation, the correcting of copy, and reading aloud in various languages were services performed by paid assistants, his two nephews, his younger daughters, and friends and disciples.

In religion Milton had moved from the low-church Anglicanism of his parents to Presbyterianism to Independency to independence. In the latter part of his life, according to his early biographer John Toland, "he was not a professed member of any particular sect among Christians, he frequented none of their assemblies, nor made use of their peculiar rites in his family." But, as Samuel Johnson observed, "his studies and meditations were an habitual prayer." Milton died on Nov. 8, 1674, "of the gout stuck in," just before his 66th birthday. His burial in the churchyard of St. Giles, Crippiegate, was attended by "all his learned and great friends in London, not without a friendly concourse of the vulgar."

Reputation. Milton's reputation grew steadily after 1667 and was well established before Joseph Addison's papers on *Paradise Lost* appeared in *The Spectator* (1712); these were instrumental in extending the poet's fame to the Continent. His influence on 18th-century verse was immense. In the 19th century two main streams of critical opinion are evident. On the one hand, the revolutionary Romantic poets William Blake and Percy Bysshe Shelley launched the "Satanist" misinterpretation of *Paradise Lost* and made its author, like themselves, a rebel; their attitude is summed up in Blake's saying that Milton was of the devil's party without knowing it (in other words, that he had projected himself into Satan, who was the poem's real hero). On the other hand, other critics—also concentrating on the epic—threw overboard Milton's beliefs and ideas as long-dead fundamentalism and attended to the poem's purely literary qualities.

The poet's influence waned during the Victorian age, and in the 20th century the new poetry and criticism launched by Ezra Pound and T.S. Eliot were strongly anti-Milton and pro-John Donne. But during the 1940s and '50s a shift in critical attitudes took place, and dozens of books and hundreds of articles were given to the ideas and beliefs of the thinker, the publicist, and the poet and brought a new refinement of perception and analysis to the aesthetic study of Milton's poetry. By the second half of the 20th century his works had regained their place in the canon of Western literature.

MAJOR WORKS

Poems. *A Maske Presented at Ludlow Castle, 1634* [*Comus*], in an enlarged text, and "Lycidas" (1638) were both reprinted in *Poems* (1645), which included nearly all the other early pieces, "L'Allegro," "Il Penseroso," etc. The second edition (1673) reprinted the 1645 *Poems,* adding two early pieces and later sonnets; four sonnets were excluded for political reasons, since they were addressed to Sir Thomas Fairfax, Cromwell, Sir Henry Vane, and Skinner (the one beginning "Cyriack, this three years' day"). *Paradise Lost,* in 10 books, appeared in 1667 (revised in 12 books, 1674); *Paradise Regained* and *Samson Agonistes* were printed together in 1671.

Prose. *Of Reformation Touching Church Discipline in England* (1641); *The Reason of Church-Government Urg'd Against Prelaty* (1642); *An Apology Against a Pamphlet Call'd A Modest Confutation of the Animadversions upon a Remonstrant Against Smectymnuus* (1642); *The Doctrine and Discipline of Divorce* (1643, enlarged 1644); *Of Education* (1644); *Areopagitica* (1644); *The Tenure of Kings and Magistrates* (1649); *Eikonoklastes* (1649); *A Treatise of Civil Power in Ecclesiastical Causes* (1659); *Considerations Touching the Likeliest Means to Remove Hirelings out of the Church* (1659); *The Readie and Easie Way to Establish a Free Commonwealth* (1660); *The History of Britain* (1670); *Of True Religion, Haeresie, Schism, Toleration, and What Best Means May Be Us'd Against the Growth of Popery* (1673); *A Brief History of Moscovia* (1682).

Works in Latin, Greek, and Italian. *Poems:* The volume entitled *Poems* (1645) contained three Greek pieces and five Italian sonnets and a canzone. Most of the notable Latin poems are mentioned above; one other, "Elegy V" ("On the Coming of Spring"), was a fervently "pagan" celebration of awakening life and sexuality.

Prose: The seven Latin speeches delivered at Cambridge and Latin letters to friends (published 1674); *Pro Populo Anglicano Defensio* (1651); *Pro Populo Anglicano Defensio Secunda* (1654); *Pro Se Defensio* (1655); *De Doctrina Christiana* (published 1825).

Editions. Milton's collected works are reproduced in two works by FRANK ALLEN PATTERSON (ed.), *The Student's Milton,* rev. ed. (1933, reissued 1961), which has almost all the works in one volume, with some apparatus, and *The Works of John Milton,* 18 vol. in 21 (1931–38). A comprehensive 1-vol. annotated edition is MERRITT Y. HUGHES (ed.), *Complete Poems and Major Prose* (1957). DON M. WOLFE (ed.), *Complete Prose Works,*

8 vol. (1953–82), includes translations of the Latin works and elaborate commentaries. J. MAX PATRICK (ed.), *The Prose of John Milton* (1967), contains annotated selections. Annotated editions of the complete poems are HELEN DARBISHIRE (ed.), *The Poetical Works of John Milton*, 2 vol. (1952–55, reissued as *Poetical Works*, 1966), with mainly textual notes; DOUGLAS BUSH (ed.), *Complete Poetical Works* (1965); JOHN CAREY and ALASTAIR FOWLER (eds.), *The Poems of John Milton* (1968); and JOHN T. SHAWCROSS (compiler), *The Complete Poetry of John Milton*, rev. ed. (1971).

Mimicry

Mimicry is a biologic phenomenon characterized by the superficial resemblance of two or more organisms that are not closely related taxonomically. This resemblance confers an advantage—such as protection from predation—upon one or both organisms through some form of "information flow" that passes between the organisms and the animate agent of selection. The agent of selection (which may be, for example, a predator, a symbiont, or the host of a parasite, depending on the type of mimicry encountered) interacts directly with the similar organisms and is deceived by their similarity. This type of natural selection distinguishes mimicry from other types of convergent resemblance that result from the action of other forces of natural selection (*e.g.*, temperature, food habits) on unrelated organisms.

In the most studied mimetic relationships the advantage is one-sided, one species (the mimic) gaining advantage from a resemblance to the other (the model). Since the discovery of mimicry in butterflies in the mid-19th century, a great many plants and animals have been found to be mimetic. In many cases the organisms involved belong to the same class, order, or even family, but numerous instances are known of plants mimicking animals and vice versa. Although the best-known examples of mimicry involve similarity of appearance, investigations have disclosed fascinating cases in which the resemblance involves sound, smell, behaviour, and even biochemistry.

A key element in virtually every mimetic situation is deception by the mimic, perpetrated upon a third party, which mistakes the mimic for the model. This third party may be the collective potential predators upon the mimic, potential prey of a predacious mimic, or even one sex of the mimic's own species. In some cases, such as host mimicry by parasites, the organism deceived is the model.

Because of the variety of situations in which mimicry occurs, a formal definition must rest upon the effect of certain key communicative signals upon the appropriate receiver and the resultant evolutionary effect upon the emitters of the signals. Mimicry may be defined as a situation in which virtually identical signals, emitted by two different organisms, have in common at least one receiver that reacts in the same manner to both signals because it is advantageous to react in that manner to one of them (that of the model), although it may be disadvantageous to react thus to the counterfeit signal.

The distinction between camouflage and mimicry is not always clear when only the model and the mimic are at hand. When the receiver is known and its reactions understood, however, the distinction is quite clear: in mimicry the signals have a special significance for the receiver and for the sender, which has evolved the signals in order to be perceived by the receiver; in camouflage the sender seeks to avoid detection by the receiver through imitation of what is neutral background to the receiver. BASIC TYPES OF MIMICRY

Batesian mimicry. In 1862 the English naturalist Henry W. Bates published an explanation for unexpected similarities in appearance between certain Brazilian forest butterflies of two distinct families. Members of one family, the Heliconiidae, are unpalatable to birds and are conspicuously coloured; members of the other family, the Pieridae, are edible to predators. Bates concluded that the conspicuous coloration of the inedible species must serve as a warning for predators that had learned of their inedibility through experience. The deceptively similar colour patterns of the edible species would provide protection from the same predators. This form of mimicry, in which a defenseless organism bears a close resemblance to a noxious and conspicuous one, is called Batesian, in honour of its discoverer.

Müllerian mimicry. Bates observed, but could not explain, a resemblance among several unrelated butterflies, all of which were known to be inedible. There seemed to be no reason for these species, each of which had an ample defense with which to back up the warning coloration, to be similar. In 1878 Fritz Müller, a German zoologist, suggested that an explanation for this so-called Bates's paradox might lie in the advantage to one inedible species in having a predator learn from another. Once the predator has learned to avoid the particular colour pattern with which it had its initial contact, it would then avoid all other similarly patterned species, edible and inedible. The initial learning experience of the predator often results in death or damage to the inedible individual that provided the lesson; there is thus some cost to the species that teaches the predator of its inedibility. Evidence indicates that there is little or no inherited recognition by certain predators; each individual learns of noxious or inedible species by sampling them. Other inedible species resembling the first, however, do not have to sacrifice individuals to teach this same predator, and the number of individuals sacrificed in educating the entire predator population is spread over all of the species sharing the same warning pattern. The tendency of inedible or noxious species to resemble each other is called Müllerian mimicry.

Edible and inedible butterflies

Aggressive mimicry. In some situations it is of advantage to a predator to resemble its prey, or a parasite its host. Aggressive mimicry, for which the phrase "a wolf in sheep's clothing" is an apt description, does not involve warning mechanisms. The mimic adopts certain of the recognition marks of its model in order to secure advantage over the model itself or over a third species that interacts with the model. The model may be mimicked during only a single stage of the life cycle, as in the case

of parasitic cuckoos, the eggs of which resemble those of their hosts (see below *The occurrence of mimicry among plants and animals*), or the model may be a prey of the mimic's victim, as in the case of angler fishes, which possess rodlike spines tipped with a fleshy "bait" to lure other fishes within reach.

Automimicry. The phenomenon of automimicry involves the advantage gained by some members of a species from its resemblance to others of the same species. Males of many bees and wasps, although defenseless, are protected from predators by their resemblance to females that are equipped with stingers. Some butterflies are able to gain protection against predators through the ability to absorb, tolerate, and retain in the immature (larval) stage, poisons from the plants on which they feed. Individuals or even subpopulations of such butterflies may fail to acquire such protection, as a result of feeding on nonpoisonous plants, but they are avoided by predators that have sampled protected individuals of the same species.

Other forms. Many forms of mimicry do not fit neatly into any of the above categories. The roles of mimic, model, and receiver may be juxtaposed and multiplied to provide intricate and remarkable relationships, the unraveling of which may take years of study. One such case involves the South American coral snakes (*Micrurus*), long recognized as dangerously poisonous—which possess a brilliant red, black, and yellow ringed pattern—and several genera of nonpoisonous and mildly poisonous "false coral snakes" with nearly identical colour patterns.

Coral snake mimicry

WARNING SYSTEMS

The chemical basis for repulsion. Many plants are characterized by the production of large amounts of metabolic end products, often called secondary metabolites—complex chemicals that include alkaloids, terpenes, phenylpropanes, resins, lignins, saponins, flavonols, and anthocyanins—stored in the plant tissues. Many such substances are also found in animals that feed upon such plants. Some animals produce substances similar to the secondary metabolites of plants; they store these substances in glandular pockets (as in toads, salamanders, and some insects) or in musk glands (as in beavers and muskrats). Arthropods, particularly insects, are notable for the production of excretory substances that serve as means of defense. Millipedes of the family Glomeridae, for example, secrete a bitter substance (a quinazoline) that repels birds; similar substances, differing only slightly in molecular structure, are found in palms. The fact that a certain chemical substance is restricted to a specific function, such as sex attraction, does not necessarily mean that it was evolved solely for that purpose. It seems rather that natural selection follows the easiest course and makes use of substances already present, and sometimes widely distributed. If so, the appearance of such substances in other organisms is not too surprising.

Protective secretions

Among the chemical compounds that protect certain plants from insects or other animals that might feed on them are the cardenolides, or cardiac glycosides. These substances have a highly specific toxic effect on the vertebrate heart and also activate the nerve centre in the brain that causes vomiting. Because the amount necessary to cause vomiting is about half the amount necessary to cause death through heart failure, an animal that samples a plant containing cardenolides is not killed but survives with the knowledge that the plant is inedible. Certain milkweeds (*Asclepias*) that contain cardenolides are the primary food of the larvae of danaine butterflies, including the familiar monarch and queen butterflies (*Danaus plexippus* and *D. gilippus*). The larvae consume the poison without ill effects and retain it through the pupal stage to adulthood. As adult butterflies, they enjoy protection from vertebrate predators.

There is, of course, no such thing as complete protection. Just as danaine larvae are able to eat the protected milkweeds, some predators are able to prey upon the protected butterflies. Birds of the Old World bee eater family (Meropidae) and a few other birds are able to eat bees because the horny beak protects them from being stung while the insect is being killed and because they have evolved behavioral mechanisms for removing the stinger (usually by wiping the insect on a perch) before swallowing the prey. Rabbits are able to eat the extremely poisonous mushrooms of the genus *Amanita* without ill effects. The larvae of the Florida feather moth (*Trichoptilus parvulus*) consume the insect-trapping glands on the leaves of the sundew (*Drosera*).

The evolution of warning systems. *The selective advantage of warning.* When an organism possesses a mechanism that provides protection from predators, there is a further advantage in preventing the potential predator from even sampling the protected organism. By the act of learning of the danger, the predator may well kill or maim the individual if, for instance, the protected species must be tasted for its inedibility to become known. Many protected insects are provided with tougher skins than their unprotected relatives, but the sampling by a vertebrate predator is almost sure to do some damage. Many noxious organisms have evolved warning (aposematic) mechanisms that serve to identify them clearly to a predator who has had prior experience with the same or similar species.

Types of warning systems

Warning systems often rely primarily on bright colours, but these may be supplemented by olfactory, acoustic, or behavioral means. The New World skunks, for example, have a prominent black and white pattern that renders them clearly recognizable to potential nocturnal predators. When threatened, skunks perform a highly stylized display dance, thus ensuring that the predator will see and recognize the warning coloration.

Acoustic warning signals are often favoured over visual ones because they allow the animal the option of remaining hidden. The rattlesnakes (*Crotalus* and relatives), which need protective coloration to avoid alerting their prey, are able to provide acoustic warning to large animals that threaten them. Many moths of the families Arctiidae and Ctenuchidae are foul-tasting but would be vulnerable to nocturnal predation by bats were it not for the emission of a series of high-pitched clicks, audible to bats, made when the moths hear the bats' own ultrasonic navigational pulses. That the moth clicks actually do serve as warnings is borne out by the fact that captive bats ignore thrown mealworms (which they normally eat) when the mealworms are accompanied by recorded moth clicks. Several species of edible moths also produce clicks and may be regarded as Batesian mimics of the unpalatable species.

The role of the receiver. In some cases, the animal who serves as the receiver of the warning signal reacts by means of an innate system that exists independently of experience. Generally, however, a predator must learn the significance of the warning signal through experience. If the predator is a slow learner, or if the warning signal is not sufficiently distinct to avoid confusion with beneficial sensory impressions that the predator receives, several experiences may be necessary. Natural selection, therefore, will favour warning systems that are devoid of ambiguity. Experimentation has shown that certain birds and mammals, at least, are capable of acquiring and retaining knowledge of some aposematic mechanisms from a single experience.

Combination of warning systems with concealing coloration. It is of obvious advantage for an aposematic organism to be able to control the display of the warning system, partly to minimize the amount of sampling, with its concomitant liability of injury, by naive receivers. Acoustic and chemical warning systems allow this. Many protected animals are coloured to match their backgrounds but provided with flash areas of warning coloration. Examples of these organisms are the tiger moths (certain of the Arctiidae), in which the hind wings are yellow or orange but are kept under the streaked brown forewings until the moth is molested..

THE OCCURRENCE OF MIMICRY AMONG PLANTS AND ANIMALS

Batesian mimicry. The stinging Hymenoptera (particularly the bees, wasps, and hornets), well protected from most predators and usually equipped with conspicuous warning coloration, are mimicked by insects of many other orders. Ladybird beetles (Coccinellidae) and leaf bee-

tles (Chrysomelidae) are inedible and are provided with prominent colours and usually with contrasting spots. A whole group of Philippine roaches of the genus *Prosoplecta* mimics these beetles, having undergone profound modification to achieve the similarity. To simulate the short, rounded form of the ladybirds, the large hind wings of the roaches are rolled and folded in a manner unparalleled in other insects.

The order Lepidoptera abounds with Batesian mimics, the best known of which is a swallowtail butterfly, *Papilio dardanus,* a widespread African species. In many populations of this species the females are polymorphic; *i.e.,* a number of different types (morphs) of coloration are found, with each morph a mimic of a species of inedible butterfly of another genus (either *Danaus* or *Amauris*). In all populations, the males are nonmimetic, retaining the same yellow and black pattern throughout. The presence of polymorphism, coupled with the ability of the lepidopterist to breed and rear this species in the laboratory, makes this an apt species for the study of colour inheritance. Investigators have found that mimicry in *P. dardanus* depends upon the action of certain primary genes, the expression of which is switched on or off by modifier genes. The modifier genes reduce the number of possible morphs to the restricted number of mimetic forms. The effects of modifier genes are not carried to the offspring when members of different geographic races are crossed. This finding suggests that each set of modifier genes is adapted to the gene complex in which it normally occurs and in which it probably evolved.

Müllerian mimicry. Müllerian mimicry often occurs in groups of unrelated species, all noxious or inedible and all possessing the same conspicuous warning coloration.

Mimicry rings

Such groups, called mimicry rings, often have associated Batesian mimics. It is not always easy to evaluate the palatability of members of such rings, and thus to distinguish Müllerian from Batesian mimics. Parallel Müllerian mimicry rings are known from South Africa, Borneo, and the tropical Americas; each contains such unrelated insects as malacodermoid and longicorn beetles, butterflies, true bugs, and spider wasps. In South America inedible butterflies of many distinct nymphalid subfamilies (Danainae, Ithomiinae, Acraeinae, and Heliconiinae) share the same warning coloration. Certain species show a highly perplexing divergence from the usual mimicry principles, however. It is axiomatic that maximum protection is gained by Müllerian mimics when all individuals employ the same signal, a principle known as signal standardization. Two species of *Heliconius* (*H. melpomene* and *H. erato*) are polymorphic, however, with each morph in one species duplicated by one in the other and with the morphs of each pair having virtually contiguous geographic ranges. Ecological and genetic evidence indicates that the racial divergence within these species was produced by differences in the abundance (or degree of protection) of different mimicry rings in different refuges, as have lasted for several thousand years, with the species coming to mimic whichever abundant, protected species was within reach by a single mutation.

Aggressive mimicry. Examples of aggressive mimicry are abundant and varied; each demonstrates its own particular variation of basic mimicry principles. The examples cited below illustrate a few of the remarkable extremes in the evolution of mimicry.

Mimicry in the fluke

Parasitic worms. The flukes (Trematoda) are a class of parasitic worms belonging to the phylum Platyhelminthes. One species, *Leucochloridium macrostomum,* resides principally in the intestine of songbirds. The eggs of the parasite pass to the outside in the feces of the birds and are readily ingested by a terrestrial snail, *Succinea,* an inhabitant of waterlogged meadows and riverbanks. The parasite eggs hatch into the first larval form within the snail. The next stage, called the sporocyst, is strikingly green in colour and bears yellow-brown rings. The sporocyst develops in the snail tissues and carries several sacs of "spores," one of which is placed into each of the snail's tentacles, or eyestalks. The sac then begins to pulsate violently, at about 40 to 70 beats per minute. The tentacle of the snail becomes greatly enlarged and eventually is transformed into a transparent covering over the pulsating sporocyst. *Succinea* usually avoids light, but specimens with this parasite do not. When the snail appears with its conspicuous, pulsing eyestalks, birds mistake the eyestalks for insect larvae, bite them off, and eat them. Within the bird, the sporocyst then hatches into the final larval stage, which grows into an adult worm. In the meantime the snail's eyestalk regenerates, and the cycle is repeated when another sac passes into the new eyestalks. Because the sporocysts of other trematodes are neither brightly coloured nor mobile, it can be concluded that the colour and pulsation of *Leucochloridium* are adaptations for arousing the interest of the insectivorous birds. Under normal circumstances the host birds do not eat snails, so the sporocyst must imitate the bird's proper food in order to be eaten and to complete its life cycle in the bird host. The process represents an unusual case of aggressive mimicry, for the parasite manipulates its hosts and causes the bird to infect itself with the parasite.

Another trematode, *Cercaria mirabilis,* is notable for its unusually large larvae form, called a cercaria. The size of this cercaria and its hopping mode of locomotion cause it to resemble a small, swimming crustacean or mosquito larva, with the result that fish mistake it for food and swallow it. Research on parasites of this kind is much easier when it is recognized that the larval stages often mimic the food of their respective hosts. Examination of the parasite often provides a suggestion as to the probable host.

Insect-luring plants. Newly hatched flesh flies (*Sarcophaga*), blowflies (*Calliphora*), and greenbottle flies (*Lucilia*) are attracted to glistening droplets or imitations of droplets. The grass of parnassus (*Parnassia palustris*) has flowers with five nectar petals, which bear glistening buttons but no nectar. They attract flies, nevertheless, and reward them with nectar in two depressions on the upper surfaces of the petals. The insectivorous sundew (*Drosera*), on the other hand, presents a deceptive lure, consisting of glistening secretory droplets on the glandular leaves, which trap insects that are then dissolved with digestive juices.

Pitcher plants

The pitcher plants (*Nepenthes, Darlingtonia, Sarracenia, Cephalotus*) have juglike leaves, which may bear flowerlike markings near their openings. Some have a flap or hood that enhances the resemblance to a flower and prevents filling with rainwater. One form, *Nepenthes,* secretes nectar at the lip of the pitcher. A foraging insect landing on this apparent flower slips on the edge and falls in. A band of gland cells below the slippery region secretes an enzyme that digests protein. The lower part of the pitcher contains a watery mixture of digestive fluids.

The cleaner mimic. One of the few cases of mimicry reported among vertebrates is that of a so-called cleaner fish. This example involves a particularly close model imitation involving shape, coloration, and behaviour. The

The wrasse model

model, a wrasse (*Labroides dimidiatus*) of the Indo-Pacific Ocean, is known as a cleaner fish because it removes and eats externally attached parasites and, occasionally, damaged skin fragments from other marine fish. It occupies specific sites, or territories, on coral reefs, where, within a six-hour period, the individual cleaner may be visited by up to 300 other fish seeking its services. The other fish are attracted by the conspicuous black and white coloration of the cleaner and by its dancelike swimming pattern, in which the tail fin is spread and the posterior part of the fish oscillates up and down. The fish undergoing cleaning acts as though it were in a trance, while the cleaner fish cleans its body, including the inside of the mouth and gills. Even large predatory fish allow themselves to be cleaned, and the much smaller cleaner almost invariably emerges uninjured from their throats. It is quite apparent that the cleaners are protected from these predators although neither inedible nor capable of self-defense.

At the cleaning stations of the cleaner fish, there is often found quite another fish, the sabre-toothed blenny (*Aspidontus taeniatus*). It is similar to the cleaner fish in size, coloration, and swimming behaviour, and it even exhibits the same dance as the cleaner. Fish that have had experience with the cleaner position themselves unsuspectingly in front of this mimic, which approaches carefully and bites off a semicircular piece of fin from the victim and

Aggressive mimicry in birds

Superficial resemblances of cuckoos to the sparrowhawk and shikra frighten other birds from their nests, allowing the cuckoos to deposit their eggs in them.

The parasitic whydah deposits its eggs in the host finch's nest. The young whydah mimics the mouth pattern of the young estrildid finch, thereby triggering feeding behaviour by the estrildid host.

eats it. After having been repeatedly bitten in this way, fish become distrustful even toward genuine cleaners. Observations in the wild indicate that younger fish are the principal victims of the mimic, whereas older fish avoid it whenever possible. It is unlikely that the ability to discriminate between the mimic and the model develops automatically with age and is independent of experience; this is borne out by the finding that adult fish kept in an aquarium and not previously exposed to the mimic confuse cleaner and mimic just as younger fish do. If such adult fish are kept with the mimics for a certain length of time, however, they eventually avoid these and the genuine cleaners. The obvious conclusion from these experiments is that other fish cannot distinguish between the model and the mimic without having had experience with both. Evidently victims of the mimic seek out and learn characteristics that enable them to distinguish between reliable and unreliable cleaners—that is, between the model and mimic, respectively. The most successful individuals among the mimics, therefore, are those that most confuse their victims. As a result, the further development of the mimic is steered in the direction determined by the characteristics of the cleaner; for example, the model occurs as a number of local races within its area of distribution, each of which shows its own peculiarities in coloration, such as a small or large black vertical stripe at the base of the pectoral fins or an orange-red spot on the flanks. In every case, the local population of the mimic shows the same special coloration as does the model in that particular area (see Figure 1).

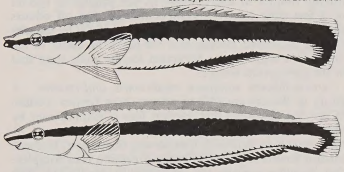

Figure 1: Differences and similarities between (top) the cleaner wrasse (*Labroides dimidiatus*) and (bottom) its mimic, the sabre-toothed blenny (*Aspidontus taeniatus*).

One of the interesting and highly unusual aspects of the cleaner–mimic relationship is that the individual characters of the mimicry pattern, especially the behavioral ones, have been traced to their origins. Certain characteristics, such as body size and shape and swimming pattern, amount to chance similarities. The mimic's drive to approach other fish, for example, is a specialization of a more general pattern, observable in non-mimicking relatives of the blenny, involving searching for food on suitable surfaces. The basic colour pattern of light and dark horizontal stripes is characteristic of fish that swim in open water, but the actual coloration of the mimicking blenny, owing to the forces of natural selection, bears a close resemblance to the cleaner wrasse. Interestingly enough, the blenny alters its coloration with its motivational state and adopts the appearance of the cleaner only under the specific conditions of self-confidence and intent to attack. As a group, blennies tend to wriggle while swimming, in order to counteract a strong tendency to sink at the tail. The sabre-toothed blenny, however, when confronted with danger holds the body stiffly without wriggling, allowing the hindquarters to sink somewhat, and advances solely by the use of the pectoral fins, in the manner common to wrasses. Superimposed on this motion is a nodding of the blenny's head, which is typical of approach-retreat conflict behaviour in blennies but which results in a simulation of the swaying dance of the cleaner. The combination of coloration and behavioral signals has a particular significance for the experienced visitor to the cleaner's station and causes it to adopt the posture that invites cleaning. In so doing, the visitor gives the mimic an opportunity to take a bite from a fin.

Behaviour mimicry

Fireflies. A form of aggressive mimicry that relies entirely on behaviour occurs in certain North American fireflies (Lampyridae). Males of these familiar nightflying beetles emit light bursts in flight according to highly specific patterns. The females, usually stationary, respond to the flash patterns of males of their own species with specific patterns of their own. The flying male responds to the appropriate female signal by approaching, landing, and courting. Most adult fireflies are short-lived and do not feed at all, but females of the genus *Photuris* have been found to feed on other beetles, including males of the genus *Photinus.* Upon perceiving a flashing male *Photinus,* the female *Photuris* responds with a flash that mimics the slower response time of the female *Photinus* (Figure 2). As the male *Photinus* approaches, the female *Photuris* even reduces the intensity of her flashes, to resemble more closely the weaker signals of the smaller female *Photinus.* The hapless male, after landing, is seized and eaten by the *Photuris.* In response to males of her own species, of course, the female *Photuris* gives a flash response quite different from that of *Photinus.*

Host mimicry by parasites. Another form of mimicry, sometimes considered an extension of aggressive mimicry, is mimicry of a host by its parasite. Most of the best-known examples occur among birds and represent some of the few known instances of mimicry in that class of animals.

Cuckoos. The European cuckoo (*Cuculus canorus*) is a brood parasite; *i.e.,* it lays its eggs in the nests of other birds, which act as foster parents for the young cuckoos. The most frequent foster parents are various species of small songbirds. Although the eggs of the various host species span a great range of colours and spotting, there is a striking correspondence in appearance between the eggs of the cuckoo and those of the host. Most small birds react unfavourably if they perceive a foreign egg in the nest and either abandon the nest, build another nest right over the first, or eject the strange egg. Each female cuckoo consistently lays eggs of one colour pattern and must therefore parasitize a particular host species. One survey has shown that of 1,642 cuckoo eggs laid in the nests of the correct (matching) hosts, only 8 percent were lost, whereas of 298 in the nests of the wrong hosts, 24 percent were lost. It is logical to conclude, therefore, that a cuckoo that lays its egg randomly, leaving the survival of the eggs to chance, would produce fewer offspring than one that selects hosts whose eggs match her own. Although the control of egg coloration is probably genetically determined, the choice of correct hosts is believed to be the result of a learning

process that takes place when the female cuckoo is a nestling and learns to recognize her own foster parents.

Parasitic weaverbirds. Brood parasitism is also found in African whydahs, or widow birds, of the subfamily Viduinae of the weaverbird family, Ploceidae. Each species of whydah parasitizes a single species of estrildid finch (Estrildidae). In this case, egg colour does not seem to be a factor in acceptance of the parasite's egg, because both groups have pure white eggs. It has been argued that the whydah, many relatives of which have spotted eggs, have evolved white eggs in order to match those of their estrildid hosts.

More significant than the mimicry of egg colour, however, is the highly specific pattern of spots and protuberances at the corners of the mouth (gape) and on the palate, tongue, and lower mandible of the nestling. This pattern, which varies from one species of finch to another, serves as a releaser for feeding behaviour on the part of the parents, which ignore any nestling that does not display the proper pattern for the particular species. In every species of parasitic weaverbird studied, the nestling has been found to match perfectly the mouth pattern of the estrildid host. In addition to mimicking the mouth patterns of their hosts, whydah nestlings also duplicate the specific begging calls and peculiar head movements of their hosts. The coloration of the juvenile plumage of the young whydah is identical to that of the host species, ensuring that the whydah will be fed after fledging. The digestive system of the young whydah is closely adapted to the particular type of food utilized by its host species, unlike that of the young cuckoo, which seems to be able to accept a variety of foods, from insects to mouse meat.

Mimicry of mouth patterns

With each species of parasitic weaverbird closely committed to a single species of estrildid finch, it is obviously important that whydah species not hybridize, for the hybrid offspring would certainly not match either possible host in all of the important features. It is surprising to find seven forms of the paradise whydah (*Steganura*) so similar in appearance that they were once considered races of one species. Each of the seven, however, has its own estrildid host species, indicating that seven species of paradise whydah are represented.

As is frequently the case with closely similar bird species, hybridization is effectively prevented through the use of species-specific vocalizations by the males. An unusual feature of this situation is that each whydah species uses the same vocal pattern as its estrildine host. The young parasitic weaverbirds learn the songs of their host species during the critical learning period common to songbirds generally. As adults, the male whydahs use these estrildid vocalizations and gain response only from females that have been reared by the same foster species. This example is the only known one of a species-isolating mechanism consisting of vocalizations learned from another species. Vocal imitations by some bird species that have not been shown to give rise to mimicry systems are nevertheless frequently called mimicry.

Mimicry to effect pollination and dispersal. In some instances, plants have been found to rely on mimicry to attract insects as aids in pollination or in the dissemination of seeds or spores.

Orchids. Many flowering plants lure insects through the use of bright colours that indicate the presence of nectar. Some orchids mimic other flowering plants without offering any nectar, relying on those that do provide nectar to reward the nectar seekers.

Flowers that resemble female insects

A group of orchids, often known by such descriptive names as fly orchid, bee orchid, and spider orchid, carries the deception further, actually mimicking the insects themselves. The best-known orchids of this type are members of the genus *Ophrys*. The labellum (lip) of the *Ophrys* flower is a specialized median petal that acts as a dummy female of a species of bee or wasp (depending on the species of *Ophrys*), the resemblance being so close that males visit the flower in an attempt to copulate with the dummy female. In the course of precopulatory and copulatory movements, the visiting insect acquires the pollen sacs (pollinia) of the orchid and subsequently transmits them to other blossoms. A similar situation occurs in an Australian orchid, *Cryptostylis leptochila,* which bears a sufficient resemblance to the female of the ichneumon wasp *Lissopimpla semipunctata* to induce copulation by the male wasp.

An important feature in the mimicry of female insects by orchids is flower size. Flowers that are too small do not provide adequate stimulus for the copulatory attempts necessary to plant the pollinia on the insect. Conversely, if the flower is too large for the insect, the insect's head does not reach the stigma of the flower (the female receptor site for pollen), and the pollinia are not deposited on the insect.

The colour of the orchid's labellum is also important in attracting and properly orienting the male insect. The males are more attracted to dark than to light colours and to a contrasting dark spot on a light background. A velvety surface is a more effective attractant than a shiny one. The centre of the labellum of *Ophrys insectifera* bears a dark red spot, almost black, whereas the lateral lobes of the labellum are a somewhat lighter purple-red. Female wasps of the genus *Gorytes,* males of which are highly attentive to this orchid, are black dorsally with dark purple wings. Where the folded wings overlap over the female's body, there is a glistening area closely resembling the shiny central spot on the flower. The overall effect is further enhanced by movements of the flower in the wind.

Flowers that emit pheromones

Odour plays a particularly strong role in attracting male insects to the mimicking orchids. Some female Hymenoptera secrete odoriferous substances (pheromones) that initiate search behaviour in the males and guide them to the stationary females. Such attractant chemicals are usually limited in effectiveness to the producing species or a few close relatives. *Ophrys* flowers give off odours similar to, if not identical with, those produced by females of their associated insects. In a few cases the odour of the flower is a more potent attractant for the male than that of the appropriate female.

Carrion flowers, stinkhorn mushrooms, and mosses. A group of flowers are able to attract dung beetles (certain of the Scarabaeidae) and carrion flies (Calliphoridae) by mimicking the odours of dung or rotting flesh used by these insects as guides to sites for egg deposition. In some carrion flowers (*e.g., Stapelia*) the deception is so complete that blowflies actually lay their eggs in the flowers. The cuckoopint (*Arum maculatum*), which has a metabolic level unequaled among plants, spreads its odour over a wide area by an elevation of temperature that increases the vaporization rate of the volatile odour substance. An elaborate mechanism in the cuckoopint ensures that a pollen-laden visitor remains long enough to deposit the pollen. The sheath of the floral structure, upon which the insect lands, is made slippery by oil droplets with the result that the insect slides down into a cup equipped with a ring of spines to prevent escape. In trying to climb out, the insect deposits pollen on the tiny female flowers, from which the insect receives nectar. During the night, the male flowers mature and cover the resting insect with pollen. Then the spines shrink, and the insect is released (Figure 3). The production of the attractant odour occurs at midday, when many carrion-seeking insects are active, on the day before the male flowers mature; the timing of the cuckoopint's odour production is controlled by a substance produced by the male flowers six to 18 hours before maturity.

The trap of the cuckoopint

A similar situation is found in stinkhorn mushrooms of the genus *Phallus,* found in woodlands and meadows of the Northern Hemisphere. The cap of the young stinkhorn is covered with a thick, greenish-black, shiny layer of gelatinous spore slime (gleba), which is eaten by blowflies and other insects attracted by the carrion-like odour. The spores pass through the digestive tracts of the insects and are voided with the feces, thus ensuring dispersal.

Some mosses (*e.g.,* some members of the genus *Splanchnum*) have flowerlike structures that are designed to attract flies to aid in spore dispersal. Insects are attracted by the mimic of a nectar-bearing true flower and by a carrion-like odour.

Defensive egg dummies. Several species of passionflower (*Passiflora*) and cruciferous plants (*Streptanthus*)

decrease their attractiveness to ovipositing female butterflies (thus reducing predation from butterfly larvae) by producing pigmented callosities that mimic the eggs of those insects. Prior to ovipositing, females visually assess the egg load on individual host plants, avoiding parts that are already "occupied." Removal of the egg mimics significantly increases the probability of an oviposition relative to similar, intact plants.

Mimicry within species. The three essential participants in mimicry—model, mimic, and receiver—need not always be members of different species. In mimicry of the host by a parasite, for instance, the host species provides both model and receiver. In another type of mimicry the mimic and receiver are members of the same species. An example of this type of mimicry is found in the small South American characoid fish *Corynopoma riisei,* in which the gill cover of the male is elongated into a thin, whitish stalk that terminates in a small, blackish plate. During courtship, the male raises the stalk and waves it jerkily in view of the female, who mistakes the tip of the stalk for an edible object, such as a tiny crustacean. As the female nears the male to grasp this supposed prey, mating takes place.

Egg mimicry in cichlid fishes

Another remarkable form of mimicry within the same species occurs in the African mouth-breeding cichlid fish of the genus *Haplochromis.* The female takes the eggs into her mouth immediately after they are laid, even before the male can fertilize them. The male, however, carries conspicuous yellow or orange spots near the base of the anal fin, which closely resemble the eggs of the particular species. Although the female is inhibited from eating while carrying eggs, she is strongly motivated to pick up loose eggs in her mouth. The male displays the fin spots to the female while releasing sperm; the female, as she attempts to pick up the false eggs, takes in sperm that fertilize the eggs in her mouth. In this case the model (real eggs), mimic (false eggs), and receiver (adult female) are all of the same species.

THE EVOLUTION OF MIMICRY

The effectiveness of warning systems. There is considerable experimental evidence to illustrate how effectively predators learn to avoid certain adverse stimuli. Chickens conditioned by electric shock to avoid drinking dark green water drank progressively more from paler solutions in proportion to the intensity of the colour. This experiment suggests that even an incomplete warning system provides a modicum of protection. The degree of protection provided is also affected by the strength of the punishment; after strong shocks the chickens drank only from very light coloured solutions. In the presence of severe punishment, an improved warning system made little additional effect once a threshold level was reached.

In other experiments, starlings (*Sturnus vulgaris*) were fed normal mealworms, two segments of which had been painted orange. To provide aposematic "models," the experimenter made other mealworms distasteful and painted the same segments green. "Mimics" were marked with green but not rendered unpalatable. There is no known instance in nature in which animals employ green for warning; there was therefore no possibility that the birds had already learned to avoid the experimental colour pattern. Before long the green-marked worms were completely avoided, regardless of palatability, even when the ratio of edible to distasteful was 60:40. This indicates that the number of mimics can exceed that of the model, when the resemblance is close, without loss of protection. When the ratio was increased to 90:10, 17 percent of the mimics were avoided, probably sufficient to a selective advantage in nature. Although a test bird would occasionally peck at a model, then reject it, the same action was sometimes shown to a mimic that it had picked up, suggesting that a premature response had been subsequently corrected.

The reconstruction of evolutionary pathways. Analysis and understanding of a given mimicry system require a rather comprehensive knowledge of morphology, behaviour, ecology, and mutual relationships of animals usually in different classes—for example, wasps (Hymenoptera), flies (Diptera), insect-eating amphibians, reptiles, birds, and small mammals. Tracing the evolution of such a complicated system requires a detailed acquaintance with a large group of forms related to each of the animals involved. Such data, in fact, are seldom available.

Reconstructing the evolution of a case of mimicry within the same species, however, is relatively simple, requiring detailed knowledge of but one rather narrow taxonomic unit. Such a reconstruction is valuable, because mimicry is an indispensable tool in the study of the evolution of animal communication, and usually starts from conspicuously elaborated signals, which postulate a signal receiver interested in them. The receiver practically always has undergone a special molding toward optimal receiving of the signal. The mutual adaptations of the sender and the receiver must be examined separately.

Mimicry and animal communication

This examination is easily made, so far as the evolution of a reaction or of a receiving mechanism is concerned, in all predators trying to find their prey and in all prey animals attempting to escape an approaching predator. The suppression of signals may be studied in predators trying to sneak up on a prey unnoticed. The elaboration of a signal, which must, of course, be important to the receiver, can only be studied after consideration of compensatory adaptations in the receiver and in situations where the sender has a one-sided interest in the signal. The deceiving signal can be derived only from one of two types: a signal developed by the receiver and another signal sender in their common interest or a signal emitted by another signal sender and made use of by the receiver only in its own interest. Both cases, by the definition given above, are called mimicry. An additional advantage is that the model is known to be the final stage toward which the mimic will evolve (so far as the signal characters are concerned),

thus indicating a trend in evolution that is still operating and that probably over time will further elaborate the mimetic signals.

If the female *Haplochromis* fish were to discriminate between real eggs and the egg dummies of the male and were to stop reacting toward the latter, her eggs would remain unfertilized. In such cases of deceptive signals developed within the same species, natural selection operates against better signal discrimination on the part of the signal receiver.

The importance of the signal receiver. Fundamental characteristics of mimicry are determined mainly by behavioral properties of the signal receiver. A precise knowledge of the identity of the receiver and a thorough study of its behaviour are therefore indispensable for the understanding of mimicry. Moreover, mimicry gradually merges into other sender–receiver systems. Palatability is a matter of degree; whole ranges of distastefulness therefore exist, even in the mimics, model and mimic in the case of Müllerian mimicry being equally unpalatable and sharing the same warning coloration. Müllerian mimicry could be considered not to be true mimicry, after all, because no one is deceived, and it is impossible to designate one as model and the other as mimic.

Although all individuals of a given wasp species look alike and are all equally protected, this phenomenon is not usually called Müllerian mimicry, simply because the signals were not independently evolved, a property known as convergence. Because, however, the male wasps have no protective properties but retain their group-specific warning coloration, this is Batesian mimicry, although model and mimic are of the same species and their signals homologous (evolved from the same source). Convergence (or independent evolution) of the signal characters, therefore, is essential only for the so-called Müllerian mimicry, and thus Müllerian mimicry is distinguished from other cases of signal standardization. The typical (Batesian) mimicry merges into Müllerian mimicry if the difference between the consequences for the receiver of reacting similarly to model and mimic diminishes; and by homology of the signal characters it further merges into general signal standardization.

Mimicry and mimesis

An insect may be protectively coloured to resemble, for example, a wasp or a twig. In the first case the coloration is called mimicry, in the second, mimesis, or protective coloration. The difference lies within the signal receiver. If the mimetic signal does not release any reaction in the receiver, the mimic is said to exhibit mimesis. This distinction is illustrated by the experiments of the Dutch biologist L. de Ruiter with stick caterpillars, which, by virtue of their close resemblance to twigs, are protected against insect-eating birds. As soon as the number of "twigs" becomes too large, however, the bird develops an interest in them, attacks some real twigs, and also finds some caterpillars. If one positive experience with the caterpillar has the same weight as a negative one with the twig (the signal remaining unchanged), the relative abundance of caterpillars and twigs determines whether all twigs are mistakenly exterminated or whether the feeding reaction toward twiglike objects disappears, thus protecting the caterpillars.

This study again illustrates the importance of the bird's ability to decide correctly which is the model and further shows how easily an object (the twig) may quite involuntarily become a "mimic." Another example illustrating the importance of a correct model is found in the common farming relationship between ants and aphids. The protuberances, called the siphones and cauda, on the abdomens of aphids resemble respectively the bases of the antennae and labium of the ant's head. The aphid's abdomen is thus mistaken by the ant for the head of a fellow ant, thereby eliciting the food-begging response, which is identical with milking. Saturated ants in turn even try to feed the abdomens of the aphids. Aphid species with reduced abdominal siphones use their hind legs as antennae dummies, the movements elicited being originally defensive movements. This situation is exactly the way in which mimicry arises. Mimetic characters need not have evolved under the selection pressure of mimicking; in fact, their earliest evolutionary stages could not even have been brought about in this way. All cases studied thus far can be traced back to an incipient stage of deceptive resemblance, initiated as a preadaptive, nondirected by-product of pre-existing species-specific features, thus providing a point of attack for new selective pressure.

The effects of selective pressure. The selective consequences for the signal receiver of responding to the model are always positive (the reaction would disappear if, on balance, it were unfavourable to the receiver). The mimic always has a selective advantage in releasing the reaction from the receiver. An unfavourable signal by the mimic would also disappear by natural selection.

The selective consequences of signaling by the model

The selective consequence for the model eliciting and obtaining the reaction from the receiver may be of several types. Consequences may be absent, if the model is an inanimate object on which natural selection does not act. They may be negative, if the model is non-aposematic (non-warning), such as the tiny crustacean, usually eaten by the signal receiver and mimicked by the male *Corynopoma* characin in order to attract the female. Or they may instead be positive, as in the wasp, which remains alive if it is avoided by the predator; in the cleaner, which feeds on parasites harmful to other fish; or in those hymenopteran females whose male-attracting signals are mimicked by certain orchids. Mutual interest is present between model and receiver in cases of aggressive mimicry where both parties belong to the same particular species and also in typical Batesian mimicry.

Constant learning by the signal receiver results in a strong selective pressure on the mimic against detectable differences from the model, but at the same time it also exerts a complementary strong pressure on the model to develop just such new differences from the mimic. Typically, it is the group of songbirds parasitized by cuckoos that has developed the most divergent egg-colour patterns; the group of estrildine finches parasitized by whydahs that has developed particular gape patterns; and among the cleaner wrasses the species *Labroides dimidiatus* mimicked by the blenny *Aspidontus* that develops into many different local races.

There is a boomerang effect, characteristic of the parasite–host relationship, that the more successfully a bird rears young cuckoos, the more certain it is that it will lose its own young, because they are killed off by the young cuckoo. Parasites that are too successful, therefore, harm themselves, for each female cuckoo needs several nests of the same host species for her eggs. In an area that contains particularly successful cuckoos, the number of reed warbler nests has been found to decrease from year to year, while the percentage of nests parasitized by cuckoos increases from year to year. This ratio means that a cuckoo that is too well adapted reduces the availability of its own hosts, while one insufficiently adapted kills off its own offspring. Presumably, selection in both directions produces a continual oscillation in the densities of hosts and cuckoos.

A similar dilemma is inflicted on human beings, who act as predators against weeds in crop fields and by winnowing select the wanted seeds from the usually smaller weed seeds. The flax dodder (*Cuscuta epilinum*), for example, which grows as a creeper around flax and linseed plants and damages them, originally had small seeds that could be easily separated from the larger flax seeds. By a mutation that produced twin seeds, the dodder has evolved the capability of being separated out and planted with the desirable flax seeds. This mutant of the flax dodder is now cultivated and spread by growers, despite being against their interests. In this case, the parasite mimics the protected plant, receiving the same protection.

The effects of geographic distribution and population density. It has been postulated that the model and the mimic should always occur in the same area—*i.e.*, be sympatric. They need not always be sympatric, however, but must always have a signal receiver in common: a model might be in Africa, for instance, and its mimic might be in Europe (or vice versa), functionally connected by a migratory bird.

Another postulate, that mimics must naturally be less

Relative populations of model and mimic

numerous than their models, means, correctly stated, that the receiver has to meet the mimic less often than the model; this postulate is based on the assumption that one experience with the model has the same aftereffect, the same weight, as has one with the mimic. This assumption, however, has been proved not always to be so; in fact, the negative experience seems usually to be the stronger one. This negative experience may result from an encounter with the model (such as a wasp) or with the mimic (for example, the sabre-toothed blenny). There might be more wasp mimics than wasps, but in cases such as that of the cleaner wrasse mimic, the mimic probably has to be less numerous than the model. The protective power of the model, of course, is reduced with an increasing number of mimics, because the predator may eat larger numbers of them before his first encounter with the model.

The importance of mimicry to evolutionary theory. The mimicry hypothesis emerged in the middle of the Darwinian controversy and provided an ideal test case for the views of Charles Darwin and his contemporary Alfred Russel Wallace on the operation of natural selection in the evolutionary change of living organisms. It is now quite evident that the basic theory of natural selection is correct and that the theory is strengthened by many detailed studies of the process by which a mimetic resemblance is brought about and selected for. In addition, investigating suitable cases of mimicry provides important insight into the evolution of signals and the "semantization" process by which signals get their meaning.

The Philosophy of Mind

One attribute that sharply distinguishes man from the rest of nature is his highly developed capacity for thought, feeling, and deliberate action. Here and there in other animals, rudiments, approximations, and limited elements of this capacity may occasionally be found; but the full-blown development that is called a mind is unmatched elsewhere in nature.

The task assumed by the discipline known as the philosophy of mind is to examine and analyze those concepts that involve the mind (including the very concept of the mind itself) in an attempt to discover the nature of each of these concepts, the relations between them, how they are to be classified, and how they are to be related to certain other concepts—especially to the concepts of matter and energy, the human body, and, in particular, the central nervous system.

It should be clear that the range of topics in the philosophy of mind goes far beyond what is intended in everyday discourse by "mind." When, for example, the layman speaks of someone as having "a good mind" or as pursuing "the pleasures of the mind," he is thinking of those particular activities that have to do with abstract reasoning, intellectual pursuits, and the exercise of intelligence. The "mind," as the term is used more technically in this article and in the philosophy of mind in general today, encompasses a variety of elements including sensation and sense perception, feeling and emotion, dreams, traits of character and personality, the unconscious, and the volitional aspects of human life, as well as the more narrowly intellectual phenomena, such as thought, memory, and belief.

PHILOSOPHY OF MIND AS A DISCIPLINE

In distinguishing the field of philosophy of mind from other sorts of investigation, one immediately obvious feature is its subject matter, the nature of mind and its various manifestations. This serves to distinguish it from empirical sciences such as astronomy and physics, which study matter in motion; from formal disciplines such as geometry and algebra, which study mathematical relationships; and from other fields of philosophy such as the philosophy of art and the philosophy of law. But subject matter alone does not serve to distinguish the philosophy of mind, since the mind is the subject of investigation of other disciplines as well—especially of psychology and of certain phases of biology, physiology, sociology, and anthropology. In comparison with these fields, it is by its method that the philosophy of mind is to be distinguished; for it proceeds not by the methods of empirical investigation—detailed sense observation, the formulation of predictions, the construction of experiments, inductive confirmation, the inventing and testing of contingent generalizations, theories, and laws—but by the method of philosophical reflection. That method consists of the examination of meanings, the analysis and clarification of concepts, the search for necessary truths, the use of deductive inference, reductio ad absurdum, and arguments with infinitely repeating terms and other forms of a priori reasoning, and the attempt to arrive at and evaluate the fundamental principles that underlie and justify the basic forms of human thought and endeavour.

Relation to other fields

Although the philosophy of mind is a distinct field of investigation, it has many important relations with other fields. First, its methods, being those of philosophy in general, are to be tested by the fruits that they have yielded in other areas: if a method has been successful in other areas, it is reasonable to try it here; if unsuccessful in other areas, it is suspect here. Second, the conclusions achieved in such fields as epistemology, metaphysics, logic, ethics, and the philosophy of religion are quite relevant to the philosophy of mind; and its conclusions, in turn, have important implications for those fields. Moreover, this reciprocity applies as well to its relations to such empirical disciplines as neurology, psychology, sociology, and history. Thus, the philosopher of mind must keep informed of developments in all related fields of investigation.

THE SEARCH FOR A CRITERION OF THE MENTAL

The bewildering variety of phenomena that fall under the heading of the mind or the mental was suggested earlier in a list. The question arises, however, whether there is some attribute that all of these mental phenomena have in common, something that characterizes them or that can serve as a criterion of the mental. More specifically, are there certain features that are either necessary or sufficient for mental phenomena?

Purposeful behaviour. Whenever a man watches a hungry animal using stealth and cunning in searching out, attacking, and killing its prey, he cannot but believe that the animal has a purpose and uses intelligence in achieving his goal. Whether it be a team of scientists designing a way of launching a man to the Moon, an ape figuring out how to screw two pieces of pipe together to get a banana that is out of reach, or—at a much lower level—a lobster trying to get out of a pot of boiling water, there seems to be a mind at work. Somewhere, as the phenomenon is traced farther down the ladder in the scheme of things toward inanimate matter, a line must eventually be drawn; but there is no agreement about where it should be drawn. It would be widely agreed that an ovum that has just been fertilized does not have a mind and that a normal adult does—but it is impossible to say exactly where in human development the change occurs. On the other hand, it would be just as erroneous to conclude that because there is no sharp dividing line there is no change as it would be to conclude that red and orange are the same colour because no sharp line divides them in the spectrum. In both instances there exists a transitional range within which the designation of a dividing line would be purely arbitrary; but at either end beyond that range a clear and definite difference is evident.

The question may then be raised as to how adequate purposeful activity is as a criterion of the mental. A major issue arises from the fact that a mechanical device can

be built that exhibits the kind of activity ordinarily called purposeful—a surface-to-air missile, for example, so designed that it will hunt for a jet aircraft by searching for, and zeroing in on, the heat exhaust, thereby finding and destroying the aircraft. Such devices, known as "servomechanisms" (of which a thermostat is a simple example), achieve an end state by systematically diminishing any deviation from that predetermined end state. There are, in addition, the modern computers, capable of receiving, storing, and retrieving information, of making inferences, and of communicating information. Near the height of modern sophistication in machine technology are those machines, combining servomechanisms and computers, designed to roam the surfaces of other planets, gathering, processing, and sending back data and thus providing what would seem to be paradigms of purposeful behaviour and raising the question whether such systems are examples of minds at work. There are three possibilities worth considering: (1) one might continue to hold that purposeful behaviour is the criterion of the mental but argue that these devices do not really meet the criterion of exhibiting purposeful behaviour; (2) one might hold that the more complex of these devices do indeed have what can be called minds—simple and rudimentary, to be sure, but still minds—"artificial intelligences" that in a very literal sense have beliefs, think thoughts, solve problems, and achieve goals; or (3) one might give up the criterion of purposeful behaviour, or at least give it up as a *sufficient* condition of the mental.

Teleological mechanisms versus mental activity

Someone defending possibility (1) would attempt to find some feature of purposeful behaviour that could not be found in any mechanical device. He might hold, for instance, that the alleged purposes of mechanical devices are built in by their designers and that it is not up to the devices to choose their purposes. Against this line of argument, however, others might assert that for a large number of organisms the basic purposes are also built in through the genetic mechanisms of heredity: basic biological drives for food, reproduction, and safety govern most of their purposeful behaviour. People who accept this point of view argue that, in most cases, the organism is not really free to choose its purposes. On this argument, even human beings seem to display such built-in purposes; and it would be specious, at least in this instance, to deny them minds on this account.

Conceding that organisms have some built-in controls, the defender of the first possibility might then argue that the higher organisms have a flexibility that allows for the development of purposive methods that are novel. Machines, he would allege, solve problems only by the methods designed into them, whereas creatures with minds can invent new methods. Against this line of argument others might argue that machines have been developed to use trial and error, analyze the outcomes of trends, and come up with new approaches that are more successful than earlier ones, and that, in an important sense, such machines might be called creative, since they "learn from experience" and use "ingenuity." Many observers assume that this trend in machine technology will continue and that machines will be developed with much, if not all, of the flexibility of many of the creatures that would unhesitatingly be acknowledged to have minds.

Machines, man, and inventiveness

The basic issue, then, is whether a philosopher would want to say that a machine has a mind if it exhibits the flexibility in purposeful activity of, say, a normal seven-year-old child, who undoubtedly has a mind. In accepting possibility (2), the philosopher would maintain that such a machine does indeed have a mind and exhibits a wide range of the phenomena called mental. Many contemporary philosophers, however, would reject that thesis, considering it a needless flaunting of common sense and an affront to ordinary language to speak of a heat-seeking missile, for example, or even a lunar robot, as having a mind. Because something essential still appears to be omitted, further attempts are made below to determine the essence of the mind.

Intentionality. Another characteristic of the mental is sometimes thought to be found in certain ways in which an individual may be said to have something as his object. Thus, thinking, believing, desiring, and other such attitudes are thought to resemble one another in that they may be said to take an object, or to be directed upon an object, in a way quite unlike anything to be found in what is purely physical. "Intentionality" is the term for this way of being directed upon an object. The concept had been emphasized by some of the Scholastics and was introduced to modern philosophy in 1874 by a German philosopher and psychologist, Franz Brentano, and clarified and defended by a U.S. philosopher, Roderick M. Chisholm, in the 20th century.

The nature of intentionality. The idea of intentionality can be explicated in the following way: if one imagines three objects arranged as in Figure 1 and then supposes that the wind blows them so that they are arranged as in Figure 2, there results, from the physical point of view, simply a new arrangement. From a psychological point of view, however, something radically new also has been introduced: one object now appears to be pointing to another—aimed at or directed toward it. It would seem that such pointing cannot be accounted for if the observer confines himself to the purely physical facts of the new configuration and that his mind has to be brought in to account for the feature of pointing to. Thus, intentionality is prima facie a reasonable candidate for the criterion of the mental.

Added characteristic of aim or direction

Figure 1: Three arbitrary physical objects in meaningless configuration (see text).

Intentionality is exhibited in a variety of phenomena. Thus, if a person experiences an emotion toward an object—*e.g.*, loves, fears, pities, envies, or reveres it—he has an intentional attitude toward it. Other examples of intentional attitudes toward an object are: looking for or expecting, believing in, doubting or conjecturing about, daydreaming, reminiscing, imagining, favouring, or disapproving—a list that seems to go on endlessly. Because it clearly comprises so many of the things that one thinks of as typically mental, intentionality, being of broader scope than purposefulness, would seem to be a more appropriate choice than purposeful behaviour for the criterion of the mental.

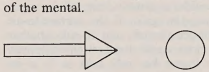

Figure 2: Physical objects with intentionality.

One of the characteristics of intentionality is what the Scholastics called "inexistence": a man may be intentionally related to an object that does not exist or to an event that does not occur. Thus, what a man looks for may not exist, and an event that he believes to occur may not occur at all. In contrast with such a nonintentional phenomenon as bumping into something, in which the object bumped into must be real, looking for something (an intentional act) does not necessarily imply that the object looked for exists. Similarly, in contrast with an explosion's resulting in the fact that many were hurt, a witness's believing that many were hurt (again an intentional act) does not imply the fact that many were hurt. Thus, existence and truth are irrelevant to intentionality.

Though this possible relationship to nonexistent objects as opposed to existent ones is a necessary feature of intentionality, it is not sufficient to define it, for there are phenomena that are equally concerned with nonexistent essences that are nonetheless nonintentional. "That lady resembles a mermaid," to use an example of Chisholm's, may be a true sentence even if mermaids, though having an essence, do not exist. Similarly, "That metal will ignite at temperatures above 1,000,000°" may be true whether or not such temperatures exist. Thus, intentionality requires further characterization if its scope is to be narrowed to exclude such examples as these.

Another characteristic of the intentional state is that not every description of its object will be appropriate. Assuming that his pen is the millionth pen produced this year, for example, a man may be in the intentional state of searching for it as his pen but not in a state of searching for the millionth pen produced this year; similarly, he may believe this is his pen and yet not believe that this is the millionth pen produced this year. This second feature of intentionality, often called "referential opacity," is such that a true sentence asserting an intentional state will become false when some alternative description of the object of that state is substituted for it (it is false that he is searching for the millionth pen).

There is no general agreement on the best way of conceiving of intentional phenomena. Brentano, at one point, thought of intentionality as being a relation between a subject and an entity, in which the entity is something that might or might not exist; but difficulties arise in characterizing the ontological status of such an entity—*i.e.,* its kind of reality. More popular today are certain linguistic approaches: intentionality may be viewed, for example, as it was by Rudolf Carnap, a philosopher of science, and others, as a relation between a subject and a piece of language or, as others have explained, as a relation between a subject and a linguistic practice or linguistic role. Under this view, the intentionality consists not in the relation of a subject to an *essence* (that of a millionth pen) but in its relation to a *sentence* ("This is the millionth pen . . . ") that has that alleged essence as its meaning. It remains to be seen whether such approaches will succeed in dealing with all intentional phenomena. It would seem to pose particular difficulty in those cases in which the intentional state is overtly directed toward some existent entity, with language playing a minor or null role, as in situations in which one feels anger, pity, or love toward someone; or when an animal is stalking its prey (which involves an intentional state). In such instances, an analysis in terms of linguistic attitudes would seem wide of the mark.

The scope of application of intentionality. The question of whether or not intentionality can apply to nonliving physical systems has become a controversial issue. If it can apply, then either intentionality would have to be given up as an exclusive criterion of the mental or else one would have to say that such systems exhibit some mental characteristics.

Application of intentionality to nonliving systems

It will be useful to consider a system designed for some purpose, taking the example again of the surface-to-air missile that searches for jet aircraft, and to ask whether it has intentionality. It does satisfy the first characteristic mentioned above: that it can be truly said to be a jet searcher regardless of whether there are or have been any jet aircraft (one could similarly design a unicorn searcher built to detect unicorns by their special horn). The question next arises whether some descriptions of the object are inappropriate. On the supposition that all and only jet aircraft have a component made of compound *X,* one can ask whether it would be true of the missile that it searches for things with a component made of compound *X.* It would seem that—unless this compound chances to be what the search system was sensitized to—the foregoing statement is a false, and thus an inappropriate, description of the device; and if so, it is plausible to regard the missile as a physical system with intentionality as that notion has been here characterized. An intentional physical system, however, would have to be of considerable complexity. One would not want to say that the left-hand complex in Figure 2 was pointed to the right-hand figure unless he had in mind that, if the right-hand figure were to shift its location, the left-hand complex would shift appropriately. If it did keep shifting appropriately, however, it would seem proper to say that it points to the right-hand figure. The question remains, however, whether *all* intentional phenomena are capable of appearing as instances in nonliving physical systems—whether such a physical system could have, for example, an emotion toward something, daydream about something, or be amused by something. Here it is very difficult to cite a plausible case; it would appear that one would have to strain such concepts considerably to apply them to nonliving systems.

The thesis that intentional phenomena are the essence of the mental thus seems problematic. Its suggestion that the jet-searching missile has a mind or partakes of the mental, as appeared in the discussion of the criterion of purposeful behaviour, would, to many scholars, appear to be quite implausible. Nor does it seem that the trouble lies in the limited number of intentional phenomena found in the missile. Even the lunar-exploration machines, with all of their flexibility and multiplicity of functions, would not be said by most analysts to have minds.

It might be possible to save intentionality as the criterion of the mental by insisting on the presence of such highly sophisticated intentional phenomena as emotions, daydreams, or amusement, but then one would have to deny minds to those human beings who lack a sense of humour, never daydream, or are cold-bloodedly unemotional, which does not seem correct either. Some progress can be made here if the question is asked whether intentionality is a necessary condition of all mental phenomena—whether there are any phenomena that are mental but nonintentional. Examples of a mental phenomenon that can most plausibly be said to be nonintentional are sensations, such as feeling pain, which lack both of the aforementioned characteristics of intentionality—inexistence and referential opacity. A man cannot feel a pain that, unbeknownst to him, does not exist; if he feels pain, there must be something he feels. Moreover, if a man feels pain, and the pain is identified with the effect of a tumour, then he does feel the effect of the tumour.

Sensations, which thus lack both of the characteristics of intentional phenomena, are not just an odd counterexample; not only do sensations comprise a large and central group of mental phenomena, but they also call attention to an important aspect of many other mental phenomena, viz., subjective experience. The arrow in Figure 2 may point to the circle, but it does not have the subjective experience of pointing, it does not feel itself pointing; and the jet-searching missile does not experience how it feels to be searching for jets. But when a person is in an intentional state, directed toward an object, he—at least sometimes—experiences, feels, or is aware of that directedness.

Clearly, this usage of "intentionality" differs somewhat from that found in medieval philosophy; and there are other features of the concept, not covered here, that are stressed by Phenomenologists and Existentialists.

Subjective experience. It is often maintained that the essence of the mental consists of states of consciousness taken as subjective experiences. When a person wakes up or regains consciousness after a general anesthetic, a host of experiences of colour and light, sounds, feelings, thoughts, and memories flood in on him. As far as his objective, observable behaviour is concerned, he may be lying unmoved and unmoving; but as far as his state of consciousness is concerned, he may be undergoing a series of subjective experiences. To take an example, when a person sees a scarlet patch, he experiences the homogeneous, spread-out, distinctive scarletness present before him. A blind or colour-blind person who has never experienced scarlet would not have the awareness of scarlet that the normally-sighted person has. He might have some vague idea, as did the hero of the story told by John Locke, a 17th-century British Empiricist:

Consciousness, "raw feels," discrimination

> A studious blind man, who had mightily beat his head about visible objects, and made use of the explication of his books and friends, to understand those names of light and colours which often came in his way, bragged one day, that he now understood what scarlet signified. Upon which his friend demanding, what scarlet was? the blind man answered, It was like the sound of a trumpet.

This reply is not totally wide of the mark; but any sighted person will have a far more precise idea of scarlet than that. What he has and what the blind person lacks is something that philosophers have called the "raw feel" of scarlet, that peculiar and special way scarlet looks.

The subjective experience of scarlet is to be contrasted with the discrimination of scarlet things. One could imagine a blind person who was able to discriminate scarlet from other colours by the use of optical instruments (*e.g.,* spectroscopes with Braille printouts). But he would lack

the subjective experience of the colour; he would not know the look of scarlet. Defenders of this view would claim that there is a great variety of subjective experiences and that the experience of colours is only one of them. Sensations (*e.g.,* the experiences of pain, tickles, throbbings, pangs, nausea, and tiredness) provide another such example. Still other subjective experiences include: the experiencing of images (afterimages, memory images, and others); feelings of exultation, depression, pride, anger, fear, and love; and thoughts (imaginings, surmisings, doubtings, and recollectings). All of these are episodes, occurring at a particular time and place, in which the subject is in a state of awareness that has a particular content.

Adequacy as a criterion of the mental. The question now arises of how adequate subjective experience is as a criterion of the mental—whether, though it is obviously a sufficient condition for something to be mental, it is a sufficient condition for something to have a mind. The Scotsman David Hume, an 18th-century philosophical Skeptic and historian, once asked whether a creature that had but one state of consciousness could be said to have a mind and concluded that it could not. In his view, it takes, at the very least, a number of states of consciousness linked by memory before one would say that the creature has a mind; and it may be that there has to be a certain level of complexity in the nature and relation of the conscious states for there to be a mind.

The unconscious, dispositional, behavioral

It is doubtful, however, whether consciousness is a necessary condition for the mental. Before Sigmund Freud, it would have been widely agreed that the notion of unconscious mental phenomena was logically impossible—a contradiction in the very terms. That view had one important exception, however: Gottfried Wilhelm Leibniz, a 17th-century Rationalist and mathematician, held that there are *petites perceptions* of which the subject is unconscious. They are so slight, so similar to others, so familiar, or in such a crowd of other perceptions, that the subject is unaware of them at the time. One of the examples that Leibniz cited is the person who is unaware of the roar of the waterfall or the rumble of the mill if he has lived nearby for some time. Leibniz seemed to have had in mind what modern psychologists call "subliminal" perceptions, viz., those below the threshold of awareness but still capable of leaving some effects on the mind. But Leibniz confined unconscious states to perceptions; he would not have allowed unconscious beliefs, desires, emotions, or judgments.

It was Freud's great contribution to have discovered a range of phenomena of which the patient was unconscious but which were very much like typically mental phenomena, especially in their behavioral manifestations. In the light of such similarities, it was plausible to extend the concept of the mental to include these unconscious phenomena—especially since they were such that the patient could become conscious of them through hypnosis or psychotherapy. Freud postulated a mechanism that he called "repression" to explain why the patient is unconscious of them.

In addition to the subliminal and the unconscious, there are more familiar characteristically mental phenomena that do not consist of states of consciousness. When a man falls into a dreamless sleep, he does not lose all his beliefs or abandon all his goals, he does not cease wanting a better world or being artistic or imaginative or lazy, nor does he forget how to do arithmetic or speak French. A person is not jealous of someone only when thinking of him, nor does a businessman have confidence in the dollar only when concentrating on business. Obviously, these mentalistic characteristics can apply in a dispositional way to people who are not at that moment expressing or exhibiting the disposition.

Furthermore, as Gilbert Ryle has pointed out in great detail, a person may use his mind on many occasions without the feeling of subjective experiences. As he says,

> When we describe people as exercising qualities of mind, we are not referring to occult episodes of which their overt acts and utterances are effects; we are referring to those overt acts and utterances themselves. (This and the following quotations attributed to Ryle are from *The Concept of Mind* by Gilbert Ryle. Copyright © 1949 by Gilbert Ryle. To be responsive to one's surroundings, to act intelligently, deliberately, with wit or good grace, to utilize arithmetic or logic, to be sympathetic or coldhearted, to drive alertly or absentmindedly—none of these requires the occurrence of subjective experiences or inner states of consciousness, the immediacy of feelings or sensations. In such activity, there may be nothing going on except performances of a particular kind, and there may be nothing more required except that under further circumstances other performances of a particular kind will be forthcoming. It is, thus, reasonable to conclude that subjective experience is not a necessary condition for the mental.

Ryle's charge of a category-mistake

Those who have put the private events of subjective experience at the centre of the mental have committed what Ryle calls a "category-mistake . . . represent[ing] the facts of mental life as if they belonged to one logical type or category, . . . when they actually belong to another." The mistake consists of taking talk about a person's mind as talk of events in a world parallel to the ordinary world but occult and mysterious. The truth, according to Ryle, is that

> to talk of a person's mind . . . is to talk of the person's abilities, liabilities and inclinations to do and undergo certain sorts of things, and of the doing and undergoing of these things in the ordinary world.

It would be rash, however, to draw the further conclusion that subjective experiences are in no way involved in whatever is mental. Returning to the case of Leibniz' *petites perceptions* that are not experienced, a person can be conscious of them in various ways, either before getting used to them or when they are alone or when their intensity or his own sensitivity is increased; and Freud's unconscious phenomena can become conscious phenomena under favourable conditions. The beliefs that an individual is not aware of in sleep are sometimes the objects of his consciousness, as are his moments of laziness and imaginativeness, his knowledge of arithmetic, and his goals. It is dubious that something that has no connection with states of consciousness could qualify as mental.

Core characteristics of subjectivity. Philosophers deeply disagree on how to characterize what is peculiar to subjective experiences. Some hold that the existence of subjective experience indicates that there are peculiar events that do not occur in the public space–time world that everyone shares and has equal access to but occur only in a private world that each person has exclusively to himself, which he cannot share with others, and to which no one else has access. Ryle has called this view, with what he admits to be "deliberate abusiveness," "the dogma of the Ghost in the Machine." He characterizes the dogma as follows:

The role of privacy

> Minds are not in space, nor are their operations subject to mechanical laws. The workings of one mind are not witnessable by other observers; its career is private. Only I can take direct cognisance of the states and processes of my own mind. A person therefore lives through two collateral histories, one consisting of what happens in and to his body, the other consisting of what happens in and to his mind. The first is public, the second private. The events in the first history are events in the physical world, those in the second are events in the mental world.

Are there private events? Even so adamant a critic of privacy as Ryle admits the existence of some private phenomena, chiefly dreams and daydreams, sensations, thoughts, and imaginings. He insists, however, that

> the sequence of your sensations and imaginings is not the sole field in which your wits and character are shown; perhaps only for lunatics is it more than a small corner of that field.

In Ryle's view, private events occupy a small and inessential place in the total range of mental phenomena; but they do occur.

The notion of privacy is really the conflation of two ideas: the metaphysical idea that mental events do not occur in space and the epistemological idea that mental events are objects of awareness solely to the person who is subject to them. Each of these may be considered in turn.

The Rationalist René Descartes, the earliest major philosopher of modern times, held that the essence of all

Non-spatiality of mental events

that is nonmental consists in being extended in space. Turning this around and broadening it, one could say that the essence of the mental consists in the lack of spatiality; *i.e.,* the lack of shape, size, and, above all, location. If the philosopher confined himself to events, he would say that necessarily a physical event occurs in some place or other, but, necessarily, a mental event does not. It would be conceded that the person who experiences the mental event does typically have a location, and this leads to the question of why the event is not located where the person is located.

A defender of the nonspatiality criterion would argue that such ascriptions of location to mental events are very different from ascriptions of location for physical events. For a physical event, it is always possible to ask whether it occurred at some point, in some part, or throughout the location. Thus, if the temperature of a body of water rises, one can ask precisely where the rise occurred—at certain points, in certain parts, or throughout the volume. But if a thought occurs, it is senseless to ask whether it occurred throughout the area or only in some part of it. Furthermore, if the water undergoing the rise in temperature is in a box, it is reasonable to say that a rise in temperature occurred in the box; but if the person having a thought is in a box, it is senseless to say that a thought occurred in the box. So the sort of ascription of location is quite different for mental events, and the criterion can still be used to mark off the mental from the physical.

The question remains whether the sort of nonspatiality that is allegedly appropriate to the mental is peculiar to it. If such a physical event as recovering from an illness or changing shape is considered, it would appear also that it does not make sense to ask whether the event occurred throughout the whole volume, in some part, or at some point. Thus, it would seem that even this modified notion of spatiality does not uniquely distinguish the mental.

Privileged status of subjectivity. Other philosophers would interpret subjective experiences not as private events but as a special way of knowing certain events, specifically by introspection. This is called the "privileged access" view. John Locke, contrasting this way of knowing with sensation, called it "reflection," defining it as "that notice which the mind takes of its own operations and the manner of them." It is a way of being aware of one's own present states without the intervention or use of the senses. The emphasis here is on the way of knowing rather than on the events known. Someone who holds the privacy view will have to hold that there is some special way of knowing these special events, but someone who holds the privileged access view is not necessarily committed to holding that the events so known are in any way special. A person could hold that one and the same event can be known both by sense perception and in some other way. Being knowable by introspection would then be the characteristic that defines events as mental. Such an account, however, would not rule out that they may also be knowable by sense perception or by inference.

Objections and rejoinders

Some contemporary philosophers deny that there is any such special way of knowing. Ryle offers three objections: first, it would require that there be simultaneously multiple attentions—in the mental event itself and in the attending to that event; though it is not denied that such divisions of attention are possible, he suggests that they are more unusual and difficult to achieve than the proponent of introspection would have the reader believe; second, because there is obviously some upper limit to the number of simultaneous attendings that a person is capable of, there will have to be some mental acts of which a person is unaware, and if it is admitted that some mental events occur without being known in this special way, it is fair to ask whether one must assume that any of them are known that way; finally, for many states of mind—*e.g.,* extreme panic or fury—the person is so involved that he is incapable of taking note of them, yet such states are not, in consequence, suspect—the person involved is as sure that they occur as he is of any so-called mental events. There is thus no need to postulate this special way of knowing to account for man's knowledge of any such events.

It is not clear how compelling Ryle's objections are. It is admitted that attention can be divided, though it may be contended that it is unusual and difficult to achieve this division. Others would reply that it is a lot more common and easier than might be thought, that it occurs whenever a man takes note of his mental states. And from the fact that he cannot take note at the same time of very many of his mental states, it hardly follows that he never does; each could still be introspectable even if it was not actually introspected on that occasion. As for Ryle's third objection, it might be that some states of mind cannot be introspected, but it does not follow that none can be introspected; they might still be private for all that. Ryle, for instance, while denying introspection, admits retrospection, a capacity to recall one's states just after they occur. It would seem, however, that there is no important difference between a concurrent "introspection" and a prompt "retrospection." One advantage of retrospection is that it would explain an individual's self-knowledge of those events that are difficult to explain in terms of introspection; *e.g.,* extreme panic or fury.

Whether a person introspects or retrospects (the truth appears to be that sometimes he does the one, sometimes the other), he would still seem to have a kind of knowledge about his own present and recently past mental states that he does not have of the mental states of others and that others do not have of his. It is not possible either to introspect or to retrospect the mental states of others; the knowledge that a man has of the present and immediately past mental states of others must be based upon perceptions or inferences from perceptions, whereas the knowledge that he has of his own present and immediately past mental states need not be, and usually is not, so based.

Introspection as defining the mental

It is possible that the notion of introspection can thus be used to define the mental. Such a definition would be of the form: a mental event is an inner event that can be introspected. The difficulty remains, however, of how "introspected" is to be defined. If it is defined merely as "known without inference or sense perception," then it would seem to apply equally to the knowledge of certain bodily events that no one would want to call mental. An individual can know without sense perception, for example, that his heart is beating rapidly or that his fingers are crossed. To rule such cases out, one can include among the senses the kinesthetic sense that utilizes nerve endings within the body—those, for instance, that register the conditions of one's own muscles. But then it might appear that one must say that sensations are not mental phenomena, since the awareness of them typically involves such nerve endings. Such an admission, however, would be fatal for the privileged access view because sensations are precisely the sort of thing to which a person is supposed to have privileged access. If, on the other hand, the philosopher makes it a matter of definition that introspection applies only to the mental, then he cannot define the mental in terms of introspection. Thus, philosophers are at the present time faced with serious and unsolved difficulties in using the notion of introspection to define the mental.

Finally, it is significant here, as it was in the discussion of subjective experience, that to much of man's mental life and to many of the exercises of his mind—*e.g.,* employments of intelligence—he has no special privileged access; there are, in addition, the unconscious phenomena that are not introspectable. So introspection cannot be a necessary condition of the mental.

A clue to a more satisfactory criterion of the mental can be found in the attack on introspection cited above. There the difficulty was noted that there does not seem to be a way of distinguishing how an individual knows his mental state from how he knows such inner physical states as the rapid beating of his heart. But it may be argued that there does seem to be a difference between these two ways of knowing: specifically, it is clear how a person could be shown that he was mistaken in believing that his heart was beating rapidly; but it is by no means clear what would show a person that he was mistaken in believing himself to be feeling a particular throbbing, pounding sensation. For mental events, the subject's own beliefs are peculiarly authoritative. This authority only holds, of course, for present mental events; it is clear that

Indubitability; incorrigibility; presumption

many things could show that a person's belief about a past mental event of his was mistaken. It is sometimes claimed that what distinguishes mental events is their so-called indubitability—the fact that a belief by the subject that the event is occurring cannot be false or in error. However, the view that first-person, present-tense reports of mental events are indubitable has come under serious attack; to make such a report is to classify, and it is argued that it is always possible to err in classification.

Instead of holding that such beliefs are indubitable, it is often more modestly maintained merely that such beliefs are "incorrigible," meaning that nothing will count as overthrowing (or correcting) such beliefs. A person who believes that he is experiencing a throbbing sensation may be mistaken; but there is nothing that will show an observer or him that he is mistaken, nothing that will entitle either of them to believe that he is mistaken. He may be experiencing a throbbing sensation even when no part of his body is actually throbbing, though the explanation for this curious fact might not be known.

It might be objected against the incorrigibility thesis that the same difficulty that arises for the alleged indubitability of first-person, present-tense beliefs about mental events also arises for their alleged incorrigibility. For if misclassification is possible, it would also seem possible to gather evidence that someone is misclassifying. If one could confuse a throbbing sensation with a different but somewhat similar sensation, it is reasonable to believe that this confusion could be known by others to have occurred. Perhaps the best that can be said for the incorrigibility thesis is that there is always a strong presumption that such beliefs are true, though this presumption can sometimes prove to be unwarranted. But then it is by no means clear that privileged authority is a unique criterion that distinguishes mental events, for such a presumption would also hold for many nonmental events as well (*e.g.*, the belief that one's heart is beating rapidly). Yet if the degree of presumptive force is taken into account, it is reasonable to say that it would be *comparatively* harder to overthrow beliefs about one's present mental events; and perhaps this is all that one needs to give the criterion force.

THE EXISTENCE AND STATUS OF THE MIND

The basic metaphysical issues in the philosophy of mind concern whether the mind exists and, if it does, what kind of existence it has and what its relation is to the rest of what exists. Materialists hold that only physical matter (and physical energy) exists. For those who hold, on the other hand, that the mind exists as an immaterial entity, there are dualistic theories for which both immaterial minds and material bodies exist, and immaterialistic theories for which only minds exist but not bodies. There are, finally, the so-called neutral monist theories for which the fundamental existents in nature are neither mental nor physical but some neutral stuff out of which both the mental and the material are formed.

The mind as material. The basic contention of Materialism is that nothing exists but matter and its purely material properties, so that the concepts that are necessary and sufficient for describing and explaining matter will be necessary and sufficient for describing everything that exists. This view can be found in the early Greek philosophers. Thales of Miletus, who lived some 2,500 years ago (6th century BC) and who is generally regarded as the first philosopher in the Western tradition, is supposed to have held that all things are composed of water in some form or other; later thinkers added air, fire, and earth to the list of fundamental elements. The philosopher Anaxagoras of Clazomenae, born about 500 BC, introduced a new factor, *Nous* (Mind), which arranged all other things in their proper order, started them in motion, and continues to control them. There is still controversy as to how his concept of Mind is to be understood, but since he spoke of Mind as being "the finest and purest of all things" and as occupying space, it is likely that he did not think of it, as some later thinkers did, as nonmaterial stuff but rather as a very special kind of material stuff.

History of Materialism

It was with the Atomists, Leucippus of Miletus and his disciple Democritus of Abdera, in the 5th and early 4th centuries BC, that Materialism was given its most developed statement. According to them, nature consists solely of an infinite number of indivisible particles, having shape, size, and impenetrability, and no further properties, and moving through an otherwise empty space. The shape, size, location, and movement of these particles make up literally all of the qualities, relations, and other features of the natural world. Such phenomena as sensations, images, sense perceptions, and thought—of particular interest to the philosophy of mind—are explicitly held to consist in the various qualities and relations of the particles.

Contemporary Materialists would, no doubt, wish to incorporate into their theory the latest findings of the physical sciences—the convertibility of matter and energy, the wave–particle duality, and the various subatomic particles and antiparticles with their peculiar properties, including the conservation of charge, direction of spin, and direction of time—but these would represent mere changes in detail. In broad outline, the theory would be the same.

Given the theory of Materialism in such broad outline, however, a serious question remains concerning the actual account to be given of such phenomena as sensations, images, perceptions, emotions, memories and expectations, desires, beliefs, thoughts, imaginings, and intentions. Among the possible views are those called eliminative Materialism, Behaviourism, and the central-state theory.

Eliminative Materialism. A philosopher might hold that there are no such things as sensations, images, perceptions, or emotions and that there never have been such. From this view, those who have believed in the existence of such things have simply been mistaken. A person might hold this view, called eliminative Materialism, on the grounds that all talk of such supposed phenomena is (1) meaningless verbiage, or (2) part of a set of theories that are outmoded, scientifically fruitless, and to be discarded, like theories about witches or the Homeric gods. On either account, it is implied that all such terms should be eliminated from the philosopher's vocabulary. There is a further doctrine, however, to the effect that all such talk is (3) meaningful but nondescriptive and without truth value. On this account, the proper function of such language is not to state facts but might be to prescribe or evaluate.

Among Materialistic views, the alternative to eliminative Materialism is some kind of reductive Materialism. According to this view, there are indeed such things as sensations, images, perceptions, and emotions, but they are only complicated forms of matter in motion. The philosopher may thus continue to use terms referring to such things (in contrast with eliminative Materialism), but he should keep in mind that no extra entities or features are being postulated over and above the physical entities with their physical features.

Two kinds of reductive Materialism

Behaviourism. If one asks reductive Materialists what sensations, images, and the like are, one will find that two alternatives have been proposed. The first is Behaviourism, the view that all such terms refer to the behaviour or movements of certain bodies, particularly of the higher animals. Thus, the Behaviourist would claim that to feel pain is to groan, writhe, blanch, moan, and so on, or at least to be disposed or tend toward such behaviour; to desire food is to engage in eating in the presence of food, in hunting in the absence of food, and so on, or at least to be disposed or tend toward such behaviour; and so also with all of the states and activities that one thinks of as mental.

Usually, Behaviourism is intended as a logical doctrine to the effect that the very meanings of the words referring to the mind, its mental states and activities, are to be analyzed in behavioral terms, that every mentalistic term is synonymous in meaning with some behavioral term. It is important to distinguish this view, logical Behaviourism, from the view of many psychologists that the most fruitful way to study psychological phenomena is to study human and animal behaviour. Such a view might be called methodological Behaviourism because it is actually the proposal that the science of psychology restrict itself to certain methods. It does not entail logical Behaviourism. Logical Behaviourism might also be distinguished from

the view that psychological and behavioral terms, though not synonymous in meaning, have, as a matter of fact, the same denotation or reference, a view that might be called de facto Behaviourism.

Central-state theory. The second type of reductive Materialism is the central-state theory. In this view, mental states and activities are identical with states and activities within the body (hence this theory is sometimes called the identity thesis). In particular, they are identical with states and activities of the central nervous system or brain. Thus, to feel pain is for the brain to be in a particular state; to desire food is for the brain to be in another state.

Distinctions parallel to those for Behaviourism can be made for the central-state theory. A psychologist might hold that the only useful way of studying psychological phenomena is to study the central nervous system; this view might then be called methodological central-statism. A philosopher might hold that the very terms referring to the mind, its mental states and activities, are synonymous with neurological terms (or, more plausibly, that they *should* be taken to be synonymous—they obviously are not synonymous as language now stands). This position, which could be called logical central-statism, would differ from the eliminative Materialism mentioned above in that it would retain mentalistic terms rather than eliminate them but would redefine them neurologically. If this came to pass, such terms might eventually disappear, a result that eliminative Materialism would strive to achieve more directly.

Plato's *psychē*

The mind as immaterial. Plato was the first important figure in the Western tradition explicitly to defend the doctrine that the mind is an entirely nonmaterial entity—without such defining material properties as size, shape, or impenetrability—separate and distinct from the human body and able to exist apart from it. Plato used the Greek word *psychē* (traditionally translated as "soul").

Plato held that the mind (*psychē*) was in charge of the body and directed its movements. In his dialogue the *Phaedrus,* Plato spoke of the mind as having both appetitive desires and the higher desires and as having, in addition, a rational capacity to control, direct, and adjudicate between the two. This rational capacity of mind is the most valuable aspect of man, the part most worthy to be nurtured and developed, and the aspect of man most likely to be immortal (much of the dialogue concerning the last hours of Socrates, the *Phaedo,* is about these topics).

Dualism. Plato was a dualist; he believed in the existence of both material entities and immaterial ones. The most explicit statement of dualism, however, is found in the writing of René Descartes, who argued that mind and matter are two separate and distinct sorts of substances, absolutely opposed in their natures, each capable of existing entirely independently of the other.

Descartes's substances

The dualist is faced with the question of how, if at all, mind and matter are related to each other. Most dualists would agree that in rocks, tables, and other material things, matter exists alone and unrelated to mind; and that at what is called death (since for Descartes the soul is immortal), immaterial minds exist unrelated to matter. In the case of a living human being, however, there are two substances: a mind and a body. Thus, the question arises of how the relation between them is to be conceived. Any dualistic theory would have to account for certain obvious facts about human beings. When people's bodies are affected in certain ways—when subjected, for example, to bright lights, loud noises, rises in temperature—people often experience colours, sounds, or sensations of warmth or of pain. Again, when people experience certain things, their bodies undergo certain changes—they shut their eyes, they put their hands to their ears, they perspire, or their faces become pale.

Interactionism; epiphenomenalism; parallelism

There are various ways that dualists have proposed to account for these facts. The most straightforward position is interactionism, the view (held by Descartes) that mind and body are capable of affecting each other causally, so that what happens in the body can produce effects in the mind and vice versa. Descartes decided that somewhere within the nerve tissues of the brain was the place where the interactions occurred and chose the pineal gland as the precise point because of its central location. (It is now known that the pineal gland cannot perform the functions that Descartes attributed to it, though its precise functions are still unknown.)

It is an implication of interactionism that there cannot be a complete explanation of brain functioning exclusively in terms of the laws of neurology because of the intervention at crucial moments of the influences of the mind. This limitation has struck many scholars as an important difficulty. One way around it is epiphenomenalism, the view that the body can affect the mind but that the mind cannot affect the body. Mental events are mere by-products of brain activity, like the exhaust from an engine or the shadows cast by moving figures. When the mind would appear to be affecting the body, as when the experience of pain seems to cause one to grimace, the epiphenomenalist hypothesizes that the very brain state that produces the experience of pain also produces the grimace.

Dualists of either the interactionist or epiphenomenalist persuasion are committed to the existence of causal relations between body and mind. Some philosophers, struck by how entirely different mind and matter are supposed to be on the dualist hypothesis, have held it to be impossible that they could affect each other. Psychophysical parallelism avoids this difficulty by postulating that mind and body are like two perfect clocks, each with its own mechanism but in constant and uniform correlation with the other. Unfortunately, the analogy does not hold very well, for the mind does not seem to have the kind of internal mechanism that would account for any precise sequence of its successive states, and without such a mechanism it would be implausible to expect a constant but noncausal correlation between those states and states of the body.

Immaterialism. Some philosophers have held the doctrine of immaterialism, so named by Bishop George Berkeley, one of the classic British Empiricists, in whose view everything that exists is mental, of "the stuff that dreams are made on," and there is no such thing as the material. There are two major alternatives here: that reality consists of one vast, all-encompassing mind, or that it consists of a plurality of minds. The former position is sometimes called absolute Idealism; the latter, which Berkeley himself held, is sometimes called subjective Idealism.

Berkeley's mentalism

The philosophy of Berkeley represents a highly developed and energetically defended statement of the position that reality consists wholly of minds, the divine Mind and the multiplicity of finite minds that includes all men. Whatever exists does so either because it is a mind or because it is dependent upon a mind; nothing material exists. Berkeley argued that the notion of the material should play no role in one's thinking, for its existence is unverifiable, its postulation unnecessary, and, at bottom, the very notion is self-contradictory. How does Berkeley view the status of tables and chairs, rocks, the Moon, and all of the other apparently material things that everyone accepts as existing? Berkeley agreed that they do indeed exist but only as collections of ideas that exist in the mind of God and that are often caused by God to exist in the minds of men as well.

There are well-known difficulties in Berkeley's view. His account of the nature of tables and other objects cannot be accepted as an account of the meanings of these terms because it is implausible to think that the concept of a divine Mind is somehow part of their meaning. Nor does it seem a plausible scientific theory about such objects because of its ad hoc character and its lack of predictive value. If the notion of God is dropped, however, the philosopher is left with the phenomenalistic theory that such objects are collections of appearances. But phenomenalism also has serious difficulties; in particular, it cannot in the end account for the difference between real objects and illusions because it cannot provide an account of the difference between circumstances in which perceptions are veridical and those in which they are not.

The other variety of immaterialism, called absolute Idealism, derives from certain doctrines of Immanuel Kant and of the classical German Idealists who followed him—Johann Fichte, Friedrich Schelling, and G.W.F. Hegel—concerning the fundamental dependence of reality on

mind or spirit in general. Among the several philosophers who have defended this view, there was, at the turn of the 20th century, F.H. Bradley, whose *Appearance and Reality* (1893; 2nd edition 1897) comprises its most systematic exposition and defense. Bradley denied that a plurality of minds exists and insisted that there is only one infinite Mind, Idea, or Experience that comprehends all of existence within it.

Neutral theories. Another important view has been that neither the mental nor the physical is really fundamental; each is an aspect of some underlying reality that is neither mental nor physical but neutral between them. There are many variants of such a view. Spinoza, a 17th-century Rationalist, held that the underlying substance, which encompassed all of reality and which he called God or Nature, had both thinking (the mental) and extension (the material) as attributes. A modern version of this position is that of Peter Strawson, a leading philosopher of the Oxford "ordinary language" school, who differs from Spinoza in holding that there is a multiplicity of substances, some of which are purely material and some of which are persons (thus he is not really a monist). Strawson conceives of persons as substances whose nature is to have both mental and physical attributes. Thus, one and the same substance can have both qualities, and the difference between the mental and the physical is conceived as a basic difference between the qualities.

Spinoza's substance and attributes

A different approach was suggested in some of Hume's writings and diversely stated by the Pragmatist William James and by various Positivists (Ernst Mach, Rudolf Carnap, and A.J. Ayer). They postulate a number of particular entities, experiences, that go to make up minds when they are related in certain ways, as by the laws of association and memory, and that go to make up bodies when the entities are related in other ways, as by the laws of perspective. Thus, a person's mind is conceived to be just the collection of his experiences, whereas a physical object is conceived to be just the collection of experiences that people can have of it. Here the difference between the mental and physical consists in the different kinds of relations obtaining between the neutral particulars, experiences.

Recently, it has been suggested by certain Linguistic philosophers that the difference between mind and body lies in two different kinds of language or conceptual systems: the physicalistic-conceptual language, on the one hand, with its spatiotemporal terms, and person-talk, on the other, with its reference to norms for assessing the rationality, moral responsibility, and ethical value of human actions.

Existentialist and Phenomenological philosophers have expressed similar conclusions, supported not so much by linguistic considerations as by general observations of man's condition as a being in the world, with a body, which he experiences and which, by its nature, affects his experience. Man can be viewed as a spatiotemporal aggregate, an object for observation, study, and manipulation, an instance of the laws of nature. But man can also be viewed as a self-moved mover, a being who alters himself and the world through the decisions he makes, who determines values and invests things with those values, who can make his life and his world according to the values that he determines, and who, in the end, can negate his values and even terminate his life by choice. Here the philosopher finds surprising similarities between some Analytic philosophers of the English-speaking world and the more speculative continental philosophers.

Existentialist and Phenomenological views

THE ANALYSIS OF MENTAL PHENOMENA

When the specific phenomena that go to make up the mental are considered, one finds that they all raise philosophical issues, only some of which can be sketched here. Mental phenomena are traditionally divided into three areas: the cognitive, which is concerned with knowledge; the affective, with feeling; and the volitional, with action. It is no longer believed that this division reflects the three so-called basic faculties that comprise the mind; nevertheless, as a very rough classification, it provides a convenient approach to the variety of mental phenomena.

The cognitive. Many philosophers since Plato have taken man's ability to know as the characteristic distinguishing him from all other animals. The very name of his species, *Homo sapiens,* means "man the knower."

If one asks what knowledge is, he has raised the central problem of a major field of philosophy, epistemology (see EPISTEMOLOGY). But there is also a very important psychological aspect to knowledge, and that is where the philosophy of mind becomes relevant. It is often claimed, for example, that knowing that something is so entails believing that it is so; and the nature of belief lies clearly within the province of the philosophy of mind. Since a person does not lose a belief when he is not consciously attending to it, the approach to belief most in favour today is to treat it as a disposition, which, like all such, comes to open expression only sporadically. Other psychological phenomena falling within the area of the cognitive are attention, sense perception, understanding, memory, inference, and doubt. The view that each of these requires a subjective experience has been effectively refuted in the writings of Ludwig Wittgenstein, one of the seminal thinkers of modern Linguistic Analysis. Remembering that the oven is still turned on may consist in nothing but getting up in the middle of a conversation, going over to the oven, and turning it off, all the while animatedly continuing the conversation. But exactly why this is called "remembering that the oven is still on" is not clear. Perhaps the best that can be said is that there are analogies between such instances of remembering and other, more self-conscious instances. It is the task of the philosophy of mind to examine, classify, and analyze the relations among such phenomena.

Psychological aspect and phenomena

The affective. Man has not only the capacity to know but also the capacity to respond emotionally to what he knows. A man may not only believe that some event will occur, but he may also dread it or welcome it. Concerning the things that a person knows, he may approve or disapprove, love or hate, pity or envy, enjoy or abhor. Here, although the subjective experience often plays an important role, it clearly is not the whole story. To enjoy doing something, as has been pointed out, is not to do the thing *and also* undergo a series of experiences of enjoyment; it may simply be to do the thing when circumstances permit and make efforts to avoid its cessation or interruption. But a disposition-to-behave approach will be less successful for other affective phenomena. For example, people have feelings about the past—regret, nostalgia, pride—feelings in which future behaviour plays a relatively minor role.

All of the affective phenomena so far considered have the property of intentionality, of being directed toward an object. It is clear, however, that this is not a sufficient condition for defining the affective, since it marks out too broad a scope—including, for example, believing, which, though intentional, falls not within the affective but within the cognitive. But neither does intentionality seem to be a necessary condition of the affective. Moods such as depression, anxiety, or joviality may not have any specific object, though it is sometimes replied that such emotions take as objects anything the person happens to think of. Sensations also do not seem to be intentional, even though they are usually classified as affects. One view is that sensations are really cognitions—the awareness of some bodily disturbance. The difficulty in trying to decide whether a sensation is an affect or a cognition further illustrates the inadequacy of the classification of mental phenomena into the cognitive, affective, and volitional.

The volitional. Intellect and emotion often come to expression in volition and action, important topics in the philosophy of mind—topics that comprise such concepts as motive, desire and purpose, deliberation, decision, intention, attempt, and action, both voluntary and involuntary.

There is a rough distinction to be made between the things that happen to a person and the things he does or makes to happen. If a person slips on the ice, it is something that happens to him; if he walks on the ice, it is something that he does. "Henry slid on the ice" is ambiguous: it may report something that happened to Henry or something that Henry did, depending upon the meaning. In this example, the observable event may be the same:

from a photograph of Henry sliding on the ice one may not be able to tell which it is. The problem of action is primarily to understand this distinction and its ramifications. Wittgenstein once put the question this way: "And the problem arises: what is left over if I subtract the fact that my arm goes up from the fact that I raise my arm?"

Wittgenstein's question on action

There are a number of different answers: (1) Actions are events produced by causes of certain sorts—volitions or acts of will according to some theories; beliefs and desires under other theories; and simply persons or agents in yet another theory. (2) Actions are events that are "caused" in a special sense; they have a teleological rather than an efficient or mechanical cause, or an immanent (or originating) cause rather than one that is merely a reaction to, or modification of, an action coming from some other source. (3) Actions are events that are properly characterized and assessed in terms of rules of conduct, or principles of rational and ethical behaviour, and for which the agent is held responsible, liable, accountable, to be praised or blamed, rewarded or punished.

Any theory of action is expected to throw light on the issue of free will, a matter of great importance for ethical theory. If the philosopher holds that free will is compatible with determinism, any of the views above will allow for free will. Even if he holds that an action is not free if it has causes that eventually lie outside the agent, his view will be compatible with the various views of action unless he holds the version of (1)—that an action is an event produced by volitions or beliefs and desires—and also holds the additional thesis (2)—that volitions or beliefs and desires themselves have causes that lie outside the agent. Only then will there be no freedom of the will.

SOME METAPHYSICAL AND EPISTEMOLOGICAL ISSUES

Personal identity through time. A person, as he goes through life, changes in many ways; but he remains the person that he was. He is that person who was born on a certain day, that person who graduated 23rd in a particular high school class, who married on a certain date in a certain place; he has a particular identity through time. It is difficult to state what exactly it is that makes a person one and the same self through time.

Bodily versus psychological criteria

An obvious starting point is the fact that throughout a person's natural life he has the same body and that this is what makes him one and the same person throughout a particular period of time. But there are difficulties in this view. First, since the body cells are constantly being replaced and in some instances whole organs are transplanted, it is not clear what makes a particular body identical with a body that existed, say, 20 years earlier. A second difficulty arises through the hypothetical possibility of brain transplants; if two brains were interchanged, in all likelihood there would be a systematic interchange of memory, beliefs, personality and character traits, skills, and habits of thought and action. Such a transplant would incline one to say that not merely a small portion of each body had been interchanged but two people as well; for one also takes as a criterion of personal identity similarities through time of memory, personality, skills, and habits. After all, a man is often willing to say that this is the same person who did something in the past, not on the basis of knowing that it is the same body but on a quite different basis—that the person recounts the past situation with great accuracy, exhibits similar personal reactions, and displays the same skills.

Because two different kinds of criteria, bodily and psychological, are used for determining personal identity, it is possible to imagine instances of conflict in which the criterion of bodily identity would indicate that it is a different person but the psychological criteria would indicate that it is the same person and vice versa. The Austro-Czech novelist Franz Kafka, known for his nightmarish works, in his short story *Die Verwandlung* (1915; *The Metamorphosis*) tells of a person who awoke one morning to find, to his horror, that he had the body of a large insect. Although his family accepted his conclusion that he was the same person even though he had an entirely different body, others would have disagreed. There is still, in fact, considerable disagreement among scholars on this whole issue—on how to state precisely the bodily criterion; on whether there is a psychological criterion as well and, if so, how it is to be formulated; on what is the basic criterion of personal identity; and on what to say about instances in which criteria conflict.

Personal immortality. Many people believe that when the human body ceases to be a living system, there is not total annihilation of the person but that in some respect the person continues to exist. The philosopher of mind can put aside the various watered-down versions of immortality in which the person continues to exist in the remote sense that people still remember him or his works or that his influence continues through history. The philosopher does look with interest, however, on the claim that there is an immortality in which a person, in his survival, meets the psychological criteria of personal identity, of inheritance of memory, beliefs, habits, and personality characteristics.

Problems of meaning and fact

It is clear that a person's view of immortality will be affected by opinions that he holds about the relation of mind to matter. Given the versions of Materialism that urge the elimination of mental terms or their definition in bodily terms or that take bodily identity to be the basic criterion of personal identity, the very notion of survival after death is completely unintelligible. Many philosophers, however, reason that, since the notion of survival is intelligible, such versions of Materialism cannot be accepted. Central-state or identity theorists would admit survival to be an intelligible notion but would view it, like lightning without electricity, as something that never happens; they would thus be in agreement with many dualists, in particular epiphenomenalists and psychophysical parallelists. Even an interactionist would be free to accept or reject survival, as would a neutral monist.

If a philosopher holds that survival is an intelligible notion, he is still left with the further question of whether it ever happens. In the past there have been various a priori arguments for survival after death. Arguments based upon the nature of the self, such as its indivisibility, can be found in Plato's *Phaedo*. Kant argued that man's moral principles require survival as a postulate. But among those today who hold that survival is intelligible, it is widely agreed that a priori arguments will not do. If there is survival, they say, it is a contingent fact and not a necessity; one must thus look to empirical data for guidance. A survey of the evidence shows that the case against survival, though strong, is by no means conclusive. One thing is clear: if there is survival, the survivors can theoretically give firsthand testimony to it, whereas if there is no survival, there will be no one to give such testimony.

Knowledge of other minds. An important problem in the theory of knowledge has been the status of the belief in other minds, the belief that one's own consciousness is not the only consciousness in existence. Though few, if any, sane persons have seriously accepted solipsism (the view that one's own is the only consciousness), the grounds for rejecting it are not at all clear.

Again, as with the problems of personal identity and personal survival, one's view of the relation of mind to matter is relevant. On various Materialistic views, the problem reduces itself to that of justifying the belief in an external world that contains other bodies of the appropriate sort and with the appropriate behaviour. But for dualists and immaterialists, who hold that mental phenomena are something irreducibly different from the physical, there is the further question of whether that something is unique to oneself or whether there are other instances of it in the world.

Direct, transcendental, analogical approaches

Some scholars claim that individuals sometimes have direct awareness of the conscious states of others, either in telepathic experiences, moments of empathy, or even in everyday social intercourse. There is, moreover, a transcendental argument, found in Kant and defended by Strawson, holding that, unless a person could be confident of the existence of other minds, he could not be confident of the existence of his own mind. A different line of reasoning, the so-called argument from analogy, is based upon the similarities between one's own body and its behaviour, on the one hand, and other human bodies and

their behaviour on the other. To pursue the argument, since a mind is known to be associated with one's own body, it is reasonable to conclude that another mind is associated with the body of another person. Finally, there is the view that the best way to explain the complex behaviour of other bodies, especially their ability to behave rationally and in particular to speak and communicate information, is to postulate other minds at work.

None of these arguments compels strong conviction, certainly not the degree of conviction that all persons feel concerning the existence of other minds. Whether stronger arguments will be found, whether philosophers must admit that there is a considerable amount of faith required here, or whether they will reformulate their concepts of the mind in a more Materialistic way to bring them in closer accord with observable data remains to be seen.

Artificial intelligence. Remarkable progress in the development of high-speed electronic computers has led many philosophers to conclude that a suitably programmed computer with a sufficient memory capacity would have an actual mind capable of intelligent thought. The term artificial intelligence denotes the area of investigation that aims to develop computers with such capabilities.

Two questions are intensely debated in this field. First, what are the theoretical limits to what can be achieved in the way of artificial intelligence? Despite phenomenal progress in recent years, no computer yet devised even approximates in its capacity the multiplicitous powers of the human mind. However, it would be most unwise at present to make dogmatic predictions about future developments. Second, assuming that the optimistic hopes of artificial intelligence researchers are realized, would such devices literally have minds or would they be mere imitations of minds? It is already common linguistic practice to describe computers as having memories, making inferences, understanding one language or another, and the like, but are such descriptions literally true or simply metaphorical? One group holds that computers will never be more than tools employed by the human intelligence to aid its own thinking. Another group holds that human intelligence itself consists of the very computational processes that could be exemplified by advanced machines, so that it would be unreasonable to deny the attribution of intelligence to such machines. The issue may remain unresolved until researchers in artificial intelligence have had more time to determine the limits of computer capabilities.

BIBLIOGRAPHY. Various formulations of Materialism can be found in the writings of the pre-Socratic philosophers, especially Leucippus and Democritus. PLATO, *Phaedo, Timaeus, Phaedrus,* and books iv and x of the *Republic,* demonstrate his dualism and his views on the nature of the soul. ARISTOTLE, *De Anima* (*On the Soul*), is a whole treatise devoted to the subject, expressing a qualified Materialism. THOMAS HOBBES, *Leviathan* (1651), is radically Materialistic; whereas RENÉ DESCARTES, *Meditationes de prima philosophia,* 2nd ed. (1642), and other writings, presents a classic interactionist dualism. Dualism of the parallelist variety can be found in the writings of Gottfried Leibniz. BENEDICT DE SPINOZA, *Ethica* (1677), rejects both Materialism and dualism, expounding a double-aspect theory. GEORGE BERKELEY, *Treatise Concerning the Principles of Human Knowledge* (1710), provides the classic statement and defense of Idealism (in his word, immaterialism). All the works above can be found in modern editions.

The contemporary interest in the philosophy of mind is largely a result of the provocative work by GILBERT RYLE, *Concept of Mind* (1949, reprinted 1984). Also of great importance was the wholly new approach to all of philosophy taken by LUDWIG WITTGENSTEIN, *Philosophical Investigations,* 3rd ed. (1958, reissued 1973). There followed a spate of journal articles, some of the best of which are in the following anthologies: LYLES BRAND (ed.), *The Nature of Human Action* (1970); ANTONY FLEW (ed.), *Body, Mind, and Death* (1964); DONALD F. GUSTAFSON (ed.), *Essays in Philosophical Psychology* (1964); HAROLD MORICK (ed.), *Introduction to the Philosophy of Mind* (1970, reissued 1981); GEORGE PITCHER (ed.), *Wittgenstein: The Philosophical Investigations* (1966); ALAN R. WHITE (ed.), *The Philosophy of Action* (1968, reprinted 1977); and OSCAR P. WOOD and GEORGE PITCHER (eds.), *Ryle* (1970). Another useful work is DAVID M. ROSENTHAL (ed.), *The Nature of Mind* (1991). Selections written from Existentialist and Phenomenological perspectives are found in STUART F. SPICKER (ed.), *The Philosophy of the Body* (1970), M. MERLEAU-PONTY, *Phenomenology of Perception* (1989; originally published in French, 1945), is also of interest. Introductory writings that include original contributions as well as balanced assessments are GERALD E. MYERS, *Self* (1969); ALAN R. WHITE, *The Philosophy of Mind* (1967, reprinted 1978); JEROME A. SHAFFER, *Philosophy of Mind* (1968); COLIN MCGINN, *The Character of Mind* (1982); PETER SMITH and O.R. JONES, *The Philosophy of Mind: An Introduction* (1986); ROM HARRÉ, *Physical Being: A Theory for a Corporeal Psychology* (1991), on how we think about the body in everyday life; and DALE JACQUETTE, *Philosophy of Mind* (1994).

Analyses of particular mental phenomena are found in G.E.M. ANSCOMBE, *Intention,* 2nd ed. (1963, reissued 1976); HARVEY RICHARD SCHIFFMAN, *Sensation and Perception,* 3rd ed. (1990), a good textbook; PETER GEACH, *Mental Acts* (1956, reissued 1971); STUART HAMPSHIRE, *Thought and Action,* new ed. PETERS, *The Concept of Motivation,* 2nd ed. (1969); RICHARD TAYLOR, *Action and Purpose* (1966, reprinted 1973); and ALAN R. WHITE, *Attention* (1964).

Works dealing with the problem of personal identity include HAROLD W. NOONAN, *Personal Identity* (1989, reissued 1993), a rigorous introduction; PETER UNGER, *Identity, Consciousness, and Value* (1990), for specialists; A.J. AYER, *The Concept of a Person* (1963); and CHRIS L. KLEINKE, *Self-Perception: The Psychology of Personal Awareness* (1978). The problem of one's knowledge of other minds is explored in HAROLD MORICK (ed.), *Wittgenstein and the Problem of Other Minds* (1967, reissued 1981); ALVIN PLANTINGA, *God and Other Minds* (1967, reissued 1990); and JOHN WISDOM, *Other Minds,* 2nd ed. (1965). A defense of dualism may be found in JOHN FOSTER, *The Immaterial Self* (1991); and W.D. HART, *The Engines of the Soul* (1988). R.J. NELSON, *The Logic of Mind,* 2nd ed. (1989), offers a mechanistic approach to philosophy of mind; whereas JOHN ECCLES and DANIEL N. ROBINSON, *The Wonder of Being Human: Our Brain and Our Mind* (1984), poses strong opposition to the "human-as-machine" approach. The implications of artificial intelligence are examined in ALAN ROSS ANDERSON (ed.), *Minds and Machines* (1964); HUBERT L. DREYFUS, *What Computers Can't Do,* rev. ed. (1979); DANIEL C. DENNETT, *Brainstorms* (1978; reissued 1981), and *Consciousness Explained* (1991); and PAUL M. CHURCHLAND, *The Engine of Reason, the Seat of the Soul* (1995). (J.A.Sh./Ed.)

Minerals and Rocks

A mineral is a naturally occurring homogeneous solid with a definite chemical composition and a highly ordered atomic arrangement; it is usually formed by inorganic processes. There are several thousand known mineral species, but only about 100 of them constitute the major mineral components of rocks; these are the so-called rock-forming minerals. Most rocks are aggregates of minerals, although a relatively small number have been found to consist of only a single mineral. Such rocks are known as monomineralic. The many ways in which minerals combine give rise to a large variety of rocks. Rocks are generally divided into three major classes on the basis of their origin: igneous, metamorphic, and sedimentary. Each of these classes, in turn, is subdivided into numerous groups according to mineral composition and texture.

This article provides a summary of the external form, internal structure, chemical composition, physical properties, and origin of minerals and their associations. It treats the principal rock-forming minerals (among which the silicates are of the greatest importance) and discusses the common representatives of other groups—sulfides, oxides, hydroxides, and carbonates, for example—as well. Each of the major classes of rocks is also described, with attention given to their physical and chemical properties, formation, and occurrence. For additional information about precious minerals, see the article DRESS AND ADORNMENT: *Jewelry: Gems*. The study of minerals and rocks is treated in EARTH SCIENCES: *Geologic sciences*.

Definition of a mineral. A mineral, which by definition must be formed through natural processes, is distinct from the synthetic equivalents produced in the laboratory. Man-made versions of minerals, including emeralds, sapphires, diamonds, and other valuable gemstones, are regularly produced in industrial and research facilities and are often nearly identical to their natural counterparts.

By its definition as a homogeneous solid, a mineral is composed of a single solid substance of uniform composition that cannot be physically separated into simpler compounds. Homogeneity is determined relative to the scale on which it is defined. A specimen that megascopically appears homogeneous, for example, may reveal several mineral components under a microscope or upon exposure to X-ray diffraction techniques. Most rocks are composed of several different minerals; *e.g.*, granite consists of feldspar, quartz, mica, and amphibole. In addition, gases and liquids are excluded by a strict interpretation of the above definition of a mineral. Ice, the solid state of water (H_2O), is considered a mineral, but liquid water is not; liquid mercury, though sometimes found in mercury ore deposits, is not classified as a mineral either. Such substances that resemble minerals in chemistry and occurrence are dubbed mineraloids and are included in the general domain of mineralogy.

Since a mineral has a definite composition, it can be expressed by a specific chemical formula. Quartz (silicon dioxide), for instance, is rendered as SiO_2, because the elements silicon (Si) and oxygen (O) are its only constituents and they invariably appear in a 1:2 ratio. The chemical makeup of most minerals is not as well defined as that of quartz, which is a pure substance. Siderite, for example, does not always occur as pure iron carbonate ($FeCO_3$); magnesium (Mg), manganese (Mn), and, to a limited extent, calcium (Ca) may sometimes substitute for the iron. Since the amount of the replacement may vary, the composition of siderite is not fixed and ranges between certain limits, although the ratio of the metal cation to the anionic group remains fixed at 1:1. Its chemical makeup may be expressed by the general formula (Fe, Mn, Mg, Ca)CO_3, which reflects the variability of the metal content.

Crystalline solids

Minerals display a highly ordered internal atomic structure that has a regular geometric form (see Figure 1). Because of this feature, minerals are classified as crystalline solids. Under favourable conditions, crystalline materials may express their ordered internal framework by a well-developed external form, often referred to as crystal form or morphology (see Figure 2). Solids that exhibit no such ordered internal arrangement are termed amorphous. Many amorphous natural solids, such as glass, are categorized as mineraloids.

Traditionally, minerals have been described as resulting exclusively from inorganic processes; however, current mineralogic practice often includes as minerals those compounds that are organically produced but satisfy all other mineral requirements. Aragonite ($CaCO_3$) is an example of an inorganically formed mineral that also has an organically produced, yet otherwise identical, counterpart; the shell (and the pearl, if it is present) of an oyster is composed to a large extent of organically formed aragonite. Minerals also are produced by the human body: hydroxylapatite [$Ca_5(PO_4)_3(OH)$] is the chief component of bones and teeth, and calculi are concretions of mineral substances found in the urinary system.

Mineral nomenclature. While minerals are classified in a logical manner according to their major anionic (negatively charged) chemical constituents into groups such as oxides, silicates, and nitrates, they are named in a far less scientific or consistent way. Names may be assigned to reflect a physical or chemical property, such as colour, or they may be derived from various subjects deemed

appropriate, as, for example, a locality, public figure, or mineralogist. Some examples of mineral names and their derivations follow: albite ($NaAlSi_3O_8$) is from the Latin word (*albus*) for "white" in reference to its colour; goethite ($FeO \cdot OH$) is in honour of Johann Wolfgang von Goethe, the German poet; manganite ($MnO \cdot OH$) reflects the mineral's composition; franklinite ($ZnFe_2O_4$) is named after Franklin, N.J., U.S., the site of its occurrence as the dominant zinc (Zn) mineral; and sillimanite (Al_2SiO_5) is in honour of the American chemist Benjamin Silliman.

Since 1960, an international committee of nomenclature has reviewed descriptions of new minerals and proposals for new mineral names and has attempted to remove inconsistencies.

Occurrence and formation of minerals. Minerals form in all geologic environments and thus under a wide range of chemical and physical conditions, such as varying temperature and pressure. The four main categories of mineral formation are (1) igneous, or magmatic, in which minerals crystallize from a melt; (2) sedimentary, in which minerals are the result of the processes of weathering, erosion, and sedimentation; (3) metamorphic, in which new minerals form at the expense of earlier ones owing to the effects of changing—usually increasing—temperature or pressure or both on some existing rock type (metamorphic minerals are the result of new mineral growth in the solid state without the intervention of a melt, as in igneous processes); and (4) hydrothermal, in which minerals are chemically precipitated from hot solutions within the Earth. The first three processes generally lead to varieties of rocks in which different mineral grains are closely intergrown in an interlocking fabric. Hydrothermal solutions, and even solutions at very low temperatures (*e.g.*, groundwater), tend to follow fracture zones in rocks that may provide open spaces for the chemical precipitation of minerals from solution. It is from such open spaces, partially filled by minerals deposited from solutions, that most of the spectacular mineral specimens have been collected. If a mineral that is in the process of growth (as a result of precipitation) is allowed to develop in a free space, it will generally exhibit a well-developed crystal form (see Figure 2), which adds to a specimen's aesthetic beauty. Similarly, geodes, which are rounded, hollow, or partially hollow bodies commonly found in limestones, may contain well-formed crystals lining the central cavity. Geodes form as a result of mineral deposition from solutions such as groundwater.

MINERALS: THEIR NATURE, CLASSIFICATION, AND ASSOCIATIONS

The nature of minerals

MORPHOLOGY

Nearly all minerals have the internal ordered arrangement of atoms and ions that is the defining characteristic of crystalline solids (see Figure 1). Under favourable conditions, minerals may grow as well-formed crystals, characterized by their smooth plane surfaces and regular geometric forms. Development of this good external shape is largely a fortuitous outcome of growth and does not affect the basic properties of a crystal. Therefore, the term crystal is most often used by material scientists to refer to any solid with an ordered internal arrangement, without regard to the presence or absence of external faces.

The external shape, or morphology, of a crystal is perceived as its aesthetic beauty, and its geometry reflects the internal atomic arrangement (see Figure 2). The external shape of well-formed crystals expresses the presence or absence of a number of symmetry elements. Such symmetry elements include rotation axes, rotoinversion axes, a centre of symmetry, and mirror planes.

Symmetry elements

A rotation axis is an imaginary line through a crystal around which it may be rotated and repeat itself in appearance one, two, three, four, or six times during a complete rotation. A sixfold rotation axis is illustrated in Figure 3A. When rotated about this axis, the crystal repeats itself each 60° (six times in a 360° rotation).

A rotoinversion axis combines rotation about an axis of rotation with inversion. Rotoinversion axes are symbolized as $\bar{1}$, $\bar{2}$, $\bar{3}$, $\bar{4}$, and $\bar{6}$. $\bar{1}$ is equivalent to a centre of symmetry (or inversion, *I*), $\bar{2}$ is equivalent to a mirror plane, $\bar{3}$ is equivalent to a threefold rotation axis plus a centre of symmetry, $\bar{4}$ is not composed of other operations and is unique, and $\bar{6}$ is equivalent to a threefold rotation axis with a mirror plane perpendicular to the axis. The morphological expression of a fourfold rotoinversion axis is illustrated in Figure 3B.

A centre of symmetry exists in a crystal if an imaginary line can be extended from any point on its surface through its centre and a similar point is present along the line equidistant from the centre (see Figure 3C). This is equivalent to $\bar{1}$, or inversion. There is a relatively simple procedure for recognizing a centre of symmetry in a well-formed crystal. With the crystal (or a wooden or plaster model thereof) laid down on any face on a tabletop, the presence of a face of equal size and shape, but inverted, in a horizontal position at the top of the crystal proves the existence of a centre of symmetry.

A mirror plane is an imaginary plane that separates a crystal into halves such that, in a perfectly developed crystal, the halves are mirror images of one another. A single mirror in a crystal, also called a symmetry plane, is illustrated in Figure 3D.

Morphologically crystals can be grouped into 32 crystal classes that represent the 32 possible symmetry elements and their combinations. These crystal classes, in turn, are grouped into six crystal systems. In decreasing overall symmetry content, beginning with the system with the highest and most complex crystal symmetry, they are isometric, hexagonal, tetragonal, orthorhombic, monoclinic, and triclinic. The systems may be described in terms of crystallographic axes used for reference. The *c* axis is normally the vertical axis. The isometric system exhibits three mutually perpendicular axes of equal length (a_1, a_2, and a_3). The orthorhombic and tetragonal systems also contain three mutually perpendicular axes; in the former system, all the axes are of different lengths (*a*, *b*, and *c*), and, in the latter, two axes are of equal length (a_1 and a_2) while the third (vertical) axis is either longer or shorter (*c*). The hexagonal system contains four axes: three equal-

length axes (a_1, a_2, and a_3) intersect one another at 120° and lie in a plane that is perpendicular to the fourth (vertical) axis of a different length. Three axes of different lengths (*a*, *b*, and *c*) are present in both the monoclinic and triclinic systems. In the monoclinic system, two axes intersect one another at an oblique angle and lie in a plane perpendicular to the third axis; in the triclinic system, all axes intersect at oblique angles.

The grouping of the 32 possible crystal classes among the crystal systems is shown in Table 1. Column 1 of the table lists the six crystal systems; column 2 gives the total symmetry content of each of the 32 crystal classes; and column 3 gives a symbolic representation for each of the 32 combinations of symmetry elements known as the Hermann-Mauguin, or international, notation. This compact and very useful notation is discussed in professional literature, such as the references given in the *Bibliography*.

Three different crystals with distinctively dissimilar symmetry contents, as expressed by their external morphology, are given in Figure 4. Figure 4A shows a well-formed monoclinic crystal with symmetry content *i*, $1A_2$, and $1m$ ($2/m$); Figure 4B features a crystal in the tetragonal system with symmetry content *i*, $1A_4$, and $1m$ ($4/m$); and Figure 4C shows a crystal in the isometric system having the highest possible symmetry content of $3A_4$, $4\bar{A}_3$, $6A_2$, and $9m$ ($4/m\bar{3}2/m$). (See Table 1.) Photographs of some well-formed crystal groups are given in Figure 5.

Each belongs to a different crystal class because of its overall symmetry content. (A) Monoclinic crystal ($2/m$). (B) Tetragonal crystal ($4/m$). (C) Isometric crystal ($4/m\bar{3}2/m$).

If two or more crystals form a symmetrical intergrowth, they are referred to as twinned crystals. A new symmetry operation (called a twin element), which is lacking in a single untwinned crystal, relates the individual crystals in a twinned position. There are three twin elements that may relate the crystals of a twin: (1) reflection by a mirror plane (twin plane), (2) rotation about a crystal direction common to both (twin axis) with the angular rotation typically 180°, and (3) inversion about a point (twin centre). An instance of twinning is defined by a twin law that specifies the presence of a plane, an axis, or a centre of twinning. If a twin has three or more parts, it is referred to as a multiple, or repeated, twin. Examples of various twin types are shown in Figure 6.

INTERNAL STRUCTURE

The external morphology of a mineral is an expression of the fundamental internal architecture of a crystalline substance—*i.e.*, its crystal structure. The crystal structure is the three-dimensional, regular (or ordered) arrangement of chemical units (atoms, ions, and anionic groups in inorganic materials; molecules in organic substances); these

chemical units (referred to here as motifs) are repeated by various translational and symmetry operations (see below). The morphology of crystals can be studied with the unaided eye in large well-developed crystals and has been historically examined in considerable detail by optical measurements of smaller well-formed crystals through the use of optical goniometers. The internal structure of crystalline materials, however, is revealed by a combination of X-ray, neutron, and electron diffraction techniques, supplemented by a variety of spectroscopic methods, including infrared, optical, Mössbauer, and resonance techniques. These methods, used singly or in combination, provide a quantitative three-dimensional reconstruction of the location of the atoms (or ions), the chemical bond

types and their positions, and the overall internal symmetry of the structure. The repeat distances in most inorganic structures and many of the atomic and ionic motif sizes are on the order of 1 to 10 angstroms (1 angstrom [Å] is equivalent to 10^{-8} centimetre [cm] or 3.94×10^{-9} inch) or 10 to 100 nanometres (nm; 1 nm is equivalent to 10^{-7} cm or 10 Å).

Symmetry elements that are observable in the external morphology of crystals, such as rotation and rotoinversion axes, mirror planes, and a centre of symmetry, also are present in their internal atomic structure. In addition to these symmetry elements, there are translations and symmetry operations combined with translations. (Translation is the operation in which a motif is repeated in a linear pattern at intervals that are equal to the translation distance [commonly on the 1 to 10 Å level].) Two examples of translational symmetry elements are screw axes (combining rotation and translation) and glide planes (combining mirroring and translation). The internal translation distances are exceedingly small and can be seen directly only by very high magnification electron-beam techniques, as used in a transmission electron microscope, at magnifications of about 600,000×. The 32 combinations of the translation-free symmetry elements are the crystal classes listed in Table 1 above. When all possible combinations of translational elements compatible with the 32 crystal classes (also known as point groups) are considered, one arrives at 230 possible ways in which translations, translational symmetry elements (screw axes and glide planes), and translation-free symmetry elements (rotation and rotoinversion axes and mirror planes) can be combined. These translation and symmetry groupings are known as the 230 space groups, representing the various ways in which motifs can be arranged in an ordered three-dimensional array. The symbolic representation of space groups is closely related to that of the Hermann-Mauguin notation of point groups as listed in column 3 of Table 1. A detailed discussion of space groups, their derivation, and notation is beyond the scope of this article. For more specific information, consult the books on mineralogy cited in the *Bibliography*.

As in the case of the illustrations of the external morphology of crystals given above (Figures 2 through 6), the three-dimensional arrangement of crystal structures must be presented on a two-dimensional page. A common method of illustration involves projecting the crystal structure onto a planar surface, as in Figure 7, which portrays the structure of a form of silicon dioxide (SiO_2) known as tridymite. The structural motif units in this case are SiO_4 tetrahedrons composed of a silicon atom surrounded by four oxygen atoms. To further aid the visualization of complex crystal structures, models of such

structures can be built or obtained commercially. Models of this sort reproduce the internal atomic arrangement on an enormously enlarged scale (*e.g.*, one angstrom might be represented by one centimetre). Two types of crystal structure models are illustrated in Figure 8.

POLYMORPHISM

Polymorphism is the ability of a specific chemical composition to crystallize in more than one form. This generally occurs as a response to changes in temperature or pressure or both. The different structures of such a chemical substance are called polymorphic forms, or polymorphs. For example, the element carbon (C) occurs in nature in two different polymorphic forms, depending on the external (pressure and temperature) conditions. These forms are graphite, with a hexagonal structure, and diamond, with an isometric structure. The composition FeS_2 occurs most commonly as pyrite, with an isometric structure, but it is also found as marcasite, which has an orthorhombic internal arrangement. The composition SiO_2 is found in a large number of polymorphs, among them quartz, tridymite, cristobalite, coesite, and stishovite. The stability field (conditions under which a mineral is stable) of these SiO_2 polymorphs is expressed in a stability diagram in Figure 9, with the external parameters of temperature and pressure as the two axes. In the general quartz field, there is additional polymorphism leading to the notation of high quartz and low quartz, each form having a slightly different internal structure. The diagram clearly indicates that cristobalite and tridymite are the high-temperature forms of SiO_2, and indeed these SiO_2 polymorphs occur in high-temperature lava flows. The high-pressure forms of SiO_2 are coesite and stishovite, and these can be found in meteorite craters, formed as a result of high explosive pressures upon quartz-rich sandstones, and in very deep-seated rock formations, as from the Earth's upper mantle.

CHEMICAL COMPOSITION

The chemical composition of a mineral is of fundamental importance because its properties greatly depend on it. Such properties, however, are determined not only by the chemical composition but also by the geometry of the constituent atoms and ions and by the nature of the electrical forces that bind them. Thus, for a complete understanding of minerals, their internal structure, chemistry, and bond types must be considered.

Various analytical techniques may be employed to obtain the chemical composition of a mineral. Quantitative chemical analyses conducted prior to 1947 mainly utilized so-called wet analytical methods, in which the mineral sample is first dissolved. Various compounds are then precipitated from the solution, which are weighed to obtain a gravimetric analysis. Since 1947 a number of analytical procedures have been introduced that provide faster but somewhat less accurate results. Most analyses performed since 1960 have made use of instrumental methods such as optical emission, X-ray fluorescence, atomic absorption spectroscopy, and electron microprobe analysis. Relatively well-established error ranges have been documented for these methods, and samples must be prepared in a specific manner for each technique. A distinct advantage of wet analytical procedures is that they make it possible to determine quantitatively the oxidation states of positively charged atoms, called cations (*e.g.*, Fe^{2+} versus Fe^{3+}), and to ascertain the amount of water in hydrous minerals. Instrumental techniques, on the other hand, cannot provide this type of information.

Chemical analyses

To ensure an accurate chemical analysis, the selected sample must contain only one mineral species (*i.e.*, the one for which the analysis is being done) and must not have undergone alteration processes. Since it is frequently difficult, and at times impossible, to obtain as much as 0.1 to 1 gram of "clean" material for analysis, the results should be accompanied by specifications on the amount of impurities present. To reduce the effect of the impurities, an instrumental technique, such as electron microprobe analysis, is often employed. In this method, quantitative analysis in situ may be performed on mineral grains only 1 micrometre (10^{-4} centimetre) in diameter.

MINERAL FORMULAS

Elements may exist in the native (uncombined) state, in which case their formulas are simply their chemical symbols: gold (Au), carbon (C) in its polymorphic form of diamond, and sulfur (S) are common examples. Most minerals, however, occur as compounds consisting of two or more elements; their formulas are obtained from quantitative chemical analyses and indicate the relative proportions of the constituent elements. The formula of sphalerite, ZnS, reflects a one-to-one ratio between atoms of zinc and those of sulfur. In bornite (Cu_5FeS_4), there are five atoms of copper (Cu), one atom of iron (Fe), and four atoms of sulfur. There exist relatively few minerals with constant composition; notable examples include quartz (SiO_2) and kyanite (Al_2SiO_5). Minerals of this sort are termed pure substances. Most minerals display considerable variation in the ions that occupy specific atomic sites within their structure. For example, the iron content of rhodochrosite ($MnCO_3$) may vary over a wide range. As ferrous iron (Fe^{2+}) substitutes for manganese cations (Mn^{2+}) in the rhodochrosite structure, the formula for the mineral might be given in more general terms—namely (Mn, Fe)CO_3. The amounts of manganese and iron are variable, but the ratio of the cation to the negatively charged anionic group remains fixed at one Mn^{2+} or Fe^{2+} atom to one CO_3 group.

COMPOSITIONAL VARIATION

As stated above, most minerals exhibit a considerable range in chemical composition. Such variation results from the replacement of one ion or ionic group by another in

a particular structure. This phenomenon is termed ionic substitution, or solid solution. Three types of solid solution are possible, and these may be described in terms of their corresponding mechanisms—namely, substitutional, interstitial, and omission.

Substitutional solid solution

Substitutional solid solution is the most common variety. For example, as described above, in the carbonate mineral rhodochrosite ($MnCO_3$), Fe^{2+} may substitute for Mn^{2+} in its atomic site in the structure.

The degree of substitution may be influenced by various factors, with the size of the ion being the most important. Ions of two different elements can freely replace one another only if their ionic radii differ by approximately 15 percent or less. Limited substitution can occur if the radii differ by 15 to 30 percent, and a difference of more than 30 percent makes substitution unlikely. These limits, calculated from empirical data, are only approximate.

The temperature at which crystals grow also plays a significant role in determining the extent of ionic substitution. The higher the temperature, the more extensive is the thermal disorder in the crystal structure and the less exacting are the spatial requirements. As a result, ionic substitution that could not have occurred in crystals grown at low temperatures may be present in those grown at higher ones. The high-temperature form of $KAlSi_3O_8$ (sanidine), for example, can accommodate more sodium (Na) in place of potassium (K) than can microcline, its low-temperature counterpart.

An additional factor affecting ionic substitution is the maintenance of a balance between the positive and negative charges in the structure. Replacement of a monovalent ion (*e.g.*, Na^+, a sodium cation) by a divalent ion (*e.g.*, Ca^{2+}, a calcium cation) requires further substitutions to keep the structure electrically neutral.

Simple cationic or anionic substitutions are the most basic types of substitutional solid solution. A simple cationic substitution can be represented in a compound of the general form A^+X^- in which cation B^+ replaces in part or in total cation A^+. Both cations in this example have the same valence (+1), as in the substitution of K^+ (potassium ions) for Na^+ (sodium ions) in the NaCl (sodium chloride) structure. Similarly, the substitution of anion X^- by Y^- in an A^+X^- compound represents a simple anionic substitution; this is exemplified by the replacement of Cl^- (chlorine ions) with Br^- (bromine ions) in the structure of KCl (potassium chloride). A complete solid-solution series involves the substitution in one or more atomic sites of one element for another that ranges over all possible compositions and is defined in terms of two end-members. For example, the two end-members of olivine [$(Mg, Fe)_2SiO_4$], forsterite (Mg_2SiO_4) and fayalite (Fe_2SiO_4), define a complete solid-solution series in which magnesium cations (Mg^{2+}) are replaced partially or totally by Fe^{2+}.

In some instances, a cation B^{2+} may replace some A^{2+} of compound A^+X^{2-}. So that the compound will remain neutral, an equal amount of A^{2+} must concurrently be replaced by a third cation, C^+. This is given in equation form as $2A^{2+} \leftrightarrows B^{3+} + C^+$; the positive charge on each side is the same. Substitutions such as this are termed coupled substitutions. The plagioclase feldspar series exhibits complete solid solution, in the form of coupled substitutions, between its two end-members, albite ($NaAlSi_3O_8$) and anorthite ($CaAl_2Si_2O_8$). Every atomic substitution of Na^+ by Ca^{2+} is accompanied by the replacement of a silicon cation (Si^{4+}) by an aluminum cation (Al^{3+}), thereby maintaining electrical neutrality: $Na^+ + Si^{4+} \leftrightarrows Ca^{2+} + Al^{3+}$.

Interstitial substitution

The second major type of ionic substitution is interstitial solid solution, or interstitial substitution. It takes place when atoms, ions, or molecules fill the interstices (voids) found between the atoms, ions, or ionic groups of a crystal structure. The interstices may take the form of channellike cavities in certain crystals, such as the ring silicate beryl ($Be_3Al_2Si_6O_{18}$). Potassium, rubidium (Rb), cesium (Cs), and water, as well as helium (He), are some of the large ions and gases found in the tubular voids of beryl.

The least common type of solid solution is omission solid solution, in which a crystal contains one or more atomic sites that are not completely filled. The best-known example is exhibited by pyrrhotite ($Fe_{1-x}S$). In this mineral, each iron atom is surrounded by six neighbouring sulfur atoms. If every iron site in pyrrhotite was occupied by ferrous iron, its formula would be FeS. There are, however, varying percentages of vacancy in the iron site, so that the formula is given as Fe_nS_{n+1} through Fe_7S_8, the latter being very near to pure FeS. The formula for pyrrhotite is normally written as $Fe_{1-x}S$, with x ranging from 0 to 0.2. It is one of the minerals referred to as a defect structure, because it has a structural site that is not completely occupied.

CHEMICAL BONDING

Electrical forces are responsible for binding together the atoms, ions, and ionic groups that constitute crystalline solids. The physical and chemical properties of minerals are attributable for the most part to the types and strengths of these binding forces; hardness, cleavage, fusibility, electrical and thermal conductivity, and the coefficient of thermal expansion are examples of such properties. On the whole, the hardness and melting point of a crystal increase proportionally with the strength of the bond, while its coefficient of thermal expansion decreases. The extremely strong forces that link the carbon atoms of diamond, for instance, are responsible for its distinct hardness. Periclase (MgO) and halite (NaCl) have similar structures; however, periclase has a melting point of 2,800° C (5,072° F), whereas halite melts at 801° C (1,474° F). This discrepancy reflects the difference in the bond strength of the two minerals: since the atoms of periclase are joined by a stronger electrical force, a greater amount of heat is needed to separate them.

The electrical forces, called chemical bonds, can be divided into five types: ionic, covalent, metallic, van der Waals, and hydrogen bonds. Classification in this manner is largely one of expediency; the chemical bonds in a given mineral may in fact possess characteristics of more

than one bond type. For example, the forces that link the silicon and oxygen atoms in quartz exhibit in nearly equal amount the characteristics of both ionic and covalent bonds. As stated above, the electrical interaction between the atoms of a crystal determine its physical and chemical properties. Thus, classifying minerals according to their electrical forces will cause those species with similar properties to be grouped together. This fact justifies classification by bond type.

Ionic bonds. Atoms have a tendency to gain or lose electrons so that their outer orbitals become stable; this is normally accomplished by these orbitals being filled with the maximum allowed number of valence electrons. Metallic sodium, for example, has one valence electron in its outer orbital; it becomes ionized by readily losing this electron and exists as the cation Na^+. Conversely, chlorine gains an electron to complete its outer orbital, thereby forming the anion Cl^-. In the mineral halite, NaCl (common, or rock, salt), the chemical bonding that holds the Na^+ and Cl^- ions together is the attraction between the two opposite charges. This bonding mechanism is referred to as ionic, or electrovalent (see Figure 10A).

Bonding in halite

Ionically bonded crystals typically display moderate hardness and specific gravity, rather high melting points, and poor thermal and electrical conductivity. The electrostatic charge of an ion is evenly distributed over its surface, and so a cation tends to become surrounded with the maximum number of anions that can be arranged around it. Since ionic bonding is nondirectional, crystals bonded in this manner normally display high symmetry (see Table 2).

Covalent bonds. In the discussion of the ionic bond, it was noted that chlorine readily gains an electron to achieve a stable electron configuration. An incomplete outer orbital places a chlorine atom in a highly reactive state, so it attempts to combine with nearly any atom in its proximity. Because its closest neighbour is usually another chlorine atom, the two may bond together by sharing one pair of electrons. As a result of this extremely strong bond, each chlorine atom enters a stable state.

The electron-sharing, or covalent, bond is the strongest of all chemical bond types. Minerals bonded in this manner display general insolubility, great stability, and a high melting point. Crystals of covalently bonded minerals tend to exhibit lower symmetry than their ionic counterparts because the covalent bond is highly directional, localized in the vicinity of the shared electrons (see Table 2).

The Cl_2 molecules formed by linking two neighbouring chlorine atoms are stable and do not combine with other molecules. Atoms of some elements, however, have more than one electron in the outer orbital and thus may bond to several neighbouring atoms to form groups, which in turn may join together in larger combinations. Carbon, in the polymorphic form of diamond, is a good example of this type of covalent bonding. There are four valence electrons in a carbon atom, so that each atom bonds with four others in a stable tetrahedral configuration (see Figure 10B). A continuous network is formed by the linkage of every carbon atom in this manner. The rigid diamond structure results from the strong localization of the bond energy in the vicinity of the shared electrons; this makes diamond the hardest of all natural substances. Diamond does not conduct electricity, because all the valence electrons of its constituent atoms are shared to form bonds and therefore are not mobile (see Table 2).

Metallic bonds. Bonding in metals is distinct from that in their salts, as reflected in the significant differences

between the properties of the two groups. In contrast to salts, metals display high plasticity, tenacity, ductility, and conductivity. Many are characterized by lower hardness and have higher melting and boiling points than, for example, covalently bonded materials. All these properties result from a metallic bonding mechanism that can be envisioned as a collection of positively charged ions immersed in a cloud of valence electrons (see Figure 10C). The attraction between the cations and the electrons holds a crystal together. The electrons are not bound to any particular cation and are thus free to move throughout the structure. In fact, in the metals sodium, cesium, rubidium, and potassium, the radiant energy of light can cause electrons to be removed from their surfaces entirely. (This result, known as the photoelectric effect, is utilized in light meters.) Electron mobility is responsible for the ability of metals to conduct heat and electricity. The native metals are the only minerals to exhibit pure metallic bonding (see Table 2).

Electron mobility in metals

Van der Waals bonds. Neutral molecules may be held together by a weak electric force known as the van der Waals bond. It results from the distortion of a molecule so that a small positive charge develops on one end and a corresponding negative charge develops on the other (see Figure 10D). A similar effect is induced in neighbouring molecules, and this dipole effect propagates throughout the entire structure. An attractive force is then formed between oppositely charged ends of the dipoles. Van der Waals bonding is common in gases and organic liquids and solids, but it is rare in minerals. Its presence in a mineral defines a weak area with good cleavage and low hardness. In graphite, carbon atoms lie in covalently bonded sheets with van der Waals forces acting between the layers (see Figure 11).

Hydrogen bonds. In addition to the four major bond types described above, there is an interaction called hydrogen bonding. This takes place when a hydrogen atom, bonded to an electronegative atom such as oxygen, fluorine, or nitrogen, is also attracted to the negative end of a neighbouring molecule. A strong dipole-dipole interaction is produced, forming a bond between the two molecules. Hydrogen bonding is common in hydroxides and in many of the layer silicates—*e.g.,* micas and clay minerals.

PHYSICAL PROPERTIES

The physical properties of minerals are the direct result of the structural and chemical characteristics of the minerals. Some properties can be determined by inspection of a hand specimen or by relatively simple tests on such a specimen. Others, such as those determined by optical and X-ray diffraction techniques, require special and often sophisticated equipment and may involve elaborate sample preparation. In the discussion that follows, emphasis is placed on those properties that can be most easily evaluated with only simple tests.

Crystal habit and crystal aggregation. The external shape (habit) of well-developed crystals can be visually studied and classified according to the crystal systems and crystal classes listed in Table 1. The majority of crystal occurrences, however, are not part of well-formed single crystals but are found as crystals grown together in aggregates. Examples of some descriptive terms for such aggregations, illustrated in Figure 12, are given here: *granular,* an intergrowth of mineral grains of approximately the same size; *lamellar,* flat, platelike individuals arranged in layers; *bladed,* elongated crystals flattened like a knife blade; *fibrous,* an aggregate of slender fibres, parallel or radiating; *acicular,* slender, needlelike crystals; *radiating,* individuals forming starlike or circular groups; *globular,* radiating individuals forming small spherical or hemispherical groups; *dendritic,* in slender divergent branches, somewhat plantlike; *mammillary,* large smoothly rounded, masses resembling mammae, formed by radiating crystals; *botryoidal,* globular forms resembling a bunch of grapes; *colloform,* spherical forms composed of radiating indi-

viduals without regard to size (this includes botryoidal, reniform, and mammillary forms); *stalactitic,* pendent cylinders or cones resembling icicles; *concentric,* roughly spherical layers arranged about a common centre, as in agate and in geodes; *geode,* a partially filled rock cavity lined by mineral material (geodes may be banded as in agate owing to successive depositions of material, and the inner surface is often covered with projecting crystals); and *oölitic,* an assemblage consisting of small spheres resembling fish roe.

Photographs of two different types of aggregations in minerals are shown in Figure 13.

Cleavage and fracture. Both these properties represent the reaction of a mineral to an external force. Cleavage is breakage along planar surfaces, which are parallel to possible external faces on the crystal. It results from the tendency of some minerals to split in certain directions that are structurally weaker than others. Some crystals exhibit well-developed cleavage, as seen by the planar cleavage in mica; perfect cleavage of this sort is characterized by smooth, shiny surfaces. In other minerals, such as quartz, cleavage is absent. Quality and direction are the general characteristics used to describe cleavage. Quality is expressed as perfect, good, fair, and so forth; cleavage directions of a crystal are consistent with its overall symmetry (see Table 1). Various types of cleavage patterns are illustrated in Figure 14.

Some crystals do not usually break in any particular direction, reflecting roughly equal bond strengths throughout the crystal structure. Breakage in such minerals is known as fracture. The term conchoidal is used to describe fracture with smooth, curved surfaces that resemble the interior of a seashell; it is commonly observed in quartz and glass (see Figure 14G). Splintery fracture is breakage into elongated fragments like splinters of wood, while hackly fracture is breakage along jagged surfaces.

Lustre. The term lustre refers to the general appearance of a mineral surface in reflected light. The main types of lustre, metallic and nonmetallic, are distinguished easily by the human eye after some practice, but the difference between them cannot be quantified and is rather difficult to describe. Metallic refers to the lustre of an untarnished metallic surface such as gold, silver, copper, or steel. These materials are opaque to light; none passes through even at thin edges. Pyrite (FeS_2), chalcopyrite ($CuFeS_2$), and galena (PbS) are common minerals that have metallic lustre. Nonmetallic lustre is generally exhibited by light-coloured minerals that transmit light, either through thick portions or at least through their edges. The following terms are used to distinguish the lustre of nonmetallic minerals: *vitreous,* having the lustre of a piece of broken glass (this is commonly seen in quartz and many other nonmetallic minerals); *resinous,* having the lustre of a piece of resin (this is common in sphalerite [ZnS]); *pearly,* having the lustre of mother-of-pearl (*i.e.,* an iridescent pearllike lustre characteristic of mineral surfaces that are

parallel to well-developed cleavage planes; the cleavage surface of talc [$Mg_3Si_4O_{10}(OH)_2$] may show pearly lustre); *greasy,* having the appearance of being covered with a thin layer of oil (such lustre results from the scattering of light by a microscopically rough surface; some nepheline [(Na, K)$AlSiO_4$] and milky quartz may exhibit this); *silky,* descriptive of the lustre of a skein of silk or a piece of satin and characteristic of some minerals in fibrous aggregates (examples are fibrous gypsum [$CaSO_4 \cdot 2H_2O$], known as satin spar, and chrysotile asbestos [$Mg_3Si_2O_5(OH)_4$]); and *adamantine,* having the brilliant lustre of diamond, exhibited by minerals with a high refractive index comparable to diamond and which as such refract light as strongly as the latter (examples are cerussite [$PbCO_3$] and anglesite [$PbSO_4$]).

Colour. Minerals occur in a great variety of colours. Because colour varies not only from one mineral to another but also within the same mineral (or mineral group), the observer must learn in which minerals it is a constant property and can thus be relied on as a distinguishing criterion. Most minerals that have a metallic lustre vary little in colour, but nonmetallic minerals can demonstrate wide variance. Although the colour of a freshly broken surface of a metallic mineral is often highly diagnostic, this same mineral may become tarnished with time. Such a tarnish may dull minerals such as galena (PbS), which has a bright, bluish lead-gray colour on a fresh surface but may become dull upon long exposure to air. Bornite (Cu_5FeS_4), which on a freshly broken surface has a brownish bronze colour, may be so highly tarnished on an older surface that it shows variegated purples and blues; hence, it is called peacock ore. In other words, in the identification of minerals with a metallic lustre, it is important for the observer to have a freshly broken surface for accurate determination of colour.

Peacock ore

A few minerals with nonmetallic lustre display a constant colour that can be used as a truly diagnostic property. Examples are malachite, which is green; azurite, which is blue; rhodonite, which is pink; turquoise, which gives its name to the colour turquoise, a greenish blue to blue-green; and sulfur, which is yellow (see Figure 15). Many nonmetallic minerals have a relatively narrow range of colours, although some have an unusually wide range. Members of the plagioclase feldspar series range from almost pure white in albite through light gray to darker gray toward the anorthite end-member. Most common garnets show various shades of red to red-brown to brown. Members of the monoclinic pyroxene group range from almost white in pure diopside to light green in diopside containing a small amount of iron as a substitute for magnesium in the structure through dark green in hedenbergite to almost black in many augites. Members of the orthopyroxene series (enstatite to orthoferrosilite) range from light beige to darker brown. On the other hand, tourmaline may show many colours (red, blue, green, brown, and black) as well as distinct colour zonation, from colourless through pink to green, within a single crystal. Similarly, numerous gem minerals such as corundum, beryl, and quartz occur in many colours; the gemstones cut from them are given varietal names. In short, in nonmetallic minerals of various kinds colour is a helpful, though not a truly diagnostic (and therefore unique), property.

Hardness. Hardness (H) is the resistance of a mineral to scratching. It is a property by which minerals may be described relative to a standard scale of 10 minerals known as the Mohs scale of hardness. The minerals that make up the Mohs scale are listed in Table 3. The degree of hardness is determined by observing the comparative ease or difficulty with which one mineral is scratched by another or by a steel tool.

For measuring the hardness of a mineral, several common objects that can be used for scratching are helpful, such as a fingernail, a copper coin, a steel pocketknife, glass plate or window glass, the steel of a needle, and a streak plate. The approximate hardness of these materials is listed next to the minerals of the Mohs scale in Table 3.

Because there is a general link between hardness and chemical composition, these generalizations can be made:

1. Most hydrous minerals are relatively soft ($H < 5$).

Table 3: Mohs Hardness Scale and Observations on Hardness of Some Additional Materials

mineral	Mohs hardness	other materials	observations on the minerals
Talc	1		very easily scratched by the fingernail; has a greasy feel
Gypsum	2	~2.2 fingernail	can be scratched by the fingernail
Calcite	3	~3.2 copper penny	very easily scratched with a knife and just scratched with a copper coin
Fluorite	4		very easily scratched with a knife but not as easily as calcite
Apatite	5	~5.1 pocketknife	scratched with a knife with difficulty
		~5.5 glass plate	
Orthoclase	6	~6.5 steel needle	cannot be scratched with a knife, but scratches glass with difficulty
Quartz	7	~7.0 streak plate	scratches glass easily
Topaz	8		scratches glass very easily
Corundum	9		cuts glass
Diamond	10		used as a glass cutter

2. Halides, carbonates, sulfates, and phosphates also are relatively soft ($H < 5\frac{1}{2}$).
3. Most sulfides are relatively soft ($H < 5$), with marcasite and pyrite being examples of exceptions ($H < 6$ to $6\frac{1}{2}$).
4. Most anhydrous oxides and silicates are hard ($H > 5\frac{1}{2}$).

Because hardness is a highly diagnostic property in mineral identification, most determinative tables use relative hardness as a sorting parameter.

Tenacity. Several mineral properties that depend on the cohesive force between atoms (and ions) in mineral structures are grouped under tenacity. A mineral's tenacity can be described by the following terms: *malleable,* capable of being flattened under the blows of a hammer into thin sheets without breaking or crumbling into fragments (most of the native elements show various degrees of malleability, but particularly gold, silver, and copper); *sectile,* capable of being severed by the smooth cut of a knife (copper, silver, and gold are sectile); *ductile,* capable

of being drawn into the form of a wire (gold, silver, and copper exhibit this property); *flexible,* bending easily and staying bent after the pressure is removed (talc is flexible); *brittle,* showing little or no resistance to breakage, and as such separating into fragments under the blow of a hammer or when cut by a knife (most silicate minerals are brittle); and *elastic,* capable of being bent or pulled out of shape but returning to the original form when relieved (mica is elastic).

Specific gravity. Specific gravity (G) is defined as the ratio between the weight of a substance and the weight of an equal volume of water at 4° C. Thus a mineral with a specific gravity of 2 weighs twice as much as the same volume of water. Since it is a ratio, specific gravity has no units.

The specific gravity of a mineral depends on the atomic weights of all its constituent elements and the manner in which the atoms (and ions) are packed together. In mineral series whose species have essentially identical structures, those composed of elements with higher atomic weight have higher specific gravities. If two minerals (as in the two polymorphs of carbon, namely, graphite and diamond) have the same chemical composition, the difference in specific gravity reflects variation in internal packing of the atoms or ions (diamond, with a G of 3.51, has a more densely packed structure than graphite, with a G of 2.23).

Measurement of the specific gravity of a mineral specimen requires the use of a special apparatus. An estimate of the value, however, can be obtained by simply testing how heavy a specimen feels. Most people, from everyday experience, have developed a sense of relative weights for even such objects as nonmetallic and metallic minerals. For example, borax ($G = 1.7$) seems light for a nonmetallic mineral, whereas anglesite ($G = 6.4$) appears heavy. Average specific gravity reflects what a nonmetallic or metallic mineral of a given size should weigh. The average specific gravity for nonmetallic minerals falls between 2.65 and 2.75, which is seen in the range of values for quartz ($G = 2.65$), feldspar ($G = 2.60$ to 2.75), and calcite ($G = 2.72$). For metallic minerals, graphite ($G = 2.23$) feels light, while silver ($G = 10.5$) seems heavy. The average specific gravity for metallic minerals is approximately 5.0, the value for pyrite. With practice using specimens of known specific gravity, a person can develop the ability to distinguish between minerals that have comparatively small differences in specific gravity by merely lifting them.

Jolly balance

Although an approximate assessment of specific gravity can be obtained by the hefting of a hand specimen of a specific monomineral, an accurate measurement can only be achieved by using a specific gravity balance. An example of such an instrument is the Jolly balance, which provides numerical values for a small mineral specimen (or fragment) in air as well as in water. Such accurate measurements are highly diagnostic and can greatly aid in the identification of an unknown mineral sample.

Magnetism. Only two minerals exhibit readily observed magnetism: magnetite (Fe_3O_4), which is strongly attracted to a hand magnet, and pyrrhotite ($Fe_{1-x}S$), which typically shows a weaker magnetic reaction. Ferromagnetic is a term that refers to materials that exhibit strong magnetic attraction when subjected to a magnetic field. Materials that show only a weak magnetic response in a strong applied magnetic field are known as paramagnetic. Those materials that are repelled by an applied magnetic force are known as diamagnetic. Because minerals display a wide range of slightly different magnetic properties, they can be separated from each other by an electromagnet. Such magnetic separation is a common procedure both in the laboratory and on a commercial scale.

Fluorescence. Some minerals, when exposed to ultraviolet light, will emit visible light during irradiation; this is known as fluorescence. Some minerals fluoresce only in shortwave ultraviolet light, others only in longwave ultraviolet light, and still others in either situation. Both the colour and intensity of the emitted light vary significantly with the wavelengths of ultraviolet light. Due to the unpredictable nature of fluorescence, some specimens of a mineral manifest it, while other seemingly similar specimens, even those from the same geographic area, do not.

Some minerals that may exhibit fluorescence are fluorite, scheelite, calcite, scapolite, willemite, and autunite. Specimens of willemite and calcite from the Franklin district of New Jersey in the United States may show brilliant fluorescent colours (see Figure 16).

Solubility in hydrochloric acid. The positive identification of carbonate minerals is aided greatly by the fact that the carbon-oxygen bond of the CO_3 group in carbonates becomes unstable and breaks down in the presence of hydrogen ions (H^+) available in acids. This is expressed by the reaction $2H^+ + CO_3^{2-} \rightarrow H_2O + CO_2$, which is the basis for the so-called fizz test with dilute hydrochloric acid (HCl). Calcite, aragonite, witherite, and strontianite, as well as copper carbonates, show bubbling, or effervescence, when a drop of dilute hydrochloric acid is placed on the mineral. This "fizz" is due to the release of carbon dioxide (CO_2). Other carbonates such as dolomite, rhodochrosite, magnesite, and siderite will show effervescence only in hot hydrochloric acid.

Fizz test

Radioactivity. Minerals containing uranium (U) and thorium (Th) continually undergo decay reactions in which radioactive isotopes of uranium and thorium form various daughter elements and also release energy in the form of alpha and beta particles and gamma radiation. The radiation produced can be measured in the laboratory or in the field using a Geiger counter or a scintillation counter. A radiation counter therefore is helpful in identifying uranium- and thorium-containing minerals, such as uraninite, pitchblende, thorianite, and autunite.

Several rock-forming minerals contain enough radioactive elements to permit the determination of the time elapsed since the radioactive material was incorporated into the mineral (see GEOCHRONOLOGY: *Absolute dating: Principles of isotopic dating.*)

Classification of minerals

Since the middle of the 19th century, minerals have been classified on the basis of their chemical composition. Under this scheme, they are divided into classes according to their dominant anion or anionic group (*e.g.,* halides, oxides, and sulfides). Several reasons justify use of this criterion as the distinguishing factor at the highest level of mineral classification. First, the similarities in properties of minerals with identical anionic groups are generally more pronounced than those with the same dominant cation. For example, carbonates have stronger resemblences to one another than do copper minerals. Secondly, minerals that have identical dominant anions are likely to be found in the same or similar geologic environments. Therefore, sulfides tend to occur together in vein or replacement deposits, while silicate-bearing rocks make up much of the Earth's crust. Third, current chemical practice employs a nomenclature and classification scheme for inorganic compounds based on similar principles.

Investigators have found, however, that chemical composition alone is insufficient for classifying minerals. Determination of internal structures, accomplished through the use of X rays, allows a more complete appreciation of the nature of minerals. Chemical composition and internal structure together constitute the essence of a mineral and determine its physical properties; thus, classification should rely on both. Crystallochemical principles—*i.e.,* those relating to both chemical composition and crystal structure—were first applied by the British physicist W. Lawrence Bragg and the Norwegian mineralogist Victor Moritz Goldschmidt in the study of silicate minerals. The silicate group was subdivided in part on the basis of composition but mainly according to internal structure. Based on the topology of the SiO_4 tetrahedrons, the subclasses include framework, chain, and sheet silicates, among others. Such mineral classifications are logical and well-defined.

Classification groups

The broadest divisions of the classification used in the present discussion are (1) native elements, (2) sulfides, (3) sulfosalts, (4) oxides and hydroxides, (5) halides, (6) carbonates, (7) nitrates, (8) borates, (9) sulfates, (10) phosphates, and (11) silicates.

NATIVE ELEMENTS

Apart from the free gases in the Earth's atmosphere, some 20 elements occur in nature in a pure (*i.e.,* uncombined) or nearly pure form. Known as the native elements, they are partitioned into three families: metals, semimetals, and nonmetals (see Table 4). The most common native metals, which are characterized by simple crystal structures, make up three groups: the gold group, consisting of gold, silver, copper, and lead; the platinum group, composed of platinum, palladium, iridium, and osmium; and the iron group, containing iron and nickel-iron. Mercury, tantalum, tin, and zinc are other metals that have been found in the native state. The native semimetals are divided into two isostructural groups (those whose members share a common structure type): (1) antimony, arsenic, and bismuth, with the latter two being more common in nature, and (2) the rather uncommon selenium and tellurium. Carbon, in the form of diamond and graphite, and sulfur are the most important native nonmetals.

Metals. Gold, silver, and copper are members of the same group (column) in the periodic table of elements (see CHEMICAL ELEMENTS: *Periodic law and table*) and therefore have similar chemical properties. In the uncombined state, their atoms are joined by the fairly weak metallic bond. These minerals share a common structure type, and their atoms are positioned in a simple cubic closest-packed arrangement. Gold and silver both have an atomic radius of 1.44 angstroms (Å), which enables complete solid solution to take place between them. The radius of copper is significantly smaller (1.28 Å), and as such copper substi-

tutes only to a limited extent in gold and silver. Likewise, native copper contains only trace amounts of gold and silver in its structure.

Physical properties

Owing to their similar crystal structure, the members of the gold group display similar physical properties. All are rather soft, ductile, malleable, and sectile; gold, silver, and copper serve as excellent conductors of electricity and heat and exhibit metallic lustre and hackly fracture. These properties are attributable to their metallic bonding. The gold-group minerals crystallize in the isometric system and have high densities as a consequence of cubic closest packing.

In addition to the elements listed above, the platinum group also includes the rarer mineral alloys platiniridium and iridosmine. The members of this group are harder than the metals of the gold group and also have higher melting points.

The iron-group metals are isometric and have a simple cubic packed structure (see Figure 17A). Its members include pure iron, which is rarely found on the surface of the Earth, and two species of nickel-iron (kamacite and taenite), which have been identified as common constituents of meteorites. The atomic radii of iron and nickel are both approximately 1.24 Å, and so nickel is a frequent substitute for iron. The terrestrial core is thought to be composed largely of such iron-nickel alloys.

Semimetals. The semimetals antimony, arsenic, and bismuth have a structure type distinct from the simple-packed spheres of the metals. In these semimetals, each atom is positioned closer to three of its neighbouring atoms than to the rest. The structure of antimony and arsenic, composed of spheres that intersect along flat circular areas, is shown in Figure 17B.

The covalent character of the bonds joining the four closest atoms is linked to the electronegative nature of the semimetals, reflected by their position in the periodic table. Members of this group are fairly brittle, and they do not conduct heat and electricity nearly as well as the native metals. The bond type suggested by these properties is intermediate between metallic and covalent; it is consequently stronger and more directional than pure metallic bonding, resulting in crystals of lower symmetry.

Nonmetals. The native nonmetals diamond, graphite, and sulfur are structurally distinct from the metals and semimetals. The structure of sulfur (atomic radius = 1.04 Å), usually orthorhombic in form, may contain limited solid solution by selenium (atomic radius = 1.16 Å).

The polymorphs of carbon, graphite and diamond, display dissimilar structures, resulting in their differences in hardness and specific gravity. In diamond, each carbon atom is bonded covalently in a tetrahedral arrangement, producing a strongly bonded and exceedingly close-knit but not closest-packed structure (see Figure 17C). The carbon atoms of graphite, however, are arranged in six-membered rings in which each atom is surrounded by three close-by neighbours located at the vertices of an equilateral triangle (see Figure 17D). The rings are linked to form sheets that are separated by a distance exceeding one atomic diameter. Van der Waals forces act perpendicular to the sheets, offering a weak bond, which, in combination with the wide spacing, leads to perfect basal cleavage and easy gliding along the sheets.

SULFIDES

This important class includes most of the ore minerals. The similar but rarer sulfarsenides are grouped here as well (see Table 5). Sulfide minerals consist of one or more metals combined with sulfur; sulfarsenides contain arsenic replacing some of the sulfur.

Sulfides are generally opaque and exhibit distinguishing colours and streaks. (Streak is the colour of a mineral's powder.) The nonopaque varieties (*e.g.*, cinnabar, realgar, and orpiment) possess high refractive indices, transmitting light only on the thin edges of a specimen.

Few broad generalizations can be made about the structures of sulfides, although these minerals can be classified into small groups according to similarities in structure. Ionic and covalent bonding are found in many sulfides, while metallic bonding is apparent in others as evidenced by their metal properties. The simplest and most symmetric sulfide structure is based on the architecture of the sodium chloride structure. A common sulfide mineral that crystallizes in this manner is the ore mineral of lead, galena. Its highly symmetric form consists of cubes modified by octahedral faces at their corners (see Figure 18). The structure of the common sulfide pyrite (FeS_2) also is modeled after the sodium chloride type; a disulfide grouping is located in a position of coordination with six surrounding ferrous iron atoms (see Figure 1). The high symmetry of this structure is reflected in the external morphology of pyrite (see Figure 2). Two other sulfide structures are illustrated in Figure 19. In the sphalerite (ZnS) structure, each zinc atom is surrounded by four sulfur atoms in a tetrahedral coordinating arrangement. In a derivative of this structure type, the chalcopyrite ($CuFeS_2$) structure, copper and iron ions can be thought of as having been regularly substituted in the zinc positions of the original sphalerite atomic arrangement.

Arsenopyrite (FeAsS) is a common sulfarsenide that occurs in many ore deposits. It is the chief source of the element arsenic.

SULFOSALTS

There are approximately 100 species constituting the rather large and very diverse sulfosalt class of minerals. Some common examples are listed in Table 5. The sulfosalts differ notably from the sulfides and sulfarsenides with regard to the role of semimetals, such as arsenic (As) and antimony (Sb), in their structures. In the sulfarsenides, the semimetals substitute for some of the sulfur in the struc-

ture, while in the sulfosalts they are found instead in the metal site. For example, in the sulfarsenide arsenopyrite (FeAsS), the arsenic replaces sulfur in a marcasite- (FeS_2-) type structure. In contrast, the sulfosalt enargite (Cu_3AsS_4) contains arsenic in the metal position, coordinated to four sulfur atoms. A sulfosalt such as Cu_3AsS_4 may also be thought of as a double sulfide, $3Cu_2S \cdot As_2S_3$.

OXIDES AND HYDROXIDES

These classes consist of oxygen-bearing minerals; the oxides combine oxygen with one or more metals, while the hydroxides are characterized by hydroxyl $(OH)^-$ groups.

The oxides are further divided into two main types: simple and multiple. Simple oxides contain a single metal combined with oxygen in one of several possible metal:oxygen ratios (X_2O): XO, X_2O, X_2O_3, etc. Ice, H_2O, is a simple oxide of the X_2O type that incorporates hydrogen as the cation. Although SiO_2 (quartz and its polymorphs) is the most commonly occurring oxide, it is discussed below in the section on silicates because its structure more closely resembles that of other silicon-oxygen compounds.

Two nonequivalent metal sites (X and Y) characterize multiple oxides, which have the form XY_2O_4.

Unlike the minerals of the sulfide class, which exhibit ionic, covalent, and metallic bonding, oxide minerals generally display strong ionic bonding. They are relatively hard, dense, and refractory.

Examples of several oxides are given in Table 6. These minerals generally occur in small amounts in igneous and metamorphic rocks and also as preexisting grains in sedimentary rocks. Several oxides have great economic value, including the principal ores of iron (hematite and magnetite), chromium (chromite), manganese (pyrolusite, as well as the hydroxides, manganite and romanechite), tin (cassiterite), and uranium (uraninite).

Members of the hematite group are of the X_2O_3 type and have structures based on hexagonal closest packing of the oxygen atoms with octahedrally coordinated (surrounded by and bonded to six atoms) cations between them. Corundum and hematite share a common hexagonal architecture (see Table 1). In the ilmenite structure, iron and titanium occupy alternate Fe-O and Ti-O layers.

XO_2-type oxides

The XO_2-type oxides are divided into two groups. The first structure type, exemplified by rutile, contains cations in octahedral coordination with oxygen. The second resembles fluorite (CaF_2); each oxygen is bonded to four cations located at the corners of a fairly regular tetrahedron, and each cation lies within a cube at whose corners are eight oxygen atoms. This latter structure is exhibited by uranium, thorium, and cerium oxides, whose considerable importance arises from their roles in nuclear chemistry.

The spinel-group minerals have type XY_2O_4 and contain oxygen atoms in approximate cubic closest packing. The cations located within the oxygen framework are octahedrally (sixfold) and tetrahedrally (fourfold) coordinated with oxygen (see Figure 20).

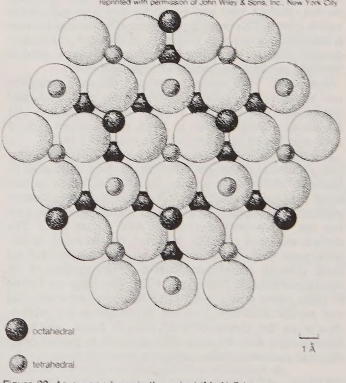

Figure 20: An oxygen layer in the spinel ($MgAl_2O_4$) structure. The large circles represent oxygen in approximate cubic closest packing; the cation layers on each side of the oxygen layer are also shown.

The $(OH)^-$ group of the hydroxides generally results in structures with lower bond strengths than in the oxide minerals. The hydroxide minerals tend to be less dense than the oxides and also are not as hard. All hydroxides form at low temperatures and are found predominantly as weathering products, as, for example, from alteration in hydrothermal veins. Some common hydroxides are brucite $[Mg(OH)_2]$, manganite $[MnO \cdot OH]$, diaspore $[\alpha\text{-}AlO \cdot OH]$, and goethite $[\alpha\text{-}FeO \cdot OH]$. The ore of aluminum, bauxite, consists of a mixture of diaspore, boehmite (γ-$AlO \cdot OH$—a polymorph of diaspore), and gibbsite $[Al(OH)_3]$, plus iron oxides. Goethite is a com-

mon alteration product of iron-rich occurrences and is an iron ore in some localities (see Figure 21).

HALIDES

Members of this class are distinguished by the large-sized anions of the halogens chlorine, bromine, iodine, and fluorine. The ions carry a charge of negative one and easily become distorted in the presence of strongly charged bodies. When associated with rather large, weakly polarizing cations of low charge, such as those of the alkali metals, both anions and cations take the form of nearly perfect spheres. Structures composed of these spheres exhibit the highest possible symmetry.

Pure ionic bonding is exemplified best in the isometric halides, for each spherical ion distributes its weak electrostatic charge over its entire surface. These halides manifest relatively low hardness and moderate-to-high melting points. In the solid state they are poor thermal and electric conductors, but when molten they conduct electricity well.

Halogen ions may also combine with smaller, more strongly polarizing cations than the alkali metal ions. Lower symmetry and a higher degree of covalent bonding prevail in these structures. Water and hydroxyl ions may enter the structure, as in atacamite [$Cu_3Cl(OH)_3$].

The halides consist of about 80 chemically related minerals with diverse structures and widely varied origins. The most common are halite (NaCl), sylvite (KCl), chlorargyrite (AgCl), cryolite (Na_3AlF_6), fluorite (CaF_2), and atacamite. The structure of sodium chloride is illustrated in Figure 22A. By the arrangement of the ions, it is evident that no molecules are present in the structure. Each cation and anion is in octahedral coordination with its six closest neighbours. The NaCl structure is found in the crystals of many *XZ*-type halides, including sylvite (KCl) and chlorargyrite (AgCl). Some sulfides and oxides of *XZ* type crystallize in this structure type as well—for example, galena (PbS), alabandite (MnS), and periclase (MgO).

NaCl structure

Several XZ_2 halides have the same structure as fluorite (CaF_2), which is shown in Figure 22B. In fluorite, calcium cations are positioned at the corners and face centres of cubic unit cells. (A unit cell is the smallest group of atoms, ions, or molecules from which the entire crystal structure can be generated by its repetition.) Each fluorine anion is in tetrahedral coordination with four calcium ions, while each calcium cation is in eightfold coordination with eight fluorine ions that form the corners of a cube around it.

Uraninite (UO_2) and thorianite (ThO_2) are two of the several oxides that have a fluorite-type structure.

CARBONATES

The carbonate minerals contain the anionic complex $(CO_3)^{2-}$, which is triangular in its coordination—*i.e.*, with a carbon atom at the centre and an oxygen atom at each of the corners of an equilateral triangle. These anionic groups are strongly bonded, individual units and do not share oxygen atoms with one another. The triangular carbonate groups are the basic building units of all carbonate minerals and are largely responsible for the properties particular to the class.

Carbonates are frequently identified using the effervescence test with acid (see above *Physical properties: Solubility in hydrochloric acid*). The reaction that results in the characteristic fizz, $2H^+ + CO_3^{2-} \rightarrow H_2O + CO_2$, makes use of the fact that the carbon-oxygen bonds of the CO_3 groups are not quite as strong as the corresponding carbon-oxygen bonds in carbon dioxide.

The common anhydrous carbonates are divided into three groups that differ in structure type: calcite, aragonite, and dolomite. The copper carbonates azurite and malachite are the only notable hydrous varieties (see Table 7).

The members of the calcite group that are given in the table share a common structure type (see Figure 23A). It can be considered as a derivative of the NaCl structure in which CO_3 groups substitute for the chlorine ions and calcium cations replace the sodium cations. As a result of the triangular shape of the CO_3 groups, the structure is rhombohedral instead of isometric as in NaCl. The CO_3 groups are in planes perpendicular to the threefold *c* axis, and the calcium ions occupy alternate planes and are bonded to six oxygen atoms of the CO_3 groups.

Calcite group structure

Members of the calcite group exhibit perfect rhombohedral cleavage. The well-developed morphology of a group of calcite crystals is shown in Figure 23B. The composition $CaCO_3$ most commonly occurs in two different polymorphs: rhombohedral calcite with calcium surrounded by six closest oxygen atoms and orthorhombic aragonite with calcium surrounded by nine closest oxygen atoms.

When CO_3 groups are combined with large divalent cations (generally with ionic radii greater than 1.0 Å), orthorhombic structures result. This is known as the aragonite structure type. Members of this group include those with large cations: $BaCO_3$, $SrCO_3$, and $PbCO_3$. Each cation is surrounded by nine closest oxygen atoms.

The aragonite group displays more limited solid solution than the calcite group. The type of cation present in aragonite minerals is largely responsible for the differences in physical properties among the members of the group. Specific gravity, for example, is roughly proportional to the atomic weight of the metal ions.

Dolomite $[CaMg(CO_3)_2]$, kutnahorite $[CaMn(CO_3)_2]$, and ankerite $[CaFe(CO_3)_2]$ are three isostructural members of the dolomite group. The dolomite structure can be consid-

ered as a calcite-type structure in which magnesium and calcium cations occupy the metal sites in alternate layers. The calcium (Ca^{2+}) and magnesium (Mg^{2+}) ions differ in size by 33 percent, and this produces cation ordering with the two cations occupying specific and separate levels in the structure. Dolomite has a calcium-to-magnesium ratio of approximately 1:1, which gives it a composition intermediate between $CaCO_3$ and $MgCO_3$.

NITRATES

The nitrates are characterized by their triangular $(NO_3)^-$ groups that resemble the $(CO_3)^{2-}$ groups of the carbonates, making the two mineral classes similar in structure. The nitrogen cation (N^{5+}) carries a high charge and is strongly polarizing like the carbon cation (C^{4+}) of the CO_3 group. A tightly knit triangular complex is created by the three nitrogen-oxygen bonds of the NO_3 group; these bonds are stronger than all others in the crystal. Because the nitrogen-oxygen bond has greater strength than the corresponding carbon-oxygen bond in carbonates, nitrates decompose less readily in the presence of acids.

Nitrate structures analogous to those of the calcite group result when NO_3 combines in a 1:1 ratio with monovalent cations whose radii can accommodate six closest oxygen neighbours. For example, nitratite ($NaNO_3$), also called soda nitre, and calcite exhibit the same structure, crystallography, and cleavage. The two minerals differ in that

Nitratite and nitre

nitratite is softer and melts at a lower temperature owing to its lesser charge; also, sodium has a lower atomic weight than calcium, causing nitratite to have a lower specific gravity as well. Similarly, nitre (KNO_3), also known as saltpetre, is an analogue of aragonite. These are two examples of only seven known naturally occurring nitrates.

BORATES

Minerals of the borate class contain boron-oxygen groups that can link together, in a phenomenon known as polymerization, to form chains, sheets, and isolated multiple groups (see Figure 24). The silicon-oxygen (SiO_4) tetrahedrons of the silicates polymerize in a manner similar to the $(BO_3)^{3-}$ triangular groups of the borates. (For further information on such structures, see below *Silicates*). A single oxygen atom is shared between two boron cations (B^{3+}), thereby linking the BO_3 groups into extended units such as double triangles, triple rings, sheets, and chains. The oxygen atom is able to accommodate two boron atoms because the small boron cation has a bond strength to each oxygen that is exactly one-half the bond energy of the oxygen ion.

Although boron is usually found in triangular coordination with three oxygens, it also occurs in fourfold coordination in tetrahedral groups. In addition, boron may exist as part of complex anionic groups such as $[B_3O_3(OH)_3]^{2-}$, consisting of one triangle and two tetrahedrons (see

SULFATES

This class is composed of a large number of minerals, but relatively few are common. The most frequently occurring sulfates are listed in Table 8. All contain anionic $(SO_4)^{2-}$ groups in their structures. These anionic complexes are formed through the tight bonding of a central S^{6+} ion to four neighbouring oxygen atoms in a tetrahedral arrangement around the sulfur. This closely knit group is incapable of sharing any of its apical oxygen atoms with other SO_4 groups; as such the tetrahedrons occur as individual, unlinked groups in sulfate mineral structures.

Barite group

Members of the barite group constitute the most important and common anhydrous sulfates. They have orthorhombic symmetry with large divalent cations bonded to the sulfate ion (see Table 8). In barite ($BaSO_4$), each barium ion is surrounded by 12 closest oxygen ions belonging to seven distinct SO_4 groups.

Anhydrite ($CaSO_4$) exhibits a structure very different from that of barite since the ionic radius of Ca^{2+} is considerably smaller than Ba^{2+}. Each calcium cation can only fit eight oxygen atoms around it from neighbouring SO_4 groups.

Gypsum ($CaSO_4 \cdot 2H_2O$) is the most important and abundant hydrous sulfate.

PHOSPHATES

Although this mineral class is large, most of its members are quite rare. Of the phosphates listed in Table 9, only apatite [$Ca_5(PO_4)_3(F, Cl, OH)$], the most important and abundant, can be considered as truly common. The members of this group are characterized by tetrahedral anionic $(PO_4)^{3-}$ complexes, which are analogous to the $(SO_4)^{2-}$ groups of the sulfates. The phosphorus ion, with a valence of positive five, is only slightly larger than the sulfur ion, which carries a positive six charge.

SILICATES

The silicates, owing to their abundance on the Earth, constitute the most important mineral class. Approximately 25 percent of all known minerals and 40 percent of the most common ones are silicates; the igneous rocks that make up more than 90 percent of the Earth's crust are composed of virtually all silicates.

The fundamental unit in all silicate structures is the silicon-oxygen $(SiO_4)^{4-}$ tetrahedron. It is composed of a central silicon cation (Si^{4+}) bonded to four oxygen atoms that are located at the corners of a regular tetrahedron (see Figure 27). The terrestrial crust is held together by the strong silicon-oxygen bonds of these tetrahedrons. Approximately 50 percent ionic and 50 percent covalent, the bonds develop from the attraction of oppositely charged ions as well as the sharing of their electrons.

The positive charge (+4) of each silicon cation is satisfied by its four bonds to oxygen atoms. Each oxygen ion (O^{2-}), however, contributes only one-half of its total bonding energy to a silicon-oxygen bond, so it is capable of also bonding to the silicon cation of another tetrahedron. The SiO_4 tetrahedrons thereby become linked by shared oxygen atoms; this is referred to as polymerization. The

degree and manner of polymerization are the bases for the variety present in silicate structures.

The silicates can be divided into groups according to structural configuration, which arises from the sharing of one, two, three, or all oxygen ions of a tetrahedron (see Figure 28). Nesosilicates have isolated groups of SiO_4, while sorosilicates contain pairs of SiO_4 tetrahedrons linked into Si_2O_7 groups. Ring silicates, also known as cyclosilicates, are closed, ringlike silicates; the sixfold variety has composition Si_6O_{18}. Silicates that are composed of infinite chains of tetrahedrons are called inosilicates; single chains have a unit composition of SiO_3 or Si_2O_6, whereas double chains contain a silicon to oxygen ratio of 4:11. Phyllosilicates, or sheet silicates, are formed when three oxygen atoms are shared with adjoining tetrahedrons. The resulting infinite flat sheets have unit composition Si_2O_5. In structures where tetrahedrons share all their oxygen ions, an infinite three-dimensional network is created with an SiO_2 unit composition. Minerals of this type are called framework silicates or tectosilicates.

As a major constituent of the Earth's crust, aluminum follows only oxygen and silicon in importance. The radius of aluminum, slightly larger than that of silicon, lies close to the upper bound for allowable fourfold coordination in crystals. As a result, aluminum can be surrounded with four oxygen atoms arranged tetrahedrally, but it can also occur in sixfold coordination with oxygen. The ability to maintain two roles within the silicate structure makes aluminum a unique constituent of these minerals. The tetrahedral AlO_4 groups are approximately equal in size to SiO_4 groups and therefore can become incorporated into the silicate polymerization scheme. Aluminum in sixfold coordination may form ionic bonds with the SiO_4 tetrahedrons. Thus, aluminum may occupy tetrahedral sites as a replacement for silicon and octahedral sites in solid solution with elements such as magnesium and ferrous iron.

Several ions may be present in silicate structures in octa-

hedral coordination with oxygen: Mg^{2+}, Fe^{2+}, Fe^{3+}, Mn^{2+}, Al^{3+}, and Ti^{4+} (see Table 10). All cations have approximately the same dimensions and thus are found in equivalent atomic sites, even though their charges range from positive two to positive four. Solid solution involving ions of different charge is accomplished through coupled substitutions, thereby maintaining neutrality of the structures.

Nesosilicates. The silicon-oxygen tetrahedrons of the nesosilicates are not polymerized; they are linked to one another only by ionic bonds of the interstitial cations. As a result of the isolation of the tetrahedral groups, the crystal habits of these minerals are typically equidimensional so that prominent cleavage directions are not present. The size and charge of the interstitial cations largely determine the structural form of the nesosilicates. The relatively high specific gravity and hardness that are characteristic of this group arise from the dense packing of the atoms within the structure. Substitution of aluminum for silicon is normally quite low. Examples of common nesosilicates are given in Table 11.

Sorosilicates. These minerals contain sets of two SiO_4 tetrahedrons joined by one shared apical oxygen (see Figure 28). A silicon-to-oxygen ratio of 2:7 is consequently present in their structures. More than 70 minerals belong to the sorosilicate group, although most are rare. Only the members of the epidote group and vesuvianite are common. Both independent $(SiO_4)^{4-}$ and double $(Si_2O_7)^{6-}$ groups are incorporated into the epidote structure, as is reflected in its formula: $Ca_2(Al, Fe)Al_2O(SiO_4)(Si_2O_7)(OH)$.

Cyclosilicates. Silicon-oxygen tetrahedrons are linked into rings in cyclosilicate structures, which have an overall Si:O ratio of 1:3. There are three closed cyclic configurations with the following formulas: Si_3O_9, Si_6O_{12}, and Si_6O_{18}. The rare titanosilicate benitoite $(BaTiSi_3O_9)$ is the only mineral that is built with the simple Si_3O_9 ring. Axinite $[(Ca, Fe, Mn)_3Al_2(BO_3)(Si_4O_{12})(OH)]$ contains Si_4O_{12} rings, along with BO_3 triangles and OH groups. The two common and important cyclosilicates, beryl $(Be_3Al_2Si_6O_{18})$ and tourmaline (which has an extremely complex formula), are based on the Si_6O_{18} ring.

Inosilicates. This class is characterized by its one-dimensional chains and bands created by the linkage of SiO_4 tetrahedrons. Single chains may be formed by the sharing of two oxygen atoms from each tetrahedron, resulting in a structure with an Si:O ratio of 1:3. Two such chains that are aligned side by side with alternate tetrahedrons sharing an additional oxygen atom form bands of double chains (see Figure 28). These structures have an Si:O ratio of 4:11. Two significant rock-forming mineral families display these structure types: the single-chain pyroxenes and the double-chain amphiboles (see below *Major rock-forming minerals: Amphiboles* and *Pyroxenes*). Some common examples are given in Table 12.

Amphiboles and pyroxenes

The amphiboles and pyroxenes share the same cations and have many similar crystallographic, chemical, and physical properties: the colour, lustre, and hardness of analogous species are alike. A distinguishing factor between the two groups, the presence of the hydroxyl radical in the amphiboles, generally gives the double-chain members lower specific gravities and refractive indices than their single-chain analogues. Their crystal habits also are different: amphiboles exhibit needlelike or fibrous crystals, while pyroxenes take the form of stubby prisms. In addition, the different chain structures of the two groups result in different cleavage angles.

Pyroxenes occur in high-temperature igneous and metamorphic rocks. They crystallize at higher temperatures than their amphibole counterparts. A pyroxene formed early in the cooling of an igneous melt or in a metamorphic fluid may later combine with water at a lower temperature to form amphibole.

Phyllosilicates. These minerals display a two-dimensional framework of infinite sheets of SiO_4 tetrahedrons (see Figure 28). An Si:O ratio of 2:5 results from the sharing of three oxygen atoms in each tetrahedron. Sixfold symmetry is exhibited in undistorted sheets. The silicate sheet framework is largely responsible for the following properties of the phyllosilicates: platy or flaky habit, single pronounced cleavage, low specific gravity, softness, and possible flexibility and elasticity of cleavage layers. Most minerals of this group contain hydroxyls positioned in the middle of the sixfold rings of tetrahedrons.

Many soil constituents, produced through rock weathering, possess a sheet structure. Phyllosilicate properties contribute greatly to the ability of soils to release and retain plant food, to reserve water from wet to dry seasons, and to accommodate organisms and atmospheric gases.

Constituents of soils

The phyllosilicate class includes several important mineral groups (see Table 13).

Tectosilicates. Almost 75 percent of the Earth's crust is composed of minerals with the three-dimensional framework of the tectosilicates. All oxygen atoms of the SiO_4 tetrahedrons of members of this class are shared with nearby tetrahedrons, creating a strongly bound structure

with an Si:O ratio of 1:2 (see Figure 28). The most important tectosilicates are listed in Table 14. Other than the zeolite group, which can accommodate water owing to the open nature of its structure, all members listed in the table are anhydrous.

Mineral associations and phase equilibrium

The preceding sections provided an overview of major mineral groups but did not treat minerals as part of assemblages in rock types nor discuss the experimental study of minerals and rock occurrences. Petrology, the scientific study of rocks, is concerned largely with identifying individual minerals in rocks, along with their abundance, grain size, and texture, because rocks typically consist of a variety of minerals (see Figure 29). Such information is essential to an understanding of the history of any rock.

Petrological research requires a strong understanding of the principles of mineralogy and mineral identification and a thorough familiarity with the theoretical and experimental studies of rock origins. The present section focuses on phase equilibrium, upon which the link between the study of minerals and the study of rocks is largely based.

Phase and phase region

A phase is a homogeneous substance that has a fixed composition and uniform chemical and physical properties. Only a mineral that displays no solid solution may therefore be considered a phase. Quartz (SiO_2), for example, is a low-temperature phase in the $Si\text{-}O_2$ (SiO_2) system, and kyanite (Al_2SiO_5) is a high-pressure phase in the $Al_2O_3\text{-}SiO_2$ (Al_2SiO_5) system. The term phase region is used when a mineral exhibits compositional variation, as in the solid-solution series between forsterite and fayalite. A phase may exist as a solid, liquid, or gas: H_2O, for example, occurs in the form of ice (solid), water (liquid), and steam (gas).

Light green grains are olivine; dark spots are magnetite and serpentine. (Bottom left) Photomicrograph of the same specimen in polarized light. (Centre right) Hand specimen of granite, a polymineralic aggregate of feldspar, quartz, biotite, and hornblende. (Top right) Cut and polished surface of the same granite (magnified 1½×. (Bottom right) Photomicrograph of the same granite in polarized light (magnified 12×). Homogeneous white and gray areas are quartz, light to dark bluish gray areas are feldspar. Areas with cross-hatching are microcline, and those with finely ruled parallel lines are sodic plagioclase. Most of the green and brown grains are biotite; the brown one in the centre is hornblende.

Equilibrium refers to the stable coexistence of two or more phases and is established relative to time. If two phases in a mixture of water and ice coexist so that the amount of each is fixed indefinitely, they are said to be in equilibrium. The minerals of some rocks have existed together since their formation for periods of several million years, yet one cannot always ascertain if these rock constituents are in equilibrium or are still undergoing changes.

A determining factor of the equilibrium state of minerals is the presence (or absence) of a reaction rim, which is a region separating two or more minerals consisting of the products of a reaction between them. The absence of any observable reaction rims between minerals that physically touch each other suggests that they were in equilibrium at the time when the rock formed. Additional chemical data regarding elemental distribution between the minerals is necessary to verify this assumption. In contrast, the presence of megascopically or microscopically visible rims indicates that some minerals were not in equilibrium. Garnet, for example, may react with coexisting biotite to produce a chlorite rim between them, revealing that the two minerals were not always in equilibrium. An experimental petrologist must assign some period of time after which the absence of further changes between phases will indicate that equilibrium has been reached. The time period is variable, depending on the speed of the reactions involved and in part on the patience of the investigator; it may range from a few hours to several years.

Components of a system

Components are the minimum number of independent chemical species that are necessary to describe the compositions of all the phases present in a system. The compound H_2O is generally used as the sole component defining the H_2O system, although H_2 and O_2 define the chemical system as well. In examinations of the stability fields of $MgSiO_3$ (enstatite), $MgSiO_3$ is normally used as the component rather than the three elements, Mg, Si, and O, or the two oxides, MgO and SiO_2. The three components generally used in the pyroxene system CaO-MgO-FeO-SiO_2 are $CaSiO_3$-$MgSiO_3$-$FeSiO_3$.

ASSEMBLAGE AND THE PHASE RULE

In the early stages of the study of a rock, the constituent minerals of the rock must be identified. Orthoclase, albite, quartz, and biotite may be found in an igneous granite. By examining the granite's texture, one may conclude that the four minerals crystallized at approximately the same elevated temperature and that orthoclase-albite-quartz-biotite is its mineral assemblage. The term assemblage is frequently applied to all minerals included in a rock but more appropriately should be used for those minerals that are in equilibrium (and are known more specifically as the equilibrium assemblage). The granite discussed above may display surficial cavities that are lined by several clay minerals and limonite (a hydrous iron oxide). The original high-temperature granite was altered to form the low-temperature clay minerals and limonite; there are consequently two distinct assemblages present in the rock: the high-temperature orthoclase-albite-quartz-biotite assemblage and the low-temperature assemblage of clay minerals and limonite.

Metamorphic rocks also may contain separate assemblages. A shale that at low temperatures was composed of a sericite-kaolin-dolomite-quartz-feldspar assemblage can become metamorphosed at higher temperatures to produce a garnet-sillimanite-biotite-feldspar assemblage.

An assemblage thus consists of minerals that formed under the same or quite comparable conditions of pressure and temperature. In practice, minerals that physically touch one another with no reaction rims or alteration products are included in the assemblage. It is likely that the minerals satisfying these conditions are in equilibrium, but additional chemical tests are commonly necessary to define the equilibrium assemblage without ambiguity.

Phase systems are governed by a phase rule, which defines the number of minerals that may coexist in equilibrium: $F = C - P + 2$, where F is the variance, or number of degrees of freedom, C is the number of independent components, and P is the number of phases. Applying this rule to a three-phase, three-component system, F is 2. This indicates that two parameters—*e.g.*, pressure and temperature—may be varied independently of one another without altering the number of phases.

PHASE DIAGRAMS

Phase (or stability) diagrams are used to illustrate the conditions under which certain minerals are stable. The following are examples of phase diagrams employed in the study of igneous, metamorphic, and sedimentary rocks. For more detailed discussions of the applications of phase diagrams in petrology, consult the books cited in the *Bibliography*.

Use in igneous petrology. In the field of igneous petrology, the researcher commonly employs a phase equilibrium approach to compare the mineral assemblages found in naturally occurring and synthetic rocks. Much can be learned from studying the melting of an igneous rock and the reverse process, the crystallization of minerals from a melt (liquid phase). Graphic representations of systems with a liquid phase are called liquidus diagrams. A three-component system (quartz [SiO_2]–kalsilite [$KAlSiO_4$]–forsterite [Mg_2SiO_4]) is illustrated through a liquidus diagram in Figure 30. The dashed contours of the diagram, called isotherms, represent temperatures at which a mineral melts. They define what is known as a liquidus surface. As temperatures decrease, the minerals will crystallize in the manner defined by the arrows on the boundaries separating the different mineral phases. A careful study of the crystalline products formed upon the cooling of melts of specific compositions allows the igneous petrologist to compare such results with minerals observed in natural igneous rocks.

Liquidus diagrams

Use in metamorphic petrology. Pressure-temperature (P-T) phase diagrams are applied in the study of the conditions under which metamorphic rocks originate. They illustrate the equilibrium relationships among various mineral phases in terms of pressure and temperature. A composite P-T diagram that includes reaction curves for several minerals is given in Figure 31. The minerals that are separated by a reaction curve may exist in equilibrium at the conditions occurring along the line. The reaction curves for Al_2SiO_5 and for muscovite + quartz ⇆ potassium-feldspar + sillimanite + H_2O are significant in metamorphic rocks that have a high aluminum oxide (Al_2O_3) content as compared to other components (*e.g.*,

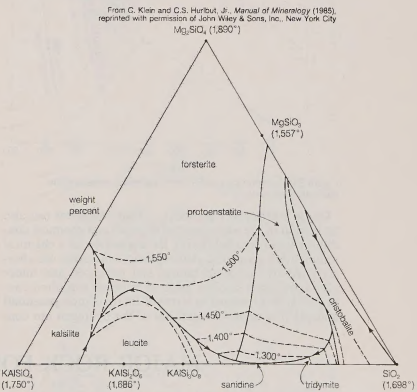

Figure 30: Melting relations among minerals in the system SiO_2 (quartz)–$KAlSiO_4$ (kalsilite)–Mg_2SiO_4 (forsterite). Temperatures next to compositions refer to the melting points of those compositions in °C. Protoenstatite, instead of enstatite, is produced in experiments of this type. The compositions of protoenstatite and enstatite are identical, but their structures differ.

calcium oxide [CaO], magnesium oxide [MgO], and ferrous oxide [FeO]). Shales enriched in clay minerals contain a rather large amount of aluminum oxide, and during metamorphism of the shale mineral reactions and recrystallization occur. In their metamorphic form, shales appear as pelitic schists, and these may include significant amounts of sillimanite, muscovite, and quartz. Such a schist may have equilibrated under the pressure and temperature conditions indicated by the shaded portion of Figure 31.

Theoretical calculations are combined with experimental observations to arrive at phase diagrams such as the one shown in Figure 31. In laboratory experiments conducted on the three polymorphs of Al_2SiO_5, chemicals of high purity are most often used as the starting materials, but extremely pure minerals may be substituted. A specimen of gem-grade kyanite that does not contain any inclusions may be reacted at high temperatures to form sillimanite (see Figure 31). The placement of the reaction curve between the kyanite and sillimanite fields is determined by the first instance of sillimanite formation from kyanite and also the initial stage of the reverse reaction. X-ray powder diffraction and optical microscopic techniques are employed to estimate the conditions under which these reactions commence, but the experimental methods are subject to some degree of uncertainty. Therefore, the reaction curves, although commonly drawn as narrow lines, may actually represent wider reaction zones. Also, the naturally occurring system is more complex than the simplified version devised in the laboratory, and so difficulty arises when attempting to relate the two. A P-T diagram such as the one given in Figure 31 serves mainly as a tool in evaluating the conditions of metamorphism, such as pressure and temperature.

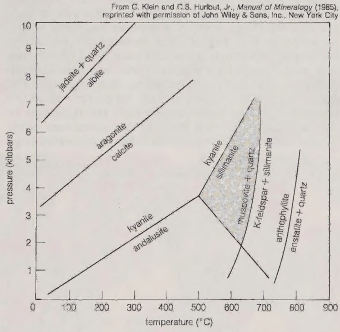

Figure 31: Reaction curves for some common metamorphic minerals (see text).

Use in sedimentary petrology. Phase diagrams can also be helpful in the assessment of physical and chemical conditions that prevailed during the deposition of a chemical sedimentary sequence. Atmospheric conditions are characterized by low temperatures and pressures, and under such conditions stability fields of minerals can often conveniently be expressed in terms of Eh (oxidation potential) and pH (the negative logarithm of the hydrogen ion concentration [H^+]; a pH of 0–7 indicates acidity, a pH of 7–14 indicates basicity, and neutral solutions have a pH of 7). For a discussion of the construction of such Eh-pH diagrams, see the references cited in the *Bibliography*.

Eh-pH diagrams

Stability relations for some iron oxides and iron sulfides at atmospheric conditions, 25° C and one atmosphere pressure, are given in Figure 32. (One standard atmosphere of pressure equals 760 millimetres, or 29.92 inches, of mercury.) A high Eh value corresponds to a compound stable under oxidizing conditions, such as hematite, while a low Eh value indicates a mineral that occurs in reducing environments, such as magnetite. Pyrite and pyrrhotite, two sulfide minerals, occur at low Eh values and at pH values of 4–9. Lines separating the fields of an Eh-pH diagram represent conditions under which the two minerals may exist in equilibrium. Hematite and magnetite, for example, are often found together in iron-bearing sediments; line *ab* of Figure 32 indicates the Eh and pH values at which their coexistence can take place. Eh-pH diagrams are valuable in providing information regarding the chemical and physical environments that existed during atmospheric weathering and during chemical sedimentation and diagenesis of sediments deposited by water at temperatures of 25° to about 100° C and approximately one atmosphere pressure. The coexistence of hematite and magnetite common in Precambrian iron-bearing rocks (those formed from 3.96 billion to 570 million years ago) may enable investigators to estimate variables such as Eh and pH that prevailed in the original ancient sedimentary basin. MAJOR ROCK-FORMING MINERALS

Of the more than 3,000 known mineral species, less than 0.1 percent make up the bulk of the Earth's crust and mantle (see Table 15). These and an additional score of minerals serve as the basis for naming most of the rocks exposed on the Earth's surface (Table 16).

Nearly all common rocks can be named by determining the presence (versus absence) of one, two, or a few of the minerals whose names are given in boldface in Table 16. Most of the less common rocks can be named by similarly identifying the additional half dozen minerals whose names are given in regular type. Essentially all rocks can be named as professional geologists name them if, in ad-

dition, the presence of the minerals whose names are in italics is known.

Mineral identification

Each of the common rock-forming minerals can be identified on the basis of its chemical composition and its crystal structure (*i.e.*, the arrangement of its constituent atoms and ions). The nonopaque minerals can also be identified by their optical properties. Fairly expensive equipment and sophisticated procedures, however, are required for such determinations. Therefore, it is fortunate that macroscopic examination, along with one or more tests, are sufficient to identify these minerals as they occur in most rocks. The following descriptions include basic chemical and structural data and the properties used in macroscopically based identifications. Optical data, which are not included in these descriptions, are available in mineralogy books.

Two important rock-forming materials that are not minerals are major components of a few rocks. These are glass and macerals. Glass forms when magma (molten rock material) is quenched—*i.e.*, cooled so rapidly that the constituent atoms do not have time to arrange themselves into the regular arrays characteristic of minerals. Natural glass is the major constituent of a few volcanic rocks—*e.g.*, obsidian (Figure 33). Macerals are macerated bits of organic matter, primarily plant materials; one or more of the macerals are the chief original constituents of all the diverse coals and several other organic-rich rocks such as oil shales (see FUELS, FOSSIL: *Coal: Genesis of macerals and rock types*).

Feldspars and feldspathoids

GENERAL CONSIDERATIONS

Feldspars make up more than 50 percent of the Earth's crust (see Table 15), and professional literature about the feldspars constitutes a large percentage of the literature of mineralogy. Basic information about the principal rock-forming members of this mineral group is provided in this section.

In the classification of igneous rocks of the International Union of Geological Sciences (IUGS), the feldspars are treated as two groups: the alkali feldspars and the plagioclase feldspars. The alkali feldspars include orthoclase, microcline, sanidine, anorthoclase, and the two-phase intermixtures called perthite. The plagioclase feldspars include members of the albite-anorthite solid-solution series.

A homogeneous alkali (Ab-Or) feldspar is stable at temperatures above the solvus, whereas two phases—one Or-rich and the other Ab-rich—may form by exsolution at temperatures below this line to form perthite. For example, the homogeneous feldspar X (= $Ab_{50}Or_{50}$) would exsolve to form a perthite made up of approximately equal amounts of albite and K-feldspar lamellae at about 630° C.

Strictly speaking, however, albite is an alkali feldspar as well as a plagioclase feldspar.

Feldspathoid is the name often applied to a group of minerals that are chemically related to the feldspars and are considered to be the specific minerals of igneous rocks usually termed alkalic, which is the designation applied to igneous rocks whose alkali content (*i.e.*, amount of sodium [Na] and/or potassium [K]) exceeds the amount required by the available silica to form one or more feldspars plus or minus mica. Minerals of the feldspathoid group whose silica contents are less than those of their feldspar analogues include nepheline, leucite, sodalite, and cancrinite.

FELDSPARS

Chemical composition. All the rock-forming feldspars are aluminosilicate minerals with the general formula AT_4O_8 in which A = potassium, sodium, or calcium (Ca); and T = silicon (Si) and aluminum (Al), with a Si:Al ratio ranging from 3:1 to 1:1. Microcline and orthoclase are potassium feldspars ($KAlSi_3O_8$), usually designated Or

in discussions involving their end-member composition. Albite ($NaAlSi_3O_8$—usually designated Ab) and anorthite ($CaAl_2Si_2O_8$—An) are end-members of the plagioclase series. Sanidine, anorthoclase, and the perthites are alkali feldspars whose chemical compositions lie between Or and Ab.

Solid solution in the feldspars

As is apparent from the preceding statements, solid solution plays an important role in the rock-making feldspars. (Members of solid-solution series are single crystalline phases whose chemical compositions are intermediate to those of two or more end-members; see above *The nature of minerals: Compositional variation.*) The alkali (Or-Ab) series exhibits complete solid solution at high temperatures but only incomplete solid solution at low temperatures; substitution of potassium for sodium is involved. The plagioclase (Ab-An) series exhibits essentially complete solid solution at both high and low temperatures; coupled substitution of sodium and silicon by calcium and aluminum occurs. The An-Or system has only limited solid-solution tendencies (see Figure 34).

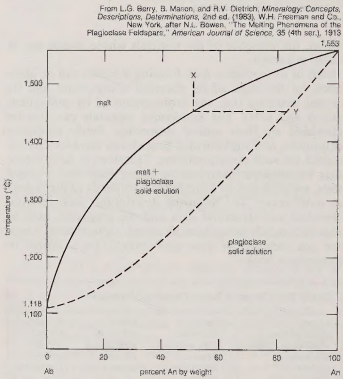

Figure 37: Solid solution in the albite (Ab)–anorthite (An) system (see text).

The most obvious differences between the high- and low-temperature diagrams are along the alkali-feldspar (Or-Ab) join (the boundary line between the phases). As indicated, sanidine and anorthoclase are high-temperature alkali feldspars, and perthite is their low-temperature analogue. Sanidine is a single-phase alkali feldspar; although frequently described chemically by the formula (K, Na)$AlSi_3O_8$, most analyzed specimens of sanidine range between Or_{50} and Or_{60}. (This designation is used to specify the fractions of the constituents. For example, Or_{60} indicates that the mineral is composed of 60 percent $KAlSi_3O_8$ and 20 (*i.e.*, 100 − 80) percent $NaAlSi_3O_8$.) Anorthoclase is a variously used name that is most often applied to apparently homogeneous alkali feldspar masses, at least some of which consist of submicroscopic lamellae (layers) of albite and orthoclase; their bulk compositions typically range between Or_{25} and Or_{60}. Perthite consists of intimate intermixtures of a potassium feldspar—either microcline or orthoclase—and a sodium-rich plagioclase that occurs as microscopic to macroscopic masses within the potassium feldspar host.

Many perthites are formed when high-temperature potassium-sodium feldspars of appropriate compositions are cooled in such a manner that the original solid-solution phase exsolves (*i.e.*, unmixes, so that a homogeneous mineral separates into two or more different minerals) to form intermixtures—sometimes termed intergrowths—of two phases (see Figure 35).

Some perthites, however, appear to have been formed as a result of partial replacement of original potassium

feldspars by sodium-bearing fluids. In any case, perthite is the name properly applied to intimate mixtures in which the potassium feldspar component predominates over the plagioclase constituent, whereas antiperthite is the name given to intimate mixtures in which the plagioclase constituent is predominant. Perthites are common, whereas antiperthites are relatively rare.

Zoned plagioclase

The plagioclase series is essentially continuous at both high and low temperatures. The names of members of the series designate relative proportions of the end-members (see Table 17). Although plagioclase grains in some rocks are essentially homogeneous, those in many rocks are zoned—*i.e.*, different parts of individual grains have different Ab and An contents (see Figure 36). One explanation for zoning in plagioclases formed from magmas can be implied from information known about the Ab-An system (see Figure 37). Upon cooling, the first crystals that form from a melt with the composition X (= An_{50}) will have the composition Y (approximately An_{83}). With further cooling, in some cases the first and subsequently formed crystals will react continuously with the remaining liquid, thereby maintaining equilibrium; when the liquid becomes totally crystallized, the system will consist of homogeneous plagioclase crystals. In cases in which such equilibrium is not maintained during cooling, the early and subsequently formed feldspars have different An contents. For example, zoned crystals may form with differing An contents arranged one on top of another so that their margins are relatively sodium-rich as compared to their earlier-formed, more calcium-rich cores. The resulting zoning may be gradational or well-defined or may assume some combination of these characteristics.

Many elements other than those required for the Or, Ab, and An end-member compositions have been recorded in analyses of feldspars. Those that have been recorded to occur as substitutions within the feldspar structures include lithium (Li), rubidium (Rb), cesium (Cs), magnesium (Mg), strontium (Sr), barium (Ba), yttrium (Y), ferrous iron (Fe^{2+}), thallium (Tl), lead (Pb), lanthanum (La) and other rare earth elements, and ammonium (NH_4) in the A position; and titanium (Ti), ferric (Fe^{3+}) and ferrous (Fe^{2+}) iron, boron (B), gallium (Ga), germanium (Ge), and phosphorus (P) in the T position. Of these, substitution of some barium for potassium and some titanium or ferric iron or both for aluminum are especially common in alkali feldspars. Several other elements also have been recorded as traces in feldspar analyses; it seems very likely, however, that some of these elements may reside in impurities—*i.e.*, within unrecognized microscopic or submicroscopic inclusions of other minerals.

Monoclinic and triclinic structures

Crystal structure. Sanidine and orthoclase are monoclinic or nearly so; the plagioclase feldspars are triclinic. All, however, have the same fundamental structure: it consists of a continuous, negatively charged, three-dimensional framework that is made up of corner-sharing SiO_4 and AlO_4 tetrahedrons (each tetrahedron consists of a central silicon or aluminum atom bonded to four oxygen atoms) and positively charged cations (*e.g.*, the potassium, sodium, and/or calcium) that occupy relatively large interstices within the framework (Figure 38). Although the framework is sufficiently elastic to adjust itself to the different sizes of the A cations, the relatively large potassium cations give structures that have a monoclinic or only slightly off-monoclinic symmetry, whereas the smaller sodium and calcium cations lead to distorted structures that have triclinic symmetry.

One aspect of the feldspar—especially the potassium feldspar—structures that is of particular interest is termed

ordering (see Figure 39). This phenomenon is indicative of the conditions under which the feldspar was formed and its subsequent thermal history. Ordering in feldspars is based on the distributional pattern of silicon and aluminum within the different tetrahedrons. It can be characterized as follows: silicon and aluminum have a random distribution within the tetrahedrons of sanidine, an arrangement termed disordered; they have a regular distribution within the constituent tetrahedrons of microcline, an arrangement termed ordered; and they are distributed within the tetrahedrons of orthoclase in a manner usually character-

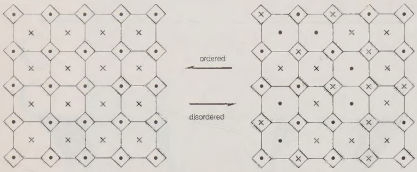

Figure 39: Schematic diagram showing ordered (left) and disordered (right) arrays within a structure having two kinds of sites—namely, the centres of the squares and the centres of the octagons—and two types of occupants—the dots and the crosses. In the ordered structure all dots are positioned within the squares and all crosses are within the octagons, whereas in the disordered structure no regular arrangement obtains.

ized as only partly ordered. The disordered structure of sanidine reflects formation at high temperatures followed by rapid cooling; the high degree of ordering of microcline reflects either growth at low temperatures or very slow cooling from higher temperatures; the partial ordering of orthoclase indicates either formation at intermediate temperatures or formation at high temperatures followed by fairly slow cooling. With regard to this phenomenon, it is also noteworthy that all plagioclase feldspars are more nearly ordered than their associated potassium feldspars regardless of the temperatures that prevailed when they were formed.

Crystals of all the common rock-forming feldspars tend to look alike (Figure 40); megascopic examination of crystal form typically cannot be used to distinguish between feldspars. The angle between the face that intersects the *b* axis and is parallel to *a* and *c* and the face that intersects the *c* axis and is parallel to *a* and *b* is 90° for the monoclinic feldspars and ranges from about 86° to roughly 89°30′ for the triclinic feldspars; the deviations from 90° are not readily discernible with the naked eye. In any case, feldspar crystals are relatively rare; almost all occur in miarolitic cavities, in pegmatite masses, or as phenocrysts within porphyries. (A porphyry is an igneous rock containing conspicuous crystals, called phenocrysts, surrounded by a matrix of finer-grained minerals or glass or both.) In most rocks, both alkali and plagioclase feldspars occur as irregularly shaped grains with only a few or no crystal faces. This general absence of crystal faces reflects the fact that crystallization of these feldspars was interfered with by previously formed minerals within the same mass.

Both crystals and irregularly shaped grains of feldspars are commonly twinned (see above *The nature of minerals: Morphology*). Some individual grains are twinned in two or more ways. Two common kinds of twinning—those designated Carlsbad twinning and albite twinning—are shown in Figure 41. Carlsbad twinning occurs in both monoclinic and triclinic feldspars; albite twinning occurs only in triclinic feldspars. Albite twinning, which is typically polysynthetic (*i.e.*, multiple or repeated), can be observed as a set of parallel lines on certain crystal or cleavage surfaces of many plagioclase feldspars (Figure 41).

Physical properties. It is important to be able to distinguish feldspar group minerals from other rock-forming minerals and from one another because their presence (versus absence), along with their relative quantities, serves as the basis for classifying and naming many rocks, especially those of igneous origin. In the laboratory, it is relatively easy to identify the feldspars by determining their chemical compositions, their structures, or their optical properties. In some cases, staining techniques are employed. Fortunately, most feldspar grains can also be identified rather easily on the basis of macroscopic examination in the field, using properties such as those described in the remainder of this section.

As might be suspected on the basis of their similar chemical compositions and structures, all of the rock-forming feldspars have several similar properties. As indicated by the fact that they lack inherent colour, feldspars can be colourless, white, or nearly any colour if impure. In general, however, orthoclase and microcline have a reddish tinge that ranges from a pale, fleshlike pink to brick-red, whereas typical rock-forming plagioclases are white to dark gray. As a group, feldspars range from transparent to nearly opaque, have nonmetallic lustres—typically vitreous to subvitreous on fractures and pearly or porcelaneous on cleavage surfaces, exhibit two cleavages—one perfect, the other good—at or near 90° to each other, and have a Mohs hardness of approximately 6.

The presence of two cleavages at or near 90° distinguishes the feldspars from all other common rock-forming minerals except halite and the pyroxenes. The hardness ($2\frac{1}{2}$) and the salty taste of halite make that distinction clear. The gray to black streak of the common rock-forming pyroxenes, which contrasts markedly with the white or slightly tinted hues of the streaks of the feldspars—including those that are dark-coloured—affords a simple way to distinguish between these minerals, even those that are similar in appearance. (Streak is the colour of a mineral's

The interdigitated appearance of this fairly typical perthite is quite different from the straight line appearance of the albite twins shown in Figure 41E.

powder, which can be produced readily by pounding or scratching the mineral with a geologic pick or hammer.)

Alkali feldspars can often be distinguished from plagioclase feldspars because most grains of the latter exhibit albite twinning (see above), which is manifested by parallel lines on certain cleavage surfaces, whereas grains of alkali feldspars do not. This criterion is not, however, absolute; some plagioclase feldspars are not polysynthetically twinned. Furthermore, upon only cursory examination some perthitic textures may be mistaken for polysynthetic twinning. Fortunately, this resemblance is seldom confusing once one has thoroughly examined several examples of both features. The two features differ rather markedly: the traces of the polysynthetic twinning are straight, whereas the perthitic textures that are most likely to be mistaken for polysynthetic twinning have an interdigitated appearance (compare Figures 41E and 42).

Another property that is sometimes used to distinguish between alkali and plagioclase feldspars is their different specific gravity values. The ideal value for the potassium-rich alkali feldspars is 2.56, which is less than the lowest value for the plagioclases (namely, 2.62 for albite).

Sanidine is usually distinguished rather easily from the other alkali feldspars because it typically appears glassy—*i.e.,* it tends to be colourless, and much of it is transparent. Microcline and orthoclase, by contrast, are characteristically white, light gray, or flesh- to salmon-coloured and subtranslucent. Except for its green variety, usually called amazopstone or amazonite, microcline can seldom be distinguished from orthoclase by macroscopic means. In the past, much microcline was misidentified as orthoclase because of the incorrect assumption that all microcline is green. Today, prudent geologists identify potassium feldspars other than sanidine simply as alkali, or in some cases potassium, feldspars when describing rocks on the basis of macroscopic examination. That is to say, they do not make a distinction between microcline and orthoclase until they have proved their identity by determining, for example, their optical properties. Upon macroscopic examination, anorthoclase is also generally identified merely as an alkali feldspar except by those who are acquainted with the rocks known to contain anorthoclase.

Identification of plagioclases

The rock-forming plagioclases can seldom be identified as to species by macroscopic means. Nevertheless, some rules of thumb can be employed: White or off-white plagioclase feldspars that exhibit a bluish iridescence (the so-called peristerites) have overall albite compositions, even though they are submicroscopic intergrowths of 70 percent An_7 and 30 percent An_{25}; and dark-coloured plagioclases that exhibit iridescence of such hues as blue, green, yellow, or orange are labradorites. In addition, the identities of associated minerals tend to indicate the approximate An-Ab contents of the plagioclase feldspars—for example, biotite most commonly accompanies albite or oligoclase; hornblende commonly occurs with andesine; and the pyroxenes, augite and/or hypersthene, typically accompany labradorite or bytownite. Additional characteristics for two of the feldspars are as follows: Microcline commonly exhibits "grid twinning." This combination of two kinds of twinning, although best seen by means of a microscope equipped to use doubly polarized light, is sometimes discernible macroscopically. (Polarized refers to light that vibrates in a single plane.) Plagioclase feldspars that constitute lamellar masses in complex pegmatites are albite; this variety is often referred to by the name cleavelandite.

Origin and occurrence. Feldspars occur in all classes of rocks. They are widely distributed in igneous rocks, which indicates that they have formed by crystallization from magma. Physical weathering of feldspar-bearing rocks may result in sediments and sedimentary rocks that contain feldspars; however, this is a rare occurrence because in most environments the feldspars tend to be altered to other substances, such as clay minerals. They also may be found in many metamorphic rocks formed from precursor rocks that contained feldspars and/or the chemical elements required for their formation. In addition, feldspars occur in veins and pegmatites, in which they were apparently deposited by highly tenuous fluids, and within sediments and soils, in which they were probably deposited by groundwater solutions. Some of the typical occurrences for the individual species are given in Table 18.

Uses. Feldspars are used widely in the glass and ceramics industries. The feldspar-rich rocks larvikite and a few anorthosites are employed as both interior and exterior facing slabs. Several feldspars are used as gemstones.

FELDSPATHOIDS

Chemical composition and crystal structure. The feldspathoid group minerals are sodium, potassium, and calcium aluminosilicates, many of which resemble the feldspars in appearance. Like the feldspars, they have framework structures that consist of silica and alumina tetrahedrons. Unlike the feldspars, however, the arrangements of the tetrahedrons differ from species to species,

*Some mineralogists consider analcime ($NaAlSi_2O_6 \cdot H_2O$) and melilite group minerals (A_2BZSiO_7, with A = Na, Ca; B = Al, Mg, Zn [zinc]; and Z = Al, Si) also to be feldspathoids. †Nepheline, the species, and other naturally occurring members of the group—kalsilite and kaliophilite—are hexagonal, carnegieite, a synthetic mineral of this group, has a low-temperature triclinic form and a high-temperature isometric form. ‡Leucite's crystal system differs with the temperature of formation, the high-temperature form having an isometric configuration. §Lazurite [$(Na, Ca)_{7-8}(Al, Si)_{12}(O, S)_{24}(SO)_6$ Cl_2 (OH_2)], a sodalite, is the blue constituent of the well-known gemstone lapis lazuli.

and the interstices may contain water and/or other simple or complex anions such as chlorine (Cl^-), carbonate (CO_3^{2-}), or sulfate (SO_4^{2-}), as well as sodium, potassium, and calcium. Consequently, different feldspathoids have somewhat different structures: some are isometric, others are hexagonal, and still others are tetragonal. Chemical formulas and crystal-system data for a few of the feldspathoids are given in Table 19.

Physical properties. The physical properties of the various feldspathoids differ from those of the feldspars and from one another. Properties of nepheline, leucite, sodalite, and cancrinite are summarized below.

Nepheline (hardness [H] 5½–6, specific gravity [G] 2.56–2.67) typically occurs as irregularly shaped, white, gray, or brownish, greasy- to waxy-appearing grains that may exhibit one rather poor cleavage (Figure 43). Simple hexagonal prisms occur as phenocrysts in some volcanic porphyries. On weathered exposures, nepheline grains are commonly weathered more than their associated minerals, thus leaving, for example, feldspar grains of nepheline syenites in relief. A simple test often used to help identify nepheline is based on the fact that it, as well as sodalite and cancrinite, reacts with acids to form gelatinous silica.

Leucite (H 5½–6, G 2.47–2.50) commonly occurs as white to light gray trapezohedrons (Figure 43). The crystal form represents the formation of leucite as an isometric mineral. However, the mineral can be shown to be tetragonal by methods such as optical studies. The crystal form of leucite indicates the conditions under which it was crystallized, and the tetragonal structure shows that it has undergone post-crystallization inversion.

Sodalite (H 5½–6, G 2.27–2.50) consists of a group of minerals. Different species of this group may exhibit different colours. The sodalite of most rocks occurs as irregularly shaped, translucent, bluish-coloured grains with a vitreous to greasy lustre (Figure 43).

Cancrinite (H 5–6, G 2.32–2.51) typically occurs as yellowish grains, some of which exhibit one perfect cleavage, that are closely associated with one or more of the other feldspathoids, most commonly nepheline.

Origin and occurrence. The feldspathoids are relatively rare. As noted previously, they are considered here primarily because they are the specific minerals used in naming alkalic igneous rocks. In this role, the feldspathoids, along with minerals of the melilite group, are referred to as foids in the IUGS classification of igneous rocks. Feldspathoids may occur along with feldspars in igneous rocks. They do not occur in igneous rocks containing original free silica—*i.e.*, in rocks that contain quartz of the same generation. They are, in fact, incompatible with consanguineous quartz (that derived from the same parent magma), as is quite apparent from the following equations:

Use in naming alkalic igneous rocks

$$\underbrace{(Na, K)_2O + Al_2O_3 + 2SiO_2}_{\text{nepheline}} + \underbrace{4SiO_2}_{\text{quartz}} \longrightarrow \underbrace{(Na, K)_2O + Al_2O_3 + 6SiO_2}_{\text{alkali feldspar}}$$

$$\underbrace{K_2O + Al_2O_3 + 4SiO_2}_{\text{leucite}} + \underbrace{2SiO_2}_{\text{quartz}} \longrightarrow \underbrace{K_2O + Al_2O_3 + 6SiO_2}_{\text{potassium feldspar}}$$

As can be seen from these equations, a feldspar would form in lieu of its feldspathoid chemical analogue in any silica-saturated magma.

Nepheline is the most common feldspathoid; it is a major constituent of many alkalic igneous rocks such as nepheline syenites. Feldspathoids also occur in a few other kinds of rocks—*e.g.*, contact-metamorphic skarns.

Uses. Nepheline is sometimes used as a source of soda, silica, and alumina in the manufacture of glass and ceramics. Leucite was formerly used in Italy for fertilizer. Sodalite, once treasured as the basic ingredient of ultramarine pigment, is still used as a gemstone and as the desired constituent of many of the blue rocks used as facing stones. (R.V.Di.)

Amphiboles

GENERAL CONSIDERATIONS

Amphiboles are a group of silicate minerals found principally in metamorphic and igneous rocks. They occur in many metamorphic rocks, especially those derived from mafic igneous rocks (those containing dark-coloured ferromagnesian minerals) and siliceous dolomites. Amphiboles also are important constituents in a variety of plutonic and volcanic igneous rocks that range in composition from granitic to gabbroic. Amphibole, from the Greek *amphibolos*, meaning "ambiguous," was named by the famous French crystallographer and mineralogist René-Just Haüy (1801) in allusion to the great variety of composition and appearance shown by this mineral group. There are 57 chemically defined end-member amphibole compositions according to the British mineralogist Bernard E. Leake. Because of the wide range of chemical substitutions permissible in the crystal structure, amphiboles can crystallize in igneous and metamorphic rocks with a wide range of bulk chemistries. Typically amphiboles form as long prismatic crystals, radiating sprays, and asbestiform (fibrous) aggregates; however, without the aid of chemical analysis, it is difficult to megascopically identify all but a few of the more distinctive end-member amphiboles. The combination of prismatic form and two diamond-shaped directions of cleavage at about 56° and 124° is the diagnostic feature of most members of the amphibole group.

CHEMICAL COMPOSITION

The complex chemical composition of members of the amphibole group can be expressed by the general formula $A_{0-1}B_2C_5T_8O_{22}(OH, F, Cl)_2$, where A = Na, K; B = Na, Li, Ca, Mn, Fe^{2+}, Mg; C = Mg, Fe^{2+}, Mn, Al, Fe^{3+}, Ti; and T = Si, Al. Nearly complete substitution may take place between sodium and calcium and among magnesium, ferrous iron, and manganese (Mn). There is limited substitution between ferric iron and aluminum and between titanium and other C-type cations. Aluminum can partially substitute for silicon in the tetrahedral (T) site. Partial substitution of fluorine (F), chlorine, and oxygen for hydroxyl (OH) in the hydroxyl site is also common. The complexity of the amphibole formula has given rise to numerous mineral names within the amphibole group. In 1978 Leake presented a precise nomenclature of 57 names that encompass the chemical variation within this group. The mineral nomenclature of the amphiboles is divided into four principal subdivisions based on B-group cation occupancy: (1) the iron-magnesium-manganese amphibole group, (2) the calcic amphibole group, (3) the sodic-calcic amphibole group, and (4) the alkali amphibole group. The chemical formulas for selected amphiboles from each of the four compositional groups are given in Table 20.

Numerous common amphiboles can be represented within the $Mg_2Si_8O_{22}(OH)_2$ (magnesio-anthophyllite)–$Fe_2Si_8O_{22}(OH)_2$ (grunerite)–"$Ca_2Si_8O_{22}(OH)_2$" (hypothetical pure calcium amphibole) compositional field (Figure 44). This diagram is commonly referred to as the amphibole quadrilateral. Complete substitution extends from tremolite $[Ca_2Mg_5Si_8O_{22}(OH)_2]$ to ferroactinolite $[Ca_2Fe_5Si_8O_{22}(OH)_2]$. Actinolite is the intermediate member of the tremolite-ferroactinolite series. The compositional range from about 0.9 $Mg_2Si_8O_{22}(OH)_2$ to about $Fe_2Mg_5Si_8O_{22}(OH)_2$ is represented by the orthorhombic amphibole known as anthophyllite. The monoclinic cummingtonite-grunerite series exists from about $Fe_2Mg_5Si_8O_{22}(OH)_2$ to $Fe_2Si_8O_{22}(OH)_2$. Intermediate amphibole compositions do not exist between anthophyllite and the tremolite-actinolite series. Compositional gaps also exist between the cummingtonite-grunerite series and other calcic amphiboles. Consequently, coexisting pairs of anthophyllite-tremolite and grunerite-ferroactinolite are found together in some rocks. Sodium-bearing amphiboles are represented by the glaucophane $[Na_2Mg_3Al_2Si_8O_{22}(OH)_2]$–riebeckite $[Na_2Fe^{2+}_3Fe^{3+}_2Si_8O_{22}(OH)_2]$ series. Additional sodium is contained in the A site of the structure of arfvedsonite $[NaNa_2Fe^{2+}_4Fe^{3+}Si_8O_{22}(OH)_2]$. For amphiboles that are not precisely characterized by their chemistry, it is not possible to assign a specific name. Hornblende is the general name used for calcic amphiboles identified only by physical or optical properties.

The amphiboles differ chemically from the pyroxenes in two major respects. Amphiboles have hydroxyl groups in

The general compositional fields are outlined, and coexisting amphibole compositions are shown by tie lines between the actinolite field and the anthophyllite-grunerite field.

their structure and are considered to be hydrous silicates that are stable only in hydrous environments where water can be incorporated into the structure as $(OH)^-$. The second major compositional difference is the presence of the A site in amphiboles that contains the large alkali elements, typically sodium cations and at times potassium cations. The pyroxenes do not have an equivalent site that can accommodate potassium. The presence of hydroxyl groups in the structure of amphiboles decreases their thermal stability relative to the more refractory (heat-resistant) pyroxenes. Amphiboles decompose to anhydrous minerals (mainly pyroxenes) at elevated temperatures.

CRYSTAL STRUCTURE

The fundamental building block of all silicate mineral structures is the silicon-oxygen tetrahedron $(SiO_4)^{4-}$. It consists of a central silicon atom surrounded by four oxygen atoms in the shape of a tetrahedron. The essential characteristic of the amphibole structure is a double chain of corner-linked silicon-oxygen tetrahedrons that extend indefinitely parallel to the c crystallographic axis, the direction of elongation (Figure 45). The tetrahedrons alternately share two and three oxygen atoms to produce a silicon-to-oxygen ratio of 4:11. The double chains repeat along their length at intervals of approximately 5.3 angstroms (Å), or 2.1×10^{-9} inch, and this defines the ideal c axis of the unit cell. The double chains are separated from other double chains and bonded to each other laterally by planes of cations and hydroxyl ions (Figure 46). This figure illustrates the double chains as well as the octahedral strips to which they are bonded. The structure contains, besides the tetrahedral sites that constitute the chains, additional cation sites labeled *A*, *M4*, *M3*, *M2*, and *M1*. The *A* site contains the large alkali ions, mainly

sodium, and is bonded to 10 to 12 oxygen and hydroxyl ions. The *A* site is filled to the extent necessary to maintain electrical neutrality, but typically the available *A* sites are not completely occupied. The *M1, M2,* and *M3* octahedrons contain the *C*-type cations and share edges to form octahedral bands parallel to the *c* crystallographic direction. *M1* and *M3* bond to four oxygen atoms and two hydroxyl anions. *M2* is coordinated by six oxygen atoms. *M4* has sixfold to eightfold coordination and accommodates the *B*-type cations. The *M4* site is most similar to the *M2* site in pyroxene and accommodates Ca^{2+}, as does the *M2* site in pyroxene. Amphiboles have two each of the *M1, M2,* and *M4* sites and one *M3* site, giving a total of seven octahedral cations in the unit cell. The structure of a monoclinic amphibole viewed down the *c* crystallographic axis is shown in Figure 47A. The tetrahedral-octahedral-tetrahedral (t-o-t) strips, also known as I beams, are approximately twice as wide in the *b* direction as the equivalent t-o-t strips in pyroxenes because of the doubling of the chains in the amphiboles. The t-o-t I beams are schematically shown in Figure 47B. The structure ruptures around the stronger I beams, as shown in Figure 47B, producing the characteristic 56° and 124° amphibole cleavage angles.

The similarity between the crystal structures of the major layer silicates (clays and micas) and the chain silicates (pyroxenes and amphiboles) has long been recognized. The structures of all of these silicates can be considered as consisting of combinations of two structural units, the pyroxene I beams and the mica sheets. Both structures contain a band of octahedrons sandwiched between two oppositely pointing chains of tetrahedrons. Combinations of these two basic structural units, or "modules," can produce all other minerals in the layer silicate and chain silicate groups. The term biopyribole has been used to describe any mineral that has both I beams and sheetlike structures. The name comes from *bio*tite (mica), *pyro*xene, and amph*ibole*. Biopyriboles have chain widths and repeat sequences like pyroxenes (single-chain repeats), amphiboles (double-chain repeats), and triple-chain repeats. The latter are intermediate between an amphibole I beam and the sheet structure of mica. Pyribole refers to any member of the biopyribole group, excluding the sheet silicates (*i.e.,* the pyroxenes and amphiboles together).

PHYSICAL PROPERTIES

Long prismatic, acicular, or fibrous crystal habit, Mohs hardness between 5 and 6, and two directions of cleavage intersecting at approximately 56° and 124° generally suffice to identify amphiboles in hand specimens. The specific gravity values of amphiboles range from about 2.9 to 3.6. Amphiboles yield water when heated in a closed tube and fuse with difficulty in a flame. Their colour ranges extensively from colourless to white, green, brown, black, blue, or lavender and is related to composition, principally the iron content. Magnesium-rich amphiboles such as anthophyllite, cummingtonite, and tremolite are colourless or light in colour. The tremolite-ferroactinolite series ranges from white to dark green with increasing iron content. The finely fibrous and massive variety of actinolite-tremolite known as nephrite jade ranges from green to

black. Common hornblende is typically black. Glaucophane and riebeckite are usually blue. Anthophyllite is gray to various shades of green and brown. The cummingtonite-grunerite series occurs in various shades of light brown. Iron-free varieties of tremolite containing manganese can have a lavender colour.

The common crystallographic habit of amphiboles is acicular or prismatic; however, most of the amphiboles are also known to crystallize in the asbestiform habit. The asbestiform variety of riebeckite is called crocidolite or blue asbestos. Amosite is a rare asbestiform variety of grunerite, named from the company Amos (Asbestos Mines of South Africa). The most important commercial asbestos material is chrysotile, the asbestiform variety of serpentine.

In thin sections, amphiboles are distinguished by several properties, including two directions of cleavage at approximately 56° and 124°, six-sided basal cross sections, characteristic colour, and pleochroism (colour variance with the direction of light propagation). Orthorhombic amphiboles exhibit less intense pleochroism than the monoclinic amphiboles. Some members of the amphibole group are shown in Figure 48.

ORIGIN AND OCCURRENCE

Exhibiting an extensive range of possible cation substitutions, amphiboles crystallize in both igneous and metamorphic rocks with a broad range of bulk chemical compositions. Because of their relative instability to chemical weathering at the Earth's surface, amphiboles make up only a minor constituent in most sedimentary rocks.

Igneous rocks. Calcic amphiboles are characteristically contained in igneous rocks. Igneous amphiboles are intermediate in composition between tremolite, tschermakite, edenite, and pargasite end-members. Typically, these amphiboles of intermediate composition are called hornblende. Hornblende occurs in various plutonic igneous rocks, including diorites, quartz diorites, and granodiorites. It also occurs as phenocrysts in andesite lavas that contained enough water for amphiboles to form. Hastingsite is found in granites and alkali-rich intrusives such as syenites. The alkali amphiboles riebeckite and arfvedsonite are found most commonly in granites, syenites, nepheline syenites, and related pegmatites. Richterite occurs as a hydrothermal product and in veins in alkaline igneous rocks.

Hornblende

Contact metamorphic rocks. Amphiboles occur in contact metamorphic aureoles around igneous intrusions. (An aureole is the zone surrounding an intrusion, which is a mass of igneous rock that solidified between other rocks located within the Earth.) The contact aureoles produced in siliceous limestones and dolomites, called skarns or calc-silicate rocks, characteristically contain metamorphic amphiboles such as tremolite or actinolite. The presence of tremolite implies a relatively low grade of metamorphism as tremolite breaks down to form the pyroxene diopside in the presence of calcite and quartz at elevated temperatures. Richterite-winchite occurs in hydrothermally metamorphosed limestones. Magnesium-rich anthophyllites are found along contact zones of granitic dikes intruding ultramafic rocks (those rich in iron and magnesium).

Regional metamorphic rocks. Many different amphiboles may be contained in regional metamorphic rocks. Commonly several amphiboles may coexist with one another in the same sample, depending on the bulk chemistry of the rock and on the pressure and temperature of metamorphism. The amphiboles typically occur with plagioclase feldspar, quartz, and biotite, as well as with chlorite and oxide minerals. In magnesium-rich rocks, tremolite, anthophyllite, and hornblende may exist together. Gedrite and cummingtonite coexist with garnet in rocks enriched in aluminum and iron. Rocks containing cummingtonite or grunerite are characteristic of metamorphosed iron formations associated with iron oxides, iron-rich sheet silicates, carbonates, and quartz. Glaucophane occurs only in such metamorphic rocks as schist, eclogite, and marble. Glaucophane associated with jadeite, lawsonite, and calcite or aragonite is the characteristic assemblage found in high-pressure, low-temperature metamorphic rocks called blueschists, which have a blue colour imparted by the glaucophane. Blueschists have basaltic bulk compositions and may also contain riebeckite. The latter also may occur in regional metamorphic schists. Tremolite-actinolite and the sheet-silicate chlorite are the principal minerals in the low-to-moderate temperature and pressure greenschist metamorphic rocks. Hornblende is characteristic of some medium-grade metamorphic rocks known as amphibolites, in which hornblende and plagioclase are the major constituents.

Coexistence in metamorphic rocks

Dehydration of amphiboles in the lower crust or mantle may be an important source of water that aids in the generation of magmas from partial melting processes.

Pyroxenes

GENERAL CONSIDERATIONS

Pyroxenes are the most significant and abundant group of rock-forming ferromagnesian silicates. They are found in almost every variety of igneous rock and also occur in rocks of widely different compositions formed under conditions of regional and contact metamorphism. The name pyroxene is derived from the Greek *pyro,* meaning "fire," and *xenos,* meaning "stranger," and was given by Haüy to the greenish crystals found in many lavas which he considered to have been accidentally included there.

Pyroxenes crystallize in both the orthorhombic and monoclinic crystal systems. Typically pyroxenes occur as stubby prismatic crystals. They are chemically analogous to the amphiboles except that, as discussed above, hydroxyls are absent in the pyroxene structure. They are similar in colour, lustre, and hardness to the amphiboles but have slightly higher densities owing to the absence of hydroxyls. Pyroxenes have two distinctive planes of cleavage with intersecting angles of about 87° and 93°. Perpendicular to their cleavage planes, pyroxenes have nearly square cross sections, which, together with the cleavage directions, are diagnostic properties.

CHEMICAL COMPOSITION

The chemical composition of minerals of the pyroxene group can be expressed by the general formula XYZ_2O_6, in which $X = Na^+, Ca^{2+}, Mn^{2+}, Fe^{2+}, Mg^{2+}, Li^+$; $Y = Mn^{2+}, Fe^{2+}, Mg^{2+}, Fe^{3+}, Al^{3+}, Cr^{3+}, Ti^{4+}$; and $Z = Si^{4+}, Al^{3+}$. The range of possible chemical substitutions in pyroxene is constrained by the sizes of the available sites in the structure and the charge of the substituting cations. The X cation sites in general are larger than the Y cation sites. Extensive atomic substitution occurs between the ideal end-member compositions. Most pyroxenes have only limited substitution of aluminum for silicon in the Z (tetrahedral) site. When a substituting ion differs in charge, electrical neutrality is maintained by coupled substitutions. For example, the pair consisting of Na^+ and Al^{3+} substitutes for 2 Mg^{2+}. Table 21 shows the five major chemical subdivisions of pyroxenes.

Exsolution of lamellae

At high temperatures, pyroxenes have more extensive fields of solid solution than they do at lower ones. Consequently, as temperatures decrease, the pyroxene adjusts its composition in the solid state by exsolving a separate phase in the form of lamellae within the host pyroxene grain. The lamellae are exsolved along specific crystallographic directions, producing oriented intergrowths with parallel and herringbone texture. There are five principal combinations of exsolution pairs: (1) augite with hypersthene lamellae, (2) augite with pigeonite lamellae, (3) augite with both pigeonite and hypersthene lamellae, (4) pigeonite with augite lamellae, and (5) hypersthene with augite lamellae.

The pyroxenes differ compositionally from the amphiboles in two major respects. Pyroxenes contain no essential water in the form of hydroxyls in their structure, whereas amphiboles are considered to be hydrous silicates. The second key chemical difference between the two is the presence of the A site in amphiboles which contains the large alkali elements, typically sodium and at times potassium; the pyroxenes do not have an equivalent site that can accommodate potassium. Hydroxyl groups in the amphibole structure decrease their thermal stability relative to the more refractory pyroxenes. At high temperatures amphiboles decompose to anhydrous minerals.

$CaSiO_3$-$MgSiO_3$-$FeSiO_3$ system

The most common pyroxenes can be represented as part of the chemical system $CaSiO_3$ (wollastonite, a pyroxenoid), $MgSiO_3$ (enstatite), and $FeSiO_3$ (orthoferrosilite; see Figure 49). Since no true pyroxenes exist with calcium contents greater than that of the diopside-hedenbergite join, the part of this system below this join is known as the pyroxene quadrilateral. Ferrous iron and magnesium substitute freely since they have similar ionic sizes and identical charges. Complete substitution exists between enstatite ($Mg_2Si_2O_6$) and orthoferrosilite ($Fe_2Si_2O_6$), and complete solid solution of iron for magnesium exists between diopside ($CaMgSi_2O_6$) and hedenbergite ($CaFeSi_2O_6$). Augite, subcalcic augite, and pigeonite lie within the interior of the pyroxene quadrilateral. Compositionally, augite is related to members of the diopside-hedenbergite series with limited substitution of Na^+ for Ca^{2+}, Al^{3+} for Mg^{2+} and Fe^{2+}, and Al^{3+} for Si^{4+} in the Z (tetrahedral) site. Augites with substantial aluminum or sodium cannot be strictly represented in the quadrilateral plane. Monoclinic pigeonite encompasses a field of magnesium-iron solid solution with a slightly higher calcium content than the orthorhombic enstatite-orthoferrosilite series. The nomenclature for the orthopyroxene series is based on the percentage of $MgSiO_3$: enstatite, 90–100; bronzite, 70–90; hypersthene, 50–70; ferrohypersthene, 30–50; eulite, 10–30; and orthoferrosilite, 0–10.

Coupled substitutions involving Na^+, Li^+, or Al^{3+} for Mg^{2+} in the enstatite structure yield pyroxenes that lie outside the quadrilateral compositional field. The coupled substitution of Na^+ and Al^{3+} for 2 Mg^{2+} in enstatite produces the pyroxene jadeite. The coupled substitution of Na^+ and Fe^{3+} for 2 Mg^{2+} produces the pyroxene aegirine (acmite). Substiution of Li^+ and Al^{3+} for 2 Mg^{2+} yields spodumene. The substitution of Al^{3+} for Mg^{2+} and Al^{3+} for Si^{4+} yields the ideal tschermakite component $MgAlSiAlO_6$.

Other less common pyroxenes with compositions outside the pyroxene quadrilateral include johannsenite [$CaMnSi_2O_6$], a variety of augite called fassaite [$Ca(Mg, Fe^{2+}, Fe^{3+}, Al)(Si, Al)_2O_6$], and kosmochlor (ureyite) [$NaCrSi_2O_6$]. Johannsenite involves the substitution of manganese for iron in hedenbergite. Kosmochlor has chromium (Cr) in place of iron or aluminum in a sodic pyroxene. The fassaite variety of the calcium pyroxene group has a variable but high aluminum content and a high Fe^{3+}:Fe^{2+} ratio.

The nature of aluminum substitution in pyroxenes varies significantly from one pyroxene to another. In the magnesium-iron pyroxene group, aluminum is usually present in only small amounts. In both jadeite and spodumene, which contain essential aluminum in the Y site, the substitution of silicon by aluminum in the Z tetrahedral site is almost negligible. In augite there can be extensive substitution of aluminum for tetrahedral silicon.

CRYSTAL STRUCTURE

The pyroxene group includes minerals that form in both the orthorhombic and monoclinic crystal systems. Or-

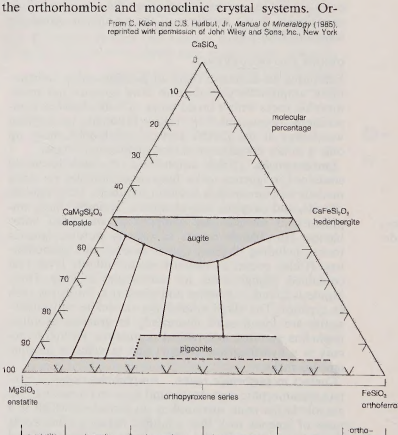

Figure 49: Pyroxene compositions in the system $CaSiO_3$ (wollastonite)–$MgSiO_3$ (enstatite)–$FeSiO_3$ (orthoferrosilite). General compositional fields are outlined, and coexisting pyroxene compositions are shown by tie lines between augite and magnesium-iron-rich pyroxenes. Nomenclature of the enstatite-orthoferrosilite solid-solution series is shown at the bottom of the diagram.

thorhombic pyroxenes are referred to as orthopyroxenes, and monoclinic pyroxenes are called clinopyroxenes. The essential feature of all pyroxene structures is the linkage of the silicon-oxygen (SiO_4) tetrahedrons by sharing two of the four corners to form continuous chains. The chains, which extend indefinitely parallel to the *c* crystallographic axis, have the composition of $(SiO_3)_n$ (Figure 50). A repeat distance of approximately 5.3 Å along the length of the chain defines the *c* axis of the unit cell. The SiO_3 chains are bonded to a layer of octahedrally coordinated cation bands which also extend parallel to the *c* axis. The octahedral layer contains two distinct cation sites called *M1* and *M2*. The size and charge of the cations that occupy the *M2* site chiefly determine the structural type of a pyroxene. Large, singly or doubly charged cations give rise to a diopside (monoclinic) structure, whereas small, singly or doubly charged cations result in an enstatite (orthorhombic) structure.

SiO_3 chains

In most pyroxenes the chains are not exactly straight as shown in Figure 50, but are rotated or kinked so that more than one type of chain is possible. The diopside, jadeite, augite, protoenstatite, and spodumene structures consist of only one chain type. Pigeonite, clinoenstatite, and omphacite have two symmetrically distinct types of tetrahedral chains. Orthopyroxenes also have two distinct types of tetrahedral chains and an octahedral stacking sequence that leads to a doubling of the *a* axis.

A representative pyroxene structure that illustrates the tetrahedral and octahedral chains in jadeite is shown in Figure 51. The octahedral strips consist of *M1* and *M2* octahedrons sandwiched between two oppositely pointing tetrahedral chains. The *M1* sites are occupied by smaller cations such as magnesium, iron, aluminum, and manganese, which are coordinated to six oxygen atoms to form a regular octahedron. In monoclinic pyroxenes, the *M2* site is a large irregular polyhedron occupied by the larger calcium and sodium cations which are in eightfold coordination. In the low-calcium orthorhombic pyroxenes, *M2* contains magnesium and iron, and the polyhedron takes on a more regular octahedral shape. The *M1* cation strip is bonded to oxygen atoms of two oppositely pointing tetrahedral chains. Together, these form a tetrahedral-octahedral-tetrahedral (t-o-t) strip. A schematic projection of the pyroxene structure perpendicular to the *c* axis and the relationship of the pyroxene cleavage to the t-o-t strips or I beams is shown in Figure 52.

The pyroxene quadrilateral

Pyroxenes in the quadrilateral with compositions near the diopside-hedenbergite join exist only in the monoclinic form. Those with compositions near the enstatite-orthoferrosilite join containing less than about 15 percent $CaSiO_3$ can be subdivided into three structural types. Those with approximately 30 percent $FeSiO_3$ are monoclinic at high temperatures (pigeonite) and invert to an orthorhombic structure at low temperatures (hypersthene). Those

with less than 30 percent $FeSiO_3$ can exist as clinoenstatite (monoclinic), protoenstatite (orthorhombic), or enstatite (orthorhombic) polymorphic structures. Pyroxenes outside the quadrilateral all have monoclinic pyroxene structures similar to that of diopside.

The inversion of high-temperature structures to low-temperature structures is often accompanied by the exsolution of lamellae of either a separate calcium-rich or magnesium-iron-rich phase. For example, as high-temperature monoclinic pigeonite slowly cools, it exsolves calcium ions to form augite lamellae and inverts to the orthorhombic hypersthene structure. Consequently, the presence of the exsolution lamellae is evidence of a previous monoclinic structure.

PHYSICAL PROPERTIES

Within hand specimens, pyroxene can generally be identified by the following characteristics: two directions of cleavage intersecting at roughly right angles (approximately 87° and 93°), stubby prismatic crystal habit with nearly square cross sections perpendicular to cleavage directions, and a Mohs hardness between 5 and 7. Specific gravity values of the pyroxenes range from about 3.0 to 4.0. Unlike amphiboles, pyroxenes do not yield water when heated in a closed tube. Characteristically, pyroxenes are dark green to black in colour, but they can range from dark green to apple-green and from lilac to colourless, depending on the chemical composition. Diopside ranges from white to light green, darkening in colour as the iron content increases. Hedenbergite and augite are typically black. Pigeonite is greenish brown to black. Jadeite is white to apple-green to emerald-green or mottled white and green and is a massive aggregate of compact fibres. Aegirine (acmite) forms long, slender prismatic crystals that are brown to green in colour. Enstatite is yellowish or greenish brown; bronzite has a submetallic bronzelike lustre; and hypersthene and more iron-rich orthopyroxenes range from brown to black. Spodumene is colourless, white, gray, pink, yellow, or green. The clear lilac-coloured variety is called kunzite, while the clear emerald-green type is known as hiddenite.

In thin sections, monoclinic pyroxenes are distinguished by two directions of cleavage at approximately 87° and 93°, eight-sided basal cross sections, and light brown or green colour (Figure 53). Orthorhombic pyroxenes differ from monoclinic pyroxenes in that they have parallel extinction.

Microscopically, many igneous pyroxenes show exsolution textures of thin lamellae of one pyroxene in a host of a different composition. The lamellae occur as oriented intergrowths that display parallel and herringbone textures (Figure 54). These lamellae result from the exsolution of a separate pyroxene phase from a host grain due to subsolidus re-equilibration (that occurs while the mineral is in the solid state) during slow cooling.

ORIGIN AND OCCURRENCE

Minerals in the pyroxene group are abundant in both igneous and metamorphic rocks. Their susceptibility to both chemical and mechanical weathering makes them a rare constituent of sedimentary rocks. Pyroxenes are classified as ferromagnesian minerals in allusion to their high content of magnesium and iron. Their conditions of formation are almost exclusively restricted to environments of high temperature, high pressure, or both. Characteristically the more common pyroxenes are found in mafic and ultramafic igneous rocks where they are associated with olivine and calcium-rich plagioclase and in high-grade metamorphic rocks such as granulites and eclogites. Enstatite, clinoenstatite, and kosmochlor occur in meteorites.

Abundance in igneous and metamorphic rocks

Igneous rocks. Magnesium-rich orthopyroxenes and calcium-rich clinopyroxenes are important constituents of basalts, gabbros, peridotites, and norites. They are the major minerals in pyroxenites. Magnesium-rich orthopyroxenes occur in the earlier-formed rocks of layered ultramafic complexes.

Uninverted pigeonites (monoclinic) are common as phenocrysts in high-temperature, rapidly cooled lavas and in some intrusives such as diabases. In slowly cooled mafic intrusive rocks, pigeonite inverts to an orthorhombic pyroxene and undergoes exsolution.

Augite is the most common pyroxene and is found primarily in mafic igneous rocks. It occurs in basalts, gabbros, andesites, diorites, and peridotites. The augites in layered ultramafic intrusions show compositional trends of increasing iron and decreasing magnesium contents with fractionation. Augite is also known to occur in lunar basalts. Although more common in metamorphic rocks, diopside is found in some mafic and ultramafic rocks.

Aegirine (acmite) and aegirine-augite occur most commonly as products of the late crystallization of alkaline magmas. They are found in alkalic rocks such as nepheline syenites and phonolites, wherein they are associated with orthoclase, feldspathoids, augite, and sodium-rich amphiboles.

Spodumene is found almost exclusively in lithium-rich granite pegmatites. Some of the world's largest known crystals are spodumene. Single crystals of spodumene exceeding 13 metres (43 feet) in length were mined for their lithium content in the Black Hills of South Dakota, U.S. Spodumene is typically associated with microcline, albite, quartz, muscovite, lepidolite, beryl, and tourmaline.

Metamorphic rocks. Iron-rich orthopyroxenes are found in metamorphosed iron formations in association with the amphibole grunerite. At higher grades of regional metamorphism, the amphibole anthophyllite breaks down to form magnesium-iron orthopyroxenes. The orthopyroxenes hypersthene and enstatite occur in high-temperature and high-pressure granulite facies rocks such as quartz-rich, garnet-bearing granulites.

Diopside results from the thermal metamorphism of siliceous limestones or dolomites according to the following decarbonation reaction:

$$CaMg(CO_3)_2 + 2SiO_2 \rightarrow CaMgSi_2O_6 + 2CO_2.$$

dolomite quartz diopside carbon dioxide

In calc-silicate skarns produced by contact metamorphism, diopside is associated with wollastonite, vesuvianite, grossular, and tremolite. Diopside also forms under

conditions of regional metamorphism by the breakdown of tremolite. Hedenbergite is a product of thermal metamorphism of iron-rich sediments where its formation is probably due to the breakdown of ferroactinolite with increasing temperature. The variety of augite called fassaite is found in quartz-free, aluminum-rich skarns associated with spinel, calcite, vesuvianite, garnet, clintonite, and diopside. Johannsenite is associated with rhodonite, bustamite, sphalerite, chalcopyrite, galena, pyrite, and magnetite in metasomatized limestones adjacent to igneous intrusions.

Aegirine (acmite) is associated with glaucophane or riebeckite in some metamorphic rocks. Jadeite is found only in metamorphic rocks. It is associated with albite, glaucophane, aragonite, lawsonite, and quartz in high-pressure, low-temperature metamorphic rocks of blueschist facies. In some localities, jadeite is associated with serpentine in glaucophane-bearing metamorphic rocks.

Omphacite is restricted in occurrence to the high-pressure and high-temperature rocks called eclogites. Eclogites represent the most deep-seated conditions of metamorphism and are characterized by an assemblage of omphacite and magnesium-rich pyrope garnet. Omphacite-bearing eclogite nodules are associated with peridotites in the kimberlite pipes of South Africa. (W.B.Si.)

Quartz and other silica minerals

GENERAL CONSIDERATIONS

Silica minerals make up approximately 12 percent of the Earth's crust and are second only to the feldspars in mineral abundance. Free silica occurs in many crystalline forms with a composition very close to that of silicon dioxide (SiO_2), 46.75 percent by weight being silicon and 53.25 percent oxygen. Quartz is by far the most commonly occurring form. Tridymite, cristobalite, and the hydrous silica mineral opal are uncommon, and vitreous (glassy) silica, melanophlogite, coesite, and stishovite have been reported from only a few localities. Several other forms have been produced in the laboratory but have not been found in nature.

PHYSICAL AND CHEMICAL PROPERTIES

The crystallographic structures of the silica minerals, except stishovite, are three-dimensional arrays of linked tetrahedrons, each consisting of a silicon atom coordinated by four oxygen atoms. The tetrahedrons are usually quite regular, and the silicon-oxygen bond distances are 1.61 ± 0.02 Å. Principal differences are related to the geometry of the tetrahedral linkages, which may cause small distortions within the silica tetrahedrons. High pressure forces silicon atoms to coordinate with six oxygen atoms, producing nearly regular octahedrons in the stishovite structure.

The silica minerals when pure are colourless and transparent and have a vitreous lustre. They are nonconductors of electricity and are diamagnetic. All are hard and strong and fail by brittle fracture under an imposed stress.

Some important physical properties of the silica minerals are compared in Table 22. All except low tridymite and coesite (among the crystalline varieties) have relatively high symmetry. There is a linear relationship between the specific gravity values listed in Table 22 and the arithmetic mean of the indices of refraction (measures of the velocity of light that is transmitted in different crystallographic directions) for silica minerals composed of linked tetrahedrons. This relationship (Figure 55) does not extend to stishovite because it is not made up of silica tetrahedrons. Melanophlogite is notable because it plots below vitreous silica on the graph. The specific gravities of silica minerals are less than those of most of the dark-coloured silicate minerals associated with them in nature; in general, the lighter-coloured rocks have lower specific gravity for this reason. Silica minerals are insoluble to sparingly soluble in strong acids except hydrofluoric acid, in which there is a correlation between specific gravity and solubility.

INDIVIDUAL SILICA MINERALS

Quartz. Quartz occurs in many varieties in almost all types of igneous, sedimentary, and metamorphic rocks. It has also been found in meteorites and in some lunar rocks.

Quartz crystals lack a centre of symmetry or planes of symmetry and have one crystallographic axis (*c*) perpendicular to three polar axes (*a*) that are 120° apart. One end of a polar axis is different from its other end; when mechanical stress is applied on such an axis, opposite electrical charges develop on each end. This leads to important applications in electronics as a frequency control and in pressure gauges and other devices. The lack of symmetry planes parallel to the vertical axis allows quartz crystals to occur as two types: left-handed or right-handed (enantiomorphism). Left-handed quartz is less than 1 percent more abundant than right-handed quartz. The structural tetrahedrons spiral upward through the crystal in the sense of the handedness parallel to the *c* axis. Similarly, if polarized light is transmitted by a quartz crystal along the *c*-axis direction, the plane is rotated in the direction of the handedness by tens of degrees per millimetre, the amount depending on the wavelength of the light. This property is used in optical instruments such as monochromators.

Left-handed and right-handed quartz crystals

The requirements for high-purity crystals for electronic frequency applications have led to the development of industrial synthesis methods based on the differences in silica solubility with temperature. Nutrient crystals are placed in the hot portion of a solution-filled autoclave, and an oriented seed crystal free from twinning is placed in the cooler portion. Crystals weighing thousands of grams can be grown in a few weeks.

Quartz shows less range in chemical composition than do most other minerals, but it commonly contains tens to hundreds of parts per million of aluminum atoms substituting for silicon atoms, with charge balance maintained by the incorporation of small atoms, such as hydrogen, lithium, or sodium. Titanium, magnesium, or iron atoms substituting for silicon atoms also have been reported, but anionic substitution (*i.e.,* substitution for the negative ion, oxygen) is limited because the linkage of the tetrahedrons is disrupted.

Colours of quartz varieties

Coloured varieties of quartz are numerous and have many causes. Most colours result from mechanically incorporated admixtures within fine-crystallized or granular quartz, but some coarse-crystallized varieties, such as amethyst (violet), citrine (yellow), milky quartz, smoky quartz or morion (black), or rose quartz, may be coloured by ions other than silicon and oxygen that occur within the crystal structure (see Figure 56). Small fractions of 1 percent by weight of iron, aluminum, manganese, titanium, hydrogen, and small alkali atoms, such as lithium and sodium, have been shown to be the cause of different colours. Heat treatment or various irradiation treatments under oxidizing or reducing atmospheres are used to change one coloured variety to another. Citrine is commonly produced by heat-treating amethyst at 250°–400° C (482°–752° F), for example.

Quartz may contain inclusions of other minerals, such as rutile (rutilated quartz), tourmaline, asbestiform amphiboles, or platy minerals, such as mica, iron oxides, or chlorite (aventurine).

Chalcedony. Chalcedony is a white, buff, or light tan, finely crystallized or fibrous quartz that forms rounded crusts, rinds, or stalactites (mineral deposits suspended from the roofs of caverns) in volcanic and sedimentary rocks as a precipitate from moving solutions. If chalcedony is conspicuously colour-banded, it may be called agate; onyx is agate with alternate bands of white and black or dark brown. Some concentrically banded "eye" agate nodules contain cores of coarsely crystalline quartz, and other agates are mottled or variegated in colour. Arborescent or dendritic (branching) dark-coloured patterns set in a lighter field are called moss agate or Mocha stone. Translucent red chalcedony is called carnelian, and translucent brown shades are referred to as sard; both are pigmented by admixed iron oxides.

Chrysoprase, plasma, and prase are names for green varieties of chalcedony coloured by admixed green minerals, such as chlorite, fibrous amphiboles, or hydrous nickel silicates. Bloodstone and heliotrope are green chalcedony with red spots.

Jasper, chert, and flint. Jasper is opaque red, brown, or yellow quartz that is pigmented by admixed iron oxides. Chert and flint are finely crystallized varieties of gray to black quartz that occur as nodules or bands in sedimentary rocks.

High quartz (β-quartz). High quartz, or β-quartz, is the more symmetrical form quartz takes at sufficiently high temperatures (about 573° C at one atmosphere of pressure), but the relationship is pressure-sensitive (see Figure 57). High quartz may be either left- or right-handed, and its *c* axis is one of sixfold symmetry rather than threefold; thus, many twin laws of ordinary quartz cannot occur. High quartz twins typically involve inclined sets of axes. High quartz can form directly from silicate magma or from high-temperature gases or solutions. It invariably undergoes the transition to ordinary quartz (low quartz) on cooling, and all ordinary quartz, when heated above the transition temperature, is transformed into high quartz. The transformation involves displacement of the linkage between the tetrahedrons; no bonds are broken.

Tridymite. Tridymite may occur as a primary magmatic phase (*i.e.*, as a direct result of crystallization from a silicate melt) in siliceous rocks but is most abundant in voids in volcanic rocks where it probably was deposited metastably from hydrous gases. Tridymite also forms in contact-metamorphosed rocks. It has been found in meteorites and is common in lunar basalts. It occurs in quantity in firebricks and other siliceous refractories. Natural tridymite has no specific commercial use.

Cristobalite. Cristobalite is probably more abundant in nature than tridymite, although it seldom forms as distinctive crystals. The devitrification (transformation from the glassy to the crystalline state) of siliceous volcanic glasses yields abundant tiny crystallites of cristobalite, and the mineral is also deposited metastably from hot hydrous gases in cavities and cracks of many volcanic rocks. It has been found in lunar basalts and in meteorites and is common in silica refractories exposed to very high temperatures.

Opal. Opal is poorly crystalline or amorphous hydrous silica that is compact and vitreous and most commonly translucent white to colourless. Precious opal reflects light with a play of brilliant colours across the visible spectrum, red being the most valued. Opal forms by precipitation from silica-bearing solutions near the Earth's surface. Electron microscopy has shown that many opals are composed of spheres of tens to a few thousand angstroms in size that are arranged in either hexagonal or cubic close packing. The spheres are composed of hydrous silica that may be either almost cristobalite-like, tridymite-like, mixtures of both, or random and nondiffracting. The specific gravity and refractive index are lower than those of pure silica minerals. The play of colours in precious opal arises from the diffraction of light from submicroscopic layers of regularly oriented silica spheres. When heated, opal may lose as much as 20 percent of its weight of water, fracture, and then crystallize to one of the silica minerals described above.

Arrangement of spheres in opal

Opal usually contains 4 to 9 percent water, but lower and much higher values have been observed. The contents of alumina, ferric oxide, and alkalis are variable but may amount to several percent in light-coloured opals and more if pigmenting minerals are also present. Precious opal has been synthesized. Opaline silica is a friable hydrous silica found near hot springs and geysers.

Vitreous silica. Vitreous silica, lechatelierite, is supercooled liquid silica. It has been observed in nature as the result of fusion of quartz by lightning strikes (fulgurites) or by shock associated with large meteorite impacts and may approach artificial, very pure silica glass in composition and physical properties.

Melanophlogite. Melanophlogite is a cubic silica mineral with a gas-hydrate structure containing many large voids. In nature these are filled with 6 to 12 percent by weight of compounds of hydrogen, carbon, and sulfur, which may be necessary for mineral growth. If these compounds are destroyed by heating, they do not cause the crystal to collapse, but the free carbon formed does darken it. Melanophlogite occurs with bitumen and forms at temperatures below 112° C on native sulfur crystals in Sicily.

Keatite. Keatite is a tetragonal form of silica known only from the laboratory, where it can be synthesized metastably over the range of temperatures from about 300° to 600° C and 400 to 4,000 bars (standard atmospheric pressure at sea level is 1,013.3 millibars, or slightly more than 1 bar, which equals 760 millimetres of mercury) in the presence of steam. It has negative thermal expansion along the *a* axis and positive thermal expansion along the *c* axis, so that the overall expansion is very low or negative.

Coesite and stishovite. Coesite and stishovite are rare dense forms of silica observed in nature only where quartz-bearing rocks have been severely shocked by a large meteorite impact, such as Meteor Crater in Arizona, U.S. Coesite is made up of tetrahedrons arranged like those in feldspars. Stishovite is the densest form of silica and consists of silicon that is octahedrally coordinated with oxygen. Both coesite and stishovite have been synthesized and found to be stable only at high pressures (Figure 57).

ORIGIN AND OCCURRENCE

Occurrence of free silica

Silicon and oxygen are the two most abundant elements in the Earth's crust, in which they largely occur in combination with other elements as silicate minerals. Free silica (SiO_2) appears as a mineral in crystallizing magma only when the relative abundance of SiO_2 exceeds that of all other cations available to form silicates. Silica minerals thus occur only in magmas containing more than about 47 percent by weight of SiO_2 and are incompatible with minerals with low cation:silica ratios—such as olivine, nepheline, or leucite. Basaltic and alkalic igneous magmas therefore can crystallize only minor amounts of silica minerals, and sometimes none are produced. The gas released from such rocks can dissolve the silica components, however, and later precipitate silica minerals upon cooling. The amount of silica minerals crystallized from magma increases with increasing silica content of magma, reaching 40 percent in some granites and rhyolites.

Solubility of silica minerals. The solubility of silica minerals in natural solutions and gases is of great importance. The solubility of all silica minerals increases regularly with increasing temperature and pressure except in the region of 340°–550° C and 0–600 bars, where retrograde solubility occurs because of changes in the physical state of water. The solubility of silica increases in the presence of anions such as OH^- and CO_3^{2-}, which form chemical complexes with it.

Quartz is the least soluble of the forms of silica at room temperature. In pure water its solubility at 25° C is about 6 parts per million, that of vitreous silica being at least 10 times greater. Typical temperate-climate river water contains 14 parts per million of silica, and enormous tonnages of silica are carried away in solution annually from weathering rocks and soils. The amount so removed may

be equivalent to that transported mechanically in many climates. Silica dissolved in moving groundwater may partially fill hollow spheroids and precipitate crystals to form geodes, or it may cement loose sand grains together to form concretions and nodules or even entire sedimentary beds into sandstone, which, when all pore space is eliminated by selective solution and nearby deposition during metamorphism, form tough, pore-free quartzite.

Rock crystal, spring deposits, and glass sands

Gases or solutions escaping from cooling igneous rocks or deep fractures commonly are saturated with silica and other compounds that, as they cool, precipitate quartz along their channelways to form veins. It may be fine-grained (as chalcedony), massive granular, or in coarse crystals as large as tens of tons. Most natural colourless quartz crystals, "rock crystal," were formed in this way.

The emergence of heated silica-bearing solutions onto the surface results in rapid cooling and the loss of complexing anions. Rapid precipitation of fine-grained silica results in formation of siliceous sinter or geyserite, as at Mammoth Hot Springs in Yellowstone National Park in the western United States.

Quartz is mechanically resistant and relatively inert chemically during rock weathering in temperate and cold climates. Thus, it becomes enriched in river, lake, and beach sediments, which commonly contain more than one-half quartz by weight. Some strata consist almost entirely of quartz over large lateral distances and tens or hundreds of metres in thickness. Known as glass sands, these strata are important economic sources of silica for glass and chemical industries. Quartz-bearing strata are abundant in metamorphic terrains. The reincorporation of free silica into complex silicates and the solution and redeposition of silica into veins is characteristic of such terrains.

The silica phase diagram. The pressure-temperature fields of stability of silica minerals are shown in Figure 57. The experimentally determined boundaries are drawn with heavy lines. Stability fields are not shown for keatite, melanophlogite, opal, or the low forms of tridymite and cristobalite because they have not been demonstrated. Quartz is the stable phase of silica under the physical conditions that prevail over most of the Earth's crust. Coesite is possible at depths of about 100 kilometres (60 miles) in the Earth's mantle, but free silica is not thought to be abundant there. Stishovite would require even greater depths of burial, and no rocks that occur on the terrestrial surface have been buried so deeply.

USES

Quartz is the only natural silica mineral used in significant quantities; millions of tons are consumed annually by many industries. The sand that is an essential ingredient of concrete and mortar is largely quartz, as are the sandstone and quartzite used as building stones. Crushed sandstone and quartzite are used for road and railway construction, roofing granules, and riprap—erosion-control linings of river channels. Quartz is hard (7 on the Mohs scale) and resists fracture because it lacks easy cleavage. These properties, combined with its ready availability, lead to its use as a sandpaper abrasive and in sandblasting; for polishing and cutting glass, stone, and metal; and for providing traction on stairs, streets, and rails. Large amounts of relatively pure quartz are used in refractory products, such as insulation and firebricks, foundry molds, and electrical insulators, because of the combination of its high melting temperatures, low coefficients of expansion, inertness of the high-temperature forms of silica, and low costs.

Relatively pure quartz is required in large tonnages as an ingredient for glass and porcelain manufacture. High purity quartz is fused to make premium grades of chemical and optical glass for which one or more of its desirable properties of low thermal expansion, high-shape stability, elasticity, low solubility, and transparency to various kinds of light can justify the greatly increased costs involved. Fibres of vitreous silica are essential for precision instruments, such as balances, galvanometers, and gravimeters. Tons of quartz of various qualities are used as raw materials for processes in which silica is not the final product. These include the production of water glass, or sodium silicate, various sols—very fine dispersions of solids in liquids—that are used as hydrophobic (water-repelling) coatings, organic silicates and silicones, silicon carbide, silicon metal, smelting flux, and alloying in metallurgy.

Quartz and its varieties have been used since antiquity as semiprecious gems, ornamental stones, and collector's items. Precious opal, a hydrous form of silica, has been a gemstone since Roman times. (D.B.S./W.B.Si.)

Micas

GENERAL CONSIDERATIONS

Of the 28 known species of the mica group, only 6 are common rock-forming minerals. Muscovite, the common light-coloured mica, and biotite, which is typically black or nearly so, are the most abundant. Phlogopite, typically brown, and paragonite, which is macroscopically indistinguishable from muscovite, also are fairly common. Lepidolite, generally pinkish to lilac in colour, occurs in lithium-bearing pegmatites. Glauconite, a green species that does not have the same general macroscopic characteristics as the other micas, occurs sporadically in many marine sedimentary sequences. All of these micas except glauconite exhibit easily observable perfect cleavage into flexible sheets. Glauconite, which most often occurs as pelletlike grains, has no apparent cleavage.

Mica nomenclature

The names of the rock-forming micas constitute a good example of the diverse bases used in naming minerals: Biotite was named for a person—Jean-Baptiste Biot, a 19th-century French physicist who studied the optical properties of micas; muscovite was named, albeit indirectly, for a place—it was originally called "Muscovy glass" because it came from the Muscovy province of Russia; glauconite, although typically green, was named for the Greek word for blue; lepidolite, from the Greek word meaning "scale," was based on the appearance of the mineral's cleavage plates; phlogopite, from the Greek word for firelike, was chosen because of the reddish glow (colour and lustre) of some specimens; paragonite, from the Greek "to mislead," was so named because it was originally mistaken for another mineral, talc.

CHEMICAL COMPOSITION

The general formula for minerals of the mica group is $XY_{2-3}Z_4O_{10}(OH, F)_2$ with X = K, Na, Ba, Ca, Cs, (H_3O), (NH_4); Y = Al, Mg, Fe^{2+}, Li, Cr, Mn, V, Zn; and Z = Si, Al, Fe^{3+}, Be, Ti. Compositions of the common rock-forming micas are given in Table 23.

Table 23: End-Member Chemical Compositions of Rock-Forming Micas*

Biotite	$K(Mg, Fe^{2+})_3(Al, Fe^{3+})Si_3O_{10}(OH, F)_2$
Phlogopite	$KMg_3Si_3AlO_{10}(F, OH)_2$
Lepidolite	$K(Li, Al)_3(Si, Al)_4O_{10}(F, OH)_2$
Muscovite	$KAl_2(Si_3Al)O_{10}(OH, F)_2$
Paragonite	$NaAl_2(Si_3Al)O_{10}(OH)_2$
Glauconite	$(K, Na)(Fe^{3+}, Al, Mg)_2(Si, Al)_4O_{10}(OH)_2$

*The micas above the broken line are trioctahedral—*i.e.*, they have three atoms in the *Y* position; those below the line are dioctahedral—*i.e.*, they have two atoms in the *Y* position.

Few natural micas have end-member compositions. For example, most muscovites contain sodium substituting for some potassium, and diverse varieties have chromium or vanadium or a combination of both replacing part of the aluminum; furthermore, the Si:Al ratio may range from the indicated 3:1 up to about 7:1. Similar variations in composition are known for the other micas. Thus, as in some of the other groups of minerals (*e.g.*, the garnets), different individual pieces of naturally occurring mica specimens consist of different proportions of ideal end-member compositions. There are, however, no complete series of solid solutions between any dioctahedral mica and any trioctahedral mica.

CRYSTAL STRUCTURE

Micas have sheet structures whose basic units consist of two polymerized sheets of silica (SiO_4) tetrahedrons. Two such sheets are juxtaposed with the vertices of their tetra-

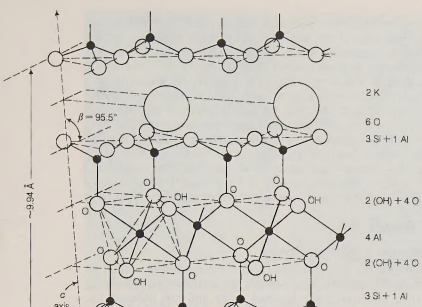

Figure 58: *The structure of mica as exemplified by muscovite.* The tabulation giving the layer by layer population of elements—to the right of the diagram—correlates with the doubled formula $K_2Al_4(Si_6Al_2)O_{20}(OH)_4$.

hedrons pointing toward each other; the sheets are cross-linked with cations—for example, aluminum in muscovite—and hydroxyl pairs complete the coordination of these cations (see Figure 58). Thus, the cross-linked double layer is bound firmly, has the bases of silica tetrahedrons on both of its outer sides, and has a negative charge. The charge is balanced by singly charged large cations—for example, potassium in muscovite—that join the cross-linked double layers to form the complete structure. The differences among mica species depend upon differences in the *X* and *Y* cations.

Polytypes

Although the micas are generally considered to be monoclinic (pseudohexagonal), there also are hexagonal, orthorhombic, and triclinic forms generally referred to as polytypes (see Table 24). The polytypes are based on the sequences and number of layers of the basic structure in the unit cell and the symmetry thus produced. Most biotites are 1M and most muscovites are 2M; however, more than one polytype is commonly present in individual specimens. This feature cannot, however, be determined macroscopically; polytypes are distinguished by relatively sophisticated techniques such as those employing X rays.

designation	crystal system	number of layers per unit cell
1M	monoclinic	1
$2M_1$	monoclinic	2
$2M_2$	monoclinic	2
2O	orthorhombic	2
3T	hexagonal (trigonal)	3
6H*	hexagonal	6
8TC	triclinic	8
12M	monoclinic	12
18M	monoclinic	18

*This polytype has not been recorded for natural micas.

The micas other than glauconite tend to crystallize as short pseudohexagonal prisms. The side faces of these prisms are typically rough, some appearing striated and dull, whereas the flat ends tend to be smooth and shiny. The end faces are parallel to the perfect cleavage that characterizes the group (Figure 59).

PHYSICAL PROPERTIES

The rock-forming micas (other than glauconite) can be divided into two groups: those that are light-coloured (muscovite, paragonite, and lepidolite) and those that are dark-coloured (biotite and phlogopite). Most of the properties of the mica group of minerals, other than those of glauconite, can be described together; here they are described as pertaining simply to micas, meaning the micas other than glauconite. Properties of the latter are described separately later in the discussion.

The perfect cleavage into thin elastic sheets is probably the most widely recognized characteristic of the micas (see Figure 59). The cleavage is a manifestation of the sheet structure described above. (The elasticity of the thin sheets distinguishes the micas from similarly appearing thin sheets of chlorite and talc.) The rock-forming micas exhibit certain characteristic colours. Muscovites range from colourless, greenish to blue-green to emerald-green, pinkish, and brownish to cinnamon-tan. Paragonites are colourless to white; biotites may be black, brown, red to red-brown, greenish brown, and blue-green. Phlogopites resemble biotites but are not black. Lepidolites are nearly colourless, pink, lavender, or tan. Biotites and phlogopites also exhibit the property termed pleochroism (or, more properly for these minerals, dichroism): When viewed along different crystallographic directions, especially using transmitted polarized light, they exhibit different colours or different absorption of light or both.

The lustre of the micas is usually described as splendent, but some cleavage faces appear pearly. The minutely crystalline variety consisting of muscovite or paragonite (or both), generally referred to as sericite, is silky.

Ward's Natural Science Establishment, Inc., Rochester, New York

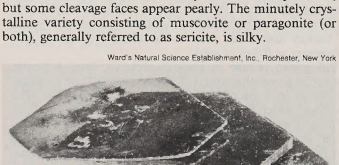

Figure 59: *Muscovite cleavage.* The perfect cleavage of muscovite permits its splitting into thin flakes.

Mohs hardness of the micas is approximately 2½ on cleavage flakes and 4 across cleavage. Consequently, micas can be scratched in either direction with a knife blade or geologic pick. Hardness is used to distinguish micas from chloritoid, which also occurs rather commonly as platy masses in some metamorphic rocks; chloritoid, with a Mohs hardness of 6½, cannot be scratched with a knife blade or geologic pick.

Specific gravity for the micas varies with composition. The overall range is from 2.76 for muscovite to 3.2 for iron-rich biotite.

Glauconite occurs most commonly as earthy to dull, subtranslucent, green to nearly black granules generally referred to as pellets. It is attacked readily by hydrochloric acid. The colour and occurrence of this mineral in sediments and sedimentary rocks formed from those sediments generally are sufficient for identification.

ORIGIN AND OCCURRENCE

Micas may originate as the result of diverse processes under several different conditions. Their occurrences, listed below, include crystallization from consolidating magmas, deposition by fluids derived from or directly associated with magmatic activities, deposition by fluids circulating during both contact and regional metamorphism, and formation as the result of alteration processes—perhaps even those caused by weathering—that involve minerals such as feldspars. The stability ranges of micas have been investigated in the laboratory, and in some associations their presence (as opposed to absence) or some aspect of their chemical composition may serve as geothermometers or geobarometers.

Distinct crystals of the micas occur in a few rocks—*e.g.*, in certain igneous rocks and in pegmatites. In most

rocks, micas occur as irregular tabular masses or thin plates (flakes), which in some instances appear bent. Although some mica grains are extremely small, all except those constituting sericitic masses have characteristic shiny cleavage surfaces.

Glauconite is formed in marine environments. It can be found on seafloors where clastic sedimentation, which results from the relocation of minerals and organic matter to sites other than their places of origin, is lacking or nearly so. Although some glauconite has been interpreted to have been formed from preexisting layered silicates (*e.g.*, detrital biotite), most of it appears to have crystallized from aluminosilicate gels—perhaps under the influence of biochemical activities that produce reducing environments.

The common rock-forming micas are distributed widely. The more important occurrences follow: Biotite occurs in many igneous rocks (*e.g.*, granites and granodiorites), is common in many pegmatite masses, and constitutes one of the chief components of many metamorphic rocks (*e.g.*, gneisses, schists, and hornfelses). It alters rather easily during chemical weathering and thus is rare in sediments and sedimentary rocks. One stage in the weathering of biotite has resulted in some confusion. During chemical weathering, biotite tends to lose its elasticity and become decolorized to silvery gray flakes. In a fairly common intermediate stage, weathered biotite is golden yellow, has a bronzy lustre, and may be mistaken by inexperienced observers as flakes of gold.

Phlogopite is rare in igneous rocks; it does, however, occur in some ultrabasic (silica-poor) rocks. For example, it occurs in some peridotites, especially those called kimberlites, which are the rocks in which diamonds occur. Phlogopite also is a rare constituent of some magnesium-rich pegmatites. Its most common occurrence, however, is in impure limestones that have undergone contact metasomatism, a process through which the chemical composition of rocks is changed.

Sources of muscovite

Muscovite is particularly common in metamorphic gneisses, schists, and phyllites. In fine-grained foliated rocks, such as phyllites, the muscovite occurs as microscopic grains (sericite) that give these rocks their silky lustres. It also occurs in some granitic rocks and is common in complex granitic pegmatites and within miarolitic druses, which are late-magmatic, crystal-lined cavities in igneous rocks. Much of the muscovite in igneous rocks is thought to have been formed late during, or immediately after, consolidation of the parent magma. Muscovite is relatively resistant to weathering and thus occurs in many soils developed over muscovite-bearing rocks and also in the clastic sediments and sedimentary rocks derived from them.

Paragonite is known definitely to occur in only a few gneisses, schists, and phyllites, in which it appears to play essentially the same role as muscovite. It may, however, be much more common than generally thought. Until fairly recently nearly all light-coloured micas in rocks were automatically called muscovite without checking their potassium:sodium ratios, so some paragonites may have been incorrectly identified as muscovites. Its weathering is essentially the same as that of muscovite.

Lepidolite occurs almost exclusively in complex lithium-bearing pegmatites but has also been recorded as a component of a few granites.

Glauconite, as noted above, is forming in some present-day marine environments. It also is a relatively common constituent of sedimentary rocks, the precursor sediments of which were apparently deposited on the deeper parts of ancient continental shelves. The name greensand is widely applied to glauconite-rich sediments. Most glauconite occurs as granules, which are frequently referred to as pellets. It also exists as pigment, typically as films that coat such diverse substrates as fossils, fecal pellets, and clastic fragments.

USES

Because of their perfect cleavage, flexibility and elasticity, infusibility, low thermal and electrical conductivity, and high dielectric strength, muscovite and phlogopite have found widespread application. Most "sheet mica" with these compositions has been used as electrical condensers, as insulation sheets between commutator segments, or in heating elements. Sheets of muscovite of precise thicknesses are utilized in optical instruments. Ground mica is used as a dusting medium to prevent, for example, asphalt tiles from sticking to each other and also as a filler, absorbent, and lubricant. Lepidolite has been mined as an ore of lithium, with rubidium generally recovered as a by-product. Glauconite-rich greensands have found use within the United States as fertilizer—*e.g.*, on the coastal plain of New Jersey—and some glauconite has been employed as a water softener because it has a high base-exchange capacity and tends to regenerate rather rapidly. Olivines

GENERAL CONSIDERATIONS

Olivines are an important rock-forming silicate mineral group. Magnesium-rich olivines are abundant in low-silica mafic and ultramafic igneous rocks and are believed to be the most abundant constituent of the Earth's upper mantle. Olivine also occurs in high-temperature metamorphic rocks, lunar basalts, and some meteorites. The name olivine derives from the unusual yellow-green to deep bottle-green colour of the magnesium-iron olivine series. Typically the name olivine is given to members of the forsterite-fayalite solid-solution series. In addition to these magnesium and ferrous iron end-members, the olivine group contains manganese (tephroite), calcium-manganese (glaucochroite), calcium-magnesium (monticellite), and calcium-iron (kirschsteinite) end-members (Table 25). Gem-quality forsterite olivine is known as peridot (Figure 60). Because of its high melting point and resistance to chemical reagents, magnesium olivine is an important refractory material—*i.e.*, it can be used in furnace linings and in kilns when other materials are subjected to heat and chemical processes.

end-members	composition	specific gravity	hardness on the Mohs scale
Forsterite	Mg_2SiO_4	3.22	7
Fayalite	Fe_2SiO_4	4.39	7
Tephroite	Mn_2SiO_4	3.78	6
Monticellite	$CaMgSiO_4$	3.08	5½
Kirschsteinite	$CaFeSiO_4$	—	—
Glaucochroite	$CaMnSiO_4$	3.41	6

CHEMICAL COMPOSITION

The composition of most olivines can be represented in the system Ca_2SiO_4-Mg_2SiO_4-Fe_2SiO_4 (Figure 61). The most abundant olivines occur in the system from forsterite (Mg_2SiO_4) to fayalite (Fe_2SiO_4). Most of the naturally occurring olivines are intermediate in composition to these two end-members and have the general formula $(Mg, Fe)_2SiO_4$. Members of the series monticellite ($CaMgSiO_4$) to kirschsteinite ($CaFeSiO_4$) are rare.

The forsterite-fayalite series

The name forsterite is restricted to those species with no more than 10 percent iron substituting for magnesium; fayalite (from Fayal Island in the Azores, where it was believed to occur in a local volcanic rock but probably was obtained from slag brought to the island as ship's ballast) is restricted to species with no more than 10 percent magnesium substituting for iron. Species intermediate in composition to forsterite and fayalite are also named; from most magnesium-rich to most iron-rich they are chrysolite (70–90 percent Mg), hyalosiderite (50–70 percent Mg), hortonolite (50–70 percent Fe), and ferrohortonite (70–90 percent Fe).

The continuity in the forsterite-fayalite series has been verified experimentally (Figure 62). At the magnesium-rich end of the solid-solution series, natural crystals may contain very small amounts of calcium, nickel, and chromium; the iron-rich members near the other end of the series may incorporate small amounts of manganese and calcium. Apart from ferrous iron, the crystalline structure of the olivines is also capable of accommodating relatively small

amounts of ferric iron; dendrites (small branching crystals) of magnetite or chromite found oriented with respect to some crystallographic direction within such olivines may be attributed to exsolution. The presence of relatively large amounts of ferric oxide in the analyses of olivines, however, clearly indicates either an advanced state of oxidation or the mechanical inclusion of co-precipitating magnetite upon crystallization from the magma.

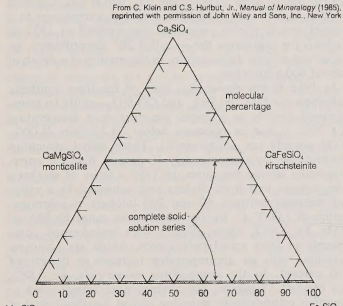

Figure 61: Olivine compositions in the system Ca_2SiO_4–Mg_2SiO_4 (forsterite)–Fe_2SiO_4 (fayalite).

In addition to the forsterite-fayalite series, other complete solid-solution series exist among the various olivine minerals. Fayalite is soluble in all proportions with ashgray tephroite (from Greek *tephros*, "ashen"), pure manganese silicate (Mn_2SiO_4); the intermediate in the series is knebelite ($FeMnSiO_4$). Tephroite and knebelite come from manganese and iron ore deposits, from metamorphosed manganese-rich sedimentary rocks, and from slags.

CRYSTAL STRUCTURE

Orthorhombic crystal system

All olivines crystallize in the orthorhombic crystal system. Olivine is classified as a nesosilicate which has isolated SiO_4 tetrahedrons bound to each other only by ionic bonds from interstitial cations. The structure of olivine can be viewed as a layered closest-packed oxygen network, with silicon ions occupying some of the tetrahedral voids and the calcium, ferrous iron, and magnesium cations occupying some of the octahedral voids (Figure 63). The layers consist of octahedrons cross-linked by independent SiO_4 tetrahedrons. There are two symmetrically nonequivalent octahedral sites, *M1* and *M2*. In magnesium-iron olivines there is no *M1* or *M2* site preference for magnesium or ferric iron. However, in calcic olivines like monticellite, calcium preferentially enters the *M2* site and magnesium occupies the *M1* site.

MINERALOGICAL CHARACTERISTICS

Physical properties. The specific gravity and hardness of the olivines are listed in Table 25. There are at least two cleavages—*i.e.*, the tendency to split along preferred crystallographic directions (perpendicular to the *a* and *b* axes in this case)—both of which are better-developed in the iron-rich varieties. Forsterite contained in certain ultrabasic rocks may show a banded structure when observed in thin sections with a polarizing microscope; in some dunites (a variety of rock consisting nearly entirely of olivine), for example, olivine is preferentially oriented so that the cleavage plane perpendicular to the *b* axis is parallel to the microscopic laminated structure of the rock. Individual grains of olivine within such rocks typically appear as oriented bands with angles of up to 10° between them. Such banding, which is undoubtedly the product of incipient mechanical deformation, also can be observed within the olivine nodules of some basalts.

Banded structures

To the unaided eye, pure forsterite appears colourless, but, as the content of ferrous oxide increases, specimens show yellow-green, dark green, and eventually brown to black tints. In thin sections under the microscope, however, even pure fayalite appears pale yellow. Pure tephroite is gray, and monticellite also appears gray or colourless.

Some variations of optical properties observed in natural olivine crystals probably result from small but varying replacements of magnesium and iron by calcium and manganese and of silicon by titanium, chromium, and ferric iron.

Crystal habit and form. The magnesium-iron olivines occur most commonly as compact or granular masses. Except for the well-shaped phenocrysts (single crystals) of such olivines found embedded in the fine-grained matrices (groundmass) of basalts, distinctly developed crystals are relatively rare. The phenocrysts in basalts are characterized by six- or eight-sided cross sections. With fayalite the morphology is often simple. Monticellite and tephroite commonly show prominent pyramidal faces. Twinning is rare. When twinning does occur, trillings (the intergrowth of three grains) may be produced, and, in monticellite, six-pointed star shapes are reported from the Highwood Mountains in Montana, U.S.

ORIGIN AND OCCURRENCE

Igneous rocks. Olivines are found most commonly in mafic and ultramafic igneous rocks such as peridotites, dunites, gabbros, and basalts. Forsteritic olivines, which have 88 to 92 percent forsterite, are the dominant phase of dunites and are common in peridotites. Gabbros and basalts typically contain forsteritic to intermediate-composition olivine ranging from 50 to 80 percent forsterite. Olivine is typically associated with calcic plagioclase, magnesium-rich pyroxenes, and iron-titanium oxides such as magnetite and ilmenite. This mineralogical association is diagnostic of the relatively high temperatures of crystallization of mafic rock types. Forsterite and protoenstatite crystallize together from about 1,550° C to roughly 1,300° C and are among the first minerals to crystallize from a mafic melt. Magnesium-rich olivine is unstable in a high-silica environment and is never found in equilibrium with quartz. The chemical reaction that precludes the stable coexistence of forsterite and quartz due to the formation of the orthopyroxene enstatite in the presence of excess silica is

$$\underset{\text{forsterite}}{Mg_2SiO_4} + \underset{\text{quartz}}{SiO_2} \longrightarrow \underset{\text{enstatite}}{Mg_2Si_2O_6}.$$

Fayalite (Fa), however, can coexist in equilibrium with quartz in iron-rich granites and rhyolites.

Olivines richer in iron than Fa_{50} are less common; they do occur in the iron-enriched layers of some intrusive rocks, however. Fayalite itself occurs in small amounts in some silicic volcanic rocks, both as a primary mineral and in the lithophysae and vugs (bubblelike hollows) of rhyolites and obsidians (volcanic glass). It also occurs in acidic plutonic rocks such as granites in association with iron-enriched amphiboles and pyroxenes.

Metamorphic rocks. Olivines also occur in metamorphic environments. Both forsterite and monticellite typically develop in the zones in which igneous intrusions make contact with dolomites. Forsterite tends to develop at lower temperatures than monticellite as the process of decarbonation in the contact zone progresses. Fayalitic olivines develop within metamorphosed iron-rich sediments. In the quaternary (*i.e.*, four-component) system Fe_2O_3-FeO-SiO_2-H_2O, fayalite is associated with the minerals greenalite (iron-serpentine), minnesotaite (iron-talc), and grunerite (iron-amphibole) in various metamorphic stages. In chemically more complex environments, which, in addition to the above components, also involve lime (CaO) and alumina (Al_2O_3), fayalite may be associated with hedenbergite, eulite (iron-rich orthopyroxene), grunerite, and almandine (iron-garnet).

Meteorites and the Earth's mantle. In meteorites, the olivine is usually a forsteritic variety containing only Fa_{15} to Fa_{30}. In the Nakhla (Egypt) meteorite (an achondrite meteorite), the olivine is more ferrous, however, containing as much as Fa_{65}. In the chondrites (stony meteorites), the olivine is commonly incorporated in the distinctive spheroidal bodies referred to as chondrules, which range up to one millimetre in diameter.

Because the rocks of the upper mantle directly below the Mohorovičić discontinuity (Moho) are believed to consist of peridotite and garnetiferous peridotite that contain olivines as their most abundant minerals, it is important to establish their behaviour when subjected to high pressures. Study of the olivine-like compound magnesium germanate, Mg_2GeO_4, showed that it has polymorphs that have both olivine and spinel structure. In the spinel structure, the oxygen atoms are arranged in cubic closest packing (in which the position of every third layer repeats that of the initial layer) instead of hexagonal closest packing (in which the position of every second layer repeats that of the initial layer) of the olivine structure. The spinel form of Mg_2GeO_4 was found to have a density exceeding that of the olivine form by 9 percent. In 1936 it was suggested that at high pressures Mg_2SiO_4 might also transform to a spinel structure; this suggestion was adopted in 1937 as a basis for explaining the so-called 20° discontinuity, an observed seismic discontinuity in the mantle at a depth of about 400 kilometres.

Relation to the spinel structure

In 1966 it was shown that each of the three synthetic olivines—Fe_2SiO_4, Ni_2SiO_4, and CO_2SiO_4—could be transformed directly to a spinel structure at a temperature of 700° C and at pressures below 70 kilobars (1,000,000 pounds per square inch). These spinel structures were denser by approximately 10 percent than the corresponding olivine structures. In 1968 a series of synthetic magnesium and iron olivines was subjected to a range of pressures between 50 and 200 kilobars at a temperature of 1,000° C. In the composition range Fe_2SiO_4 to $(Mg_{0.8}Fe_{0.2})_2SiO_4$, these olivines were transformed completely to their spinel polymorphs, which are isometric crystals, with an accompanying increase in density of 10 percent. In the composition range $(Mg_{0.8}Fe_{0.2})_2SiO_4$ to Mg_2SiO_4, however, the olivines were transformed to another orthorhombic structure (called β-orthosilicate) at a pressure of about 130 kilobars and a temperature of 1,000° C. This β-phase polymorph, with a density only 8 percent greater than that of the corresponding olivine structure, is believed to be the stable phase in the field of its synthesis. The change in the crystalline structure of olivine to its spinel polymorph, accompanied by a change in the structure of magnesium-iron pyroxenes to a new garnetlike structure at depths of 350 to 450 kilometres in the mantle, is believed to be responsible for the observed abrupt change in the velocity of seismic waves at these depths (see also EARTHQUAKES).

The spinel polymorph of olivine has been recorded in the Tenham (Queensland, Australia) chondrite as pseudomorphs after olivine. Portions of some large grains of olivine immediately adjacent to black, shock-generated veins are recognized as transforms to the spinel phase; the associated plagioclase feldspar was converted to maskelynite. The composition of the spinel phase in the meteorite has been analyzed by means of an electron probe and found to be $(Mg_{0.75}Fe_{0.25})_2SiO_4$; in thin sections it appears blue-gray to violet-blue. It has been named ringwoodite after Alfred E. Ringwood, an Australian earth scientist who synthesized spinel phases with compositions and properties close to those of the mineral found in the meteorite. More recently, ringwoodite also has been found in the Coorara

(Western Australia) meteorite in association with a garnet phase. The β-phase polymorph has not yet been observed in shocked meteorites—*i.e.*, those that have undergone impact shock—but it is highly probable that it, too, exists in relative abundance within the Earth's mantle.

Other occurrences. Knebelite olivines are restricted to iron-manganese ore deposits, to their associated skarn (lime-bearing silicate rocks) zones, and to metamorphosed manganiferous sediments. At Franklin, N.J., U.S., tephroite and glaucochroite occur in the same deposit as roepperite, a knebelite containing 10.7 percent by weight of zinc oxide (ZnO).

Sources of monticellite

Monticellite occurs in some alkali peridotites and within limestones near their contact with peridotites. Pure kirschsteinite is known only from slags and has not yet been observed as part of a natural mineral assemblage. The most plausible natural environments for kirschsteinite are altered limestones; it is possible the mineral has remained unrecognized in such rocks because its optical properties (the chief means of identification) are similar to those of the much more common magnesium-iron olivines. A kirschsteinite containing 31 percent by weight of other olivines, particularly monticellite, has been reported from a nepheline-melilite in north Kivu region, Zaire.

Glaucochroite, pure calcium and manganese silicate ($CaMnSiO_4$), is rare, reported only from a deposit in Franklin, N.J., where it occurs with tephroite. The limited availability of manganese in parent magmas is thought to account for the rarity of minerals intermediate in the solid-solution series between the calcium-rich olivines monticellite, glaucochroite, and kirschsteinite.

Alteration products and weathering. Olivines gelatinize in even weak acids and offer little resistance to attack by weathering agents and hot mineralizing (hydrothermal) solutions. The forsteritic olivines are altered principally through leaching, which results in the removal of magnesium and the addition of water and some iron. The chemical reactions are usually complex and involve hydration, oxidation, and carbonation. The fayalitic olivines are altered principally through oxidation and the removal of silica. The usual products of alteration are the minerals serpentine, iddingsite, and bowlingite, all of which may occur as pseudomorphs (forms with the outward appearance of the original mineral but which have been completely replaced by another mineral). Serpentine, which is the most common alteration product of olivine in ultramafic rocks, often is accompanied by magnesite. Iddingsite and bowlingite are variable in composition, and, even though they appear optically homogeneous, each actually consists of an intimate mixture of several distinct minerals. X-ray diffraction analyses of iddingsite show that the mineral goethite ($FeO \cdot OH$) is an important component. Also included with the mixture may be hematite (Fe_2O_3), as well as a silicate phase related to vermiculite or montmorillonite. Iddingsite develops almost exclusively from the olivines of extrusive or shallow intrusive rocks and practically never from the olivines of plutonic and metamorphic rocks. The process of "iddingsitation" of olivine may set in even before the complete consolidation of the lava or the hypabyssal magma. This is evident from the observation of rock textures in which shells of iddingsite surrounding a core of olivine are, in turn, surrounded by more unaltered olivine.

Olivine in beach sands

The mechanical weathering of olivine-rich rocks leads to the release of olivine particles that, in the absence of much chemical weathering, may accumulate to produce green or greenish black sands. Conspicuous examples of such sands occur on the beaches of the islands of Oahu and Hawaii, particularly at Diamond Head (Oahu) and South Point (Hawaii). Alluvial sands rich in olivine are also known from Navajo county of Arizona and from New Mexico in the United States; these sands provide the clear olivine (peridot) used in jewelry. (C.E.T./W.B.Si.)

Garnets

GENERAL CONSIDERATIONS

Garnets, a group of minerals favoured by lapidaries since ancient times and used widely as an abrasive, occur in rocks of each of the major classes. In most rocks, however, garnets occur in only minor amounts—*i.e.*, they are accessory minerals. Nevertheless, as a consequence of their distinctive appearances, they are frequently recognized in hand specimens and become part of the name of the rock in which they are contained—*e.g.*, garnet mica schist.

CHEMICAL COMPOSITION

Garnets comprise a group of silicates with the general formula $A_3B_2(SiO_4)_3$ in which A = Ca, Fe^{2+}, Mg, Mn^{2+}; B = Al, Cr, Fe^{3+}, Mn^{3+}, Si, Ti, V, Zr; and Si may be replaced partly by Al, Ti, and/or Fe^{3+}. In addition, many analyses indicate the presence of trace to minor amounts of Na, beryllium (Be), Sr, scandium (Sc), Y, La, hafnium (Hf), niobium (Nb), molybdenum (Mo), cobalt (Co), nickel (Ni), copper (Cu), silver (Ag), Zn, cadmium (Cd), B, Ga, indium (In), Ge, tin (Sn), P, arsenic (As), F, and rare earth elements. Grossular is often recorded as having a composition containing water, but the true substitution seems to involve 4 H^+ for Si^{4+}; and a complete series appears to exist between grossular $[Ca_3Al_2(SiO_4)_3]$ and hydrogrossular $[Ca_3Al_2(SiO_4)_{3-x}(H_4O_4)_x]$. Other hydrogarnets have been reported—*e.g.*, hydroandradite and hydrospessartine; the general formula for hydrogarnets would be $A_3B_2(SiO_4)_{3-x}(H_4O_4)_x$, and the general formula for an end-member hydrogarnet would be $A_3B_2(H_4O_4)_3$.

Nearly all natural garnets exhibit extensive substitution; solid-solution series—some complete, others only partial—exist between several pairs of the group. In practice, the name of the end-member that makes up the largest percentage of any given specimen is usually applied—*e.g.*, a garnet with the composition $Al_{45}Py_{25}Sp_{15}Gr_9An_6$ would be called almandine. End-member compositions of the garnets that are relatively common in rocks are given in Table 26.

Table 26: End-Member Compositions of the Common Rock-Forming Garnets

Andradite (An)	$Ca_3Fe_2(SiO_4)_3$	ugrandite
Uvarovite (U)§	$Ca_3Cr_2(SiO_4)_3$	ugrandite

*†‡In some reports these species are recorded, respectively, as almandite, spessartite, and grossularite. §This garnet is not a common rock-forming garnet; it is, however, noteworthy from the standpoint of solid-solution considerations.

Solid-solution series

Analyses of natural specimens suggest that the following solid-solution series exist: in the pyralspite subgroup, a complete series between almandine and both pyrope and spessartine (Figure 64); in the ugrandite subgroup, a continuous series between grossular and both andradite and uvarovite; less than a complete series between any member of the pyralspite subgroup and any member of the ugrandite subgroup; and an additional series between pyrope and andradite and one or more of the less common

garnets (*e.g.*, pyrope with knorringite [$Mg_3Cr_2(SiO_4)_3$] and andradite with schorlomite [$Ca_3Ti_2(Fe_2, Si)O_{12}$]).

A few well-studied garnets from metamorphic rocks have been shown to be chemically zoned with layers of differing compositions. Most of the differences thus far described appear to reflect, for the most part, differences in occupants of the *A* structural positions. Laboratory experiments have indicated that some series involving garnets exist at high pressures or high temperatures or when both conditions prevail, but such series are not known to be represented by natural specimens. This may suggest that the required conditions do not obtain during the genesis of common rocks.

CRYSTAL STRUCTURE

Garnets consist of groups of independent, distorted SiO_4 tetrahedrons, each of which is linked, by sharing corners, to distorted BO_6 (*e.g.*, aluminum- and/or iron-centred) octahedrons, thus forming a three-dimensional framework. The interstices are occupied by *A* divalent metal ions (*e.g.*, Ca, Fe^{2+}, Mg, and Mn), so that each one is surrounded by eight oxygen atoms that are at the corners of a distorted cube. Therefore, each oxygen is coordinated by two *A*, one *B*, and one silicon cation (see Figure 65). The configuration of the array is such that garnets are isometric (cubic).

Garnets other than pyrope commonly occur as well-developed crystals; pyrope only rarely exists as good crystals. The typical forms of the crystals have 12 or 24 sides and are called dodecahedrons and trapezohedrons, respectively, or they are combinations of such forms (see Figure 66). All tend to be nearly equant. A few studies have led to the suggestion that these crystal habits can be correlated with chemical composition—*i.e.*, that dodecahedrons are most likely to be grossular-rich; that trapezohedrons tend to be pyrope-, almandine-, or spessartine-rich; and that combinations are generally andradite-rich. In any case, many garnets have individual faces that are not well developed, and thus the crystals are roughly spherical. Garnet also occurs in fine to coarse granular masses.

Dodecahedrons and trapezohedrons

PHYSICAL PROPERTIES

The diverse garnets can be distinguished from other common rock-forming minerals rather easily since they do not physically resemble any of them. All garnets have vitreous to resinous lustres. Most are translucent, although they may range from transparent to nearly opaque. Garnets lack cleavage but tend to be brittle. They have Mohs hardness values of 6½ to 7½; their specific gravities, which vary with composition, range from about 3.58 (pyrope) to 4.32 (almandine). Their habits, also noteworthy, have already been described (Figure 66).

A garnet's predominant end-member constituent can only be defined absolutely by, for example, chemical analysis or differential thermal analysis (DTA), a method based on the examination of the chemical and physical changes resulting from the application of heat to a mineral. Nonetheless, in many rocks a garnet can be named tentatively as to its probable composition after only macroscopic examination if its colour is considered in conjunction with the identity of its associated minerals and geologic occurrence. This is true despite the fact that even individual garnet species may assume several different colours: almandine's colour range is deep red to dark brownish red; pyrope may be pink to purplish or deep red to nearly black; spessartine may be brownish orange, burgundy, or reddish brown; grossular may be nearly colourless, white, pale green, yellow, orange, pink, yellowish brown, or brownish red; and andradite may be honey yellow or greenish yellow, brown, red, or nearly black.

Garnet colours

The availability of garnets of several colours, along with properties that make them rather durable and relatively easily worked, is responsible for their widespread use as gemstones.

ORIGIN AND OCCURRENCE

The rock-forming garnets are most common in metamorphic rocks. A few occur in igneous rocks, especially granites and granitic pegmatites. Garnets derived from such rocks occur sporadically in clastic sediments and sedimentary rocks. Typical occurrences of the common rock-forming garnets are given in Table 27.

Inclusions in garnets

Garnets commonly contain many inclusions—*i.e.*, fragments of other rocks and minerals (see Figure 67). Pinwheel garnet and snowball garnet are designations sometimes applied to those garnets whose inclusions appear to have been rotated. These garnets occur sporadically in foliated metamorphic rocks. Although their presence in diverse rocks has been interpreted variously, present-day consensus appears to be that they represent rotation during growth under conditions of dynamic metamorphism that involved differential pressures (see below *Metamorphic rocks: Origin of metamorphic rocks*).

Iron-rich garnets are frequently weathered to rusty masses that consist largely of limonite, and spessartine has weathered to masses of manganese oxide ores under tropical conditions (*e.g.*, in India and Brazil). Garnets as a group, however, are relatively resistant to most weathering processes. Consequently, they occur in some sandy sediments and sandstones. Indeed, the red-coloured grains that are commonly found along some beaches after storms are garnets.

USES

Use as gemstones

The hardness, lack of cleavage, and tendency to break into irregular grains have led to the recovery, crushing, and size-sorting of garnet for use in abrasives such as sandpaper. In addition, as previously mentioned, garnets are used as gemstones. Transparent red and reddish purple pyrope from the Middle East and from Czechoslovakia have been utilized in this capacity for centuries. Green andradite is cut, polished, and marketed as the highly prized stone demantoid. Synthetic garnets with certain compositions, many of which do not have natural representatives, serve important functions because they are ferrimagnetic or antiferromagnetic or because they possess properties particularly suitable for use in lasers. Clay minerals

GENERAL CONSIDERATIONS

The term clay is generally applied to (1) a natural material with plastic properties, (2) particles of very fine size, customarily those defined as particles smaller than two micrometres (7.9×10^{-5} inch), and (3) very fine mineral fragments or particles composed mostly of hydrous-layer silicates of aluminum, though occasionally containing magnesium and iron. Although, in a broader sense, clay minerals can include virtually any mineral of the above-cited particle size, the definition adapted here is restricted to represent hydrous-layer silicates and some related short-range ordered aluminosilicates, both of which occur either exclusively or frequently in very fine-size grades.

The development of X-ray diffraction techniques in the 1920s and the subsequent improvement of microscopic and thermal procedures enabled investigators to establish that clays are composed of a few groups of crystalline minerals. The introduction of electron microscopic methods proved very useful in determining the characteristic shape and size of clay minerals. More recent analytical techniques such as infrared spectroscopy, neutron diffraction analysis, Mössbauer spectroscopy, and nuclear magnetic resonance spectroscopy have helped advance scientific knowledge of the crystal chemistry of these minerals.

Clay minerals are composed essentially of silica, alumina or magnesia or both, and water, but iron substitutes for aluminum and magnesium in varying degrees, and appreciable quantities of potassium, sodium, and calcium are frequently present as well. Some clay minerals may be expressed using ideal chemical formulas as the following: $2SiO_2 \cdot Al_2O_3 \cdot 2H_2O$ (kaolinite), $4SiO_2 \cdot Al_2O_3 \cdot H_2O$ (pyrophyllite), $4SiO_2 \cdot 3MgO \cdot H_2O$ (talc), and $3SiO_2 \cdot Al_2O_3 \cdot 5FeO \cdot 4H_2O$ (chamosite). The SiO_2 ratio in a formula is the key factor determining clay mineral types. These minerals can be classified on the basis of variations of chemical composition and atomic structure into nine groups: (1) kaolin-serpentine (kaolinite, halloysite, lizardite, chrysotile), (2) pyrophyllite-talc, (3) mica (illite, glauconite, celadonite), (4) vermiculite, (5) smectite (montmorillonite, nontronite, saponite), (6) chlorite (sudoite, clinochlore, chamosite), (7) sepiolite-palygorskite, (8) interstratified clay minerals (*e.g.*, rectorite, corrensite, tosudite), and (9) allophane-imogolite. Information and structural diagrams for these groups are given below.

Classification groups

Kaolinite is derived from the commonly used name kaolin, which is a corruption of the Chinese Gaoling (Pinyin; Wade-Giles: Kao-ling) meaning "high ridge," the name of a hill near Ching-te-chen where the occurrence of the mineral is known as early as the 2nd century BC. Montmorillonite and nontronite are named after the localities Montmorillon and Nontron, respectively, in France, where these minerals were first reported. Celadonite is from the French *céladon* (meaning grayish yellow-green) in allusion to its colour. Because sepiolite is a light and porous material, its name is based on the Greek word for cuttlefish, the bone of which is similar in nature. The name saponite is derived from the Latin *sapon* (meaning soap), owing to its appearance and cleaning ability. Vermiculite is from the Latin *vermiculari* ("to breed worms"), because of its physical characteristic of exfoliation upon heating, which causes the mineral to exhibit a spectacular volume change from small grains to long wormlike threads. Baileychlore, brindleyite, corrensite, sudoite, and tosudite are examples of clay minerals that were named after distinguished clay mineralogists—Sturges W. Bailey, George W. Brindley, Carl W. Correns, and Toshio Sudō, respectively. (R.E.G./Hi.K.)

STRUCTURE

General features. The structure of clay minerals has been determined largely by X-ray diffraction methods. The essential features of hydrous-layer silicates were revealed by various scientists including Charles Mauguin, Linus C. Pauling, W.W. Jackson, J. West, and John W. Gruner

through the late 1920s to mid-1930s. These features are continuous two-dimensional tetrahedral sheets of composition Si_2O_5, with SiO_4 tetrahedrons (Figure 68) linked by the sharing of three corners of each tetrahedron to form a hexagonal mesh pattern (Figure 69A). Frequently, silicon atoms of the tetrahedrons are partially substituted for by aluminum and, to a lesser extent, ferric iron. The apical oxygen at the fourth corner of the tetrahedrons, which is usually directed normal to the sheet, forms part of an adjacent octahedral sheet in which octahedrons are linked by sharing edges (Figure 70). The junction plane between tetrahedral and octahedral sheets consists of the shared apical oxygen atoms of the tetrahedrons and unshared hydroxyls that lie at the centre of each hexagonal ring of tetrahedrons and at the same level as the shared apical oxygen atoms (Figure 71). Common cations that coordinate the octahedral sheets are Al, Mg, Fe^{3+}, and Fe^{2+}; but occasionally Li, V, Cr, Mn, Ni, Cu, and Zn substitute in considerable amounts. If divalent cations (M^{2+}) are in the octahedral sheets, the composition is $M^{2+}(OH)_2O_4$ and all the octahedrons are occupied. If there are trivalent cations (M^{3+}), the composition is $M^{3+}_2(OH)_2O_4$ and two-thirds of the octahedrons are occupied, with the absence of the third octahedron (Figure 72). The former type of octahedral sheet is called trioctahedral, and the latter dioctahedral. If all the anion groups are hydroxyl ions in the compositions of octahedral sheets, the resulting sheets may be expressed by $M^{2+}(OH)_2$ and $M^{3+}(OH)_3$, respectively. Such sheets, called hydroxide sheets, occur singly, alternating with silicate layers in some clay minerals. Brucite, $Mg(OH)_2$, and gibbsite, $Al(OH)_3$, are typical examples of minerals having similar structures. There are two major types for the structural "backbones" of clay minerals called silicate layers. The unit silicate layer formed by aligning one octahedral sheet to one tetrahedral sheet is referred to as a 1:1 silicate layer, and the exposed surface of the octahedral sheet consists of hydroxyls. In another type, the unit silicate layer consists of one octahedral sheet sandwiched by two tetrahedral sheets that are oriented in opposite directions and is termed a 2:1 silicate layer (Figure 73). These structural features, however, are limited to idealized geometric arrangements.

Trioctahedral and dioctahedral sheets

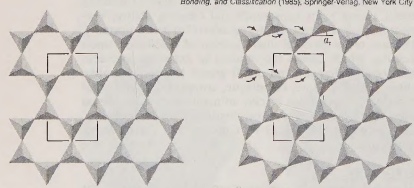

Figure 69: (A) Ideal hexagonal tetrahedral sheet. (B) Contracted sheet of ditrigonal symmetry owing to the reduction of mesh size of the tetrahedral sheet by rotation of the tetrahedrons.

Real structures of clay minerals contain substantial crystal strains and distortions, which produce irregularities such as deformed octahedrons and tetrahedrons rather than polyhedrons with equilateral triangle faces, ditrigonal symmetry modified from the ideal hexagonal surface symmetry, and puckered surfaces instead of the flat planes made up by the basal oxygen atoms of the tetrahedral sheet. One of the major causes of such distortions is dimensional "misfits" between the tetrahedral and octahedral sheets. If the tetrahedral sheet contains only silicon in the cationic site and has an ideal hexagonal symmetry, the longer unit dimension within the basal plane is 9.15 Å, which lies between the corresponding dimensions 8.6 Å of gibbsite and 9.4 Å of brucite. To fit the tetrahedral sheet into the dimension of the octahedral sheet, alternate SiO_4 tetrahedrons rotate (up to a theoretical maximum of 30°) in opposite directions to distort the ideal hexagonal array into a doubly triangular (ditrigonal) array (Figure 69B). By this distortion mechanism, tetrahedral and octahedral sheets of a wide range of compositions resulting from ionic substitutions can link together and maintain silicate layers. Among ionic substitutions, those between ions of distinctly different sizes most significantly affect geometric configurations of silicate layers.

Distortion of structural units

Another significant feature of layer silicates, owing to their similarity in sheet structures and hexagonal or near-hexagonal symmetry, is that the structures allow various ways to stack up atomic planes, sheets, and layers, which may be explained by crystallographic operations such as translation or shifting and rotation, thereby distinguishing them from polymorphs (*e.g.*, diamond-graphite and calcite-aragonite). The former involves one-dimensional variations, but the latter generally three-dimensional ones. The variety of structures resulting from different stacking sequences of a fixed chemical composition are termed polytypes. If such a variety is caused by ionic substitutions that are minor but consistent, they are called polytypoids.

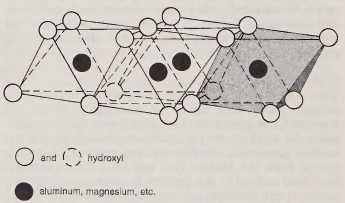

Figure 70: Single octahedron (shaded) and the sheet structure of octahedral units.

Kaolin-serpentine group. Minerals of this groups are 1:1 layer silicates. Their basic unit of structure consists of tetrahedral and octahedral sheets in which the anions at the exposed surface of the octahedral sheet are hydroxyls (see Figure 71). The general structural formula may be expressed by $Y_{2-3}Z_2O_5(OH)_4$, where Y are cations in the octahedral sheet such as Al^{3+} and Fe^{3+} for dioctahedral species and Mg^{2+}, Fe^{2+}, Mn^{2+}, and Ni^{2+} for trioctahedral species, and Z are cations in the tetrahedral sheet, largely Si and, to a lesser extent, Al and Fe^{3+}. A typical dioctahedral species of this group is kaolinite, with an ideal structural formula of $Al_2Si_2O_5(OH)_4$. Kaolinite is electrostatically neutral and has triclinic symmetry. Oxygen atoms and hydroxyl ions between the layers are paired with hydrogen bonding (see above *The nature of minerals: Chemical bonding: Hydrogen bonds*). Because of this weak bonding, random displacements between the layers are quite common and result in kaolinite minerals of lower crystallinity than that of the triclinic kaolinite. Dickite and nacrite are polytypic varieties of kaolinite. Both of them consist of a double 1:1 layer and have monoclinic symmetry, but they distinguish themselves by different stacking sequences of the two 1:1 silicate layers.

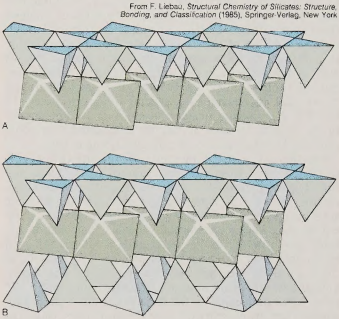
Halloysite also has a composition close to that of kaolinite and is characterized by its tubular nature in contrast to the platy nature of kaolinite particles. Although tubular forms are the most common, other morphological varieties are also known: prismatic, rolled, pseudospherical, and platy forms. The structure of halloysite is believed to be similar to that of kaolinite, but no precise structure has been revealed yet. Halloysite has a hydrated form with a composition of $Al_2Si_2O_5(OH)_4 \cdot 2H_2O$. This hydrated form irreversibly changes to a dehydrated variety at relatively low temperatures (60° C) or upon being exposed to conditions of low relative humidity. The dehydrated form has a basal spacing about the thickness of a kaolinite layer (approximately 7.2 Å), and the hydrated form has a basal spacing of about 10.1 Å. The difference of 2.9 Å is approximately the thickness of a sheet of water one molecule thick. Consequently, the layers of halloysite in the hydrated form are separated by monomolecular water layers that are lost during dehydration.

Hydrated and dehydrated forms of halloysite



In trioctahedral magnesium species, chrysotile, antigorite, and lizardite are commonly known; the formula of these three clay minerals is $Mg_3Si_2O_5(OH)_4$. Chrysotile crystals have a cylindrical roll morphology, while antigorite crystals exhibit an alternating wave structure. These morphological characteristics may be attributed to the degree of fit between the lateral dimensions of the tetrahedral and octahedral sheets. On the other hand, lizardite crystals are platy and often have a small amount of substitution of aluminum or ferric iron for both silicon and magnesium. This substitution appears to be the main reason for the platy nature of lizardite. Planar polytypes of the trioctahedral species are far more complicated than those of dioctahedral ones, owing to the fact that the trioctahedral silicate layer has a higher symmetry because all octahedral cationic sites are occupied. In addition, recent detailed structural investigations have shown that there are considerable numbers of hydrous-layer silicates whose structures are periodically perturbed by inversion or revision of SiO_4 tetrahedrons. Modulated structures therefore produce two characteristic linkage configurations: strips and islands. Antigorite is an example of the strip configuration in the modulated 1:1 layer silicates. Greenalite, a species rich in ferrous iron, also has a modulated layer structure containing an island configuration.

Pyrophyllite-talc group. Minerals of this group have the simplest form of the 2:1 layer with a unit thickness of approximately 9.2 to 9.6 Å—*i.e.*, the structure consists of an octahedral sheet sandwiched by two tetrahedral sheets (Figure 73B). Pyrophyllite and talc represent the dioctahedral and trioctahedral members, respectively, of the group. In the ideal case, the structural formula is expressed by $Al_2Si_4O_{10}(OH)_2$ for pyrophyllite and by $Mg_3Si_4O_{10}(OH)_2$ for talc. Therefore, the 2:1 layers of these minerals are electrostatically neutral and are held together with van der Waals bonding (see above *The nature of minerals: Chemical bonding: Van der Waals bonding*). One-layer triclinic and two-layer monoclinic forms are known for polytypes of pyrophyllite and talc. The ferric iron analogue of pyrophyllite is called ferripyrophyllite.

Figure 73: Schematic presentation of (A) 1:1 layer structures and (B) 2:1 layer structures.

Mica mineral group. Mica minerals have a basic structural unit of the 2:1 layer type like pyrophyllite and talc, but some of the silicon atoms (ideally one-fourth) are always replaced by those of aluminum. This results in a charge deficiency that is balanced by potassium ions between the unit layers. The sheet thickness (basal spacing or dimension along the direction normal to the basal plane) is fixed at about 10 Å. Typical examples are muscovite, $KAl_2(Si_3Al)O_{10}(OH)_2$, for dioctahedral species, and phlogopite, $KMg_3(Si_3Al)O_{10}(OH)_2$, and biotite, $K(Mg, Fe)_3(Si_3Al)O_{10}(OH)_2$, for trioctahedral species. (Formulas rendered may vary slightly due to possible substitution within certain structural sites.) Various polytypes of the micas are known to occur. Among them, one-layer monoclinic (1M), two-layer monoclinic (2M, including $2M_1$ and $2M_2$), and three-layer trigonal (3T) polytypes are most common. The majority of clay-size micas are dioctahedral aluminous species; those similar to muscovite are called illite and generally occur in sediments. The illites are different from muscovite in that the amount of substitution of aluminum for silicon is less; sometimes only one-sixth of the silicon ions are replaced. This reduces a net unbalanced-charge deficiency from 1 to about 0.65 per unit chemical formula. As a result, the illites have a lower potassium content than the muscovites. To some extent, octahedral aluminum ions are replaced by magnesium (Mg^{2+}) and iron ions (Fe^{2+}, Fe^{3+}). In the illites, stacking disorders of the layers are common, but their polytypes are often unidentifiable.

Substitution of aluminum

Celadonite and glauconite are ferric iron-rich species of dioctahedral micas. The ideal composition of celadonite may be expressed by $K(Mg, Fe^{3+})(Si_{4-x}Al_x)O_{10}(OH)_2$,

where $x = 0$–0.2. Glauconite is a dioctahedral mica species with tetrahedral Al substitution greater than 0.2 and octahedral Fe^{3+} or R^{3+} (total trivalent cations) greater than 1.2. Unlike illite, a layer charge deficiency of celadonite and glauconite arises largely from the unbalanced charge due to ionic substitution in the octahedral sheets.

Vermiculite. The vermiculite unit structure consists of sheets of trioctahedral mica or talc separated by layers of water molecules; these layers occupy a space about two water molecules thick (approximately 4.8 Å). Substitutions of aluminum cations (Al^{3+}) for silicon cations (Si^{4+}) constitute the chief imbalance, but the net charge deficiency may be partially balanced by other substitutions within the mica layer; there is always a residual net charge deficiency commonly in the range from 0.6 to 0.8 per $O_{10}(OH)_2$. This charge deficiency is satisfied with interlayer cations that are closely associated with the water molecules between the mica layers. In the natural mineral, the balancing cation is magnesium (Mg^{2+}). The interlayer cation, however, is readily replaced by other inorganic and organic cations. A number of water molecules are related to the hydration state of cations located at the interlayer sites. Therefore, the basal spacing of vermiculite changes from about 10.5 to 15.7 Å, depending on relative humidity and the kind of interlayer cation. Heating vermiculite to temperatures (depending on its crystal size) as high as 500° C drives the water out from between the mica layers, but the mineral quickly rehydrates at room temperature to maintain its normal basal spacing of approximately 14 to 15 Å if potassium or ammonium ions are not present in the interlayer sites. It has been reported that some dioctahedral analogues of vermiculite occur in soils.

Interlayer cations

Smectite. The structural units of smectite (Figure 74) can be derived from the structures of pyrophyllite and talc. Unlike pyrophyllite and talc, the 2:1 silicate layers of smectite have a slight negative charge owing to ionic substitutions in the octahedral and tetrahedral sheets. The net charge deficiency is normally smaller than that of vermiculite—from 0.2 to 0.6 per $O_{10}(OH)_2$—and is balanced by the interlayer cations as in vermiculite. This weak bond offers excellent cleavage between the layers. The distinguishing feature of the smectite structure is that water and other polar molecules (in the form of certain organic substances) can, by entering between the unit layers, cause the structure to expand in the direction normal to the basal plane. Thus this dimension may vary from about 9.6 Å,

when there are no polar molecules between the unit layers, to nearly complete separation of the individual layers.

The structural formula of smectites of the dioctahedral aluminous species may be represented by $(Al_{2-y}Mg_y^{2+})(Si_{4-x}Al_x)O_{10}(OH)_2M_{x+y}^{+} \cdot nH_2O$, where M^+ is the interlayer exchangeable cation expressed as a monovalent cation and where x and y are the amounts of tetrahedral and octahedral substitutions, respectively ($0.2 \leq x + y \leq 0.6$). The smectites with $y > x$ are called montmorillonite and those with $x > y$ are known as beidellite. In the latter type of smectites, those in which ferric iron is a dominant cation in the octahedral sheet instead of aluminum and magnesium, are called nontronite. Although less frequent, chromium (Cr^{3+}) and vanadium (V^{3+}) also are found as dominant cations in the octahedral sheets of the beidellite structure, and chromium species are called volkonskoite. The ideal structural formula of trioctahedral ferromagnesian smectites, the series saponite through iron saponite, is given by $(Mg, Fe^{2+})_3(Si_{4-x}Al_x)O_{10}(OH)_2M_x^{+} \cdot nH_2O$. The tetrahedral substitution is responsible for the net charge deficiency in the smectite minerals of this series. Besides magnesium and ferrous iron, zinc, cobalt, and manganese are known to be dominant cations in the octahedral sheet. Zinc-dominant species are called sauconite. There are other types of trioctahedral smectites in which the net charge deficiency arises largely from the imbalanced charge due to ionic substitution or a small number of cation vacancies in the octahedral sheets or both conditions. Ideally x is zero, but most often it is less than 0.15. Thus, the octahedral composition varies to maintain similar amounts of the net charge deficiency as those of other smectites. Typical examples are $(Mg_{3-y}\square_y)$ and $(Mg_{3-y}\,Li_y)$ for stevensite and hectorite, respectively. [The $\square$ denotes a vacant site in the structure. $(Mg_{3-y}\square_y)$ indicates, therefore, that y sites out of three are vacant.]

Tetrahedral and octahedral substitutions

Chlorite. The structure of the chlorite minerals consists of alternate micalike layers and brucitelike hydroxide sheets about 14 Å thick (Figure 75). Structural formulas of most trioctahedral chlorites may be expressed by four end-member compositions:

$(Mg_5Al)(Si_3Al)O_{10}(OH)_8$	(clinochlore)
$(Fe_5^{2+}Al)(Si_3Al)O_{10}(OH)_8$	(chamosite)
$(Mn_5Al)(Si_3Al)O_{10}(OH)_8$	(pennantite)
$(Ni_5Al)(Si_3Al)O_{10}(OH)_8$	(nimite)

The unbalanced charge of the micalike layer is compen-

sated by an excess charge of the hydroxide sheet that is caused by the substitution of trivalent cations (Al^{3+}, Fe^{3+}, etc.) for divalent cations (Mg^{2+}, Fe^{2+}, etc.). Chlorites with a muscovite-like silicate layer and an aluminum hydroxide sheet are called donbassite and have the ideal formula of $Al_{4.33}(Si_2Al)O_{10}(OH)_8$ as an end-member for the dioctahedral chlorite. In many cases, the octahedral aluminum ions are partially replaced by magnesium, as in magnesium-rich aluminum dioctahedral chlorites called sudoite. Cookeite is another type of dioctahedral chlorite, in which lithium substitutes for aluminum in the octahedral sheets.

Thermal stability of chlorite

Chlorite structures are relatively thermally stable compared to kaolinite, vermiculite, and smectite minerals and are thus resistant to high temperatures. Because of this, after heat treatment at 500°–700° C, the presence of a characteristic X-ray diffraction peak at 14 Å is widely used to identify chlorite minerals.

Interstratified clay minerals. Many clay materials are mixtures of more than one clay mineral. One such mixture involves the interstratification of the layer clay minerals where the individual component layers of two or more kinds are stacked in various ways to make up a new structure different from those of its constituents. These interstratified structures result from the strong similarity that exists between the layers of the different clay minerals (Figure 76), all of which are composed of tetrahedral and octahedral sheets of hexagonal arrays of atoms, and from the distinct difference in the heights (thicknesses) of clay mineral layers.

From T. Sudo *et al., Electron Micrographs of Clay Materials; Developments in Sedimentology* 31 (1981), Elsevier Scientific Publishing Co., New York

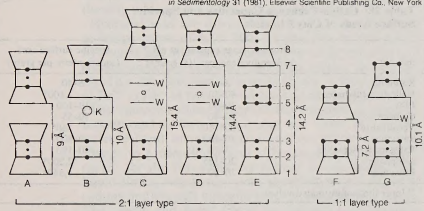

Figure 76: Diagrammatic representation of the layer structures, comparing the relative thickness of the unit structures. (A) Pyrophyllite-talc. (B) Mica. (C) Smectite. (D) Vermiculite. (E) Chlorite. (F) Kaolinite-serpentine. (G) 10 Å halloysite.

The most striking examples of interstratified structures are those having a regular *ABAB* . . . -type structure, where *A* and *B* represent two component layers. There are several minerals that are known to have structures of this type—*i.e.,* rectorite (dioctahedral mica/montmorillonite), tosudite (dioctahedral chlorite/smectite), corrensite (trioctahedral vermiculite/chlorite), hydrobiotite (trioctahedral mica/vermiculite), aliettite (talc/saponite), and kulkeite (talc/chlorite). Other than the *ABAB* . . . type with equal numbers of the two component layers in a structure, many modes of layer-stacking sequences ranging from nearly regular to completely random are possible. The following interstratifications of two components are found in these modes in addition to those given above: illite/smectite, glauconite/smectite, dioctahedral mica/chlorite, dioctahedral mica/vermiculite, and kaolinite/smectite.

Layer-stacking sequences

As the mixing ratio (proportion of the numbers of layers) for the two component layers varies, the number of possible layer-stacking modes increases greatly. For interstratified structures of three component layers, structures consisting of illite/chlorite/smectite and illite/vermiculite/smectite have been reported. Because certain interstratified structures are known to be stable under relatively limited conditions, their occurrence may be used as a geothermometer or other geoindicator.

Sepiolite and palygorskite. Sepiolite and palygorskite are papyrus-like or fibrous (Figure 77) hydrated magnesium silicate minerals and are included in the phyllosilicate group because they contain a continuous two-dimensional tetrahedral sheet of composition Si_2O_5. They differ, however, from the other layer silicates because they lack continuous octahedral sheets. The structures of sepiolite and palygorskite are alike and can be regarded as consisting of narrow strips or ribbons of 2:1 layers that are linked stepwise at the corners (Figure 78). One ribbon is linked to the next by inversion of the direction of the apical oxygen atoms of SiO_4 tetrahedrons; in other words, an elongated rectangular box consisting of continuous 2:1 layers is attached to the nearest boxes at their elongated corner edges. Therefore, channels or tunnels due to the absence of the silicate layers occur on the elongated sides of the boxes. The elongation of the structural element is related to the fibrous morphology of the minerals and is parallel to the *a* axis. Since the octahedral sheet is discontinuous, some octahedral magnesium ions are exposed at the edges and hold bound water molecules (OH_2). In addition to the bound water, variable amounts of zeolitic (*i.e.,* free) water (H_2O) are contained in the rectangular channels. The major difference between the structures of sepiolite and palygorskite is the width of the ribbons, which is greater in sepiolite than in palygorskite. The width determines the number of octahedral cation positions per formula unit. Thus, sepiolite and palygorskite have the ideal compositions $Mg_8Si_{12}O_{30}(OH)_4(OH_2)_4(H_2O)_8$ and $(Mg, Al, \square)_5Si_8O_{20}(OH)_2(OH_2)_4(H_2O)_4$, respectively.

Imogolite and allophane. Imogolite is an aluminosilicate with an approximate composition of $SiO_2 \cdot Al_2O_3 \cdot 2.5H_2O$. This mineral was discovered in 1962 in a soil derived from glassy volcanic ash known as "imogo." Electron-optical observations indicate that imogolite has a unique mor-

phological feature of smooth and curved threadlike tubes varying in diameter from 10 to 30 nanometres (3.9×10^{-7} to 1.2×10^{-6} inches) and extending several micrometres in length (Figure 79). The structure of imogolite that most closely fits the observed data is given in Figure 80. The structure is cylindrical and consists of a modified gibbsite sheet in which the hydroxyls of one side of a gibbsite octahedral sheet lose protons and bond to silicon atoms that are located at vacant octahedral cation sites of gibbsite. Thus, three oxygen atoms and one hydroxyl as the fourth anion around one silicon atom make up an isolated SiO_4 tetrahedron as in orthosilicates, and such tetrahedrons make a planar array on the side of a gibbsite sheet. Because silicon-oxygen bonds are shorter than aluminum-oxygen bonds, this effect causes that sheet to curve. As a result, the curved sheet ideally forms a tubelike structure with inner and outer diameters of about 6.4 Å and 21.4 Å, respectively, and with all hydroxyls exposed at the surface. The number of modified gibbsite units therefore determines the diameter of the threadlike tubes.

Allophane can be regarded as a group of naturally occurring hydrous aluminosilicate minerals that are not totally amorphous but are short-range (partially) ordered. Allophane structures are characterized by the dominance of Si-O-Al bonds—*i.e.,* the majority of aluminum atoms are tetrahedrally coordinated. Unlike imogolite, the morphology of allophane varies from fine, rounded particles through ring-shaped particles to irregular aggregates. There is a good indication that the ring-shaped particles may be hollow spherules or polyhedrons. Sizes of the small individual allophane particles are on the order of 30–50 Å in diameter. In spite of their indefinable structure, their chemical compositions surprisingly fall in a relatively narrow range, as the SiO_2:Al_2O_3 ratios are mostly between 1.0 and 2.0. In general, the SiO_2:Al_2O_3 ratio of allophane is higher than that of imogolite. (Hi.K.)

CHEMICAL AND PHYSICAL PROPERTIES

Ion exchange. Depending on deficiency in the positive or negative charge balance (locally or overall) of mineral structures, clay minerals are able to adsorb certain cations and anions and retain them around the outside of the structural unit in an exchangeable state, generally without affecting the basic silicate structure. These adsorbed ions are easily exchanged by other ions. The exchange reaction differs from simple sorption because it has a quantitative relationship between reacting ions. The range of the cation-exchange capacities of the clay minerals is given in Table 28.

Exchange capacities vary with particle size, perfection of crystallinity, and nature of the adsorbed ion; hence, a range of values exists for a given mineral rather than a single specific capacity. With certain clay minerals—such as imogolite, allophane, and to some extent kaolinite—that have hydroxyls at the surfaces of their structures, exchange capacities also vary with the pH (index of acidity or alkalinity) of the medium, which greatly affects dissociation of the hydroxyls.

Under a given set of conditions, the various cations are not equally replaceable and do not have the same replacing power. Calcium, for example, will replace sodium more easily than sodium will replace calcium. Sizes of potassium and ammonium ions are similar, and the ions are fitted in the hexagonal cavities of the silicate layer. Vermiculite and vermiculitic minerals preferably and irreversibly adsorb these cations and fix them between the layers. Heavy metal ions such as copper, zinc, and lead are strongly attracted to the negatively charged sites on the surfaces of the 1:1 layer minerals, allophane and imogolite,

which are caused by the dissociation of surface hydroxyls of these minerals.

The ion-exchange properties of the clay minerals are extremely important because they determine the physical characteristics and economic use of the minerals.

Clay-water relations. Clay materials contain water in several forms. The water may be held in pores and may be removed by drying under ambient conditions. Water also may be adsorbed on the surface of clay mineral structures and in smectites, vermiculites, hydrated halloysite, sepiolite, and palygorskite; this water may occur in interlayer positions or within structural channels. Finally, the clay mineral structures contain hydroxyls that are lost as water at elevated temperatures.

Zeolitic and bound water adsorption

The water adsorbed between layers or in structural channels may further be divided into zeolitic and bound waters. The latter is bound to exchangeable cations or directly to the clay mineral surfaces. Both forms of water may be removed by heating to temperatures on the order of 100°–200° C and in most cases, except for hydrated halloysite, are regained readily at ordinary temperatures. It is generally agreed that the bound water has a structure other than that of liquid water; its structure is most likely that of ice. As the thickness of the adsorbed water increases outward from the surface and extends beyond the bound water, the nature of the water changes either abruptly or gradually to that of liquid water. Ions and molecules adsorbed on the clay mineral surface exert a major influence on the thickness of the adsorbed water layers and on the nature of this water. The nonliquid water may extend out from the clay mineral surfaces as much as 60–100 A.

Hydroxyl ions are driven off by heating clay minerals to temperatures of 400°–700° C. The rate of loss of the hydroxyls and the energy required for their removal are specific properties characteristic of the various clay minerals. This dehydroxylation process results in the oxidation of Fe^{2+} to Fe^{3+} in ferrous-iron-bearing clay minerals.

The water-retention capacity of clay minerals is generally proportional to their surface area (see Table 28). As the water content increases, clays become plastic and then change to a near-liquid state. The amounts of water required for the two states are defined by the plastic and liquid limits, which vary with the kind of exchangeable cations and the salt concentration in the adsorbed water. The plastic and liquid limits for different clay minerals are given in Table 29. The plasticity index (PI), the difference between the two limits, gives a measure for the rheological (flowage) properties of clays. A good example is a comparison of the PI of montmorillonite with that of allophane or palygorskite. The former is considerably greater than either of the latter, indicating that montmorillonite has a prominent plastic nature. Such rheological properties of clay minerals have great impact on building foundations, highway construction, chemical engineering, and soil structure in agricultural practices.

Interactions with inorganic and organic compounds. Smectite, vermiculite, and other expansible clay minerals can accommodate relatively large, inorganic cations between the layers. Because of this multivalency, the interlayer space is only partially occupied by such inorganic cations that are distributed in the space like islands. Hydroxy polymers of aluminum, iron, chromium, zinc, and titanium are known examples of the interlayering materials. Most of these are thermally stable and hold as pillars to allow a porous structure in the interlayer space. The resulting complexes, often called pillared clays, exhibit attractive properties as catalysts—namely, large surface area, high porosity, regulated pore size, and high solid acidity.

Pillared clays

Cationic organic molecules, such as certain aliphatic and aromatic amines, pyridines, and methylene blue, may replace inorganic exchangeable cations present in the interlayer of expansible minerals. Polar organic molecules may replace adsorbed water on external surfaces and in interlayer positions. Ethylene glycol and glycerol are known to form stable specific complexes with smectites and vermiculites. The formation of such complexes is frequently utilized for identifying these minerals. As organic molecules coat the surface of a clay mineral, the surface of its constituent particles changes from hydrophilic to hydrophobic, thereby losing its tendency to bind water. Consequently, the affinity of the material for oil increases, so that it can react with additional organic molecules. As a result, the surface of such clay materials can accumulate organic materials. Some of the clay minerals can serve as catalysts for reactions in which one organic substance is transformed to another on the mineral's surface. Some of these organic reactions develop particular colours that may be of diagnostic value in identifying specific clay minerals. Organically clad clay minerals are used extensively in paints, inks, and plastics.

Physical properties. Clay mineral particles are commonly too small for measuring precise optical properties. Reported refractive indices of clay minerals generally fall within a relatively narrow range from 1.47 to 1.68. In general, iron-rich mineral species show high refractive indices, whereas the water-rich porous species have lower ones. Specific gravities of most clay minerals are within the range from 2 to 3.3. Their hardness generally falls below $2\frac{1}{2}$, except for antigorite, whose hardness is reported to be $2\frac{1}{2}$–$3\frac{1}{2}$.

Specific gravities

Size and shape. These two properties of clay minerals have been determined by electron micrographs. Well-crystallized kaolinite occurs as well-formed, six-sided flakes, frequently with a prominent elongation in one direction. Halloysite commonly occurs as tubular units with an outside diameter ranging from 0.04 to 0.15 micrometre.

Electron micrographs of smectite often show broad undulating mosaic sheets. In some cases the flake-shaped units are discernible, but frequently they are too small or too thin to be seen individually without special attention.

Illite occurs in poorly defined flakes commonly grouped together in irregular aggregates. Although their sizes vary more widely, vermiculite, chlorite, pyrophyllite, talc, and serpentine minerals except for chrysotile are similar in character to the illites. Chrysotile occurs in slender tube-shaped fibres having an outer diameter of 100–300 Å. Their lengths commonly reach several micrometres. Electron micrographs show that palygorskite occurs as elongated laths, singly or in bundles. Frequently the individual laths are many micrometres in length and 50 to 100 Å in width. Sepiolite occurs in similar lath-shaped units (see Figure 77). As mentioned above, allophane occurs in very small spherical particles (30–50 Å in diameter), individually or in aggregated forms, whereas imogolite occurs in long (several micrometres in length) threadlike tubes (see Figure 79).

High-temperature reactions. When heated at temperatures beyond dehydroxylation, the clay mineral structure may be destroyed or simply modified, depending on the composition and structure of the substance. In the presence of fluxes, such as iron or potassium, fusion may rapidly follow dehydroxylation. In the absence of such components, particularly for aluminous dioctahedral minerals, a succession of new phases may be formed at increasing temperatures prior to fusion. Information concerning high-temperature reactions is important for ceramic science and industry.

Solubility. The solubility of the clay minerals in acids varies with the nature of the acid and its concentration, the acid-to-clay ratio, the temperature, the duration of treatment, and the chemical composition of the clay min-

eral attacked. In general, ferromagnesian clay minerals are more soluble in acids than their aluminian counterparts. Incongruent dissolutions may result from reactions in a low-acid-concentration medium where the acid first attacks the adsorbed or interlayer cations and then the components of the octahedral sheet of the clay mineral structure. When an acid of higher concentration is used, such stepwise reactions may not be recognizable, and the dissolution appears to be congruent. One of the important factors controlling the rate of dissolution is the concentration in the aquatic medium of the elements extracted from the clay mineral. Higher concentration of an element in the solution hinders to a greater degree the extractions of the element.

In alkaline solutions, a cation-exchange reaction first takes place, and then the silica part of the structure is attacked. The reaction depends on the same variables as those stated for acid reactions.

OCCURRENCE

Soils. All types of clay minerals have been reported in soils. Allophane, imogolite, hydrated halloysite, and halloysite are dominant components in ando soils, which are the soils developed on volcanic ash. Smectite is usually the sole dominant component in vertisols, which are clayey soils. Smectite and illite, with occasional small amounts of kaolinite, occur in mollisols, which are prairie chernozem soils. Illite, vermiculite, smectite, chlorite, and interstratified clay minerals are found in podzolic soils. Sepiolite and palygorskite have been reported in some aridisols (desert soils), and kaolinite is the dominant component in oxisols (lateritic soils). Clay minerals other than those mentioned above usually occur in various soils as minor components inherited from the parent materials of those soils.

Agricultural use

Soils composed of illite and chlorite are better suited for agricultural use than kaolinitic soils because of their relatively high ion-exchange properties and hence their capacity to hold plant nutrients. Moderate amounts of smectite, allophane, and imogolite in soils are advantageous for the same reason, but when present in large amounts these clay minerals are detrimental because they are impervious and have too great a water-holding capacity.

Recent sediments. Sediment accumulating under nonmarine conditions may have any clay mineral composition. In the Mississippi River system, for example, smectite, illite, and kaolinite are the major components in the upper Mississippi and Arkansas rivers, whereas chlorite, kaolinite, and illite are the major components in the Ohio and Tennessee rivers. Hence, in the sediments at the Gulf of Mexico, as a weighted average, smectite, illite, and kaolinite are found to be the major components in the clay mineral composition. Although kaolinite, illite, chlorite, and smectite are the principal clay mineral components of deep-sea sediments, their compositions vary from place to place. In general, illite is the dominant clay mineral in the North Atlantic Ocean (greater than 50 percent), while smectite is the major component in the South Pacific and Indian oceans. In some limited regions, these compositions are significantly altered by other factors such as airborne effects, in which sediments are transported by winds and deposited when the carrying force subsides. The high kaolinite concentration off the west coast of Africa near the Equator reflects this effect.

Under highly saline conditions in desert areas, as in soils, palygorskite and sepiolite also form in lakes and estuaries (perimarine environments).

Ancient sediments. Analyses of numerous ancient sediments in many parts of the world indicate that smectite is much less abundant in sediments formed prior to the Mesozoic Era (from 245 to 66.4 million years ago) with the exception of those of the Permian Period (from 286 to 245 million years ago) and the Carboniferous Period (360 to 286 million years ago), in which it is relatively abundant.

The available data also suggest that kaolinite is less abundant in very ancient sediments than in those deposited after the Devonian Period (408 to 360 million years ago). Stated another way, the very old argillaceous (clay-rich) sediments called physilites are composed largely of illite and chlorite. Palygorskite and sepiolite have not been reported in sediments older than Tertiary age—*i.e.*, those more than about 66 million years old.

Kaolinite and illite have been reported in various coals. Bentonite generally is defined as a clay composed largely of smectite that occurs in sediments of pyroclastic materials as the result of devitrification of volcanic ash in situ.

Sediments affected by diagenesis. As temperature and pressure increase with the progression of diagenesis, clay minerals in sediments under these circumstances change to those stable under given conditions. Therefore, certain sensitive clay minerals may serve as indicators for various stages of diagenesis. Typical examples are the crystallinity of illite, the polytypes of illite and chlorite, and the conversion of smectite to illite. Data indicate that smectite was transformed into illite through interstratified illite-smectite mineral phases as diagenetic processes advanced. Much detailed work has been devoted to the study of the conversion of smectite to illite in lower Cenozoic-Mesozoic sediments because such conversion appears to be closely related to oil-producing processes.

Hydrothermal deposits. All the clay minerals, except palygorskite and sepiolite, have been found as alteration products associated with hot springs and geysers and as aureoles around metalliferous deposits. In many cases, there is a zonal arrangement of the clay minerals around the source of the alteration, a process which involves changes in the composition of rocks caused by hydrothermal solutions. The zonal arrangement varies with the type of parent rock and the nature of the hydrothermal solution. An extended kaolinite zone occurs around the tin-tungsten mine in Cornwall-Devon, Eng. Mica (sericite), chlorite, tosudite, smectite, and mica-smectite interstratifications are contained in an extensive clay zone formed in a close association with kuroko (black ore) deposits. Smectites are known to occur as alteration products of tuff and rhyolite. Pottery stones consisting of kaolinite, illite, and pyrophyllite occur as alteration products of acidic volcanic rocks, shales, and mudstone.

ORIGIN

Synthetic formation. All the clay minerals, with the possible exception of halloysite, have been synthesized from mixtures of oxides or hydroxides and water at moderately low temperatures and pressures. Kaolinite tends to form in alumina-silica systems without alkalies or alkaline earths. Illite is formed when potassium is added to such systems; and either smectite or chlorite results upon the addition of magnesium, depending on its concentration. The clay minerals can be synthesized at ordinary temperatures and pressures if the reactants are mixed together very slowly and in greatly diluted form.

Clay minerals of certain types also have been synthesized by introducing partial structural changes to clay minerals through the use of chemical treatments. Vermiculite can be formed by a prolonged reaction in which the potassium of mica is exchanged with any hydrated alkali or alkaline earth cation. Chloritic minerals can be synthesized by precipitating hydroxide sheets between the layers of vermiculite or montmorillonite. The reverse reactions of these changes are also known. A mechanism of mineral formation involving a change from one mineral to another is called transformation and can be distinguished from neoformation, which implies a mechanism for the formation of minerals from solution.

Transformation and neoformation

Formation in nature. In nature both mineral formation mechanisms, neoformation and transformation, are induced by weathering and hydrothermal and diagenetic actions.

The formation of the clay minerals by weathering processes is determined by the nature of the parent rock, climate, topography, vegetation, and the time period during which these factors operated. Climate, topography, and vegetation influence weathering processes by their control of the character and direction of movement of water through the weathering zone (see also GEOMORPHIC PROCESSES: *Weathering*).

In the development of clay minerals by natural hydrothermal processes, the presence of alkalies and alkaline earths influences the resulting products in the same manner as

shown by synthesis experiments. Near-neutral hydrothermal solutions bring about rock alteration, including the formation of illite, chlorite, and smectite, whereas acid hydrothermal solutions result in the formation of kaolinite.

INDUSTRIAL USES

Ancient use in bricks and soaps

Clays are perhaps the oldest materials from which humans have manufactured various artifacts. The making of fired bricks possibly started some 5,000 years ago and was most likely humankind's second earliest industry after agriculture. The use of clays (probably smectite) as soaps and absorbents was reported in *Natural History* by the Roman author Pliny the Elder (*c.* AD 77).

Clays composed of kaolinite are required for the manufacture of porcelain, whiteware, and refractories. Talc, pyrophyllite, feldspar, and quartz are often used in whiteware bodies, along with kaolinite clay, to develop desirable shrinkage and burning properties. Clays composed of a mixture of clay minerals, in which illite is most abundant, are used in the manufacture of brick, tile, stoneware, and glazed products. In addition to its use in the ceramic industry, kaolinite is utilized as an extender in aqueous-based paints and as a filler in natural and synthetic polymers.

Smectitic clays (bentonite) are employed primarily in the preparation of muds for drilling oil wells. This type of clay, which swells to several times its original volume in water, provides colloidal and wall-building properties. Palygorskite and sepiolite clays also are used because of their resistance to flocculation under high salinity conditions. Certain clay minerals, notably palygorskite, sepiolite, and some smectites, possess substantial ability to remove coloured bodies from oil. These so-called fuller's earths are used in processing many mineral and vegetable oils. Because of their large absorbing capacity, fuller's earths are also used commercially for preparing animal litter trays and oil and grease absorbents. Acid treatment of some smectite clays increases their decolorizing ability. Much gasoline is manufactured by using catalysts prepared from a smectite, kaolinite, or halloysite type of clay mineral.

Tons of kaolinite clays are used as paper fillers and paper coating pigments. Palygorskite-sepiolite minerals and acid-treated smectites are used in the preparation of no-carbon-required paper because of the colour they develop during reactions with certain colourless organic compounds.

Clays have a tremendous number of miscellaneous uses, and for each application a distinct type with particular properties is important. (R.E.G./Hi.K.)

Calcite

GENERAL CONSIDERATIONS

The carbonate minerals calcite, aragonite, and dolomite have been calculated to make up approximately 15 percent of the Earth's sediments and sedimentary rocks and about 2 percent of the terrestrial crust (see above Table 15). A large percentage of the calcite, the most abundant of these carbonate minerals, occurs in limestones, which constitute noteworthy proportions of many sequences of marine sediments. Calcite is also the chief component of marls, travertines, calcite veins, most speleothems (cave deposits), many marbles and carbonatites, and some ore-bearing veins.

Calcite is the stable form of $CaCO_3$ at most temperatures and pressures. The orthorhombic polymorph of $CaCO_3$, aragonite, though frequently deposited in nature, is metastable at room temperature and pressure and readily inverts to calcite; the inversion has been shown experimentally to be spontaneous when aragonite is heated to 400° C in dry air and at lower temperatures when it is in contact with water. Hexagonal vaterite, the other natural polymorph of $CaCO_3$, is extremely rare and has been shown in the laboratory to transform into calcite or aragonite or both penecontemporaneously with its formation—*i.e.,* it appears to be metastable under essentially all known natural conditions.

CHEMICAL COMPOSITION

Some natural calcites are essentially pure $CaCO_3$; others contain noteworthy percentages of other cations (*e.g.,* Mg, Mn, Fe, bromine [Br], Sr, and/or Y), substituting for some of their calcium. In general, however, only minor substitution occurs. Only manganese and magnesium are known to substitute extensively for the calcium: manganocalcite and calcian rhodochrosite (*i.e.,* calcium-bearing $MnCO_3$) have been identified, and solid solution has been shown to be possible from pure $CaCO_3$ to 40 percent $MnCO_3$ and from pure $MnCO_3$ to about 25 percent $CaCO_3$. Metastable magnesian calcites containing from approximately 5 to 18 percent $MgCO_3$ occur rather widely as biogenic skeletal material and as cement in some modern marine sediments. Magnesian calcites at the lower end of this range of $MgCO_3$ contents constitute some marine oöids and calcareous tufas.

Substitution for calcium

Between 60 and 70 elements have been recorded in minor or trace amounts in limestone analyses. Some of these elements may occur as substitutions within calcite; others seem more likely to represent minor constituents, such as clay minerals, within the analyzed rocks.

The chemical composition of calcite is responsible for the test that is widely used to identify it, especially in the field. This test is based on the fact that calcite reacts with dilute hydrochloric acid (HCl), and the reaction is manifested by vigorous effervescence. (The dilution of the HCl usually used is about 90:10 [water:concentrated HCl].) The reactions involved are

$$CaCO_3 + 2HCl \rightarrow CaCl_2 + H_2CO_3$$

and

$$H_2CO_3 \rightarrow H_2O + CO_2.$$

The effervescence is due to the spontaneous breakdown of the carbonic acid (H_2CO_3) to produce carbon dioxide gas, CO_2 (see above *The nature of minerals: Physical properties: Solubility in hydrochloric acid*).

CRYSTAL STRUCTURE

The structure of calcite—one of the first mineral structures to be determined by X-ray methods—has been described on three different bases. The two most frequently used bases, illustrated in Figure 81, are the true rhombohedral unit cell, which is the acute rhombohedron, and the cleavage rhombohedron setup. The true unit cell includes 2 $CaCO_3$ with calcium ions at the corners of the rhombohedrons and CO_3 groups, each of which consists of a carbon ion at the centre of a planar group of oxygen atoms whose centres define an equilateral triangle. The configuration can be considered another way: the structure consists of alternating sheets of hexagonally arranged calcium ions and CO_3 complex anions (see Figure 81). This array is

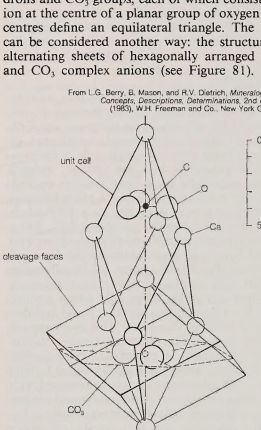

Figure 81: *The crystal structure of calcite.*
This schematic diagram shows both the true unit cell (the acute rhombohedron, which contains 2[$CaCO_3$]) and an alternative cell based on the cleavage rhombohedron.

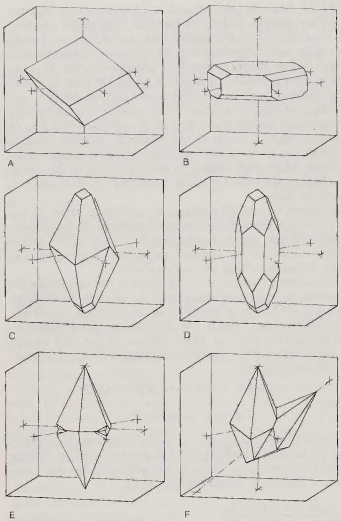

Figure 82: *Calcite crystals.*
Some of the many fairly common crystal habits represented by natural calcite crystals are illustrated here. (A)–(D) are untwinned crystals; (E) and (F) are twinned.

in the hexagonal (trigonal) crystal system. The threefold symmetry is quite obvious in both crystals and cleavage rhombohedrons (Figure 82). The crystals occur most commonly in cavities in rocks—*e.g.*, in vugs (including druses), in vesicles in igneous rocks, and lining partially filled fissures.

PHYSICAL PROPERTIES

Diverse colours of impure calcite

Calcite is colourless or white when pure but may be of almost any colour—reddish, pink, yellow, greenish, bluish, lavender, black, or brown—owing to the presence of diverse impurities. It may be transparent, translucent, or opaque. Its lustre ranges from vitreous to dull; many crystals, especially the colourless ones, are vitreous, whereas granular masses, especially those that are fine-grained, tend to be dull. Calcite is number 3 on the Mohs hardness scale; thus, it can be scratched readily by a knife blade or geologic pick. It has a specific gravity of 2.71. Three perfect cleavages give calcite its six-sided polyhedrons with diamond-shaped faces; the angles defining the faces are 78° and 102° (see Figure 83). Some calcites fluoresce under ultraviolet light; some are also triboluminescent (luminescent when scratched). When light passes through some minerals, it is split into two rays that travel at different speeds and in different directions. This phenomenon is known as birefringence. The difference between the velocities is especially notable in calcite, and consequently crystals of a colourless variety—sometimes called Iceland spar—exhibit double refraction that can be observed with the naked eye. (See also LIGHT: *Polarization and electromagnetic theory: Polarized light: Double refraction.*)

The previously described fact that calcite effervesces vigorously with dilute hydrochloric (muriatic) acid distinguishes calcite from dolomite, which it tends to resemble in both appearance and occurrence. (Dolomite effervesces only when powdered and with only a slow, smoldering action.)

In rocks made up predominantly of calcite, the mineral is typically granular, with grains ranging from those discernible only under a microscope to those that are a few millimetres in greatest dimension. The colour of most of these rocks is gray or tan, but some calcite marbles are white and a few are multicoloured.

ORIGIN AND OCCURRENCE

A large percentage of the calcite in rocks was deposited in sedimentary environments; consequently, calcite is a constituent of several diverse sediments, sedimentary rocks, and their metamorphosed products. A minor amount of the Earth's calcite is of magmatic (*i.e.*, igneous) origin; it is the chief constituent of the rare rock called calcite carbonatite. Calcite also occurs widely in veins: some of the veins are wholly or largely calcite; others contain valuable ore minerals and are usually described as ore veins, even though calcite is the predominant constituent.

Clastic limestones

The sedimentary rocks composed largely of calcite include limestones of chemical and biochemical origin and also limestones usually referred to as clastic because they consist of transported fragments of previously deposited, typically biogenetic materials. Travertine, chalk, and calcarenite, respectively, are examples of these kinds of limestones (Figure 84).

Many limestones have gained their mineralogical makeups and textures during diagenesis. Aragonite, the orthorhombic polymorph of $CaCO_3$, was deposited and subsequently transformed into the calcite of some limestones; magnesian calcites that constitute some organic skeletal parts and cements of marine sediments were the precursors of the calcite of many other limestones. During diagenesis, most of the magnesian calcites were transformed into stable assemblages of rather pure calcite, often along with scattered grains of dolomite.

When sedimentary and diagenetic limestones undergo metamorphism, the calcite is frequently recrystallized and tends to become coarsely crystalline. The resulting rocks are calcite marbles. Some calcite marbles, however, appear to have had dolostone rather than limestone precursors; *i.e.*, the dolostone underwent dedolomitization during metamorphism. The calcite grains in some marbles have cleavage planes that are curved; this is usually interpreted to reflect recrystallization during deformation or plastic flowage associated with dynamic metamorphism.

The calcite of carbonatites is generally thought to have formed from dense H_2O-CO_2 fluids that in many ways are more like the volatile-rich fluids from which pegmatites are believed to have been deposited than the more "normal" magmas from which igneous rocks such as granites and basalt have consolidated. These rocks closely resemble marbles, and some masses of both marble and carbonatite

were originally misidentified, one as the other. In most cases, the identities of the accessory minerals serve as ready criteria for differentiating between an igneous and metamorphic origin.

Calcite is deposited by solutions, either ordinary groundwater solutions or hydrothermal solutions associated with magmatic activities. Such calcite constitutes the cement for many clastic sediments—*e.g.*, some sandstones—and also the calcite or aragonite of speleothems and of both calcite and calcitic ore-bearing veins.

Calcite breaks down in most areas where chemical weathering takes place. It is dissolved and its products are carried in surface-water and groundwater solutions. The excavation of caves is a subsurface manifestation of these processes, just as their subsequent filling-in with speleothems is a manifestation of one of the modes whereby calcite is deposited. As might be suspected, most karst topography, which is characterized by sinkholes and underground drainage, occurs in areas underlain by limestone.

USES

Calcite has many uses. Since ancient times, limestone has been burned to quicklime (CaO), slaked to hydrated lime [$Ca(OH)_2$], and mixed with sand to make mortar. Limestone is one of the ingredients used in the manufacture of portland cement and is often employed as a flux in metallurgical processes, such as the smelting of iron ores. Crushed limestone is utilized widely as riprap, as aggregate for both concrete and asphalt mixes, as agricultural lime, and as an inert ingredient of medicines. Marble is used for statuary and carvings, and as polished slabs it is a popular facing stone. The term marble is used differently in the marketplace than in geology; in the marketplace, it is applied to any coarse-grained carbonate rock that will take a good polish rather than to metamorphic carbonate-rich rocks exclusively. Some coarsely crystalline diagenetic limestones are among the most widely used commercial "marbles." Travertine is also a popular facing stone, usually for interior use. Iceland spar has been employed for optical purposes for nearly two centuries. These uses constitute only a few of the many applications of calcite.

GENERAL CONSIDERATIONS

As mentioned in the section on calcite, dolomite along with calcite and aragonite makes up approximately 2 percent of the Earth's crust (see above Table 15). The bulk of the dolomite constitutes dolostone formations that occur as thick units of great areal extent in many sequences of chiefly marine strata. (The rock dolostone is referred to by only the mineral name—*i.e.*, dolomite—by many geologists.) The Dolomite Alps of northern Italy are a well-known example. Other relatively common occurrences of the mineral dolomite are in dolomite marble and dolomite-rich veins. It also occurs in the rare igneous rock known as dolomite carbonatite.

From the standpoint of its origin, the dolomite of dolostones is one of the most interesting of all the major rock-forming minerals. As discussed below, a large percentage of the dolomite in thick marine dolostone units is thought by many geologists and geochemists to have been formed by replacement of $CaCO_3$ sediment rather than by direct precipitation.

CHEMICAL COMPOSITION

The chemical formula of dolomite is $CaMg(CO_3)_2$. Ferrous iron commonly substitutes for some of the magnesium, and a complete series very likely extends between dolomite and ankerite [$\sim CaFe(CO_3)_2$]. Manganese also substitutes for magnesium, but typically only to the extent of a few percent and in most cases only along with iron. Other cations known to substitute—albeit in only relatively minor amounts—within the dolomite structure are barium and lead for calcium and zinc and cobalt for magnesium.

Nearly all the natural elements have been recorded

as present in at least trace quantities in dolostones. It is, however, unclear which ones actually occur in the dolomite; some of them may occur within other mineral constituents of the analyzed rocks. Indeed, only a few of these elements—*e.g.*, strontium, rubidium, boron, and uranium (U)—are known definitely to occur within the dolomite structure.

Distinction between calcite and dolomite

Dolomite effervesces with dilute hydrochloric acid, but slowly rather than vigorously as calcite does; in general, it appears to smolder slowly, and in some cases it does so only after the rock has been powdered or the acid warmed, or both. This difference in the character of the effervescence serves as the test usually used to distinguish dolomite from calcite in the field. In the laboratory, staining techniques, also based on chemical properties or typical compositions, may be used to distinguish between these minerals. The stains generally employed are especially valuable for investigating rocks made up of alternate lamellae of dolostone and limestone composition.

CRYSTAL STRUCTURE

In a somewhat simplified way, the dolomite structure can be described as resembling the calcite structure but with magnesium ions substituted for calcium ions in every other cation layer. Thus, the dolomite structure can be viewed as ideally comprising a calcium layer, a CO_3 layer, a magnesium layer, another CO_3 layer, and so forth (see Figure 85). However, as described for the potassium feldspars,

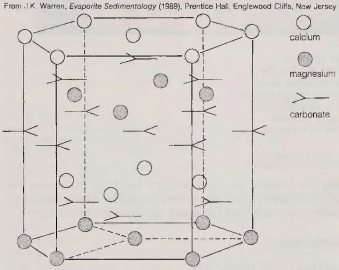

Figure 85: The layered structure of dolomite.

dolomites—unlike calcites—may also exhibit order-disorder relationships. This results because the purity of some of the cation layers may be less than ideal—*i.e.*, some of the "calcium layers" may contain magnesium, and some of the "magnesium layers" may contain some calcium. The term protodolomite is frequently applied to Holocene dolomites (those formed during approximately the last 10,000 years) that have less than ideal dolomite structures. Most dolomites of ancient dolostones, however, appear to be well ordered. Modifications that may reflect diverse calcium-versus-magnesium layering aberrations are treated extensively in professional literature.

PHYSICAL PROPERTIES

Dolomite crystals are colourless, white, buff-coloured, pinkish, or bluish. Granular dolomite in rocks tends to be light to dark gray, tan, or white. Dolomite crystals range from transparent to translucent, but dolomite grains in rocks are typically translucent or nearly opaque. The lustre ranges from subvitreous to dull. Dolomite, like calcite, cleaves into six-sided polyhedrons with diamond-shaped faces. Relations between lamellar twinning and cleavage planes of dolomite, however, differ from those of calcite (see Figure 86), and this difference may be used to distinguish the two minerals in coarse-grained rocks such as marbles. Dolomite has a Mohs hardness of $3\frac{1}{2}$ to 4 and a specific gravity of 2.85 ± 0.01. Some dolomites are triboluminescent.

Sizes of dolomite grains

The dolomite of most dolostones is granular, with the individual grains ranging in size from microscopic up to a few millimetres across. Most dolomite marbles are coarsely granular with individual grains ranging between two and six millimetres (.079 and .24 inch) in greatest dimension. Vein dolomite grains may be up to several centimetres across. Saddle-shaped groups of dolomite crystals, most of which occur on fracture surfaces, measure from 0.5 to 2 centimetres (0.20 to 0.79 inch) across (see Figure 87).

ORIGIN AND OCCURRENCE

Dolomite occurs widely as the major constituent of dolostones and dolomite marbles. As mentioned above, the origin of dolomite-rich rocks in marine sequences remains an unresolved problem of petrogenesis.

Dolomite—actually protodolomite—is known to have formed fairly recently in restricted environments such as on supratidal flats. None, however, is known to have formed recently within more common marine environments that appear to be represented by thick dolostone units deposited in the geologic past. Also, no dolomite has been synthesized in an environment comparable to natural conditions. Thus, the explanation for the formation of dolomite in these marine units remains in question. It is now thought that dolostones may be of various origins. Indeed, several different models have been suggested for dolomite formation, each based on diverse considerations, combined with empirical and/or experimental data.

Except for models invoking formation of dolomite by direct precipitation, a process thought by most geologists to apply to only a small percentage of all dolostones, each model is based on the assumption that the dolomite of dolostones has been formed by conversion of $CaCO_3$ sediment or sedimentary rocks to dolostone. Thus, the models have been formulated to account for this conversion, which is known as dolomitization.

The most widely discussed models for dolomitization, either partial or complete, involve four chief variables: time,

location with respect to the sediment-seawater interface, composition and derivation of the solutions involved, and fluxing mechanisms. The time ranges from dolomitization that occurs penecontemporaneously with deposition to that which takes place subsequent to relatively deep burial of the precursor sediments. The location ranges from at or very near the sediment-seawater interface to well beneath some overlying sediments that were deposited at a later time. The solutions supply the magnesium needed and must have the appropriate pH and concentrations of other necessary ions; these solutions are generally considered to be seawater (either "normal" seawater or brines concentrated by evaporation), connate water, meteoric water, or some combination of these waters. (Connate refers to water that becomes enclosed within sediments upon their deposition; meteoric water is derived from the atmosphere as rain or snow, which often occurs in pore spaces within rocks.) The fluxing mechanisms are generally attributed to density differences of the solutions involved and the permeability characteristics available for percolation through the precursor sediment. There also are additional direct and indirect controls—*e.g.*, climate, biochemical processes, and HDO:H_2O and/or D_2O:H_2O ratios in the water. (The symbol D represents deuterium, the hydrogen isotope with a nucleus containing one neutron in addition to the single proton of the ordinary hydrogen nucleus.) In any case, it has been shown that some dolostones have gained their current characteristics as a consequence of certain combinations of these conditions and processes.

Conditions of dolomitization

Criteria involving factors such as the identity of associated rocks and the coarseness of the grains of dolostones have been suggested for use in attributing one versus the other hypothesized models to certain occurrences of dolostone. None, however, has been accepted as an absolute criterion by many carbonate petrologists.

The desire for an understanding of dolomitization of sedimentary strata has been based on economic as well as scientific interests. In many places, dolomitization has led to increases in permeability and porosity and thus increased the potential of such rock strata as good oil, gas, and groundwater reservoirs and, in some cases, even as hosts of certain kinds of ore deposits.

The other fairly common dolomite occurrences include the following: Dolostones have been metamorphosed to both dolomite and calcite marbles; dedolomitization processes account for the latter. Some dolomite marbles are nearly pure dolomite. Dolomite carbonatites are of the same general origin as calcite carbonatites (see above *Calcite: Origin and occurrence*). The dolomite present in dolomite veins has also been ascribed diverse origins; some appears to have been deposited by percolating connate or meteoric groundwater, and some seems more likely to have been deposited by hydrothermal solutions charged with magmatic volatiles.

USES

Dolomite is used as a source of magnesium metal and of magnesia (MgO), which is a constituent of refractory bricks. Dolostone is often used instead of limestone as an aggregate for both cement and bitumen mixes and also as a flux in blast furnaces. The use of dolostone as a flux has increased, especially since environmental contamination has become a widely heeded consideration, because the resulting slag can be employed for such things as lightweight aggregate, whereas that formed when limestone is used cannot. Such is the case because dolostone-based slag does not slake (disintegrate in water), but limestone-based slag does.

Use as a flux

Other common rock-forming minerals

The 10 minerals listed above in Table 16 that are not described in the preceding sections are important rock-forming minerals even though they do not make up large percentages of any common rocks. Each of these minerals is a major constituent of some sizable rock masses, occurs widely as an accessory mineral in many common rocks, or assumes both roles. Consequently, they warrant brief description here.

MAGNETITE AND CHROMITE

Magnetite (Fe_3O_4—that is, $Fe^{2+}Fe^{3+}_2O_4$) and chromite ($Fe^{2+}Cr_2O_4$) are both members of the spinel group. The spinels, comprising some 21 species (including the well-known gemstone balas ruby), are cubic (isometric) and commonly occur as octahedrons (Figure 88). Magnetite and chromite are opaque and dark gray to iron-black; magnetite is strongly magnetic. Magnetite and chromite are the major constituents of the rocks called magnetitite and chromitite, respectively. In addition, each is a common accessory mineral in one or more igneous rocks. Magnetite also occurs widely in several metamorphic and sedimentary rocks; one or both of these minerals occur in several placer deposits. Magnetite has been recovered as iron ore; chromite is the only important commercial mineral of chromium.

HALITE, GYPSUM, AND ANHYDRITE

Halite (NaCl), gypsum ($CaSO_4 \cdot 2H_2O$), and anhydrite ($CaSO_4$) are the major constituents of the sedimentary rocks rock salt, rock gypsum, and rock anhydrite, respectively. These rocks are usually referred to as evaporites. Halite, the mineral name for common salt, is cubic and is typically colourless or white but may be tinted various colours by impurities. It breaks into cubes because of its three perfect cleavages at right angles to each other and has a characteristic salty taste. Gypsum is monoclinic and commonly occurs as tabular crystals, either simple or twinned, and also forms coarse to fine granular masses. It is typically colourless or white but may be red, orange, brown, or black because of the presence of impurities, and it cleaves into plates that may be bent but are not flexible. Gypsum is so soft (Mohs hardness of 2) that it can be scratched easily with one's fingernail. Anhydrite is orthorhombic and resembles granular dolomite in many rocks, but it does not react with dilute hydrochloric acid. When altered, anhydrite usually takes on a thin coating of white gypsum. Halite has been recovered from rock salt deposits for diverse uses for at least seven millennia. The

major use of gypsum is for the manufacture of plaster of paris.

EPIDOTE

Epidote is the name given to both a group of minerals and a mineral species. Epidote, the species $[Ca_2(Al, Fe)_3(SiO_4)_3(OH)]$, crystallizes in the monoclinic system. Its presence in rocks is generally recognized on the basis of its yellowish to bilious-green colour (Figure 89). Macroscopically, it is usually distinguished from olivine, which it may closely resemble, on the basis of its association with quartz. Epidote commonly occurs in quartz-bearing metamorphic and igneous rocks, whereas olivine occurs only rarely in rocks that contain quartz. Epidote may be cut as a gem.

HEMATITE

Hematite (α-Fe_2O_3) is hexagonal. Although it is present as silvery-gray, highly lustrous platelike masses in some rocks, it is most widely encountered as the henna-red pigment of many diverse rocks—*e.g.*, red sandstones and many other red beds. Some sedimentary rocks and their metamorphosed products contain such high percentages of hematite that they have been recovered as iron ore. Hematite may also be used as a polishing powder and as a paint pigment.

LIMONITE

Limonite is the catchall name widely applied to hydrous iron oxide minerals. Goethite [α-$Fe^{+}O(OH)$], which is hexagonal, is the most common of these minerals; indeed, in nature most FeO(OH) minerals ultimately become this α-phase. Goethite, much of which has the general colour of iron rust, occurs wherever chemical weathering affects rocks that contain one or more iron-bearing minerals. In some cases, only surficial stains have resulted; in others, masses large enough to constitute iron ore deposits have been formed. Goethite also is common in modern sediments; *e.g.*, it is the typical iron mineral in marine ferromanganese nodules.

PYRITE AND PYRRHOTITE

Common sulfide minerals

Pyrite (FeS_2) and pyrrhotite ($Fe_{1-x}S$) are the most common sulfide minerals. Brassy yellow pyrite (Figure 90), often called "fool's gold," occurs variously as an accessory mineral in many rocks, in veins, and even as a chief component of some fossils. Pyrrhotite, which typically has a bronzelike appearance and is slightly magnetic, is a common accessory mineral in mafic igneous rocks. Both of these minerals, which are associated with each other in some deposits, have yielded large quantities of sulfur recovered for uses such as the production of sulfuric acid.

THE NATURE OF ROCKS

General considerations

ROCK TYPES

Rocks are, as noted above, aggregates of mineral grains or crystals. They are classified into three major types according to origin: (1) igneous, (2) sedimentary, and (3) metamorphic.

Igneous rocks are those that solidify from a melt (called magma, a molten mixture of rock-forming minerals and usually volatiles such as gases and steam). Since their constituent minerals are crystallized from molten material, igneous rocks are formed at high temperatures. They originate from processes deep within the Earth—typically at depths of about 50 to 200 kilometres (30 to 120 miles)—in the mid- to lower-crust or in the upper mantle. Igneous rocks are subdivided into two categories: intrusive (emplaced in the crust), and extrusive (extruded onto the surface of the land or ocean bottom), in which case the cooling molten material is called lava.

Sedimentary rocks are those that are deposited and lithified (compacted and cemented together) at the Earth's surface, with the assistance of running water, wind, ice, or living organisms. Most are deposited from the land surface to the bottoms of lakes, rivers, and oceans. Sedimentary rocks are generally stratified—*i.e.*, they have layering. Layers may be distinguished by differences in colour, particle size, type of cement, or internal arrangement.

Metamorphic rocks are those formed by changes in pre-existing rocks under the influence of high temperature, pressure, and chemically active solutions. The changes can be chemical (compositional) and physical (textural) in character. Metamorphic rocks are formed by processes deep within the Earth that produce new minerals, textures, and crystal structures. The recrystallization that takes place does so essentially in the solid state, rather than by complete remelting, and can be aided by ductile deformation and the presence of interstitial fluids such as water. Metamorphism often produces apparent layering, or banding, because of the segregation of minerals into separate bands.

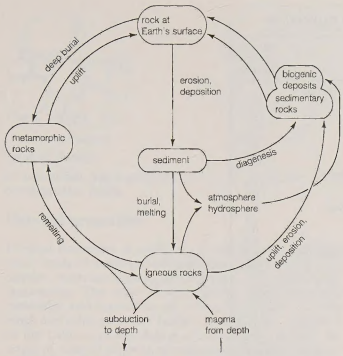

Figure 91: The rock cycle.

ROCK CYCLE

Geologic materials—mineral crystals and their host rock types—are cycled through various forms. The process depends on temperature, pressure, time, and changes in environmental conditions in the Earth's crust and at its surface. The rock cycle illustrated in Figure 91 reflects the basic relationships among igneous, metamorphic, and sedimentary rocks. Erosion includes weathering (the physical and chemical breakdown of minerals) and transportation to a site of deposition. Diagenesis is, as previously explained, the process of forming sedimentary rock by compaction and natural cementation of grains, or crystallization from water or solutions, or recrystallization. The conversion of sediment to rock is termed lithification.

ABUNDANCE OF ROCK TYPES

An estimate of the distribution of rock types in large structural units of the terrestrial crust is given in Table 30. The relative abundance of main rock types and minerals in the crust is shown in Table 31.

Texture

The texture of a rock is the size, shape, and arrangement of the grains (for sedimentary rocks) or crystals (for igneous and metamorphic rocks). Also of importance are the rock's extent of homogeneity (*i.e.*, uniformity of composition throughout) and the degree of isotropy. The latter is the extent to which the bulk structure and composition are the same in all directions in the rock.

Analysis of texture can yield information about the rock's source material, conditions and environment of deposition (for sedimentary rock) or crystallization and recrystallization (for igneous and metamorphic rock, respectively), and subsequent geologic history and change.

The common textural terms used for rock types with respect to the size of the grains or crystals, are given in Table 32. The particle-size categories are derived from the Udden-Wentworth scale developed for sediment. For igneous and metamorphic rocks, the terms are generally used as modifiers—*e.g.*, medium-grained granite. Aphanitic is a descriptive term for small crystals, and phaneritic for larger ones. Very coarse crystals (those larger than 3 centimetres, or 1.2 inches) are termed pegmatitic.

Udden-Wentworth scale

For sedimentary rocks, the broad categories of sediment size are coarse (greater than 2 millimetres, or 0.08 inch), medium (between 2 and $^1/_{16}$ millimetres), and fine (under $^1/_{16}$ millimetre). The latter includes silt and clay, which both have a size indistinguishable by the human eye and are also termed dust. Most shales (the lithified version of clay) contain some silt. Pyroclastic rocks are those formed from clastic (from the Greek word for broken) material ejected from volcanoes. Blocks are fragments broken from solid rock, while bombs are molten when ejected.

The term rock refers to the bulk volume of the material, including the grains or crystals as well as the contained void space. The volumetric portion of bulk rock that is not occupied by grains, crystals, or natural cementing material is termed porosity. That is to say, porosity is the ratio of void volume to the bulk volume (grains plus void space). This void space consists of pore space between grains or crystals, in addition to crack space. In sedimentary rocks, the amount of pore space depends on the degree of compaction of the sediment (with compaction generally increasing with depth of burial), on the packing arrangement and shape of grains, on the amount of cementation, and on the degree of sorting. Typical cements are siliceous, calcareous or carbonate, or iron-bearing minerals.

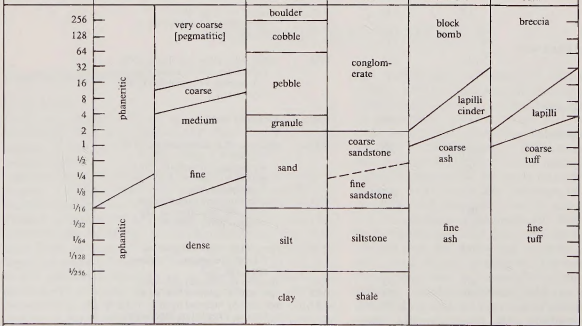
Sorting

Sorting is the tendency of sedimentary rocks to have grains that are similarly sized—*i.e.*, to have a narrow range of sizes (see Figure 92). Poorly sorted sediment displays a wide range of grain sizes and hence has decreased porosity. Well-sorted indicates a grain size distribution that is fairly uniform. Depending on the type of close-packing of the grains, porosity can be substantial. It should be noted that in engineering usage—*e.g.*, geotechnical or civil engineering—the terminology is phrased oppositely and is referred to as grading. A well-graded sediment is a (geologically) poorly sorted one, and a poorly graded sediment is a well-sorted one.

Total porosity encompasses all the void space, including those pores that are interconnected to the surface of the sample as well as those that are sealed off by natural cement or other obstructions. Thus the total porosity (φ_T) is

$$\varphi_T = 100\left(1 - \frac{\text{Vol}_G}{\text{Vol}_B}\right)\%,$$

where Vol_G is the volume of grains (and cement, if any) and Vol_B is the total bulk volume. Alternatively, one can calculate φ_T from the measured densities of the bulk rock and of the (mono)mineralic constituent. Thus,



$$\varphi_T = 100\left(1 - \frac{\rho_B}{\rho_G}\right)\%,$$

where ρ_B is the density of the bulk rock and ρ_G is the density of the grains (*i.e.*, the mineral, if the composition is monomineralogic and homogeneous). For example, if a sandstone has a ρ_B of 2.38 grams per cubic centimetre (g/cm^3) and is composed of quartz (SiO_2) grains having ρ_G of 2.65 g/cm^3, the total porosity is

$$\varphi_T = 100\left(1 - \frac{2.38}{2.65}\right) = 10.2\%.$$

Apparent (effective, or net) porosity is the proportion of void space that excludes the sealed-off pores. It thus measures the pore volume that is effectively interconnected and accessible to the surface of the sample, which is important when considering the storage and movement

of subsurface fluids such as petroleum, groundwater, or contaminated fluids.

Physical properties

Physical properties of rocks are of interest and utility in many fields of work, including geology, petrophysics, geophysics, materials science, geochemistry, and geotechnical engineering. The scale of investigation ranges from the molecular and crystalline up to terrestrial studies of the Earth and other planetary bodies. Geologists are interested in the radioactive age dating of rocks to reconstruct the origin of mineral deposits; seismologists formulate prospective earthquake predictions using premonitory physical or chemical changes; crystallographers study the synthesis of minerals with special optical or physical properties; exploration geophysicists investigate the variation of physical properties of subsurface rocks to make possible detection of natural resources such as oil and gas, geothermal energy, and ores of metals; geotechnical engineers examine the nature and behaviour of the materials on, in, or of which such structures as buildings, dams, tunnels, bridges, and underground storage vaults are to be constructed; solid-state physicists study the magnetic, electrical, and mechanical properties of materials for electronic devices, computer components, or high-performance ceramics; and petroleum reservoir engineers analyze the response measured on well logs or in the processes of deep drilling at elevated temperature and pressure.

Mineral properties

Since rocks are aggregates of mineral grains or crystals, their properties are determined in large part by the properties of their various constituent minerals. In a rock these general properties are determined by averaging the relative properties and sometimes orientations of the various grains or crystals. As a result, some properties that are anisotropic (*i.e.*, differ with direction) on a submicroscopic or crystalline scale are fairly isotropic for a large bulk volume of the rock. Many properties are also dependent on grain or crystal size, shape, and packing arrangement, the amount and distribution of void space, the presence of natural cements in sedimentary rocks, the temperature and pressure, and the type and amount of contained fluids (*e.g.*, water, petroleum, gases). Because many rocks exhibit a considerable range in these factors, the assignment of representative values for a particular property is often done using a statistical variation.

Some properties can vary considerably, depending on whether measured in situ (in place in the subsurface) or in the laboratory under simulated conditions. Electrical resistivity, for example, is highly dependent on the fluid content of the rock in situ and the temperature condition at the particular depth.

DENSITY

Density varies significantly among different rock types because of differences in mineralogy and porosity. Knowledge of the distribution of underground rock densities can assist in interpreting subsurface geologic structure and rock type.

In strict usage, density is defined as the mass of a substance per unit volume; however, in common usage, it is taken to be the weight in air of a unit volume of a sample at a specific temperature. Weight is the force that gravitation exerts on a body (and thus varies with location), whereas mass (a measure of the matter in a body) is a fundamental property and is constant regardless of location. In routine density measurements of rocks, the sample weights are considered to be equivalent to their masses, because the discrepancy between weight and mass would result in less error on the computed density than the experimental errors introduced in the measurement of volume. Thus, density is often determined using weight rather than mass. Density should properly be reported in kilograms per cubic metre (kg/m^3), but is still often given in grams per cubic centimetre (g/cm^3).

Specific gravity

Another property closely related to density is specific gravity. It is defined, as noted above, as the ratio of the weight or mass in air of a unit volume of material at a stated temperature to the weight or mass in air of a unit volume of distilled water at the same temperature. Specific gravity is dimensionless (*i.e.*, has no units).

The bulk density of a rock is $\rho_B = W_G/V_B$, where W_G is the weight of grains (sedimentary rocks) or crystals (igneous and metamorphic rocks) and natural cements, if any, and V_B is the total volume of the grains or crystals plus the void (pore) space. The density can be dry if the pore space is empty, or it can be saturated if the pores are filled with fluid (*e.g.*, water), which is more typical of the subsurface (in situ) situation. If there is pore fluid present,

$$\text{(saturated) } \rho_B = \frac{W_G + W_{fl}}{V_B},$$

where W_{fl} is the weight of pore fluid. In terms of total porosity, saturated density is

$$\text{(saturated) } \rho_B = \rho_G(1 - \varphi_T) + \rho_{fl}\varphi_T,$$

and thus

$$\varphi_T = \frac{\rho_G - \rho_B}{\rho_G - \rho_{fl}},$$

where ρ_f is the density of the pore fluid. Density measurements for a given specimen involve the determination of any two of the following quantities: pore volume, bulk volume, or grain volume, along with the weight.

A useful way to assess the density of rocks is to make a histogram plot of the statistical range of a set of data. The representative value and its variation can be expressed as follows: (1) mean, the average value, (2) mode, the most common value (*i.e.*, the peak of the distribution curve), (3) median, the value of the middle sample of the data set (*i.e.*, the value at which half of the samples are below and half are above), and (4) standard deviation, a statistical measure of the spread of the data (plus and minus one standard deviation from the mean value includes about two-thirds of the data).

Dry bulk densities

A compilation of dry bulk densities for various rock types found in the upper crust of the Earth is listed in Table 33. A histogram plot of these data, giving the percent of the samples as a function of density is shown in Figure 93. The parameters given include (1) sample division, the range of density in one data column—*e.g.*, 0.036 g/cm³ for Figure 93, (2) number of samples, and (3) standard deviation. The small inset plot is the percentage of samples (on the vertical axis) that lie within the interval of the "mode − x" to the "mode + x," where x is the horizontal axis.

In Figure 93, the most common (modal) value of the distribution falls at 2.63 g/cm³, roughly the density of quartz, an abundant rock-forming mineral. Few density values for these upper crustal rocks lie above 3.3 g/cm³. A few fall well below the mode, even occasionally under 1 g/cm³. The reason for this is shown in Figure 94, which illustrates the density distributions for granite, basalt, and sandstone. Granite is an intrusive igneous rock with low porosity and a well-defined chemical (mineral) composition; its range of densities is narrow. Basalt is, in most cases, an extrusive igneous rock that can exhibit a large variation in porosity (because entrained gases leave voids called vesicles), and thus some highly porous samples can have low densities. Sandstone is a clastic sedimentary rock that can have a wide range of porosities depending on the degree of sorting, compaction, packing arrangement of grains, and cementation. The bulk density varies accordingly.

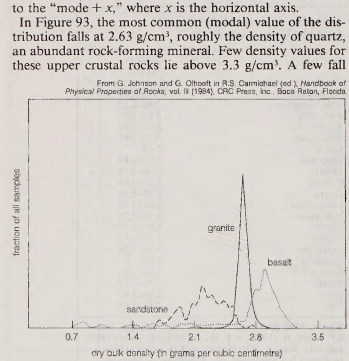

Figure 94: Dry density distribution of three different rock types: basalt, granite, and sandstone.

Other distribution plots of dry bulk densities are given in Figures 95 and 96, with a sample division of 0.036 g/cm³ for Figures 95 and 96A and of 0.828 percent for Figure 96B. Table 34 lists typical ranges of dry bulk densities for a variety of other rock types as prepared by the American geologists Gordon R. Johnson and Gary R. Olhoeft.

The density of clastic sedimentary rocks increases as the rocks are progressively buried. This is because of the increase of overburden pressure, which causes compaction, and the progressive cementation with age. Both compaction and cementation decrease the porosity.

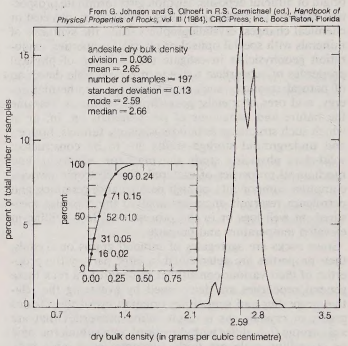

Figure 95: Density distribution for andesite.

Representative densities for common rock-forming minerals (*i.e.*, ρ_G) and rocks (*i.e.*, ρ_B) are listed in Table 35. The bulk densities for sedimentary rocks, which typically have variable porosity, are given as ranges of both dry ρ_B and (water-) saturated ρ_B. The pore-filling fluid is usually briny water, often indicative of the presence of seawater when the rock was being deposited or lithified. It should be noted that the bulk density is less than the grain density of the constituent mineral (or mineral assemblage), depending on the porosity. For example, sandstone (characteristically quartzose) has a typical dry bulk density of 2.0–2.6 g/cm³, with a porosity that can vary from low to more than 30 percent. The density of quartz itself is 2.65 g/cm³. If porosity were zero, the bulk density would equal the grain density.

Saturated bulk density is higher than dry bulk density, owing to the added presence of pore-filling fluid. Table 35 also lists representative values for density of seawater, oil, and methane gas at a subsurface condition—pressure of 200 bars (one bar = 0.987 atmosphere, or 29.53 inches of mercury) and a temperature of about 80° C (176° F).

MECHANICAL PROPERTIES

Stress and strain

When a stress σ (force per unit area) is applied to a material such as rock, the material experiences a change in dimension, volume, or shape. This change, or deformation, is called strain (ε). Stresses can be axial—*e.g.*, directional tension or simple compression—or shear (tangential), or all-sided (*e.g.*, hydrostatic compression). The terms stress

Rock mechanics

The study of deformation resulting from the strain of rocks in response to stresses is called rock mechanics. When the scale of the deformation is extended to large geologic structures in the crust of the Earth, the field of study is known as geotectonics.

The mechanisms and character of the deformation of rocks and Earth materials can be investigated through laboratory experiments, development of theoretical models based on the properties of materials, and study of deformed rocks and structures in the field. In the laboratory, one can simulate—either directly or by appropriate scaling of experimental parameters—several conditions. Two types of pressure may be simulated: confining (hydrostatic), due to burial under rock overburden, and internal (pore), due to pressure exerted by pore fluids contained in void space in the rock. Directed applied stress, such as compression, tension, and shear, is studied, as are the effects of increased temperature introduced with depth in the Earth's crust. The effects of the duration of time and the rate of applying stress (*i.e.*, loading) as a function of time are examined. Also, the role of fluids, particularly if they are chemically active, is investigated.

A simple apparatus for deforming rocks is shown schematically in Figure 97. This is for biaxial stress application: a directed (uniaxial) compression is applied while a confining pressure is exerted (by pressurized fluid) around the cylindrical specimen. This simulates deformation at depth within the Earth. An independent internal pore-fluid pressure also can be exerted. The rock specimen can be jacketed with a thin, impermeable sleeve (*e.g.*, rubber or copper) to separate the external pressure medium from the internal pore fluids (if any). The specimen is typically a few centimetres in dimension.

and pressure are sometimes used interchangeably, but often stress refers to directional stress or shear stress and pressure (P) refers to hydrostatic compression. For small stresses, the strain is elastic (recoverable when the stress is removed and linearly proportional to the applied stress). For larger stresses and other conditions, the strain can be inelastic, or permanent.

Elastic constants

In elastic deformation, there are various constants that relate the magnitude of the strain response to the applied stress. These elastic constants include the following:

(1) Young's modulus (E) is the ratio of the applied stress to the fractional extension (or shortening) of the sample length parallel to the tension (or compression). The strain is the linear change in dimension divided by the original length.

(2) Shear modulus (μ) is the ratio of the applied stress to the distortion (rotation) of a plane originally perpendicular to the applied shear stress; it is also termed the modulus of rigidity.

(3) Bulk modulus (k) is the ratio of the confining pressure to the fractional reduction of volume in response to the applied hydrostatic pressure. The volume strain is the change in volume of the sample divided by the original volume. Bulk modulus is also termed the modulus of incompressibility.

(4) Poisson's ratio (σ_p) is the ratio of lateral strain (perpendicular to an applied stress) to the longitudinal strain (parallel to applied stress).

For elastic and isotropic materials, the elastic constants are interrelated. For example,

$$\sigma_p = \frac{E}{2\mu} - 1;$$

$$E = 3k(1 - 2\sigma_p);$$

and

$$\mu = \frac{3}{2}k\left(\frac{1 - 2\sigma_p}{1 + \sigma_p}\right).$$

The following are the common units of stress:

1 bar = 10^6 dynes per square centimetre
= 10^5 newtons per square metre, or pascals (Pa)
= 0.1 megapascal (*i.e.*, 0.1×10^6 Pa).

Thus 10 kilobars = 1 gigapascal (*i.e.*, 10^9 Pa).

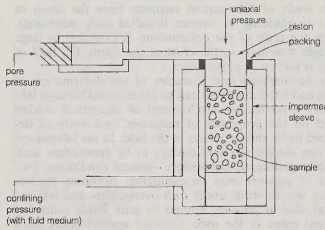

Figure 97: Simple experimental apparatus for use in rock mechanics studies.

Another apparatus for exerting high pressure on a sample is shown in Figure 98. It was designed in 1968 by Akira Sawaoka, Naoto Kawai, and Robert Carmichael to give hydrostatic confining pressures up to 12 kilobars (1.2 gigapascal), additional directed stress, and temperatures up to a few hundred degrees Celsius. The specimen is positioned on the baseplate; the pressure is applied by driving in pistons with a hydraulic press. The end caps can be locked down to hold the pressure for time experiments and to make the device portable.

Apparatuses have been developed, typically using multi-anvil designs, which extend the range of static experimental conditions—at least for small specimens and limited times—to pressures as high as about 1,700 kilobars and temperatures of about 2,000° C. Such work has been pioneered by researchers such as Peter M. Bell and Ho-Kwang Mao, who conducted studies at the Geophysical Laboratory of the Carnegie Institution in Washington, D.C. Using dynamic techniques (*i.e.*, shock from explosive impact generated by gun-type designs), even higher pressures up to 7,000 kilobars (700 gigapascal)—which is nearly twice the pressure at the centre of the Earth and seven million times greater than the atmospheric pressure at the Earth's surface—can be produced for very short times. A leading figure in such ultrapressure work is A. Sawaoka at the Tokyo Institute of Technology.

Ultra-pressure work

In the upper crust of the Earth, hydrostatic pressure increases at the rate of about 320 bars per kilometre, and temperature increases at a typical rate of 20°–40° C per kilometre, depending on recent crustal geologic history. Additional directed stress, as can be generated by large-scale crustal deformation (tectonism), can range up to 1 to 2 kilobars. This is approximately equal to the ultimate strength (before fracture) of solid crystalline rock at surface temperature and pressure (see below). The stress released in a single major earthquake—a shift on a fault plane—is about 50–150 bars.

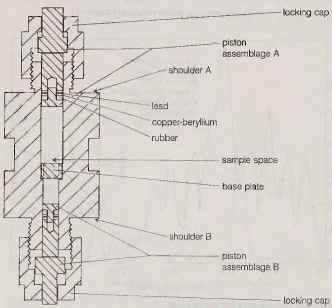

Figure 98: Cross section of a high-pressure "bomb" (see text).

In studying the deformation of rocks one can start with the assumption of ideal behaviour: elastic strain and homogeneous and isotropic stress and strain. In reality, on a microscopic scale there are grains and pores in sediments and a fabric of crystals in igneous and metamorphic rocks. On a large scale, rock bodies exhibit physical and chemical variations and structural features. Furthermore, conditions such as extended length of time, confining pressure, and subsurface fluids affect the rates of change of deformation. Figure 99 shows the generalized transition from brittle fracture through faulting to plastic-flow deformation in response to applied compressional stress and the progressive increase of confining pressure.

The deformation of materials is characterized by stress-strain relations. For elastic-behaviour materials, the strain is proportional to the load (*i.e.*, the applied stress). The strain is immediate with stress and is reversible (recoverable) up to the yield point stress, beyond which permanent strain results. For viscous material, there is laminar (slow, smooth, parallel) flow; one must exert a force to maintain motion because of internal frictional resistance to flow, called the viscosity. Viscosity varies with the applied stress, strain rate, and temperature. In plastic behaviour, the material strains continuously (but still has strength) after the yield point stress is reached; however, beyond this point there is some permanent deformation. In elasticoviscous deformation, there is combined elastic and viscous behaviour. The material yields continuously (viscously) for a constant applied load. An example of such behaviour is creep, a slow, permanent, and continuous deformation occurring under constant load over a long time in such materials as crystals, ice, soil and sediment, and rocks at depth. In firmoviscous behaviour, the material is essentially solid but the strain is not immediate with application of stress; rather, it is taken up and released exponentially. A plasticoviscous material exhibits elastic behaviour for initial stress (as in plastic behaviour), but after the yield point stress is reached, it flows like a viscous fluid.

Creep

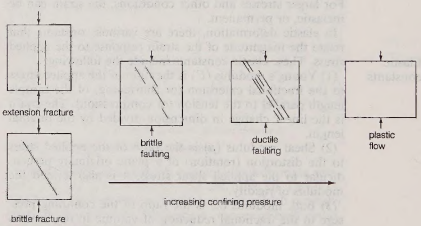

Figure 99: Deformation as affected by increased confining pressure.

Some representative values of elastic constants and properties are listed in Table 36. The coefficient of viscosity (η) is the ratio of applied stress to the rate of straining (change of strain with time). It is measured in units of poise; one poise equals one dyne-second per square centimetre.

Rheology is the study of the flow deformation of materials. The concept of rheidity refers to the capacity of a material to flow, arbitrarily defined as the time required with a shear stress applied for the viscous strain to be 1,000 times greater than the elastic strain. It is thus a measure of the threshold of fluidlike behaviour. Although such behaviour depends on temperature, relative comparisons can be made. Some representative values of rheidity times are given in Table 37.

Typical stress-strain (deformation) curves for rock materials are shown in Figure 100. The stress σ, compression in the figure, is force per unit area. The strain ε is fractional shortening of the specimen parallel to the applied compression; it is given here in percent. The brittle material behaves elastically nearly until the point of fracture (denoted X), whereas the ductile (plastically deformable) material is elastic up to the yield point but then has a

range of plastic deformation before fracturing. The ability to undergo large permanent deformation before fracture is called ductility. For plastic deformation, the flow mechanisms are intracrystalline (slip and twinning within crystal grains), intercrystalline motion by crushing and fracture (cataclasis), and recrystallization by solutioning or solid diffusion.

If the applied stress is removed while a ductile material is in the plastic range, part of the strain is recoverable (elastically), but there is permanent deformation. The ultimate strength is the highest point (stress) on a stress-strain curve, often occurring at fracture (which is the complete loss of cohesion). The strength of a material is its resistance to failure (destruction of structure) by flow or fracture; it is a measure of the stress required to deform a body. Typical compressive strengths (the stress required to cause failure under compression) are given in Table 36.

Ultimate strength

Table 37: Rheidity Threshold of Fluidlike Deformation

material	approximate time
Ice (*e.g.*, glacier)	2 weeks
Gypsum	1 year
Rock salt (*e.g.*, salt dome)	10–20 years
Serpentine (a mafic silicate mineral)	10,000 years

The behaviour and mechanical properties of rocks depend on a number of environmental conditions. (1) Confining pressure increases the elasticity, strength (*e.g.*, yield point and ultimate fracture stress), and ductility. (2) Internal pore-fluid pressure reduces the effective stress acting on the sample, thus reducing the strength and ductility. The effective, or net, confining pressure is the external hydrostatic pressure minus the internal pore-fluid pressure. (3) Temperature lowers the strength, enhances ductility, and may enhance recrystallization. (4) Fluid solutions can enhance deformation, creep, and recrystallization. (5) Time is an influential factor as well. (6) The rate of loading (*i.e.*, the rate at which stress is applied) influences mechanical properties. (7) Compaction, as would occur with burial to depth, reduces the volume of pore space for sedimentary rocks and the crack porosity for crystalline rocks.

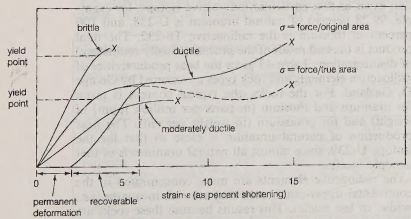

Figure 100: Typical stress-strain curves for rock materials. Each *X* represents the point of fracture for the corresponding material.

Rocks, which are typically brittle at the Earth's surface, can undergo ductile deformation when buried and subjected to increased confining pressure and temperature for long periods of time. If stress exceeds their strength or if they are not sufficiently ductile, they will fail by fracture—as a crystal, within a bed or rock, on an earthquake fault zone, and so on—whereas with ductility they can flow and fold.

Some strengths for various rock types under different temperatures and confining pressures are listed in Table 38. The plastic yield strength here is the stress at a 2 percent strain; the ultimate strength, as stated above, is the highest point (stress) on the stress-strain curve.

An increase in confining pressure causes brittle fracture to become shear slippage and eventually causes flow (ductile) behaviour. This transition is also aided by higher temperature, decreased internal pore-fluid pressure, and slower strain rate.

THERMAL PROPERTIES

Flux

Heat flow (or flux), q, in the Earth's crust or in rock as a building material, is the product of the temperature gradient (change in temperature per unit distance) and the material's thermal conductivity (k, the heat flow across a surface per unit area per unit time when a temperature difference exists in unit length perpendicular to the surface). Thus,

$$q = \frac{dT}{dz} \times k.$$

The units of the terms in this equation are given below, expressed first in the centimetre-gram-second (cgs) system and then in the International System of Units (SI) system, with the conversion factor from the first to the second given between them.

q, heat flow:
calories per square centimetre per second (cal/cm² · sec) $\times \frac{1}{23.9} \times 10^{-6} =$ watts per square metre (W/m²)

$\frac{dT}{dz}$, temperature gradient:
degrees Celsius per kilometre (°C/km, practical unit for Earth) $\times 10^{-3} =$ degrees Celsius per metre (°C/m)

k, thermal conductivity:
calories per square centimetre per second per degree Celsius (cal/cm² · sec · °C) $\times \frac{1}{23.9} \times 10^{-3} =$ watts per metre per degree Celsius (W/m · °C)

Thermal conductivity. Thermal conductivity can be determined in the laboratory or in situ, as in a borehole or deep well, by turning on a heating element and measuring the rise in temperature with time. It depends on several factors: (1) chemical composition of the rock (*i.e.*, mineral content), (2) fluid content (type and degree of saturation of the pore space); the presence of water increases the thermal conductivity (*i.e.*, enhances the flow of heat), (3) pressure (a high pressure increases the thermal conductivity by closing cracks which inhibit heat flow), (4) temperature, and (5) isotropy and homogeneity of the rock.

Typical values of thermal conductivities of rock materials are given in Table 40. For crystalline silicate rocks—the dominant rocks of the "basement" crustal rocks—the lower values are typical of ones rich in magnesium and iron (*e.g.*, basalt and gabbro) and the higher values are typical of those rich in silica (quartz) and alumina (*e.g.*, granite). These values result because the thermal conductivity of quartz is relatively high, while that for feldspars is low.

Thermal expansion. The change in dimension—linear or volumetric—of a rock specimen with temperature is expressed in terms of a coefficient of thermal expansion. This is given as the ratio of dimension change (*e.g.*, change in volume) to the original dimension (volume, V) per unit of temperature (T) change:

$$\frac{1}{V}\frac{\Delta V}{\Delta T}.$$

Most rocks have a volume-expansion coefficient in the range of 15–33 × 10⁻⁶ per degree Celsius under ordinary conditions. Quartz-rich rocks have relatively high values because of the higher volume expansion coefficient of quartz. Thermal-expansion coefficients increase with temperature. Table 41 lists some linear-expansion coefficients,

$$\frac{1}{L}\frac{\Delta L}{\Delta T},$$

where L represents length. All data are based on at least three samples.

Radioactive heat generation. The spontaneous decay (partial disintegration) of the nuclei of radioactive elements provides decay particles and energy. The energy, composed of emission kinetic energy and radiation, is converted to heat; it has been an important factor in affecting the temperature gradient and thermal evolution of the Earth. Deep-seated elevated temperatures provide the heat that causes rock to deform plastically and to move, thus generating to a large extent the processes of plate tectonics—plate motions, seafloor spreading, continental drift, and subduction—and most earthquakes and volcanism.

Some elements, or their isotopes (nuclear species with the same atomic number but different mass numbers), decay with time. These include elements with an atomic number greater than 83—of which the most important are uranium-235, uranium-238, and thorium-232—and a few with a lower atomic number, such as potassium-40.

Potassium	K-40	(89%) Ca-40 (11%) Argon-40	0.01	1.4* 11.9*
Rubidium	Rb-87	Sr-87	27.8	48.8

*$t_{1/2}$ for K-40 as a whole is 1.25×10^9 years.

The heat generated within rocks depends on the types and abundances of the radioactive elements and their host minerals. Such heat production, A, is given in calories per cubic centimetre per second, or 1 calorie per gram per year = 4.186×10^7 ergs per gram per year = 1.327 ergs per gram per second. The rate of radioactive decay, statistically an exponential process, is given by the half-life, $t_{1/2}$. The half-life is the time required for half the original radioactive atoms to decay for a particular isotope. Half-life

Some radioactive decay series are listed in Table 42. The isotopic abundance is the percent of the natural element that exists as that particular radioactive isotope; for example, 99.28 percent of natural uranium is U-238, and 100 percent of thorium is the radioactive Th-232. The final product is the end result of the process (usually multistage) of disintegration. Table 43 gives the heat productivities of radioactive elements and rock types as reported by George D. Garland. For the rocks, the typical content is given for uranium and thorium (in parts per million [ppm] of weight) and for potassium (in weight percent). The heat production of natural uranium is close to that for the isotope U-238, since almost all natural uranium is of that isotopic species.

The radioactive elements are more concentrated in the continental upper-crust rocks that are rich in quartz (*i.e.*, acidic, or less mafic). This results because these rocks are differentiated by partial melting of the upper-mantle and oceanic-crust rock. The radioactive elements tend to be preferentially driven off from these rocks for geochemical

reasons. A compilation of heat productivities of various rock types is given in Table 44.

ELECTRICAL PROPERTIES

The electrical nature of a material is characterized by its conductivity (or, inversely, its resistivity) and its dielectric constant, and coefficients that indicate the rates of change of these with temperature, frequency at which measurement is made, and so on. For rocks with a range of chemical composition as well as variable physical properties of porosity and fluid content, the values of electrical properties can vary widely.

Resistivity and conductivity

Resistance (R) is defined as being one ohm when a potential difference (voltage; V) across a specimen of one volt magnitude produces a current (i) of one ampere; that is, $V = Ri$. The electrical resistivity (ρ) is an intrinsic property of the material. In other words, it is inherent and not dependent on sample size or current path. It is related to resistance by $R = \rho L/A$ where L is the length of specimen, A is the cross-sectional area of specimen, and units of ρ are ohm-centimetre; 1 ohm-centimetre equals 0.01 ohm-metre. The conductivity (σ) is equal to $1/\rho$ ohm^{-1} · centimetre^{-1} (or termed mhos/cm). In SI units, it is given in mhos/metre, or siemens/metre.

Some representative values of electrical resistivity for rocks and other materials are listed in Table 45. Materials that are generally considered as "good" conductors have a resistivity of 10^{-5}–10 ohm-centimetre (10^{-7}–10^{-1} ohm-metre) and a conductivity of 10–10^7 mhos/metre. Those that are classified as intermediate conductors have a resistivity of 100–10^6 ohm-centimetre (1–10^7 ohm-metre) and a conductivity of 10^{-7}–1 mhos/metre. "Poor" conductors, also known as insulators, have a resistivity of 10^{10}–10^{17} ohm-centimetre (10^8–10^{15} ohm-metre) and a conductivity of 10^{-15}–10^{-8}. Seawater is a much better conductor (*i.e.*, it has lower resistivity) than fresh water owing to its higher content of dissolved salts; dry rock is very resistive. In the subsurface, pores are typically filled to some degree by fluids. The resistivity of materials has a wide range—copper is, for example, different from quartz by 22 orders of magnitude.

For high-frequency alternating currents, the electrical response of a rock is governed in part by the dielectric constant, ε. This is the capacity of the rock to store electric charge; it is a measure of polarizability in an electric field. In cgs units, the dielectric constant is 1.0 in a vacuum. In SI units, it is given in farads per metre or in terms of the ratio of specific capacity of the material to specific capacity of vacuum (which is 8.85×10^{-12} farads per metre). The dielectric constant is a function of temperature, and of frequency, for those frequencies well above 100 hertz (cycles per second).

Dielectric constant

Electrical conduction occurs in rocks by (1) fluid conduction—*i.e.*, electrolytic conduction by ionic transfer in briny pore water—and (2) metallic and semiconductor (*e.g.*, some sulfide ores) electron conduction. If the rock has any porosity and contained fluid, the fluid typically dominates the conductivity response. The rock conductivity depends on the conductivity of the fluid (and its chemical composition), degree of fluid saturation, porosity and permeability, and temperature. If rocks lose water, as with compaction of clastic sedimentary rocks at depth, their resistivity typically increases. Ranges of electrical resistivities for various rock types are given in Figure 101, and the variation of electrical resistivity for granodiorite, as the frequency and temperature are changed, is shown in Figure 102.

MAGNETIC PROPERTIES

The magnetic properties of rocks arise from the magnetic properties of the constituent mineral grains and crystals. Typically, only a small fraction of the rock consists of magnetic minerals. It is this small portion of grains that determines the magnetic properties and magnetization of the rock as a whole, with two results: (1) the magnetic properties of a given rock may vary widely within a given rock body or structure, depending on chemical inhomo-

geneities, depositional or crystallization conditions, and what happens to the rock after formation; and (2) rocks that share the same lithology (type and name) need not necessarily share the same magnetic characteristics. Lithologic classifications are usually based on the abundance of dominant silicate minerals, but the magnetization is determined by the minor fraction of such magnetic mineral grains as iron oxides. The major rock-forming magnetic minerals are iron oxides and sulfides.

Although the magnetic properties of rocks sharing the same classification may vary from rock to rock, general magnetic properties do nonetheless usually depend on rock type and overall composition. The magnetic properties of a particular rock can be quite well understood provided one has specific information about the magnetic properties of crystalline materials and minerals, as well as about how those properties are affected by such factors as temperature, pressure, chemical composition, and the size of the grains. Understanding is further enhanced by information about how the properties of typical rocks are dependent on the geologic environment and how they vary with different conditions.

An understanding of rock magnetization is important in at least three different areas: prospecting, geology, and materials science. In magnetic prospecting, one is interested in mapping the depth, size, type, and inferred composition of buried rocks. The prospecting, which may be done from ground surface, ship, or aircraft, provides an important first step in exploring buried geologic structures and may, for example, help identify favourable locations for oil, natural gas, and economic mineral deposits.

Rock magnetization has traditionally played an important role in geology. Paleomagnetic work seeks to determine the remanent magnetization (see below) and thereby ascertain the character of the Earth's field when certain rocks were formed. The results of such research have important ramifications in stratigraphic correlation, age dating, and reconstructing past movements of the Earth's crust. Indeed, magnetic surveys of the oceanic crust provided for the first time the quantitative evidence needed to cogently demonstrate that segments of the crust had undergone large-scale lateral displacements over geologic time, thereby corroborating the concepts of continental drift and seafloor spreading, both of which are fundamental to the theory of plate tectonics (see PLATE TECTONICS).

J_s is the saturation (or "spontaneous") magnetization; $J_{r,sat}$ is the remanent magnetization that remains after a saturating applied field is removed; J_r is the residual magnetization left by some magnetization process other than IRM saturation; H_c is the coercive field; and $H_{c,r}$ is the field necessary to reduce J_r to zero.

The understanding of magnetization is increasingly important in materials science as well. The design and manufacture of efficient memory cores, magnetic tapes, and permanent magnets increasingly rely on the ability to create materials having desired magnetic properties.

Basic types of magnetization

There are six basic types of magnetization: (1) diamagnetism, (2) paramagnetism, (3) ferromagnetism, (4) antiferromagnetism, (5) ferrimagnetism, and (6) superparamagnetism.

Diamagnetism arises from the orbiting electrons surrounding each atomic nucleus. When an external magnetic field is applied, the orbits are shifted in such a way that the atoms set up their own magnetic field in opposition to the applied field. In other words, the induced diamagnetic field opposes the external field. Diamagnetism is present in all materials, is weak, and exists only in the presence of an applied field. The propensity of a substance for being magnetized in an external field is called its susceptibility (k) and it is defined as J/H, where J is the magnetization (intensity) per unit volume and H is the strength of the applied field. Since the induced field always opposes the applied field, the sign of diamagnetic susceptibility is negative. The susceptibility of a diamagnetic substance is on the order of -10^{-6} electromagnetic units per cubic centimetre (emu/cm^3). It is sometimes denoted κ for susceptibility per unit mass of material.

Paramagnetism results from the electron spin of unpaired electrons. An electron has a magnetic dipole moment—which is to say that it behaves like a tiny bar magnet—and so when a group of electrons is placed in a magnetic

field, the dipole moments tend to line up with the field. The effect augments the net magnetization in the direction of the applied field. Like diamagnetism, paramagnetism is weak and exists only in the presence of an applied field, but since the effect enhances the applied field, the sign of the paramagnetic susceptibility is always positive. The susceptibility of a paramagnetic substance is on the order of 10^{-4} to 10^{-6} emu/cm^3.

Ferromagnetism also exists because of the magnetic properties of the electron. Unlike paramagnetism, however, ferromagnetism can occur even if no external field is applied. The magnetic dipole moments of the atoms spontaneously line up with one another because it is energetically favourable for them to do so. A remanent magnetization can be retained. Complete alignment of the dipole moments would take place only at a temperature of absolute zero (0 kelvin [K], or −273.15° C). Above absolute zero, thermal motions begin to disorder the magnetic moments. At a temperature called the Curie temperature, which varies from material to material, the thermally induced disorder overcomes the alignment, and the ferromagnetic properties of the substance disappear. The susceptibility of ferromagnetic materials is large and positive. It is on the order of 10 to 10^4 emu/cm^3. Only a few materials—iron, cobalt, and nickel—are ferromagnetic in the strict sense of the word and have a strong residual magnetization. In general usage, particularly in engineering, the term ferromagnetic is frequently applied to any material that is appreciably magnetic.

Antiferromagnetism occurs when the dipole moments of the atoms in a material assume an antiparallel arrangement in the absence of an applied field. The result is that the sample has no net magnetization. The strength of the susceptibility is comparable to that of paramagnetic materials. Above a temperature called the Néel temperature, thermal motions destroy the antiparallel arrangement, and the material then becomes paramagnetic. Spincanted (anti)ferromagnetism is a special condition which occurs when antiparallel magnetic moments are deflected from the antiferromagnetic plane, resulting in a weak net magnetism. Hematite (α-Fe_2O_3) is such a material.

Ferrimagnetism is an antiparallel alignment of atomic dipole moments which does yield an appreciable net magnetization resulting from unequal moments of the magnetic sublattices. Remanent magnetization is detectable (see below). Above the Curie temperature the substance becomes paramagnetic. Magnetite (Fe_3O_4), which is the most magnetic common mineral, is a ferrimagnetic substance.

Superparamagnetism occurs in materials having grains so small (about 100 angstroms) that any cooperative alignment of dipole moments is overcome by thermal energy.

Rocks and minerals may retain magnetization after the removal of an externally applied field, thereby becoming permanent weak magnets. This property is known as remanent magnetization and is manifested in different forms, depending on the magnetic properties of the rocks and minerals and their geologic origin and history. Delineated below are the kinds of remanent magnetization frequently observed.

Types of remanent magnetization

CRM (chemical, or crystallization, remanent magnetization) can be induced after a crystal is formed and undergoes one of a number of physicochemical changes, such as oxidation or reduction, a phase change, dehydration, recrystallization, or precipitation of natural cements. The induction, which is particularly important in some (red) sediments and metamorphic rocks, typically takes place at constant temperature in the Earth's magnetic field.

DRM (depositional, or detrital, remanent magnetization) is formed in clastic sediments when fine particles are deposited on the floor of a body of water. Marine sediments, lake sediments, and some clays can acquire DRM. The Earth's magnetic field aligns the grains, yielding a preferred direction of magnetization.

IRM (isothermal remanent magnetization) results from the application of a magnetic field at a constant (isothermal) temperature, often room temperature.

NRM (natural remanent magnetization) is the magnetization detected in a geologic in situ condition. The NRM of a substance may, of course, be a combination of any of the other remanent magnetizations described here.

PRM (pressure remanent, or piezoremanent, magnetization) arises when a material undergoes mechanical deformation while in a magnetic field. The process of deformation may result from hydrostatic pressure, shock impact (as produced by a meteorite striking the Earth's surface), or directed tectonic stress. There are magnetization changes with stress in the elastic range, but the most pronounced effects occur with plastic deformation when the structure of the magnetic minerals is irreversibly changed.

TRM (thermoremanent magnetization) occurs when a substance is cooled, in the presence of a magnetic field, from above its Curie temperature to below that temperature. This form of magnetization is generally the most important, because it is stable and widespread, occurring in igneous and sedimentary rocks. TRM also can occur when dealing exclusively with temperatures below the Curie temperature. In PTRM (partial thermoremanent magnetization) a sample is cooled from a temperature below the Curie point to yet a lower temperature.

VRM (viscous remanent magnetization) results from thermal agitation. It is acquired slowly over time at low temperatures and in the Earth's magnetic field. The effect is weak and unstable but is present in most rocks.

Hysteresis

The concept of hysteresis is fundamental when describing and comparing the magnetic properties of rocks. Hysteresis is the variation of magnetization with applied field and illustrates the ability of a material to retain its magnetization, even after an applied field is removed. Figure 103 illustrates this phenomenon in the form of a plot of magnetization (J) versus applied field (H_{ex}). J_s is the saturation (or "spontaneous") magnetization when all the magnetic moments are aligned in their configuration of maximum order. It is temperature-dependent, reaching zero at the Curie temperature. $J_{r,sat}$ is the remanent magnetization that remains when a saturating (large) applied field is removed, and J_r is the residual magnetization left by some process apart from IRM saturation, as, for example, TRM. H_c is the coercive field (or force) that is required to reduce $J_{r,sat}$ to zero, and $H_{c,r}$ is the field required to reduce J_r to zero.

Magnetic susceptibility is a parameter of considerable diagnostic and interpretational use in the study of rocks. This is true whether an investigation is being conducted in the laboratory or magnetic fields over a terrain are being studied to deduce the structure and lithologic character of buried rock bodies. Susceptibility for a rock type can vary widely, depending on magnetic mineralogy, grain size and shape, and the relative magnitude of remanent magnetization present, in addition to the induced magnetization from the Earth's weak field. The latter is given as $J_{induced} = kH_{ex}$, where k is the (true) magnetic susceptibility and H_{ex} is the external (*i.e.*, the Earth's) magnetic field. If there is an additional remanent magnetization with its ratio (Q_n) to induced magnetization being given by

$$Q_n = \frac{J_{remanent}}{kH_{ex}},$$

then the total magnetization is

$$\begin{aligned} J &= J_{induced} + J_{remanent} \\ &= kH_{ex} + Q_n kH_{ex} \\ &= k(1 + Q_n)H_{ex} \\ &= k_{app}H_{ex}, \end{aligned}$$

where k_{app}, the "apparent" magnetic susceptibility, is $k(1 + Q_n)$.

Magnetic minerals

The major rock-forming magnetic minerals are the following iron oxides: the titanomagnetite series, $x\mathrm{Fe_2TiO_4} \cdot (1 - x)\mathrm{Fe_3O_4}$, where $\mathrm{Fe_3O_4}$ is magnetite, the most magnetic mineral; the ilmenohematite series, $y\mathrm{FeTiO_3} \cdot (1 - y)\mathrm{Fe_2O_3}$, where α-$\mathrm{Fe_2O_3}$ (in its rhombohedral structure) is hematite; maghemite, γ-$\mathrm{Fe_2O_3}$ (in which some iron atoms are missing in the hematite structure); and limonite (hydrous iron oxides). They also include sulfides—namely, the pyrrhotite series, $y\mathrm{FeS} \cdot (1 - y)\mathrm{Fe}_{1-x}\mathrm{S}$.

Table 46 gives some typical values of the apparent susceptibility for various rock types, which usually include some remanent as well as induced magnetization. Values are higher for mafic igneous rocks, especially as the content of magnetite increases. This is illustrated in Figure 104, which illustrates that susceptibility increases with magnetite content for igneous and ore rocks.

A distribution of measured (true) susceptibilities for various rock types is shown in Table 47. Basic refers to those rocks high in iron and magnesium silicates and magnetite, extrusive means formed by cooling after extruding onto the land surface or seafloor. The data in each category are based on at least 45 samples.

Table 48 lists representative values for the magnetic properties J_n (natural remanent magnetization), k (susceptibility), and ratio Q_n. Natural remanent magnetization is some combination of remanences; typically TRM in an igneous rock, perhaps DRM or CRM or both in a sedimentary rock, and all with an additional VRM. The ratio Q_n is typically higher for rocks with a strong, stable remanence—*e.g.*, magnetite-rich and fine-grained extrusive rocks such as seafloor basalts. (R.S.Ca.)

IGNEOUS ROCKS

Igneous rocks, as previously noted, are those formed from the solidification of magma, which is a hot (600° to 1,300° C, or 1,100° to 2,400° F) molten or partially molten rock material. The Earth is composed predominantly of a large mass of igneous rock with a very thin veneer of weathered material—namely, sedimentary rock. Whereas sedimentary rocks are produced by processes operating mainly at the Earth's surface by the disintegration of mostly older igneous rocks, igneous—and metamorphic—rocks are formed by internal processes that cannot be directly observed and that necessitate the use of physical-chemical arguments to deduce their origins. Because of the high temperatures within the Earth, the principles of chemical equilibrium are applicable to the study of igneous and metamorphic rocks, with the latter being restricted to those rocks formed without the direct involvement of magma.

Magma is thought to be generated within the plastic asthenosphere (the layer of partially molten rock underlying the Earth's crust) at a depth below about 60 kilometres (40 miles). Because magma is less dense than the surrounding solid rocks, it rises toward the surface. It may settle within the crust or erupt at the surface from a volcano as a lava flow. Rocks formed from the cooling and solidification of magma deep within the crust are distinct from those erupted at the surface mainly owing to the differences in physical and chemical conditions prevalent in the two environments. Within the Earth's deep crust the temperatures and pressures are much higher than at its surface; consequently, the hot magma cools slowly and crystallizes completely, leaving no trace of the liquid magma. The slow cooling promotes the growth of minerals large enough to be identified visually without the aid of a microscope (called phaneritic, from the Greek *phaneros*, meaning "visible"). On the other hand, magma erupted at the surface is chilled so quickly that the individual minerals have little or no chance to grow. As a result, the rock is either composed of minerals that can be seen only with the aid of a microscope (called aphanitic, from the Greek *aphanēs*, meaning "invisible") or contains no minerals at all (in the latter case, the rock is composed of glass, which is a highly viscous liquid). This results in two groups: (1) plutonic intrusive igneous rocks that solidified deep within the crust and (2) volcanic, or extrusive, igneous rocks formed at the Earth's surface. Some intrusive rocks, known as subvolcanic, were not formed at great depth but were instead injected near the surface where lower temperatures result in a more rapid cooling process; these tend to be aphanitic and are referred to as hypabyssal intrusive rocks.

Intrusive and extrusive rocks

The deep-seated plutonic rocks can be exposed at the surface for study only after a long period of denudation or by some tectonic forces that push the crust upward or

by a combination of the two conditions. (Denudation is the wearing away of the terrestrial surface by processes including weathering and erosion.) Generally, the intrusive rocks have cross-cutting contacts with the country rocks that they have invaded, and in many cases the country rocks show evidence of having been baked and thermally metamorphosed at these contacts. The exposed intrusive rocks are found in a variety of sizes, from small veinlike injections to massive dome-shaped batholiths, which extend for more than 100 square kilometres (40 square miles) and make up the cores of the great mountain ranges.

Extrusive rocks occur in two forms: (1) as lava flows that flood the land surface much like a river and (2) as fragmented pieces of magma of various sizes (pyroclastic materials), which often are blown through the atmosphere and blanket the Earth's surface upon settling. The coarser pyroclastic materials accumulate around the erupting volcano, but the finest pyroclasts can be found as thin layers located hundreds of kilometres from the opening. Most lava flows do not travel far from the volcano, but some low-viscosity flows that erupted from long fissures have accumulated in thick (hundreds of metres) sequences, forming the great plateaus of the world (*e.g.*, the Columbia River plateau of Washington and Oregon and the Deccan Plateau in India). Both intrusive and extrusive magmas have played a vital role in the spreading of the ocean basin, in the formation of the oceanic crust, and in the formation of the continental margins. Igneous processes have been active since the formation of the Earth some 4.6 billion years ago. Their emanations have provided the water for the oceans, the gases for the primordial oxygen-free atmosphere, and many valuable mineral deposits.

Composition

CHEMICAL COMPONENTS

The great majority of the igneous rocks are composed of silicate minerals (meaning that the basic building blocks for the magmas that formed them are made of silicon [Si] and oxygen [O]), but minor occurrences of carbonate-rich igneous rocks are found as well. Indeed, in 1960 a sodium carbonate (Na_2CO_3) lava with only 0.05 weight percent silica (SiO_2) was erupted from Ol Doinyo Lengai, a volcano in northern Tanzania, Africa. Because of the limited occurrence of such carbonate-rich igneous rocks, however, the following discussion will consider the chemistry of silicate rocks only. The major oxide components of the silicate igneous rocks are given in Table 49. The major oxides of the rocks generally correlate well with their silica content: those rocks with low silica content are enriched in magnesium oxide (MgO) and iron oxides (FeO, Fe_2O_3, and Fe_3O_4) and are depleted in soda (Na,O) and potash (K_2O); those with a large amount of silica are depleted in magnesium oxide and iron oxides but are enriched in soda and potash. Both calcium oxide (CaO) and alumina (Al_2O_3) are depleted in the rocks that have a silica content of less than about 45 weight percent, but, above 45 percent, calcium oxide can be as high as 10 percent; this amount decreases gradually as the silica increases. Alumina in rocks that contain more than 45 percent silica is generally above approximately 14 weight percent, with the greatest abundance occurring at an intermediate silica content of about 56 weight percent. Because of the importance of silica content, it has become common practice to use this feature of igneous rocks as a basis for subdividing them into the following groups: silicic (or acid, an old and discredited but unfortunately entrenched term), rocks having more than 66 percent silica; intermediate, rocks with 55 to 66 percent silica; and subsilicic, rocks containing less than 55 percent silica. The latter may be further divided into two groups: basic, rocks with 45 to 55 percent silica and ultrabasic, those containing less than 45 percent. The subsilicic rocks, enriched as they are in iron (Fe) and magnesium (Mg), are termed femic (from *f*errous iron and *m*agnesium), whereas the silicic rocks are referred to as sialic (from *si*lica and *al*uminum, with which they are enriched) or salic (from silica and *al*uminum).

Silica content

The silica content also reflects the mineral composition of the rocks. As the magma cools and begins to crystallize, silica is taken from the magma to be combined with the other cationic oxides to form the silicate minerals. For example, one mole of SiO_2 is combined with one mole of MgO to make the magnesium-rich pyroxene, $MgSiO_3$ (enstatite): $SiO_2 + MgO \rightarrow MgSiO_3$. Two moles of SiO_2 are needed to be combined with one mole each of CaO and Al_2O_3 to make the calcium-rich plagioclase, $CaAl_2Si_2O_8$ (anorthite). However, in a case where magma does not have enough silica relative to the magnesium oxide to produce the pyroxene, the magma will compensate by making a magnesium-olivine (forsterite; Mg_2SiO_4), along with the pyroxene, since the olivine requires only one-half as much silica for every mole of magnesium oxide. On the other hand, a silicic magma may have excess silica such that some will be left after all the silicate minerals were formed from the combination of the oxides; the remaining "free" silica crystallizes as quartz or its polymorphs. The former case usually occurs in subsilicic rocks that characteristically will have silicate minerals like magnesium-olivine, sodium-nepheline ($NaAlSiO_4$, which requires only one mole of silicon for every mole of sodium [Na]), and leucite ($KAlSi_2O_6$, which requires only two moles of silicon to one mole of potassium [K]). These three minerals substitute in part for enstatite, albite ($NaAlSi_3O_8$, requiring three moles of silicon for one mole of sodium), and orthoclase feldspar ($KAlSi_3O_8$, requiring three moles of silicon for one mole of potassium), respectively. Quartz clearly will not be present in these rocks. Minerals such as magnesium-olivine, nepheline, and leucite are termed undersaturated (with respect to silica), and the subsilicic rocks that contain them are termed undersaturated as well. In the case of rocks that have excess silica, the silicic rocks will have quartz and magnesium-pyroxene, which are considered saturated minerals, and the rocks that contain them are termed supersaturated.

MINERALOGICAL COMPONENTS

The major mineralogical components of igneous rocks can be divided into two groups: felsic (from *fel*dspar and *si*lica) and mafic (from *ma*gnesium and *f*errous iron). The felsic minerals include quartz, tridymite, cristobalite, feldspars (plagioclase and alkali feldspar), feldspathoids (nepheline and leucite), muscovite, and corundum. Because felsic minerals lack iron and magnesium, they are generally light in colour and consequently are referred to as such or as leucocratic. The mafic minerals include olivine, pyroxenes, amphiboles, and biotites, all of which are dark in colour. Mafic minerals are said to be melanocratic. These terms can be applied to the rocks, depending on the relative proportion of each type of mineral present. In this regard, the term colour index, which refers to the total percentage of the rock occupied by mafic minerals, is useful. Felsic rocks have a colour index of less than 50, while mafic rocks have a colour index above 50. Those rocks that have a colour index above 90 are referred to as ultramafic. These terms are to be used only for the mineralogical content of igneous rocks because they do not necessarily correlate directly with chemical terms. For example, it is common to find a felsic rock composed almost entirely of the mineral plagioclase, but in chemical terms, such a rock is a subsilicic basic rock. Another example is an ig-

Felsic and mafic rocks

neous rock consisting solely of pyroxene. Mineralogically it would be termed ultramafic, but chemically it is a basic igneous rock with a silica content of about 50 percent.

The influence of supersaturation and undersaturation on the mineralogy of a rock was noted above. During the crystallization of magmas, supersaturated minerals will not be formed along with undersaturated minerals. Supersaturated minerals include quartz and its polymorphs and a low-calcium orthorhombic pyroxene (called hypersthene). These cannot coexist with any of the feldspathoids (*e.g.*, leucite and nepheline) or magnesium-rich olivine. In volcanic rocks that have been quenched (cooled rapidly) such that only a small part of the magma has been crystallized, it is possible to find a magnesium-rich olivine crystal surrounded by a glass that is saturated or supersaturated. In this case, the outer rim of the olivine may be corroded or replaced by a magnesium-rich pyroxene (called a reaction rim). The olivine was the first to be crystallized, but it was in the process of reacting with the saturated magma to form the saturated mineral when an eruption halted the reaction. Had the magma been allowed to crystallize fully, all the magnesium-rich olivine would have been transformed into the magnesium-rich pyroxene and quartz may have been crystallized.

Accessory minerals present in igneous rocks in minor amounts include allanite, apatite, garnets, ilmenite, magnetite, sphene, spinel, and zircon. Glass may be a major phase in some volcanic rock but, when present, is usually found in minor amounts. Igneous rocks that were exposed to weathering and circulating groundwater have undergone some degree of alteration. Common alteration products are talc or serpentine formed at the expense of olivine, chlorites replacing pyroxene and amphiboles, iron oxides replacing any mafic mineral, clay minerals and epidote formed from the feldspars, and calcite that may be formed at the expense of any calcium-bearing mineral by interaction with a carbon dioxide (CO_2)-bearing solution. Glass is commonly altered to clay minerals and zeolite. In some cases, however, glass has undergone a devitrification process (in which it is transformed into a crystalline material) initiated by reaction of the glass with water or by subsequent reheating. Common products of devitrification include quartz and its polymorphs, alkali feldspar, plagioclase, pyroxene, zeolite, clays, and chlorite.

Textural features

The texture of an igneous rock normally is defined by the size and form of its constituent mineral grains and by the spatial relationships of individual grains with one another and with any glass that may be present. Texture can be described independently of the entire rock mass, and its geometric characteristics provide valuable insights into the conditions under which the rock was formed.

Among the most fundamental properties of igneous rocks are crystallinity and granularity, two terms that closely reflect differences in magma composition and the differences between volcanic and various plutonic environments of formation. Crystallinity generally is described in terms of the four categories shown in Table 50.

Table 50: Crystallinity Categories of Igneous Rocks

crystallinity	rock term
Entirely crystalline	holocrystalline
Crystalline material and subordinate glass	hemicrystalline or hypocrystalline
Glass and subordinate crystalline material	hemihyaline or hypohyaline
Entirely glassy	holohyaline or hyaline

Those holocrystalline rocks in which mineral grains can be recognized with the unaided eye are called phanerites, and their texture is called phaneritic; some examples are shown in Figure 105. Those with mineral grains so small that their outlines cannot be resolved without the aid of a hand lens or microscope are termed aphanites, and their texture is termed aphanitic (see Figure 106). Aphanitic rocks are further described as either microcrystalline or cryptocrystalline, according to whether or not their individual constituents can be resolved under the microscope. The subaphanitic, or hyaline, rocks are referred to as glassy, or vitric, in terms of granularity.

Aphanitic and glassy textures represent relatively rapid cooling of magma and, hence, are found mainly among the volcanic rocks. Slower cooling, either beneath the Earth's surface or within very thick masses of lava, promotes the formation of crystals and, under favourable circumstances of magma composition and other factors, their growth to relatively large sizes. The resulting phaneritic rocks are so widespread and so varied that it is convenient to specify their grain size as shown in Table 51.

Crystal formation

Table 51: Categories of Rock Grain Size

terms in common use	general grain size	
	igneous rocks in general	pegmatites
Fine-grained	<1 mm	<1 in.
Medium-grained	1–5 mm	1 in.–4 in.
Coarse-grained	5 mm–2 cm	4 in.–12 in.
Very coarse-grained	>2 cm	>12 in.

The general grain size ordinarily is taken as the average diameter of dominant grains in the rock; for the pegmatites, which are special rocks with extremely large crystals, it can refer to the maximum exposed dimensions of dominant grains. Most aphanitic rocks are characterized by mineral grains less than 0.3 millimetre (0.01 inch) in diameter, and those in which the average grain size is less than 0.1 millimetre (0.004 inch) are commonly described as dense.

A major part of rock texture is fabric or pattern, which is a function of the form and outline of its constituent grains, their relative sizes, and their mutual relationships in space. Many specific terms have been employed to shorten the description of rock fabrics, and even the sampling offered here may seem alarmingly extensive. It should be noted, however, that fabric provides some of the most useful clues to the nature and sequence of magmatic crystallization.

The degree to which mineral grains show external crystal faces can be described as euhedral or panidiomorphic (fully crystal-faced), subhedral or hypidiomorphic (partly faced), or anhedral or allotriomorphic (no external crystal faces). Quite apart from the presence or absence of crystal faces, the shape, or habit, of individual mineral grains is described by such terms as equant, tabular, platy, elongate, fibrous, rodlike, lathlike, needlelike, and irregular. A more general contrast can be drawn between grains of equal (equant) and inequal dimensions. Even-grained, or equigranular, rocks are characterized by essential minerals that all exhibit the same order of grain size, but this implied equality need not be taken too literally. For such rocks the combination terms panidiomorphic-granular, hypidiomorphic-granular, and allotriomorphic-granular are applied according to the occurrence of euhedral, subhedral, and anhedral mineral grains within them. Many fine-grained allotriomorphic-granular rocks are more simply termed sugary, saccharoidal, or aplitic.

Rocks that are unevenly grained, or inequigranular, are generally characterized either by a seriate fabric, in which the variation in grain size is gradual and essentially continuous, or by a porphyritic fabric, involving more than one distinct range of grain sizes. Both of these kinds of texture are common. The relatively large crystals in a porphyritic rock ordinarily occur as separate entities, known as phenocrysts, set in a groundmass or matrix of much finer-grained crystalline material or glass (see Figure 106). Quite commonly in many volcanic rocks, phenocrysts are aggregated. When this is observed, the term glomeroporphyritic is used to describe the texture, and the aggregate is referred to as a glomerocryst. In some cases, such glomerocrysts are monomineralic, but more commonly they are composed of two or more minerals. Based on chemical composition, texture, and other criteria such as isotopic analysis, it has been demonstrated that some phenocrysts and glomerocrysts were not crystallized from the

host magma but rather were accidentally torn from the country rock by the magma as it rose to the surface. When this has occurred, these phenocrysts are referred to as xenocrysts, while the aggregates can be termed xenoliths. The size of phenocrysts is essentially independent of their abundance relative to the groundmass, and they range in external form from euhedral to anhedral. Most of them are best described as subhedral. Because the groundmass constituents span almost the full ranges of crystallinity and granularity, porphyritic fabric is abundantly represented among the phaneritic, aphanitic, and glassy rocks.

The sharp break in grain size between phenocrysts and groundmass reflects a corresponding change in the conditions that affected the crystallizing magma. Thus, the phenocrysts of many rocks probably grew slowly at depth, following which the nourishing magma rose to the Earth's surface as lava, cooled much more rapidly, and congealed to form a finer-grained or glassy groundmass. A porphyritic volcanic rock with a glassy groundmass is described as having a vitrophyric texture and the rock can be called a vitrophyre. Other porphyritic rocks may well reflect less drastic shifts in position and perhaps more subtle and complex changes in conditions of temperature, pressure, or crystallization rates. Many phenocrysts could have developed at the points where they now occur, and some may represent systems with two fluid phases, magma and coexisting gas. Appraisals of the composition of phenocrysts, their distribution, and their periods of growth relative to the accompanying groundmass constituents are important to an understanding of many igneous processes.

The articulation of mineral grains is described in terms of planar, smoothly curved, sinuous, sutured, interlocked, or irregular surfaces of mutual boundary. The distribution and orientation of mineral grains and of mineral grains and glass are other elements of fabric that can be useful in estimating the conditions and sequence of mineral formation in igneous rocks. The following are only a few of the most important examples:

Directive textures are produced by the preferred orientation of platy, tabular, or elongate mineral grains to yield grossly planar or linear arrangements; they are generally a result of magmatic flowage.

Graphic texture refers to the regular intergrowth of two minerals, one of them generally serving as a host and the other appearing on surfaces of the host as striplike or cuneiform units with grossly consistent orientation; the graphic intergrowth of quartz in alkali feldspar is a good example.

Ophitic texture is the association of lath-shaped euhedral crystals of plagioclase, grouped radially or in an irregular mesh, with surrounding or interstitial large anhedral crystals of pyroxene; it is characteristic of the common rock type known as diabase.

Poikilitic texture describes the occurrence of one mineral that is irregularly scattered as diversely oriented crystals within much larger host crystals of another mineral.

Reaction textures occur at the corroded margins of crystals, from the corrosive rimming of crystals of one mineral by finer-grained aggregates of another, or as a result of other features that indicate partial removal of crystalline material by reaction with magma or other fluid.

Pyroclastic texture

Pyroclastic texture results from the explosive fragmentation of volcanic material, including magma (commonly the light, frothy pumice variety and glass fragments called shards), country rock, and phenocrysts. Fragments less than 2 millimetres in size are called ash, and the rock formed of these is called tuff; fragments between 2 and 64 millimetres are lapilli and the rock is lapillistone; fragments greater than 64 millimetres are called bombs if rounded or blocks if angular, and the corresponding rock is termed agglomerate or pyroclastic breccia, respectively. Commonly, many of these pyroclastic rocks have been formed by dense hot clouds that hug the ground and behave much like a lava flow and hence are given the name pyroclastic flow. Most of these flows are composed of ash-size material; therefore, they are called ash flows and the rocks deposited by them are called ash-flow tuffs. A more general term for rocks deposited by these flows that does not specify size of fragments is ignimbrite. Ash-flow tuffs and other ignimbrites often have zones in which the fragments have been welded. These zones are termed welded tuffs and display a directive planar texture (called eutaxitic) that results from compaction and flattening of pumice fragments. Such pyroclastic flows were responsible for many of the deposits of the eruption of Mount St. Helens in Washington State, U.S., on May 18, 1980. Most eruptions eject fragments that are borne by the wind and deposited subaerially (on the land surface). These deposits are said to be ash-fall tuffs and are recognized by their

lamination (formation in thin layers that differ in grain size or composition). They commonly blanket the topography in contrast to the ash-flow deposits, which flow around topographic highs and which are completely unsorted.

Replacement textures occur where a mineral or mineral aggregate has the external crystal form of a preexisting different mineral (pseudomorphism) or where the juxtaposition of two minerals indicates that one was formed at the expense of the other.

Finally, crystal zoning describes faintly to very well-defined geometric arrangements of portions within individual crystals that differ significantly in composition (or some other property) from adjacent portions; most common are successive shells grouped concentrically about the centres of crystals, presumably reflecting shifts in conditions during crystal growth.

Structural features

The structure of an igneous rock is normally taken to comprise the mutual relationships of mineral or mineral-glass aggregates that have contrasting textures, along with layering, fractures, and other larger-scale features that transect or bound such aggregates. Structure often can be described only in relation to masses of rock larger than a hand specimen, and most of its individual expressions can be closely correlated with physical conditions that existed when the rock was formed.

SMALL-SCALE STRUCTURAL FEATURES

Among the most widespread structural features of volcanic rocks are the porelike openings left by the escape of gas from the congealing lava. Such openings are called vesicles, and the rocks in which they occur are said to be vesicular. Where the openings lie close together and form a large part of the containing rock, they impart to it a slaglike, or scoriaceous, structure. Their relative abundance is even greater in the type of sialic glassy rock known as pumice, which is essentially a congealed volcanic froth. Most vesicles can be likened to peas or nuts in their ranges of size and shape; those that were formed when the lava was still moving tend to be flattened and drawn out in the direction of flow. Others are cylindrical, pearlike, or more irregular in shape, depending in part on the manner of escape of the gas from the cooling lava; most of the elongate ones occur in subparallel arrangements.

Many vesicles have been partly or completely filled with quartz, chalcedony, opal, calcite, epidote, zeolites, or other minerals. These fillings are known as amygdules, and the rock in which they are present is amygdaloidal. Some are concentrically layered, others also include centrally disposed series of horizontal layers, and still others are featured by central cavities into which well-formed crystals project.

Features of glassy rocks

Spherulites are light-coloured subspherical masses that commonly consist of tiny fibres and plates of alkali feldspar radiating outward from a centre. Most range from pinpoint to nut size, but some are as much as several feet in diameter. The relatively large ones tend to be internally complex and to contain concentric shells of feldspar fibres with or without accompanying quartz, tridymite, or glass. Spherulites occur mainly in glassy volcanic rocks; they also are present in some partly or wholly crystalline rocks that include shallow-seated intrusive types. Many evidently are products of rapid crystallization, perhaps at points of gas concentration in the freezing magmas. Others, in contrast, were formed more slowly, by devitrification of volcanic glasses, presumably not long after they congealed and while they were still relatively hot.

Lithophysae, also known as stone bubbles, consist of concentric shells of finely crystalline alkali feldspar separated by empty spaces; thus, they resemble an onion or a newly blooming rose. Commonly associated with spherulites in glassy and partly crystalline volcanic rocks of salic composition, many lithophysae are about the size of walnuts. They have been ascribed to short episodes of rapid crystallization, alternating with periods of gas escape when the open spaces were developed by thrusting the feldspathic shells apart or by contraction associated with cooling. The curving cavities commonly are lined with tiny crystals of quartz, tridymite, feldspar, topaz, or other minerals deposited from the gases.

Some glassy rocks of silicic composition are marked by domains of strongly curved, concentrically disposed fractures that promote breakage into rounded masses of pinhead to walnut size. Because their surfaces often have a pearly or shiny lustre, the name perlite is applied to such rocks. Perlite is most common in glassy silicic rocks that have interacted with water to become hydrated. During the hydration process, water enters the glass, breaking the silicon-oxygen bonds and causing an expansion of the glass structure to form the curved cracks. The extent of hydration of glass, indicating the amount of perlite that has been formed from the glass, depends on the climate and on time. In a given area where the climate is expected to be consistent, the thickness of the hydration of the glass surface has been used by archaeologists to date artifacts such as arrowheads composed of the dark volcanic glass known as obsidian and made by early native Americans.

Numerous structural features of comparably small scale occur among the intrusive rocks; these include miarolitic, orbicular, plumose, and radial structures. Miarolitic rocks are salic phanerites distinguished by scattered pods or layers, ordinarily several centimetres in maximum thickness, within which their essential minerals are coarser-grained, subhedral to euhedral, and otherwise pegmatitic in texture. Many of these small interior bodies, called miaroles, contain centrally disposed crystal-lined cavities that are known as druses or miarolitic cavities. An internal zonal disposition of minerals also is common, and the most characteristic sequence is alkali feldspar with graphically intergrown quartz, alkali feldspar, and a central filling of quartz. Miarolitic structure probably represents local concentration of gases during very late stages in consolidation of the host rocks.

The term orbicular is applied to rounded, onionlike masses with distinct concentric layering that are distributed in various ways through otherwise normal-appearing phaneritic rocks of silicic to basic composition. The layers within individual masses are typically thin, irregular, and sharply defined, and each differs from its immediate neighbours in composition or texture. Some layers contain tabular or prismatic mineral grains that are oriented radially with respect to the containing orbicule and, hence, are analogous to spherulitic layers in volcanic rocks. The minerals of most orbicules are the same as those of the enclosing rock, but they are not necessarily present in the same proportions. The concentric structure appears to reflect rhythmic crystallization about specific centres, commonly at early stages in consolidation of the general rock mass.

Orbicular structures

The normal fabric of some relatively coarse-grained plutonic rocks is interrupted by clusters of crystals with radial grouping but without concentric layering. A characteristic plumelike, spraylike, or rosettelike structure is imparted by the markedly elongate form of the participating crystals or crystal aggregates, which seem to have developed outward from common centres by direct crystallization from magma or by replacement of preexisting solid material.

LARGE-SCALE STRUCTURAL FEATURES

Many kinds of larger-scale features occur among both the intrusive and the extrusive rocks (see Figure 107). Most of these are mentioned later in connection with rock occurrence or are discussed in other articles, but several are properly introduced here:

Clastic structures. These are various features that express the accumulation of fragments or the rupturing and dislocation of solid material. In volcanic environments they generally result from explosive activity or the incorporation of solid fragments by moving lava; as such, they characterize the pyroclastic rocks. Among the plutonic rocks, they appear chiefly as local to very extensive zones of pervasive shearing, dislocation, and granulation, commonly best recognized under the microscope. Those developed prior to final consolidation of the rock are termed protoclastic; those developed after final consolidation, cataclastic.

Richard H. Jahns

Flow structures. These are planar or linear features that result from flowage of magma with or without contained crystals. Various forms of faintly to sharply defined layering and lining typically reflect compositional or textural inhomogeneities, and they often are accentuated by concentrations or preferred orientation of crystals, inclusions, vesicles, spherulites, and other features.

Fractures. These are straight or curving surfaces of rupture directly associated with the formation of a rock or later superimposed upon it. Primary fractures generally can be related to emplacement or to subsequent cooling of the host rock mass. The columnar jointing found in many basic volcanic rocks is a typical result of contraction upon cooling.

Inclusions. These are rounded to angular masses of solid material enclosed within a rock of recognizably different composition or texture. Those consisting of older material not directly related to that of their host are known as xenoliths, and those representing broken-up and detached older parts of the same igneous body that encloses them are termed cognate xenoliths or autolithes.

Xenoliths and autolithes

Pillow structures. These are aggregates of ovoid masses, resembling pillows or grain-filled sacks in size and shape, that occur in many basic volcanic rocks. The masses are separated or interconnected, and each has a thick vesicular crust or a thinner and more dense glassy rind. The interiors ordinarily are coarser-grained and less vesicular. Pillow structure is formed by rapid chilling of highly fluid lava in contact with water or water-saturated sediments, accompanied by the development of budlike projections with tough, elastic crusts. As additional lava is fed into each bud, it grows into a pillow and continues to enlarge until rupture of the skin permits escape of fresh lava to form a new bud and a new pillow.

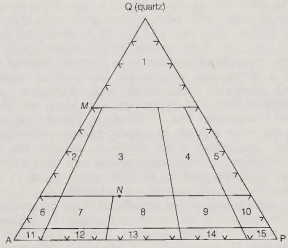
Segregations. These are special types of inclusions that are intimately related to their host rocks and in general are relatively rich in one or more of the host-rock minerals. They range from small pods to extensive layers and from early-stage crystal accumulations formed by gravitational settling in magma to very late-stage concentrations of coarse-grained material developed in place.

Zonal structures. These are arrangements of rock units with contrasting composition, or texture, in an igneous body, commonly in a broadly concentric pattern. Chilled margins, the fine-grained or glassy edges along the borders of many extrusive and shallow-seated intrusive bodies, represent quenching of magma along contacts with cooler country rock. Other kinds of zones generally reflect fractional crystallization of magma and are useful in tracing courses of magmatic differentiation, as will be noted later.

Classification of igneous rocks

Igneous rocks are classified on the basis of mineralogy, chemistry, and texture. As discussed earlier, texture is used to subdivide igneous rocks into two major groups: (1) the plutonic rocks, with mineral grain sizes that are visible to the naked eye, and (2) the volcanic and hypabyssal types, which are usually too fine-grained or glassy for their mineral composition to be observed without the use of a petrographic microscope. Being rather coarsely grained, phaneritic rocks readily lend themselves to a classification based on mineralogy since their individual mineral components can be discerned, but the volcanic rocks are more difficult to classify because either their mineral composition is not visible or the rock has not fully crystallized owing to fast cooling. As a consequence, various methods employ chemical composition as the criterion for volcanic igneous rock classification. A commonly used technique was introduced at the beginning of the 20th century by the American geologists C. Whitman Cross, Joseph P. Iddings, Louis V. Pirsson, and Henry S. Washington. In this method, the mineral composition of the rock is recalculated into a standard set of typically occurring minerals that theoretically could have developed from the complete equilibrium crystallization at low temperatures of a magma of the indicated bulk composition. The calculated hypothetical mineral composition is called the norm, and the minerals constituting the standard set are termed normative minerals, since they are ordinarily found in igneous rocks. The rock under analysis may then be classified according to the calculated proportions of the normative minerals.

Because other methods for calculating the norm have been devised, this original norm is referred to as the CIPW norm after the initials of the four petrologists who devised the system. The norm calculation allows the petrologist studying an aphanitic rock to "see" the mineral assemblage that corresponds well with the actual mineral assemblage of a plutonic rock of the same composition that had crystallized under equilibrium conditions. Moreover, the norm has been shown to have a thermodynamic basis. The concept of silica saturation discussed above is incorporated into the norm, which will show whether a magma of a certain composition is supersaturated, saturated, or undersaturated by the presence or absence of normative minerals such as quartz, hypersthene, olivine, and the feldspathoids.



CIPW norm

CLASSIFICATION OF PLUTONIC ROCKS

A plutonic rock may be classified mineralogically based on the actual proportion of the various minerals of which it is composed (called the mode). In any classification scheme, boundaries between classes are set arbitrarily; however, if the boundaries can be placed closest to natural divisions or gaps between classes, they will seem less random and subjective, and the standards will facilitate universal understanding. In order to set boundaries nearest to the population lows (of constituent minerals) and to achieve an international consensus, a poll among the world's petrologists was conducted and a modal classification for plutonic igneous rocks was devised. Based mainly on this poll, the International Union of Geological Sciences (IUGS) Subcommission on the Systematics of Igneous Rocks in 1973 suggested the use of the modal composition for all plutonic igneous rocks with a colour index less than 90 (Figure 108) and for those plutonic ultramafic rocks with a colour index greater than 90 (Figure 109).

The plotting of rock modes on these triangular diagrams is simpler than it may appear. If the colour index is less than 90 and quartz (Q) is present, then the three components, Q + A (alkali feldspar) + P (plagioclase), are recalculated from the mode to sum to 100 percent and Figure 108 is used. Each component is represented by the corners of the equilateral triangle, the length of whose sides are divided into 100 equal parts. Any composition plotting at a corner, therefore, has a mode of 100 percent of the corresponding component. Any point on the sides of the triangle represents a mode composed of the two adjacent corner components. For example, a rock with 60 percent Q and 40 percent A will plot on the QA side at a location 60 percent of the distance from A to Q (see point *M* in Figure 108). A rock containing all three components will plot within the triangle. Since the sides of the triangle

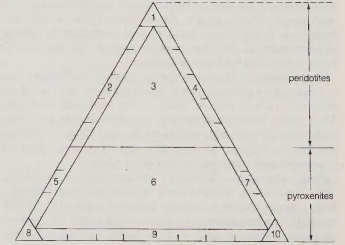
are divided into 100 parts, a rock having a mode of 20 percent Q and 80 percent A + P (in unknown proportions for the moment) will plot on the line that parallels the AP side and lies 20 percent of the distance toward Q from the side AP. If this same rock has 30 percent P and 50 percent A, the rock mode will plot at the intersection of the 20 percent Q line described above, with a line paralleling the QA side at a distance 30 percent toward P from the QA side (see point *N* in Figure 108). The third intersecting line for the point is necessarily the line paralleling the QP side at 50 percent of the distance from the side QP toward A.

A rock with 25 percent Q, 35 percent P, and 40 percent A plots in the granite field, whereas one with 25 percent Q, 60 percent P, and 15 percent A plots in the granodiorite field. The latter is close to the average composition of the continental crust of the Earth. Igneous rocks normally do not exceed about 50 percent quartz, and the feldspathoidal rocks are relatively rare. The most common plutonic rocks are those in fields numbered 3, 4, 5, 8, 9, 10, and 15. These are found in what have been called granite (used in a loose sense) batholiths, which are irregularly shaped large bodies covering an area greater than 100 square kilometres. Batholiths constitute the cores of the great mountain ranges, such as the Rockies in western North America and the Sierra Nevada in California, U.S. Typically these batholiths are composites of smaller intrusions, each of which may display several different rock types. The average composition is close to that of a granodiorite, but in many batholiths the sequence of intrusions progresses from basic to acidic, with gabbro or quartz diorite being emplaced first. In the Sierra Nevada batholith, the dominant rocks are quartz monzonite and granodiorite, with intrusions including quartz diorite in the far western rim and granite in the east. Batholiths contain medium- to coarse-grained rocks with hypidiomorphic-granular texture. The rocks are generally leucocratic; diorites and quartz diorites typically contain less than 30 percent mafic minerals—*e.g.*, hornblende and biotite. Pyroxenes are rare but are more commonly found in the gabbros. Mineralogically the ratio of hornblende to biotite, the colour index, the calcium content of the plagioclase feldspar, and the ratio of plagioclase to alkali feldspar decrease from diorite to quartz diorite to granodiorite and granite. Common accessory minerals include apatite, sphene, and an opaque mineral such as magnetite or ilmenite.



Ideally it would be preferable to use the same modal scheme for volcanic rocks. This is recommended whenever possible; hence, for this purpose, the volcanic or hypabyssal equivalent of the plutonic rocks are listed in parentheses in Figure 108. It should be noted that the dividing lines and boxes are identical to those for the plutonic rocks.

CLASSIFICATION OF VOLCANIC AND HYPABYSSAL ROCKS

Owing to the aphanitic texture of volcanic and hypabyssal rocks, their modes cannot be readily determined; consequently, a chemical classification is widely accepted and employed by most petrologists. One popular scheme is based on the use of both chemical components and normative mineralogy. Because most lay people have little access to analytic facilities that yield igneous rock compositions, only an outline will be presented here in order to provide an appreciation for the classification scheme.

The first major division is based on the alkali (soda + potash) and silica contents (see Figure 110), which yield two groups, the subalkaline and alkaline rocks. The subalkaline rocks have two divisions based mainly on the iron content (Figure 111) with the iron-rich group called the tholeiitic series and the iron-poor group called calc-alkalic. The former group is most commonly found along the oceanic ridges and on the ocean floor; the latter group is characteristic of the volcanic regions of the continental margins (convergent, or destructive, plate boundaries; see below *Forms of occurrence: Distribution of igneous rocks on the Earth's surface*). In some magmatic arcs (groups of islands arranged in a curved pattern), notably Japan, both the tholeiitic and calc-alkalic series occur. This is the case, for example, in the volcanoes of northeastern Honshu, the largest of Japan's four main islands, and both series may be found within the same volcano. The alkaline rocks frequently occur on oceanic islands (usually formed during the late stages of magma consolidation after tholeiitic eruptions) and in continental rifts (extensive

fractures). Based on the relative proportions of soda and potash, the calc-alkalic series is subdivided into the sodic and potassic series.

Chemically the subalkaline rocks are saturated with respect to silica; consequently, they have normative minerals such as hypersthene [low-calcium orthopyroxene, $(Mg, Fe)_2Si_2O_6$] and quartz but lack nepheline and olivine (in the presence of quartz). This chemical property also is reflected in the mode of the basic members that have two pyroxenes, hypersthene and augite [$Ca(Mg, Fe)Si_2O_6$], and perhaps quartz. Plagioclase is common in phenocrysts, but it can also occur in holocrystalline rocks in the microcrystalline matrix along with the pyroxenes and an iron–titanium oxide phase. In addition to the differences in iron content between the tholeiitic and calc-alkalic series, the latter has a higher alumina content (16 to 20 percent), and the range in silica content is larger (48 to 75 percent compared to 45 to 63 percent for the former). Hornblende and biotite phenocrysts are common in the calc-alkalic andesites and dacites but are lacking in the tholeiites except as alteration products. The dacites and rhyolites commonly have phenocrysts of plagioclase, alkali feldspar (usually sanidine), and quartz in a glassy matrix. Hornblende and plagioclase phenocrysts are more widespread in dacites than in rhyolites, which have more biotite and alkali feldspar. When occurring near volcanic vents, (openings from which volcanic materials are brought to the Earth's surface), basalts and andesites of both series are found as tuffs or agglomerates; otherwise, they typically occur as flows. Dacite and rhyolite occur as flows near vents but are most commonly found as tuffs composed of fragmented pieces of glass, phenocrysts, and rock.

The alkaline rocks typically are chemically undersaturated with respect to silica; hence they lack normative hypersthene (*i.e.*, they have only one pyroxene, the calcium-rich augite) and quartz but have normative nepheline. Microscopic examination of the alkali olivine basalts usually reveals phenocrysts with an abundance of olivine, one pyroxene (augite, which is usually titanium-rich), and plagioclase. Nepheline may be seen in the matrix. Trachytes typically are leucocratic with an abundance of feldspars aligned roughly parallel to the direction of the lava flow.

Origin and distribution

ORIGIN OF MAGMAS

Basaltic magmas that form the oceanic crust of the Earth are generated in the asthenosphere at a depth of about 70 kilometres. The mantle rocks located at depths from about 70 to 200 kilometres are believed to exist at temperatures slightly above their melting point, and possibly 1 or 2 percent of the rocks occur in the molten state. As a result, the asthenosphere behaves plastically, and upon penetrating this zone seismic waves experience a slight drop in velocity; this shell came to be known as the low velocity zone. Only after the acceptance of the plate tectonic theory has this zone become known as the asthenosphere (see PLATE TECTONICS). The most common mantle rock within the asthenosphere is peridotite, which is composed predominantly of magnesium-rich olivine, along with lesser amounts of chromium diopside and enstatite and an even smaller quantity of garnet. Peridotite may undergo partial melting to produce magmas with different compositions.

Low velocity zone

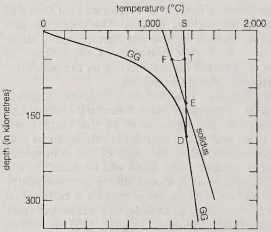

Figure 112: A proposed temperature distribution within the Earth. The geothermal gradient is represented by the curve GG. The melting curve (solidus) for a representative mantle rock is shown. The adiabatic rise of mantle rock is illustrated by the curve DS. See text for further explanation.

Theories on the generation of basaltic magma mainly attribute its origin to the derivation of heat from within peridotite rather than by some outside source such as the radioactive decay of uranium, thorium, and potassium, which are only of minor consequence. Because of the difference in composition between basalt and peridotite, only a small amount of heat is needed to produce about 3 to at most 25 percent melt. Many theories have been proposed, but only the simplest and most popular is discussed here. The change in the temperature of the Earth as a function of depth, given by the estimated geothermal gradient, and the experimentally based melting curve (solidus) of the peridotite are illustrated in Figure 112. At depth D, the geothermal gradient curve and the solidus of the peridotite have their closest approach, but the peridotite is still solid. Diverse mechanisms have been proposed to explain the cause for the intersection here of the two curves. One theory suggests that a decrease in pressure (equivalent to depth) at constant composition and without loss of heat will cause the peridotite to melt along the curve DS. This is identical to an adiabatic cooling process (one without an overall loss or gain of heat) in which temperature will drop slightly owing to the expansion of the rock that occurs in response to the pressure decrease. The drop in temperature is about 10 times smaller than the drop in temperature along the solidus for the same decrease in pressure. Physically, the peridotite rises to a lesser depth

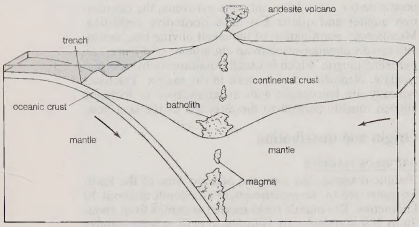

Figure 113: Collision of a continental plate with an oceanic plate. The oceanic plate is shown subducting below the continental crust. Melting of the crust or of the mantle above the subducting plate occurs only at a depth of about 100 kilometres below the Earth's surface.

owing to convection in the mantle (the zone below the Earth's crust) without any exchange of heat. Melting is initiated when the curve DS intersects the melting curve at point E. As the peridotite continues to rise, it will follow the melting curve, continually producing more melt. This results from the peridotite providing its own heat. To illustrate this, consider the peridotite following the adiabatic curve DS from E to point T where it is (T − F) degrees above the melting curve. Allowing the peridotite to cool at this pressure from T to F releases heat that will be consumed in the melting process. The peridotite can be thought of as making similar but infinitesimally small steps like E to T to F as it moves along the solidus. In this way heat is provided for the melting as the peridotite moves continuously along the solidus.

Granitic and andesitic magmas

Granitic, or rhyolitic, magmas and andesitic magmas are generated at convergent plate boundaries where the oceanic lithosphere (the outer layer of the Earth composed of the crust and upper mantle) is subducted so that its edge is positioned below the edge of the continental plate or another oceanic plate. Heat will be added to the subducting lithosphere as it moves slowly into the hotter depths of the mantle. The andesitic magma is believed to be generated in the wedge of mantle rock below the crust and above the subducted plate (Figure 113) or within the subducted plate itself. The former requires the partial melting of a "wet" peridotite. Experiments conducted at pressures simulating mantle conditions have demonstrated that peridotite will produce andesitic melts during partial melting under hydrous conditions. The latter theory suggests that the subducted basaltic crust is partially melted and may be combined with some subducted oceanic sediments to form andesites. A third theory involves the mixing of basaltic magma that was generated in the mantle with granitic or rhyolitic magma or with crustal rocks. The silicic magmas can be formed by a combination of two processes; the presence of water under pressure lowers the melting temperature by as much as 200° C (392° F) and thereby expedites magma generation. At a convergent plate boundary, the lower continental crust is heated to a temperature near its melting point by being pushed downward into hotter regions of the mantle. Basaltic or andesitic magma generated below the crust may accumulate near the Moho, which is a discontinuity that separates the Earth's crust from its mantle. As the magma cools, it crystallizes and releases its latent heat of crystallization. This evolved heat is transferred to the lower crustal rocks along with the simple heat released by cooling. If the lower crustal rocks contain some water, their melting temperatures would be lowered and the heating provided by the above processes would possibly be sufficient to partially melt the crustal rocks producing rhyolitic magma.

NATURE OF MAGMAS

Magmas are chemically complex fluid systems that differ in many ways from ordinary solutions, in which water is the solvent and the dominant constituent. They can be thought of as mutual solutions, or melts, of rock-forming components that are variously present as simple ions, as complex ions and ionic groups, and as molecules. The most abundant of the simple ions in common magmas are such singly and doubly charged cations as Na^+, K^+, Ca^{2+}, Mg^{2+}, and Fe^{2+}. Because these ions can move about rather freely in the system, they occupy no fixed positions with respect to other ions that are present. In contrast, the smaller and more highly charged cations, notably Si^{4+}, Al^{3+}, and (to a lesser degree) Fe^{3+}, are surrounded or screened by O^{2-} ions and other anions (negative ions) to form parts of relatively stable complex ions such as $(SiO_4)^4$, $(AlO_4)^{5-}$, and $(FeO_4)^{9-}$. Simple anions, including F^-, Cl^-, O^{2-}, and $(OH)^-$, ordinarily are present in much smaller amounts. Water, hydrochloric acid (HCl), hydrogen fluoride (HF), carbon dioxide (CO_2), and other volatile molecular substances occur as well, generally in equilibrium with ionic forms such as $(OH)^-$, Cl^-, F^-, and $(CO_3)^{2-}$.

Because the bond that unites silicon and oxygen is a remarkably strong one, $(SiO_4)^{4-}$ ions are stable in magmas even at exceedingly high temperatures. They also tend to join with one another, or polymerize, to form more complex anionic groups, a tendency that is especially great in the more silicic magmas. The joining is accomplished by a sharing of oxygen ions between adjacent silicon ions to form Si-O-Si bridges like those in many silicate and aluminosilicate minerals; in the simplest such case, $(Si_2O_7)^{6-}$ ions are the result. Because the $(AlO_4)^{5-}$ ions also have a strong tendency to polymerize, most of the large ionic groups in magmas probably contain both silicon and aluminum ions. These groups, which resemble the frameworks of many rock-forming minerals but are geometrically less regular, significantly affect the viscosity and crystallization of magmas.

Viscosity of magmas

The viscosity of magmas, which spans an enormous range of values, affects their flow behaviour, the movements of crystals and inclusions of foreign matter within them, the diffusion of materials through them, the growth of crystals from them, and the explosivity of eruptions (when aided by growth of gas bubbles near the surface). Lava flows are thin and rapid for low-viscosity magmas, but thick and slow for viscous flows. Fluid magma promotes the growth of large crystals such as the ones found in pegmatites, but crystal growth is prevented in viscous magmas, which usually are quenched as glass. Highly explosive eruptions such as occurred at Mount St. Helens commonly result from gas bubbles nucleating, growing, and rising in a highly viscous magma. It can be demonstrated thermodynamically that the overpressure (excess rock pressure) developed in growing and rising bubbles is inversely proportional to their radii. In fluid magmas, gas bubbles grow large in size and rise quickly, which causes their pressures to be expended; hence, only a spectacular fountaining of hot lava is observed at the surface. In contrast, a viscous magma prevents the growth of bubbles, so that they will rise slowly while retaining excess pressure; as a result, the associated volcano erupts violently. Energies equivalent to the amount produced by several nuclear bombs are released in such explosions. Viscosity increases greatly with decreasing temperature and less markedly with increasing pressure. It also can be governed in part by the amount and distribution of any solid materials or bubbles of gas present, which both tend to increase viscosity. Finally, it varies considerably among magmas of differing gross composition, mainly because of the differences in the degree of Si-O and Al-O polymerization. Thus, highly silicic magmas generally are more viscous than basic ones by several orders of magnitude, a difference reflected by contrasts in the eruptive behaviour of rhyolitic and basaltic lavas. Basaltic magmas at 1,100° C can be at least 100,000 times more viscous than water at room temperature, whereas rhyolitic magmas at 800° C are at least 10 million times more viscous than room-temperature water. The presence of volatile constituents can markedly increase the fluidity of magmas, even those that are rich in SiO_2. This effect has been attributed to the breaking of Si-O-Si bridges through substitution of ions such as F^- and $(OH)^-$ for shared O^{2-} ions in elements of the polymerized groups.

A typical magma can be broadly viewed as an assemblage of relatively large and rather closely packed oxygen ions,

among which some cations have considerable mobility; others, such as Si^{4+} and Al^{3+}, tend to occupy positions that are more fixed. The entire system is a dynamic one, however, and even the largest of the Si-O and Al-O ion groups are constantly changing form and position as bonds are broken and new ones are established. If the magma quickly loses thermal energy and cools to a glass, these internal movements are sharply restricted, and the various constituents become essentially frozen in position. If cooling is slower, the contained complex ions and polymerized ion groups have time to assume more regular arrangements and to be stabilized by cations of appropriate size, charge, and other properties. Crystalline solids are thereby formed. Their regular internal structure is relatively conserving of space, and so they have somewhat higher specific gravities than the magma from which they were nourished.

CRYSTALLIZATION FROM MAGMAS

Crystallization temperatures

Because magmas are multicomponent solutions, they do not crystallize at a single temperature at a given pressure like water at 0° C and one atmosphere pressure. Rather, they crystallize over a wide range of temperatures beginning at liquidus temperatures for basaltic magmas as high as 1,150° C and ending as a complete solid at a low solidus temperature of about 800° C. During their crystallization at constant pressure, common minerals that make up basaltic magma (*e.g.*, olivine) become unstable at some temperature and react with the liquid to form a more stable phase. In the case of olivine, this phase is pyroxene. This reaction relationship is best illustrated with the use of a phase diagram of a portion of the olivine Mg_2SiO_4 (forsterite) + SiO_2 (cristobalite, a high-temperature form of quartz) binary system at one atmosphere (see Figure 114).

After N. Bowen and O. Andersen, "The Binary System MgO-SiO_2," *American Journal of Science*, vol. 37 (1914)

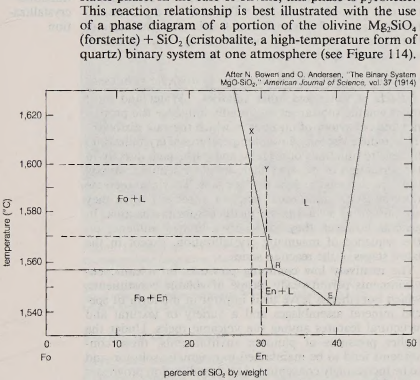

Figure 114: Phase diagram of a part of the Mg_2SiO_4 (forsterite, or Fo)–SiO_2 (silica) system at one atmosphere of pressure. En = enstatite and L = liquid. See text for further discussion.

Consider a mixture X of two minerals in the proportions 28 percent cristobalite and 72 percent forsterite. At a temperature of 1,601° C, this mixture is entirely liquid. At temperatures below 1,557° C, forsterite (Fo) and enstatite (En) are stable, but between 1,557° and 1,600° C, forsterite and the liquid whose composition is represented by L are in equilibrium. At a temperature of 1,570° C, there is about 7 percent forsterite and 93 percent liquid. As the liquid X cools, it intersects the liquidus freezing curve at a temperature of 1,600° C, where forsterite begins to crystallize. As the temperature drops further, the liquid follows the liquidus down toward R, the peritectic point (incongruent melting point in a binary system), while it continually crystallizes more forsterite. It should be noted that the liquid composition is becoming enriched in silica, until at R, it has more silica than enstatite. At this point the forsterite reacts with the liquid to yield two moles of $MgSiO_3$ (enstatite) for every mole of Mg_2SiO_4 that combines with one mole of SiO_2 removed from the liquid R. This can be written as a chemical equation:

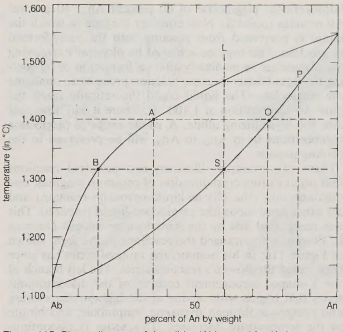

Figure 115: Phase diagram of the albite (Ab)–anorthite (An) system at one atmosphere of pressure. The curve that includes points A and B is the liquidus, and the curve with points P, O, and S is the solidus (see text).

After N. Bowen, "Melting Phenomena of the Plagioclase Feldspars," *American Journal of Science*, vol. 34 (1913)

$Mg_2SiO_4 + SiO_2 \rightleftarrows 2MgSiO_3$. Because SiO_2 is removed from the liquid R, a proportionate amount of enstatite must be crystallized from the liquid to keep its composition at point R. In the case of the starting composition X, which is depleted in SiO_2 relative to enstatite, the peritectic liquid, R, will be consumed by the reaction prior to the forsterite, and the resultant mixture will consist of forsterite and enstatite. However, in the case in which the starting composition is Y, which is enriched in silica relative to enstatite, the forsterite will be depleted before the liquid, and the reaction will yield the liquid and enstatite. Only in the case where the starting composition matches that of enstatite will the liquid and the forsterite be consumed at the same time, leaving only enstatite. The starting composition X represents the most common crystallization behaviour for saturated tholeiitic basaltic magmas; consequently, these magmas will experience a reaction between the liquid and the olivine, forsterite, at some point during their crystallization. This means that the liquid will be consumed by the reaction with forsterite and crystallization will cease. If, however, forsterite can be removed physically from the liquid before the reaction can occur, the reaction will be prevented and the peritectic liquid (like R in the figure) will remain to crystallize the pyroxene, enstatite, and move down toward the eutectic temperature (like E in the figure) where cristobalite and enstatite will crystallize. (For further explanation of eutectic and peritectic systems, see also MATTER: *Phase changes and equilibria: Phase diagrams: Binary systems.*)

Albite-anorthite system

Most of the common minerals found in igneous rocks are solid-solution phases. These include olivine, pyroxene, amphibole, biotite, and plagioclase feldspars. Crystallization behaviour is illustrated best by using the $NaAlSi_3O_8$ (albite or Ab)–$CaAl_2Si_2O_8$ (anorthite or An) plagioclase system shown in Figure 115. Consider a liquid of composition L (60 percent An + 40 percent Ab) which is at an initial temperature of 1,500° C. On cooling it will begin crystallizing plagioclase with 85 percent An (point P on the solidus) at the liquidus temperature of about 1,470° C. As cooling continues further, the liquid will move down the liquidus toward B while simultaneously reacting continuously with the early-formed plagioclase to convert it to a homogeneous plagioclase that is more albitic and in equilibrium with the liquid. For example, when the liquid has reached A, at 1,400° C, about 65 percent plagioclase with about 73 percent An (point O on the solidus) has crystallized from the liquid, which is now at about 36 percent An and 64 percent Ab. Finally, when the temperature of about 1,330° C is reached (B in the figure), the last small amount of the liquid of composition 20 percent An + 80 percent Ab is consumed in the reaction and a

homogeneous plagioclase of 60 percent An + 40 percent Ab remains (point S). Now consider the case in which the liquid is prevented from reacting with the early-formed plagioclase. This may be achieved by physically removing the plagioclase immediately after its formation or by cooling the liquid faster than the reaction process can consume the plagioclase. The liquid could theoretically reach the pure Ab composition at 1,100° C, where it will disappear into the crystallizing albite. A whole range of plagioclase compositions from An_{84} to An_{00} will be preserved in the cooling process.

These two examples illustrate two principal reactions that occur during crystallization of common magmas, one discontinuous (the olivine-liquid-pyroxene reaction) and the other continuous (the plagioclase-liquid reaction). This was recognized first by the American petrologist Norman L. Bowen, who arranged the reactions in the form shown in Figure 116; in his honour, the mineral series has since been called the Bowen's reaction series. The left branch of the Y-shaped arrangement consists of the discontinuous series that begins with olivine at the highest temperature and progresses through pyroxene, amphibole, and biotite as the temperature decreases. This series is discontinuous because the reaction occurs at a fixed temperature at constant pressure wherein the early-formed mineral is converted to a more stable crystal. Each mineral in the series displays a different silicate structure that exhibits increased polymerization as the temperature drops; olivine belongs to the island silicate structure type; pyroxene, the chain; amphibole, the double chain; and biotite, the sheet. On the other hand, the right branch is the continuous reaction series in which plagioclase is continuously reacting with the liquid to form a more albitic phase as the temperature decreases. In both cases, the liquid is consumed in the reaction. When the two reaction series converge at a low temperature, minerals that will not react with the remaining liquid approach eutectic crystallization. Potash feldspar, muscovite, and quartz are crystallized. The phases that are crystallized first are the common minerals that compose basalt or gabbro, like bytownite or labradorite with pyroxene and minor amounts of olivine. Andesite or diorite minerals, such as andesine with either pyroxene or amphibole, crystallize next and are followed by orthoclase and quartz, which are the essential constituents of rhyolite or granite. A basaltic liquid at the top of the Y can descend to the bottom of the series to crystallize quartz only if the earlier reactions are prevented. As demonstrated above, complete reactions between early-formed minerals and the liquid depletes the supply of the liquid, thereby curtailing the progression down the series. One means by which basaltic magma can be transformed to rocks lower in the series is by fractional crystallization. In this process, the early-formed minerals are removed from the liquid by gravity (such minerals as olivine and pyroxene are denser than the liquid from which they crystallized), and so unreacted liquid remains later in the series.

Bowen's reaction series

Another method of creating different daughter magmas

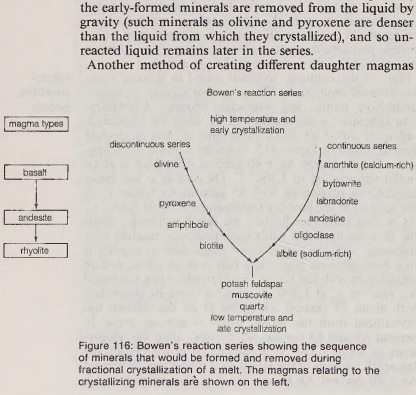

Figure 116: Bowen's reaction series showing the sequence of minerals that would be formed and removed during fractional crystallization of a melt. The magmas relating to the crystallizing minerals are shown on the left.

from a parent is by having the latter react with its wall rocks. Consider a magma that is crystallizing pyroxene and labradorite. If the magma tears from its wall minerals, say, olivine and anorthite, which are formed earlier than pyroxene and labradorite in the series, they will react with the liquid to form these same minerals with which the magma is in equilibrium. The heat for driving this reaction comes directly from the magma itself. More pyroxene and labradorite will crystallize during the reaction and will release their latent heats of crystallization. On the other hand, if a mineral (quartz, for example) formed at a later stage than pyroxene or labradorite falls from the rock wall into the magma, the latent heat provided by further crystallization of pyroxene and labradorite will cause it to dissolve. This situation will occur only if the quartz from the wall rock is at a lower temperature than the magma. It will cause the magma to transfer its heat to the quartz in a cooling process. The cooling of the magma will necessarily be accompanied by the crystallization of the minerals already present. In both cases, the composition of the parent magma will be changed by the xenolithic (foreign rock) contamination. The contaminant need not belong to the reaction series in order for it to cause reactions or dissolution. In most cases, the end result will be a shift from the original composition of the parent magma toward that of the contaminant. This process in which wall rocks are incorporated into the magma is called assimilation. Because assimilation is accompanied by crystallization, it is likely that both fractional crystallization and assimilation will take place simultaneously. This combined process, referred to as AFC for assimilation–fractional crystallization, has been proposed as the mechanism by which andesites are produced from basalts.

Assimilation–fractional crystallization

VOLATILE CONSTITUENTS AND LATE MAGMATIC PROCESSES

Effects of water and other volatiles. Water and most other volatile substances profoundly influence the properties and behaviour of magmas in which they are dissolved. They reduce viscosity, lower temperatures of crystallization by tens to hundreds of degrees, and participate directly in the formation of minerals that contain essential hydroxyl (OH) or elements such as the halogens. They also increase rates of crystallization and reaction, especially when they are present as a fluid phase distinct from the magma. In general, however, they have only a limited influence on the sequence of magmatic crystallization, except in the latest stages of the reaction series.

The relatively low confining pressures in volcanic environments permit ready escape of volatile constituents, which nonetheless leave their imprint in the form of special mineral assemblages and a variety of textural and structural features among the volcanic rocks. Under the higher pressures of plutonic environments, these constituents tend to be maintained in magmatic solution and to be increasingly concentrated as crystallization progresses with falling temperature. Few members of the reaction series require them as compositional contributors; water, for example, is not thus used until amphiboles or micas begin to form, and even then the amounts removed from the melt rarely are large. Escape of volatiles from the system can occur "osmotically" if the enclosing rocks are pervious to them but not to the magma, but in general they are fractionated in favour of the residual melt until their concentration reaches the limit of solubility under the prevailing conditions of temperature and effective confining pressure. When this happens, normally at a very late stage of magmatic crystallization, they are exsolved from the melt as a separate fluid phase that under most circumstances is a supercritical gas. This process has been referred to as resurgent boiling, a somewhat misleading term because the exsolved fluid is not necessarily expelled from the system.

Pegmatites and late-stage mineralization. Coexistence of residual magma and a volatile-rich fluid (generally aqueous) promotes the partitioning and segregation of constituents, as well as the growth of very large crystals. The exsolved fluid, with its very low viscosity, not only can move readily through open spaces in the nearly solid igneous rock and in adjacent rocks but also serves as

a medium through which various substances can diffuse rapidly in response to concentration gradients. Thus, it plays an important role in the formation of such special rock types as the pegmatites (Figure 117) and lamprophyres, special features such as miaroles and plumose mineral aggregates, and many kinds of ore deposits whose constituents are derived from the original magma.

Most plutonic systems remain at elevated temperatures for long periods of time after all magma has been used up, and during these periods hydrothermal conditions normally obtain. These depend upon the continued presence of a typically aqueous fluid that further facilitates crystallization and exchanges of materials. It speeds up exsolution within homogeneous solid phases and devitrification of any glass that may be present, and it is a potent agent in the alteration, leaching, and replacement of minerals. Rock textures thereby are modified, especially along boundaries between original mineral grains, and details of composition also can be much changed. In some instances the bulk chemistry of the rock is markedly affected.

Hydrothermal alteration

The hydrothermal alterations favour development of phases such as albite, carbonates, chlorites, clay minerals, epidotes, iron oxides, micas, silica minerals, talc, and zeolites, and many of them are accompanied by gross changes in volume. (R.H.J./A.M.K.)

EXTRUSIVE IGNEOUS ROCKS

Extrusive igneous rocks are the products of volcanic activity. They appear at the surface as molten lava that spreads in sheets and hardens, or they are made up of fragments of magma ejected from vents by violent gaseous explosions. Large-scale extrusive features include stratovolcanoes (composite cones), shield volcanoes, lava domes, and cinder cones. Smaller extrusive features include lava flows known as pahoehoe and aa. For a detailed description of the principal forms of extrusive igneous rocks, see VOLCANISM: *Volcanic landforms: Major types of volcanic landforms.*

INTRUSIVE IGNEOUS ROCKS

Erosion of volcanoes will immediately expose shallow intrusive bodies such as volcanic necks and diatremes (see Figure 118). A volcanic neck is the "throat" of a volcano and consists of a pipelike conduit filled with hypabyssal rocks. Ship Rock in New Mexico and Devil's Tower in Wyoming are remnants of volcanic necks, which were exposed after the surrounding sedimentary rocks were eroded away. Many craterlike depressions may be filled with angular fragments of country rock (breccia) and juvenile pyroclastic debris. When eroded, such a depression exposes a vertical funnel-shaped pipe that resembles a volcanic neck with the exception of the brecciated filling.

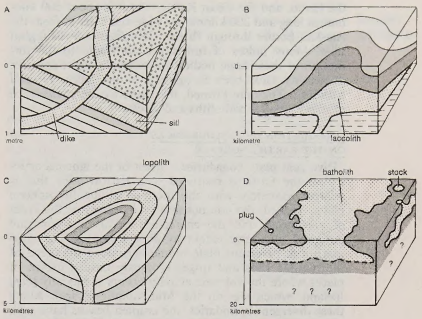

Figure 118: Forms of intrusive igneous rock bodies in hypothetical sections of Earth strata. Note the change of scale from A through D.

These pipes are dubbed diatremes. Many diatremes are formed by explosion resulting from the rapid expansion of gas—carbon dioxide and water vapour. These gases are released by the rising magma owing to the decrease in pressure as it nears the surface. Some diatremes contain kimberlite, a peridotite that contains a hydrous mineral called phlogopite. Kimberlite may contain diamonds.

Dikes are usually tabular bodies that may radiate from the central vent of a volcano or from a volcanic neck (see Figure 118). Not all dikes are associated with volcanoes, but they can be distinguished by their discordant relationship with the structure of the country rock that they cut across. Many dikes are only a few metres wide, but large ones, such as the dike that feeds the Muskox intrusion in the Northwest Territories of Canada, reach widths of more than 150 metres. Related to dikes are features that maintain a concordant relationship with the structure of the country rocks. Magmas may force their way between layers of country rock and solidify parallel to them to form sills (see Figure 118). On the west bank of the Hudson River opposite New York City, the 300-metre-thick Palisades sill is exposed and can be traced for 80 kilometres. A laccolith also is concordant with country rock, but it is distinguished from a sill by having a flat floor with a domed (mushroom-shaped) roof (see Figure 118). Laccoliths were first described in the Henry Mountains of Utah, where they may measure up to 200 metres thick with basal diameters exceeding three kilometres. Rocks of intermediate silica content generally make up these domed intrusions. In contrast, lopoliths are saucer-shaped bodies with a concave upward roof and floor and are commonly composed of mafic rocks. Lopoliths are huge in size; the Bushveld intrusive complex in South Africa, for example, has an area of about 66,000 square kilometres and an exposed thickness of 8 kilometres. The Muskox intrusion, mentioned above, is another large lopolith, which is estimated to be about 80 kilometres long and 11 kilometres wide (roof rocks covering part of the intrusion prevent an exact measurement). These lopoliths are commonly layered with igneous minerals and rocks; in the Bushveld intrusion, one layer about 1 metre thick consisting of almost pure chromite (an ore of chromium) extends for tens of kilometres. Large irregularly shaped plutons are called either stocks or batholiths (see Figure 118), depending on their sizes. Plutons larger than 100 square kilometres in area are termed batholiths, while those of lesser size are called stocks. It may be possible, however, that some stocks are the visible portions of batholiths that have not been exposed by erosion. Batholiths (from the Greek word *bathos*, meaning depth) are deep-seated crustal intrusions, whereas stocks may be formed at shallow depths only a few kilometres below the surface. Rocks ranging from quartz diorite to granite are commonly found in batholiths. Large batholiths in North America include the Sierra Nevada,

Laccoliths and lopoliths

the Idaho, and the Coast Range, which is about 600 kilometres long and 200 kilometres wide and extends from the Alaskan border through British Columbia to Washington state. Many pulses of intrusions contribute to the formation of these large bodies; for example, eight episodes of activity have been recognized in the Sierra Nevada batholith. They are formed, therefore, by the coalescence of many smaller batholiths and stocks.

DISTRIBUTION OF IGNEOUS ROCKS ON THE EARTH'S SURFACE

Divergent plate boundaries. Most of the igneous activity on the Earth is restricted to a narrow zone that is related intimately with the motions of the lithospheric plates. Indeed, the composition of the magma, the types of volcanism, and the characteristics of intrusions are governed to a large extent by plate tectonics. The magmatism at divergent plate boundaries along the crests of the oceanic rises and ridges is mostly unseen except in places where the volcanic activity occurs subaerially (*e.g.,* Iceland, which sits on the Mid-Atlantic Ridge). Along these divergent boundaries, the erupted basalts have such a restricted compositional range that they are referred to as mid-ocean-ridge basalt (MORB). They are subalkaline tholeiites that contain olivine in the norm and less than 0.25 percent potash. The chemistry suggests that MORB was generated from a mantle that was depleted of volatile elements (*e.g.,* lanthanum [La], cerium [Ce], sodium, and potassium) in a previous partial melting process. A wide rift valley marks the crest of most of the oceanic ridges and rises. The valley is bounded by faults created by the divergent forces and is floored in its centre by a fracture zone (a mass of rock with many small breakages). These faults and fractures are the conduits for the MORB magmas that flood the valley, build volcanoes, and produce dikes by filling the conduits. Layer 2 of the oceanic crust results from these magmatic activities (see Figure 119). As the plates diverge, MORB becomes the ocean floor on which oceanic sediments (layer 1) are deposited. This makes MORB the most abundant rock on the surface of the Earth.

Mid-ocean-ridge basalt

Below the collection of lavas and dikes in layer 2 are found gabbro and diorite. They represent the plutonic rocks formed as a result of differentiation of the MORB magma that fed the volcanic activity along the rift. (Differentiation is the process in which more than one rock type is derived from a single parent magma.) These coarse-grained intrusives account for about 4 to 5 kilometres of layer 3, which rests on a sequence of layered ultramafic rocks. The rocks were formed by the gravitative accumulation of mafic minerals from the original MORB magma that filled a large chamber below the ridge axis.

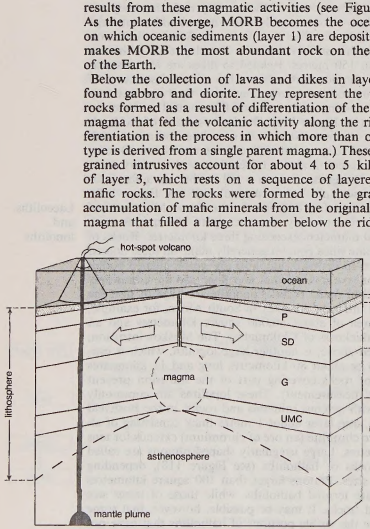

Figure 119: Idealized cross section of a divergent plate boundary showing the structure of the oceanic lithosphere. Layer 1 is composed of sedimentary rocks. P = pillow basalts, SD = sheeted dike complex, G = gabbro, UMC = ultramafic cumulate. Arrows indicate the direction of movement of the diverging plates. Also shown is a hot-spot volcano formed from a rising mantle plume anchored beneath the lithosphere.

Below this layered sequence is mantle rock that is highly deformed and depleted (of elements such as lanthanum, cerium, sodium, and potassium that have been removed by repeated partial melting). Because seismic waves cannot distinguish between layered ultramafic rocks, which are not true mantle rocks, and ultramafic mantle rocks, the Moho actually is positioned between layer 3 and the layered ultramafics. The sequences consisting of layer 1 (limestone and chert sedimentary rocks), layer 2 of MORB lavas and dikes, and layer 3 of gabbro and diorite and the ultramafic rocks are known as ophiolites. Many geologists believe that ophiolites formed at oceanic ridges were emplaced by tectonic forces at convergent plate boundaries and then became exposed in highly deformed orogenic (mountain) belts. In fact, the same sequences of rocks were first reported in the Alps and were considered deep-seated intrusions. Some geologists still argue that all ophiolites were not formed at divergent plate boundaries.

Away from the axis of divergence, the composition of the volcanic rocks becomes more diverse. Most of the magmatism is related to hot spots, which are hot rising plumes of mantle rock that are anchored beneath the moving lithospheric plates (see Figure 119). The Hawaiian Islands owe their existence to the magmatism associated with a hot spot that currently is located just southeast of the large island of Hawaii. This mantle plume not only provides magma for the eruptions at Kilauea Volcano but also is responsible for the submarine volcano named Loihi that will eventually become a new island. Most of the islands are built on a tholeiite basalt base, but the caps of the volcanoes are alkali basalts. The final episodes of volcanic activity on an island are extremely undersaturated; nephelinites and olivine melilite nephelinites are common products. The alkali basalts have differentiated to more silica-rich compositions, with hawaiites, mugearites, and trachytes being erupted in minor amounts. The two active volcanoes on Hawaii, Mauna Loa and Kilauea, are still erupting tholeiite basalts. Tholeiites on all the islands far from the ocean ridge crests are different from MORB in that they are enriched in lanthanum, cerium, sodium, and potassium.

Mauna Loa and Kilauea

Convergent plate boundaries. Igneous rocks associated with convergent plate boundaries have the greatest diversity. In this case, granite batholiths underlie the great composite volcanoes and consist of rocks ranging from basalt through andesite to dacite and rhyolite. These boundaries are destructive and consume the subducting oceanic lithosphere formed at the divergent centres. The rocks generated, however, are added on (accreted) to the continent. Oceanic trenches outline the junction of the colliding plates, but the igneous activity takes place on the overriding plate along a line at least about 100 kilometres above the subducting plate (see Figure 113). In other words, no volcanism occurs between this 100-kilometre line (called the volcanic front) and the trench. The horizontal distance between the trench and the volcanic front depends on the angle of subduction; the steeper the angle, the shorter the distance. Volcanism occurs from this volcanic axis inland for a few hundred kilometres. The dominant rock constituting the composite volcanoes is andesite, but in some younger island arcs basalt tends to be more common, and in older volcanic areas dacite or rhyolite becomes prominent. Two different series of rocks are found in some volcanic chains. In Japan a tholeiitic series and a calc-alkalic series sometimes erupt from the same volcano. The former is characterized by lower magnesium, potassium, nickel, chromium, uranium, and thorium and a higher iron:magnesium ratio. Mineralogically, the tholeiitic series characteristically contains pigeonite (a low-calcium monoclinic pyroxene) in the groundmass of the basalts and andesites. The calc-alkalic series lacks pigeonite but instead has hypersthene. Most of the composite volcanoes of the Cascades Range in Oregon and Washington in the northwestern United States are characteristically calc-alkalic. In some volcanic arcs in areas farthest from the trench, a potassic series is found. In Japan the volcanoes within the Japan Sea and farthest from the Japan Trench have alkali basalt compositions.

In older areas of convergence, the composite volcanoes

have been eroded, exposing the deeper plutonic granite batholiths that extend the entire length of the convergent boundaries. The batholiths are predominantly granodiorite, but gabbro through granite occur as well. It seems anomalous to find diorite, the plutonic equivalent of andesite, in low abundance since andesite is the dominant rock type of the volcanoes that were above these batholiths. Two basic types of granite have been recognized. The more common variety is located closer to the trench, has hornblende as its mafic mineral, is enriched in sodium and calcium, and has mantle chemical signatures; it is called I-type granite. The other type, called S-type granite, has muscovite and biotite and is depleted in sodium but enriched in aluminum such that corundum occurs in the norm and isotopic signatures. This suggests that such granites were formed by partial fusion of sedimentary rocks.

Flood basalts. On the continental plates at areas away from active convergence, the magmatism is confined to rift valleys and local hot spots. The volume of magma produced is minor in comparison to that generated at oceanic rises and at convergent plate boundaries. Flood basalts are the most common form of occurrence. They span the rock record from the Precambrian to the Tertiary (from about 3.9 billion to 1.6 million years ago) and are found worldwide. The 1.1-billion-year-old Keweenawan flood basalts in the Lake Superior region of northern Michigan may have formed in a rift that failed. The rifting of Pangaea that began during Jurassic time (approximately 208 to 144 million years ago) generated flood basalt eruptions all along the newly opened Atlantic Ocean. Two voluminous eruptions associated with the opening of the South Atlantic produced the Paraná basalt in Brazil and the Karroo (or Karoo) in South Africa. The Deccan Plateau basalts in India were formed in the rift valleys associated with the breakup of Gondwana during the Cretaceous Period (approximately 144 to 66.4 million years ago). Chemically, the most abundant basalts are supersaturated tholeiites with normative quartz, but olivine tholeiites and alkali basalts also are found. Feeder dike swarms (groups consisting of many parallel dikes) and sills are common in flood basalt plateaus. Alkaline rocks, such as those found in the East African Rift System, occur as well but are less abundant. This rift system stretches southward from the Red Sea–Gulf of Aden to Lake Victoria. Undersaturated basalts are most common in these rifts. During one eruption, a magma composed mostly of sodium carbonate issued from a volcanic vent that had been erupting alkali basalts.

Other terrestrial occurrences. Other diverse and unusual igneous rocks are found in the stable continental areas far from plate boundaries. These include the large layered basaltic intrusions—namely, the Stillwater Complex in Montana, the Muskox intrusion in the Northwest Territories of Canada, the Bushveld Complex in South Africa, and the Skaergaard intrusion in eastern Greenland. Tholeiitic magma underwent a fractional crystallization process that deposited layers of ultramafic rocks overlain by gabbroic and anorthositic layers. The end products of this fractionation are quartz- and feldspar-bearing rocks with a peculiar texture (known as graphic intergrowth) in which quartz and feldspar are intimately intergrown with each other. These rocks are called granophyres. Such layered intrusions have some economic importance; some of them contain thick (a few metres) layers of chromite, which is the source of chromium and also platinum. Two other rare occurrences in cratonic (stable) areas of the Earth's crust are the kimberlites and carbonatites. Both are of economic value because they yield diamonds and niobium, respectively. Kimberlites are mica peridotites that are found in pipes. The stable interiors of South Africa and Siberia have widespread occurrences, but these pipes also are found in North America, Australia, Brazil, and India. In North America, near Murfreesboro, Ark., individuals can pay a fee to search for diamonds in the Prairie Creek kimberlite pipe located in the Crater of Diamonds State Park. Not all kimberlites contain diamonds. When diamonds do occur, they constitute less than one part per million of the rock. Carbonatites are igneous rocks rich in carbonate (containing at least 50 percent) that commonly occur in ring complexes in association with other silica-poor rocks such as nepheline syenites. In North America, carbonatites have been found in dozens of localities in northern Ontario and western Quebec.

Basaltic intrusions

Extraterrestrial occurrences. The dominant igneous rock on the Earth's surface is basalt. It appears that such is also the case on Earth's close neighbours. The lunar maria are covered with basalt lava flows. These lunar basalts have a mineralogy similar to that of terrestrial basalts, but chemically they have no water, a lower amount of alkalis and alumina, and a higher iron oxide and chromium content. On the lunar highlands, plagioclase-rich rocks are most common; these include anorthosites, gabbros, troctolites (olivine-plagioclase rock), and minor basalt. It appears that basalt is common on Mars as well. The large shield volcano Olympus Mons must have been formed from eruptions of fluid basalt flows. The X-ray fluorescence analyses performed by the Vikings 1 and 2 landers showed that the rocks are basaltic. Venus apparently has volcanic features, but full chemical analysis has not yet revealed the rock compositions. (A.M.K.)

SEDIMENTARY ROCKS

Definition, formation, and significance

Sedimentary rocks are produced by the weathering of preexisting rocks and the subsequent transportation and deposition of the weathering products. Weathering refers to the various processes of physical disintegration and chemical decomposition that occur when rocks at the Earth's surface are exposed to the atmosphere (mainly in the form of rainfall) and the hydrosphere. These processes produce soil, unconsolidated rock detritus, and components dissolved in groundwater and runoff. Erosion is the process by which weathering products are transported away from the weathering site, either as solid material or as dissolved components, eventually to be deposited as sediment. Any unconsolidated deposit of solid weathered material constitutes sediment. It can form as the result of deposition of grains from moving bodies of water or wind, from the melting of glacial ice, and from the downslope slumping (sliding) of rock and soil masses in response to gravity, as well as by precipitation of the dissolved products of weathering under the conditions of low temperature and pressure that prevail at or near the surface of the Earth.

Sedimentary rocks are the lithified equivalents of sediments. They typically are produced by cementing, compacting, and otherwise solidifying preexisting unconsolidated sediments. Some varieties of sedimentary rock, however, are precipitated directly into their solid sedimentary form and exhibit no intervening existence as sediment. Organic reefs and bedded evaporites are examples of such rocks. Because the processes of physical (mechanical) weathering and chemical weathering are significantly different, they generate markedly distinct products and two fundamentally different kinds of sediment and sedimentary rock: (1) terrigenous clastic sedimentary rocks and (2) allochemical and orthochemical sedimentary rocks.

Clastic terrigenous sedimentary rocks consist of rock and mineral grains, or clasts, of varying size, ranging from clay-, silt-, and sand- up to pebble-, cobble-, and boulder-size materials. These clasts are transported by gravity, mudflows, running water, glaciers, and wind and eventually are deposited in various settings (*e.g.*, in desert dunes, on alluvial fans, across continental shelves, and in river deltas). Because the agents of transportation commonly sort out discrete particles by clast size, terrigenous clastic sedimentary rocks are further subdivided on the basis of average clast diameter. Coarse pebbles, cobbles, and boulder-size gravels lithify to form conglomerate and breccia; sand becomes sandstone; and silt and clay form siltstone, claystone, mudrock, and shale.

Chemical sedimentary rocks form by chemical and or-

ganic reprecipitation of the dissolved products of chemical weathering that are removed from the weathering site. Allochemical sedimentary rocks, such as many limestones and cherts, consist of solid precipitated nondetrital fragments (allochems) that undergo a brief history of transport and abrasion prior to deposition as nonterrigenous clasts. Examples are calcareous or siliceous shell fragments and oöids, which are concentrically layered spherical grains of calcium carbonate. Orthochemical sedimentary rocks, on the other hand, consist of dissolved constituents that are directly precipitated as solid sedimentary rock and thus do not undergo transportation. Orthochemical sedimentary rocks include some limestones, bedded evaporite deposits of halite, gypsum, and anhydrite, and banded iron formations.

Sedimentary rock shell

Sediments and sedimentary rocks are confined to the Earth's crust, which is the thin, light outer solid skin of the Earth ranging in thickness from 40–100 kilometres (25 to 62 miles) in the continental blocks to 4–10 kilometres in the ocean basins. Igneous and metamorphic rocks constitute the bulk of the crust. The total volume of sediment and sedimentary rocks can be either directly measured using exposed rock sequences, drill-hole data, and seismic profiles or indirectly estimated by comparing the chemistry of major sedimentary rock types to the overall chemistry of the crust from which they are weathered. Both methods indicate that the Earth's sediment-sedimentary rock shell forms only about 5 percent by volume of the terrestrial crust, which in turn accounts for less than 1 percent of the Earth's total volume. On the other hand, the area of outcrop and exposure of sediment and sedimentary rock comprises 75 percent of the land surface and well over 90 percent of the ocean basins and continental margins. In other words, 80–90 percent of the surface area of the Earth is mantled with sediment or sedimentary rocks rather than with igneous or metamorphic varieties. The sediment-sedimentary rock shell forms only a thin superficial layer. The mean shell thickness in continental areas is 1.8 kilometres; the sediment shell in the ocean basins is roughly 0.3 kilometre. Rearranging this shell as a globally encircling layer (and depending on the raw estimates incorporated into the model), the shell thickness would be roughly 1–3 kilometres.

Despite the relatively insignificant volume of the sedimentary rock shell, not only are most rocks exposed at the terrestrial surface of the sedimentary variety, but many of the significant events in Earth history are most accurately dated and documented by analyzing and interpreting the sedimentary rock record instead of the more voluminous igneous and metamorphic rock record. When properly understood and interpreted, sedimentary rocks provide information on ancient geography, termed paleogeography. A map of the distribution of sediments that formed in shallow oceans along alluvial fans bordering rising mountains or in deep, subsiding ocean trenches will indicate past relationships between seas and landmasses. An accurate interpretion of paleogeography and depositional settings allows conclusions to be made about the evolution of mountain systems, continental blocks, and ocean basins, as well as about the origin and evolution of the atmosphere and hydrosphere. Sedimentary rocks contain the fossil record of ancient life-forms that enables the documentation of the evolutionary advancement from simple to complex organisms in the plant and animal kingdoms. Also, the study of the various folds or bends and breaks or faults in the strata of sedimentary rocks permits the structural geology or history of deformation to be ascertained.

Finally, it is appropriate to underscore the economic importance of sedimentary rocks. For example, they contain essentially the world's entire store of oil and natural gas, coal, phosphates, salt deposits, groundwater, and other natural resources.

Geologic sciences

Several subdisciplines of geology deal specifically with the analysis, interpretation, and origin of sediments and sedimentary rocks. Sedimentary petrology is the study of their occurrence, composition, texture, and other overall characteristics, while sedimentology emphasizes the processes by which sediments are transported and deposited. Sedimentary petrography involves the classification and study of sedimentary rocks using the petrographic microscope. Stratigraphy covers all aspects of sedimentary rocks, particularly from the perspective of their age and regional relationships as well as the correlation of sedimentary rocks in one region with sedimentary rock sequences elsewhere. (For further information about these fields, see EARTH SCIENCES: *Geologic sciences.*)

Classification systems

In general, geologists have attempted to classify sedimentary rocks on a natural basis, but some schemes have genetic implications (*i.e.,* knowledge of origin of a particular rock type is assumed), and many classifications reflect the philosophy, training, and experience of those who propound them. No scheme has found universal acceptance, and discussion here will centre on some proposals.

The book *Rocks and Rock Minerals* by Louis V. Pirsson was first published in 1908, and it has enjoyed various revisions. Sedimentary rocks are classified there rather simplistically according to physical characteristics and composition into detrital and nondetrital rocks (see Table 52).

Numerous other attempts have been made to classify sedimentary rocks. The most significant advance occurred in 1948 with the publication in the *Journal of Geology* of three definitive articles by the American geologists Francis J. Pettijohn, Robert R. Shrock, and Paul D. Krynine. Their classifications provide the basis for all modern discussion of the subject. The nomenclature associated with several schemes of classifying clastic and nonclastic rocks will be discussed in the following sections, but a rough division of sedimentary rocks based on chemical composition is shown in Figure 120.

Categories of sedimentary rocks

For the purposes of the present discussion, three major categories of sedimentary rocks are recognized: (1) terrigenous clastic sedimentary rocks, (2) carbonates (limestone and dolomite), and (3) noncarbonate chemical sedimentary rocks. Terrigenous clastic sedimentary rocks are composed of the detrital fragments of preexisting rocks and minerals and are conventionally considered to be equivalent to clastic sedimentary rocks in general. Because most of the clasts are rich in silica, they are also referred to as siliciclastic sedimentary rocks. Siliciclastics are further subdivided on the basis of clast diameter into conglomerate and breccia, sandstone, siltstone, and finer-than-silt-sized mudrock (shale, claystone, and mudstone). The carbonates, limestones and dolomites, consist of the minerals aragonite, calcite, and dolomite. They are chemical sedimentary rocks in the sense that they possess at least in part a crystalline, interlocking mosaic of precipitated carbonate mineral grains. However, because individual grains such as fossil shell fragments exist for some period of time as sedimentary clasts, similar to transported quartz or feldspar clasts, most carbonates bear some textural affinities to the terrigenous clastic sedimentary rocks. The noncar-

bonate chemical sedimentary rocks include several rock types that are uncommon in the sedimentary rock record but remain important either from an economic point of view or because their deposition requires unusual settings. Specific varieties discussed below include siliceous rocks (cherts), phosphate rocks (phosphorites), evaporites, iron-rich sedimentary rocks (iron formations and ironstones), and organic-rich (carbonaceous) deposits in sedimentary rocks (coal, oil shale, and petroleum).

Despite the diversity of sedimentary rocks, direct measurement of the relative abundance of the specific types based on the study of exposed sequences suggests that only three varieties account for the bulk of all sedimentary rocks: mudrock, 47 percent; sandstone, 31 percent; and carbonate, 22 percent. Another method, which involves comparing the chemical composition of major sedimentary rock types with the chemistry of the Earth's continental crust, yields somewhat different numbers: mudrock, 79 percent; sandstone, 13 percent; and carbonate, 8 percent. Most sedimentary petrologists concede that the sedimentary rock record preserved and exposed within the continental blocks is selectively biased in favour of shallow-water carbonates and sandstones. Mudrocks are preferentially transported to the ocean basins. Consequently, indirect estimates based on chemical arguments are probably more accurate.

TERRIGENOUS CLASTIC ROCKS

A prominent physical feature of terrigenous clastic rocks is texture—that is, the size, shape, and arrangement of the constituent grains. These rocks have a fragmental texture: discrete grains are in tangential contact with one another. Terrigenous clastic sedimentary rocks are further subdivided on the basis of the mean grain diameter that characterizes most fragments, using the generally accepted size limits shown in Table 53. Granules, pebbles, cobbles, boulders, and blocks constitute the coarse clastic sediments; sand-size (arenaceous) clasts are considered medium clastic sediments; and fine clastics sediments consists of silt- and clay-size materials.

The simplest way of classifying coarse clastic sedimentary rocks is to name the rock and include a brief description of its particular characteristics. Conglomerates and breccias differ from one another only in clast angularity. The former consist of abraded, somewhat rounded, coarse clasts, whereas the latter contain angular, coarse clasts. Thus, a pebble conglomerate is a coarse clastic sedimentary rock whose discrete particles are rounded and range from 4 to 64 millimetres (0.2 to 2.5 inches) in diameter. A more precise description reveals the rock types of the mineral fragments that compose the conglomerate—for example, a granite-gneiss pebble conglomerate.

Sandstones have long intrigued geologists because they are well exposed, are abundant in the geologic record, and provide an enormous amount of information about depositional setting and origin. Many classification schemes have been developed for sandstones, only the most popular of which are reviewed below. Most schemes emphasize the relative abundance of sand-size quartz, feldspar, and rock fragment components, as well as the nature of the material housed between this sand-size "framework" fraction (see below *Sandstones*). Sandstone classification

Fine clastics are commonly, but rather simplistically, referred to as mudrocks. Mudrocks actually can include any

clastic sedimentary rock in which the bulk of the clasts have diameters finer than $^1/_{16}$ millimetre. Varieties include siltstone (average grain size between $^1/_{16}$ and $^1/_{256}$ millimetre) and claystone (discrete particles are mostly finer than $^1/_{256}$ millimetre). Mud is a mixture of silt- and clay-size material, and mudrock is its indurated product. Shale is any fine clastic sedimentary rock that exhibits fissility, which is the ability to break into thin slabs along narrowly spaced planes parallel to the layers of stratification. Despite the great abundance of the fine clastics, disagreement exists as to what classification schemes are most useful for them, and an understanding of their origin is hindered by analytical complexities (see below *Mudrocks*).

CARBONATE ROCKS: LIMESTONES AND DOLOMITES

Limestones and dolostones (dolomites) make up the bulk of the nonterrigenous sedimentary rocks. Limestones are for the most part primary carbonate rocks. They consist of 50 percent or more calcite and aragonite (both $CaCO_3$). Dolomites are mainly produced by the secondary alteration or replacement of limestones; *i.e.*, the mineral dolomite [$CaMg(CO_3)_2$] replaces the calcite and aragonite minerals in limestones during diagenesis. A number of different classification schemes have been proposed for carbonates, and the many categories of limestones and dolomites in the geologic record represent a large variety of depositional settings (see below *Limestones and dolomites*).

NONCARBONATE CHEMICAL SEDIMENTARY ROCKS

Noncarbonate chemical sedimentary rocks differ in many respects from carbonate sedimentary rocks and terrigenous clastic sedimentary rocks, and there is no single classification that has been universally accepted. This is a reflection of the great variation in mineral composition, texture, and other properties of these rock types. Such rocks as ironstones and banded iron formations (limonite, goethite, hematite, siderite, and chamosite), phosphorites, evaporites (rock salt, gypsum, and other salts), siliceous rocks (cherts), and organic-rich (carbonaceous) deposits of oil, natural gas, and coal in sedimentary rocks occur in much less abundance than carbonates and siliciclastic sedimentary rocks, although they may form thick and widespread deposits.

Classification schemes that incorporate all types of noncarbonate chemical sedimentary rocks do not exist because no triangular or tetrahedral scheme can accommodate all of them. Several of the major types are shown in the tetrahedron in Figure 121 (see also the discussion of noncarbonate sedimentary rocks below). (H.J.Bi./F.L.S.)

Properties of sedimentary rocks

TEXTURE

Texture refers to the physical makeup of rock—namely, the size, shape, and arrangement (packing and orientation) of the discrete grains or particles of a sedimentary rock. Two main natural textural groupings exist for sedimentary rocks: clastic (or fragmental) and nonclastic (essentially crystalline). Noncarbonate chemical sedimentary rocks in large part exhibit crystalline texture, with individual mineral grains forming an interlocking arrangement. Depositional setting is an insignificant factor in both determining crystal size and altering crystalline texture. The size of crystals is controlled to a greater degree by the rate of precipitation, and their texture is modified by postdepositional recrystallization (reflecting the diagenetic environment). As a result, little attention is paid to crystalline textures other than providing a simple description of it (for example, coarsely crystalline versus finely crystalline). Also, even though carbonate rocks commonly include allochems that behave as clasts, they too are commonly diagenetically altered. Consequently, only cursory efforts are made to texturally characterize limestones and dolomites. Therefore, the following discussion deals in detail only with the textural techniques applied to terrigenous (siliciclastic) sedimentary rocks.

Clastic and nonclastic rocks

Grain size. Particle size is an important textural parameter of clastic rocks because it supplies information on the conditions of transportation, sorting, and deposition of the sediment and provides some clues to the history of events that occurred at the depositional site prior to final induration. Determining the sizes of the discrete particles that constitute a sedimentary rock can be difficult, particularly if the rock is firmly indurated (cemented, compacted, and lithified). Various methods of measuring grain-size distribution have been devised; likewise several different grade-size schemes exist.

The size of particulate materials that make up sediments and sedimentary rocks are measured by weighing the proportions that accumulate in a series of wire mesh screen sieves, by visually counting grains with a petrographic microscope, or by determining the rate at which particles of varying diameter accumulate in a water-filled glass cylinder (known as a settling tube).

The millimetre and phi unit grade scales and terminology given in Table 54 are the standard ones used for sediments and sedimentary rocks. In the millimetre scale, each size grade differs from its predecessor by the constant ratio of 1:2; each size class has a specific class name used to refer to the particles included within it. This millimetre, or Udden-Wentworth, scale is a geometric grade scale since there is a constant ratio between class limits. Such a scheme is well suited for the description of sediments because it gives equal significance to size ratios, whether they relate to gravel, sand, silt, or clay. The phi scale is a useful, logarithmic-based modification of the Udden-Wentworth scale. Grain-size diameters in millimetres are converted to phi units using the conversion formula: phi (φ) $= -\log_2 S$, where φ is size expressed in phi units and S is the grain size in millimetres. Phi values for grains coarser than one millimetre are negative, while those for grains finer than one millimetre are positive.

Phi scale

After the grain-size distribution for a given sediment or sedimentary rock has been determined by sieving, microscopic analysis, or use of a settling tube, it can be characterized using standard statistical measures in either of two ways: (1) visual inspection of various types of graphs that plot overall percent abundance versus grain-size diameter (*e.g.*, histograms or bar diagrams, size frequency and cumulative size frequency curves, and probability curves that compare the actual grain-size distribution to a normal straight-line Gaussian distribution) or (2) arithmetic calculations made using diameter values in either millimetres or phi units that are read off the graphic plots and inserted into standard formulas. For siliciclastic sedimentary rocks, the following standard statistical measures are conventionally described for grain-size distributions: (1) mode, the most frequently occurring particle size or size class, (2) median, the midpoint size of any grain-size distribution, (3) mean, an estimate of the arithmetic average particle size, (4) sorting or standard deviation, a measure of the range, scatter, or variation in grain size, (5) skewness, the degree of symmetry or asymmetry of the grain-size distribution, which is in turn a function of the coincidence

or noncoincidence of mean, median, and mode, and (6) kurtosis (peakedness) of a grain-size distribution, which compares sorting in the central portion of the population with that in the tails.

Analysis of grain-size distribution is conducted with the disputed assumption that particular transporting agents and depositional settings (*e.g.*, river delta deposits versus shallow marine longshore-bar sands) impose a distinctive textural "fingerprint" on the sediments they produce. Despite continuing efforts, the success of the various graphic and arithmetic approaches in characterizing grain-size distributions is debatable, as is their reliability in pinpointing ancient depositional settings. The grain-size distribution of sediments in many settings commonly appears to be inherited or to exhibit as much variation within a single environment as between different ones.

Form, roundness, and surface texture

Particle shape. Three different but related properties determine particle shape: form, roundness, and surface texture. Particle form is the overall shape of particles, typically defined in terms of the relative lengths of the longest, shortest, and intermediate axes. Particles can be spherical, prismatic, or bladelike. Roundness or angularity is a measure of the smoothness of particles. Surface texture refers to the presence or absence of small, variously shaped markings (pits, polish, scratches) that may occur on grain surfaces.

Each of these attributes of particle shape is traditionally measured in a standard fashion for the purpose of identifying the transporting agent and the depositional environment. Form is determined either by painstakingly measuring individual particles in three dimensions or by Fourier shape analysis, which uses harmonics analysis and computer digitizing to provide a precise description of particles in two dimensions. Form alone has limited usefulness in inferring depositional setting but more accurately reflects the mineralogy of the grains involved. Roundness is characterized by visually comparing grains to standard silhouette profiles as, for example, those shown in Figure 122. It is largely the result of abrasion history, which is controlled by the depositional agent and environment. For example, windblown and surf zone sands are well-rounded, while glacial sands and turbidity current deposits are angular. Particle roundness or angularity also reflects mineralogy (soft minerals are abraded more readily than hard minerals), clast size (coarse particles become rounded more rapidly than do fine ones), and transport distance

(sands become more abraded and hence rounder as the distance traveled increases). Particle surfaces can be visually examined for pitting, markings, and polish through the use of a microscope or hand lens, or in some cases, a scanning electron microscope (SEM). Certain surface textures have been genetically linked to specific depositional agents; for example, classic V-shaped percussion marks identify quartz grains of the beach and nearshore zones.

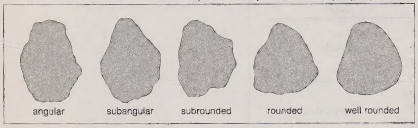

Figure 122: Roundness classes of sedimentary particles.

Fabric. The fabric of a sedimentary rock controls the rock's porosity and permeability and therefore its ability to hold and/or transmit fluids such as oil and water. The orientation, or lack thereof, of the crystals or grains that make up a sedimentary rock constitutes one aspect of fabric. Genetically, there are two principal varieties of oriented fabrics: primary (or depositional) and secondary (or deformational). Primary fabrics are produced while the sediment is accumulating. For example, river currents and some submarine gravity flows generate sediments whose flaky and prismatic constituent particles have long or short axes parallel with one another to produce an oriented fabric. Secondary fabrics result from a rotation of the constituent elements under stress or from the growth of new elements during diagenesis. Fabrics in coarse clastic sedimentary rocks like conglomerates and sandstones can be determined by measuring and plotting dimensional directions, such as the long axes of pebbles or sand grains. In mudrocks, fabrics can be ascertained by studying the platelike arrangement of mica and clay minerals.

Orientation and packing

In addition to orientation, a factor known as packing contributes to a rock's fabric. Packing refers to the distribution of grains and intergranular spaces (either empty or filled with cement or fine-grained matrix) in a sedimentary rock. It is controlled by grain size and shape and by the degree of compaction of a sedimentary rock; in turn it determines the rock's bulk density. A description of packing is generally based on the analysis of thin sections of a sedimentary rock using a petrographic microscope. Particular attention is paid to the number of grain-to-grain contacts (packing proximity) and to comparisons between the sum of the lengths of grains to the total length of a traverse across a thin section (packing density).

MINERALOGICAL AND GEOCHEMICAL COMPOSITION

Minerals that make up sedimentary rocks are of two principal types—namely, detrital and authigenic. Detrital minerals, such as grains of quartz and feldspar, survive weathering and are transported to the depositional site as clasts. Authigenic minerals, like calcite, halite, and gypsum, form in situ within the depositional site in response to geochemical processes. The chemical compounds that constitute them ultimately are generated by chemical weathering and are transported from the weathering site to the point of precipitation primarily in solution. Clay minerals are abundant in sedimentary rocks, particularly mudrocks, and some are detrital. They may have been produced at the weathering site by the partial decomposition of minerals like feldspar. They are transported as clasts, however, and thus can be regarded simply as fine- to very fine-textured detrital particles. Other clay minerals form authigenically at the site of deposition. Some of the important clay minerals are kaolinite, halloysite, montmorillonite, illite, vermiculite, and chlorite (see above *Major rock-forming minerals: Clay minerals*).

The mean chemical composition of the major varieties of sedimentary rocks exhibits wide variation as shown above in Figure 120. Significant contrasts in overall composition among sandstones, carbonates, and mudrocks reflect fundamental differences not only in the mechanisms by which detrital minerals of different sizes are transported and deposited but also in the chemical conditions that permit precipitation of various authigenic minerals.

Diagenesis includes all physicochemical, biochemical, and physical processes (short of metamorphism) that modify sediments in the time between their deposition and their analysis. Lithification, the process by which sediment is converted into solid sedimentary rock, is one result of diagenesis. Many diagenetic processes such as cementation, recrystallization, and dolomitization are essentially geochemical processes; others like compaction are fundamentally physical processes. All diagenetic changes occur at the low temperatures and pressures characteristic of surface and near-surface environments. These changes can take place almost immediately after sediment formation, or they can occur hundreds or even millions of years later.

Sedimentary structures

Sedimentary structures are the larger, generally three-dimensional physical features of sedimentary rocks; they are best seen in outcrop or in large hand specimens rather than through a microscope. Sedimentary structures include features like bedding, ripple marks, fossil tracks and trails, and mud cracks. They conventionally are subdivided into categories based on mode of genesis. Structures that are produced at the same time as the sedimentary rock in which they occur are called primary sedimentary structures. Examples include bedding or stratification, graded bedding, and cross-bedding. Sedimentary structures that are produced shortly after deposition and as a result of compaction and dessication are called penecontemporaneous sedimentary structures. Examples include mud cracks and load casts. Still other sedimentary structures like concretions, vein fillings, and stylolites form well after deposition and penecontemporaneous modification; these are known as secondary structures. Finally, others like stromatolites and organic burrows and tracks, though they may in fact be primary, penecontemporaneous, or even secondary, may be grouped as a fourth category—organic sedimentary structures.

Considerable attention is paid to the sedimentary structures exhibited by any sedimentary rock. Primary sedimentary structures are particularly useful because their abundance and size suggest the probable transporting and depositional agents. Certain varieties of primary sedimentary structures like cross-bedding and ripple marks display orientations that are consistently related to the direction

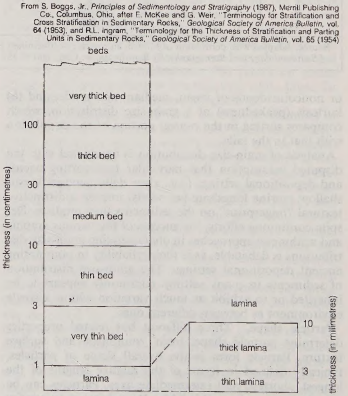

Figure 123: Descriptive terms for the thickness of beds and laminae.

of current movement. Such structures are referred to as directional sedimentary structures because they can be used to infer the ancient paleocurrent pattern or dispersal system by which a sedimentary rock unit was deposited.

Top and bottom indicators

Other sedimentary structures are stratigraphic "top and bottom" indicators. For example, the progressive upward decrease in clastic grain size diameters, known as graded bedding, would allow a geologist to determine which way is stratigraphically "up"—*i.e.,* toward the younger beds in a dipping sedimentary bed. The suite (repeated sequence) of sedimentary structures in any single stratigraphic unit is another attribute by which that unit may be physically differentiated from others in the region. (F.L.S.)

EXTERNAL STRATIFICATION

Stratification (or bedding) is expressed by rock layers (units) of a general tabular or lenticular form that differ in rock type or other characteristics from the material with which they are interstratified (sometimes stated as interbedded, or interlayered). These beds, or strata, are of varying thickness and areal extent. The term stratum identifies a single bed, or unit, normally greater than one centimetre in thickness and visibly separable from superjacent (overlying) and subjacent (underlying) beds. "Strata" refers to two or more beds, and the term lamina is sometimes applied to a unit less than one centimetre in thickness. Thus, lamination consists of thin units in bedded, or layered, sequence in a natural rock succession, whereas stratification consists of bedded layers, or strata, in a geologic sequence of interleaved sedimentary rocks.

For most stratified sedimentary rocks, the arrangement of layers is one of unequal thickness, ranging from very thin laminae to discrete beds that measure a few to many metres in thickness. The terms thick and thin as applied to bedding, or stratification, are relative, reflecting the training of a particular geologist as well as experience with a specific stratigraphic section or sections. Some quantitative values that have been proposed are shown in Figure 123.

BEDDING TYPES AND BEDDING-PLANE FEATURES

Types. It is common to discover a rhythmic pattern in a pile of stratified sedimentary rocks represented by a repetitive sequence of rock types. In most instances of such cyclic sedimentation, the bedding, or stratification, is horizontal or essentially so; that is, the transporting, sorting, and depositing agents of wind, running water, and lake and ocean currents and waves accumulated the laminae and strata in a flat-lying or horizontal arrangement. They are termed well-bedded, a type of primary stratification.

Primary stratification in sediments and sedimentary rocks can be cross-bedded (cross-stratified), graded, and imbricate and can also display climbing laminae, ripples, and beds. A simplified classification of cross-stratification into three principal types (simple, planar, and trough) is shown in Figure 124.

Graded and imbricate bedding

Graded bedding simply identifies strata that grade upward from coarse-textured clastic sediment at their base to finer-textured materials at the top (Figure 125). The stratification may be sharply marked so that one layer is set off visibly from those above and beneath it. More commonly, however, the layers are blended. This variety of bedding results from a check in the velocity of the transporting agent, and thus coarse-textured sediment (gravel, for example) is deposited first, followed upward by pebbles, granules, sand, silt, and clay. It is commonly associated with submarine density currents.

Imbricate bedding is a shingle structure in a deposit of flattened or disk-shaped pebbles or cobbles (Figure 125). That is to say, elongated and commonly flattened pebbles and cobbles in gravelly sediment are deposited so that they overlap one another like roofing shingles. Imbricate bedding forms where high-velocity currents move over a streambed or where strong currents and waves break over a gradually sloping beach, thereby forming beach shingle.

Growth structures in sedimentary rocks are in situ features that accumulate largely as the result of organic buildups within otherwise horizontal or nearly flat-lying strata. Reefs and stromatolites are two common varieties of such growth structures.

Bedding-plane features. Upper surfaces of beds commonly display primary sedimentary features that are classified as bedding-plane structures. A three-dimensional view may be obtained if some of these can be seen from the side as well as from the top of a pile of strata. They include such features as ripples (ripple marks), climbing ripples, rills, pits, mud cracks, trails and tracks, salt and ice casts and molds, and others. Bedding-plane markings and irregularities can be allocated to one of three classes: (1) those on the base of a bed (load and current structures and organic markings), (2) those within a bed (parting lineation), and (3) those on top of a bed (ripple marks, pits, impressions, mud cracks, tracks and trails of organisms, and others).

DEFORMATION STRUCTURES

In addition to sedimentary structures that are normally associated with bedding planes, there are other such structures that result from deformation during or shortly after

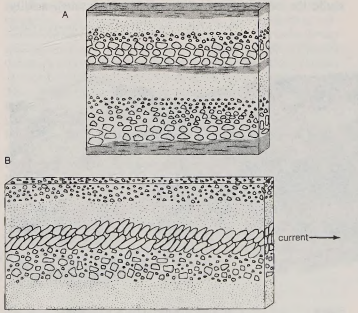

Figure 125: (A) Graded bedding. (B) Imbricate bedding.

sedimentation but before induration of the sediment into rock. These are nontectonic features—*i.e.*, they are not bends and folds brought about by metamorphism or other such causes. Deformation structures can be grouped into several classes, as follows: (1) founder and load structures, (2) convoluted structures, (3) slump structures, (4) injection structures, such as sandstone dikes or sills, and (5) organic structures. Pillow and convoluted structures are shown in Figures 126 and 127.

Structures found on the bottom of a bed are called sole markings, because they formed on the "sole" of the bed. Sole marks are commonly formed on sandstone and limestone beds that rest upon shale beds. They are termed casts, because they are fillings of depressions that formed on the surface of the underlying mud. They originate (1) by unequal loading upon the soft and plastic wet mud, (2) by the action of currents across the upper mud surface, or (3) by the activities of organisms on this surface. Load casts form as the result of downsinking of sandstone or limestone into the mud beneath. Current marks can form by the action of water currents on upper surfaces of the beds or by "tools" (such as wood and fossils) that are transported by currents over soft sediment.

Sedimentary environments

The sedimentary environment is the specific depositional setting of a particular sedimentary rock and is unique in terms of physical, chemical, and biological characteristics. The physical features of a sedimentary environment include water depth and the velocity and persistence of currents. Chemical characteristics of an environment include the salinity (proportion of dissolved salts), acidity or basicity (pH), oxidation potential (Eh), pressure, and temperature. The biological characteristics are mainly the assemblage of fauna and flora that populate the setting. These conditions, combined with the nature of the transporting agent and the source area, largely determine the properties of the sediments deposited within the environment. A number of ways of classifying depositional environments exist, but most modern schemes employ a geomorphologic approach. That is to say, an environment is defined in terms of a distinct geomorphic unit or landform, modern examples of which are readily visible for comparative purposes—*e.g.*, a river delta, an alluvial fan, a submarine fan, or the abyssal floor of an ocean basin.

Individual environments are further grouped into (1) marine environments, which include the nearshore, shallow littoral zone and the offshore, deep littoral zone, as well as deepwater realms, (2) mixed marine and nonmarine settings such as the beach and supratidal zones, and (3) nonmarine settings like lacustrine and various alluvial settings. Each environment is associated with a set of criteria that constitutes its distinguishing features. (H.J.Bi./F.L.S.)

Sedimentary rock types

CONGLOMERATES AND BRECCIAS

Conglomerates and breccias are sedimentary rocks composed of coarse fragments of preexisting rocks held together either by cement or by a finer-grained clastic matrix. Both contain significant amounts (at least 10 percent) of coarser-than-sand-size clasts. Breccias are consolidated rubble; their clasts are angular or subangular as shown in Figure 128. Conglomerates are consolidated gravel whose clasts are subrounded to rounded. Sometimes the term rudite (or rudaceous) is used to collectively refer to both breccias and conglomerates.

A number of classification schemes have been proposed to further subdivide conglomerates and breccias. One scheme is purely descriptive, partitioning these coarse clastic sedimentary rocks on the basis of grain size (*e.g.*, boulder breccia versus cobble conglomerate) or composition or both (chert pebble breccia versus limestone cobble conglomerate). Yet another scheme differentiates individual conglomerates and breccias according to depositional agency and environmental setting (alluvial fan conglomerate as opposed to beach conglomerate). The best classification systems incorporate objective physical characteristics of both composition and texture as well as mode of genesis. Conglomerates and breccias belong to four genetic categories: (1) epiclastic, produced by the physical disintegration (weathering) of preexisting rocks, (2) pyroclastic, produced by the explosive activity of volcanoes, (3) cataclastic, formed by local earth movements (fault breccias) or solution phenomena (collapse breccias), and (4) meteoritic, produced by the impact of extraterrestrial bodies on the Earth's surface. In a strict sense, epiclastic conglomerates and breccias are the only true sedimentary rocks, because they alone are produced by weathering. (E.t.H./F.L.S.)

Figure 127: Convolute lamination, Krosno Beds (Oligocene), from Mymon, central Carpathians, Pol.

There are two principal types of epiclastic conglomerates and breccias: intraformational, derived penecontemporaneously by eroding, transporting, and depositing material from within the depositional basin itself; and interformational, derived from source rocks that lie outside the area in which the deposit occurs. Epiclastic conglomerates and breccias together probably make up no more than 1 or 2 percent of the conventional sedimentary rock record.

Epiclastic conglomerates and breccias

Intraformational conglomerates and breccias are widespread in the geologic record but are volumetrically unimportant. They occur as laterally continuous bands or horizons within sequences of shallow-water marine or nonmarine deposits. Their origin is commonly related to the existence of brief episodes of strong bottom-hugging currents capable of ripping up recently deposited, unconsolidated sediment. For example, shallow marine limestone deposits commonly have thin bands of boulder-, cobble-, and pebble-size carbonate clasts (edgewise conglomerate or breccia beds) that are generated when storm waves erode and redeposit carbonate mud layers. Likewise, high-velocity river currents that accompany torrential rains

give rise to shale pebble conglomerates and breccias within sequences of floodplain alluvium. Other intraformational conglomerates and breccias mix shallow- and deep-water sedimentary rock clasts encased in a finer-grained matrix of deeper-water material. Such deposits accumulate as depositional aprons that flank the scarps (steep slopes) bounding shallow-water platformal areas such as the modern Great Bahama and Little Bahama banks off Florida in the southeastern United States.

Interformational conglomerates and breccias, the coarse clastic sedimentary rocks derived by the weathering of preexisting rocks outside the depositional basin, are most important from the points of view of both volume and geologic significance (see Figure 129). They can be subdivided into two specific categories: (1) orthoconglomerates (and breccias) and (2) paraconglomerates (and breccias).

Orthoconglomerates. These rocks contain less than 15 percent matrix—*i.e.,* material composed of clasts finer than granule size (2-millimetre diameter or less). They typically exhibit an intact fabric that has a clast-supported framework such that the individual granules, pebbles, cobbles, and boulders touch each other. The space between framework components either is empty or is filled with chemical cement, finer-than-granule clasts, or both. Orthoconglomerates may be composed of large clasts of a single rock or mineral type (oligomictic orthoconglomerates), or they may contain a variety of rock and mineral clast types (petromictic orthoconglomerates).

Oligomictic and petromictic

Orthoconglomerates (and orthobreccias) are deposited by highly turbulent water. For example, beach deposits commonly contain lenses and bands of oligomictic orthoconglomerate, composed mainly (95 percent or more) of stable, resistant, coarse clasts of vein quartz, quartzite, quartz sandstone, and chert. Such deposits are typically generated in the upper reaches of winter storm beaches where strong surf can sift, winnow, and abrade coarse pebbles and boulders. The most indestructible components are thereby consolidated as orthoconglomeratic lenses that are interfingered with finer-grained, quartz-rich beach sandstones. Petromictic orthoconglomerates and breccias, on the other hand, reflect the existence of high-relief (mountainous) source areas. Topographically high source areas signify tectonic mobility in the form of active folding or faulting or both. The existence of petromictic orthoconglomerates and breccias in the geologic record is therefore significant: their presence and age not only pinpoint the timing and location of mountain building accompanied by sharp uplift and the possibility of regionally significant fault scarps but also can be used to infer the past distribution of physiographic features such as mountain fronts, continental block margins, continental shelf-continental slope boundaries, and the distribution of oceanic trenches and volcanic island arcs.

Bedding (layering and stratification) in orthoconglomerates, if apparent at all, is typically thick and lenticular. Graded bedding, in which size decreases from bottom to top, is common: because agitated waters rarely subside at once, declining transport power causes a gradual upward decrease in maximum clast size. Relative to the bedding, the pebbles in sandy conglomerates tend to lie flat, with their smallest dimension positioned vertically and the greatest aligned roughly parallel to the current. In closely packed orthoconglomerates, however, there is often a distinct imbrication; *i.e.,* flat pebbles overlap in the same direction like roof shingles. Imbrication is upstream on riverbeds and seaward on beaches.

Orthoconglomerates are quite important economically because they hold enormous water reserves that are easily released through wells. This feature is attributable to their high porosity and permeability. Porosity is the volume percentage of "void" (actually fluid- or air-filled) space in a rock, whereas permeability is defined as the rate of flow of water at a given pressure gradient through a unit volume. The interconnectedness of voids in orthoconglomerates contributes to their permeability. Also, because the chief resistance to flow is generally due to friction and capillary effects, the overall coarse grain size makes conglomerates even more permeable. The high degree of porosity and permeability causes orthoconglomerates to generate excellent surface drainage, so they are to be avoided as dam and reservoir sites.

Paraconglomerates. Paraconglomerates and breccias, also called diamictites, exhibit a disrupted, matrix-supported fabric; they contain 15 percent or more (sometimes as much as 80 percent) sand-size and finer clastic matrix. The coarse detrital clasts "float" in a finer-grained detrital matrix. They actually are mudrocks in which there is a sprinkling of granules, pebbles, cobbles, or boulders, or some combination of them. Accordingly, they are sometimes referred to as conglomerate mudstones or pebbly mudstones.

Although diamictites originate in a variety of ways, they are not deposited by normal currents of moving water. Some are produced by submarine landslides, massive slumping, or dense, sediment-laden, gravity-driven turbidity flows. Paraconglomerates that can be definitively related to such mechanisms are called tilloids. Tilloids commonly make up olistostromes, which are large masses of coarse blocks chaotically mixed within a muddy matrix.

Tills and tillites

The terms till (when unconsolidated) and tillite (when lithified) are used for diamictites that appear to have been directly deposited by moving sheets of glacial ice. Tillites typically consist of poorly sorted angular and subangular, polished and striated blocks of rock floating in an unstratified clay matrix. The clasts may exhibit a weak but distinct alignment of their long axes approximately parallel to the direction of ice flow. Tillites are notoriously heterogeneous in composition: clasts appear to be randomly mixed together without respect to size or compositional stability. These clasts are derived mainly from the underlying bedrock. Extremely coarse, far-traveled blocks and boulders are called erratics.

Other rarer diamictites, known as laminated pebbly (or cobbly or bouldery) mudstones, consist of delicately laminated mudrocks in which scattered coarser clasts occur. Laminations within the muddy component are broken

and bent. They are located beneath and adjacent to the larger clasts but gently overlap or arch over them, suggesting that the coarse clasts are dropstones (*i.e.*, ice-rafted blocks released as floating masses of ice melt).

SANDSTONES

Sandstones are siliciclastic sedimentary rocks that consist mainly of sand-size grains (clast diameters from 2 to 1/16 millimetre) either bonded together by interstitial chemical cement or lithified into a cohesive rock by the compaction of the sand-size framework component together with any interstitial primary (detrital) and secondary (authigenic) finer-grained matrix component. They grade, on the one hand, into the coarser-grained siliciclastic conglomerates and breccias described above, and, on the other hand, into siltstones and the various finer-grained mudrocks described below. Like their coarser analogues—namely, conglomerates and breccias—sand-size (also called arenaceous) sedimentary rocks are not exclusively generated by the physical disintegration of preexisting rocks. Varieties of limestone that contain abundant sand-size allochems like oöids and fossil fragments are, in at least a textural sense, types of sandstones, although they are not terrigenous siliciclastic rocks. Such rocks, called calcarenites when lithified or carbonate sands when unconsolidated, are more properly discussed as limestones. Also, pyroclastic sandstones or tuffs formed by lithifying explosively produced volcanic ash deposits can be excluded from this discussion because their origin is unrelated to weathering.

Sandstones are significant for a variety of reasons. Volumetrically they constitute between 10 and 20 percent of the Earth's sedimentary rock record. They are resistant to erosion and therefore greatly influence the landscape. When they are folded, they create the backbone of mountain ranges like the Appalachians of eastern North America, the Carpathians of east-central Europe, the Pennines of northern England, and the Apennine Range of Italy; when flat-lying, they form broad plains and plateaus like the Colorado and Allegheny plateaus. Sandstones are economically important as major reservoirs for both petroleum and water, as building materials, and as valuable sources of metallic ores. Most significantly, they are the single most useful sedimentary rock type for deciphering Earth history. Sandstone mineralogy is the best indicator of sedimentary provenance: the nature of a sedimentary rock source area, its composition, relief, and location. Sandstone textures and sedimentary structures also are reliable indexes of the transportational agents and depositional setting.

Uses of sandstones

Sandstone components and colour. There are three basic components of sandstones: (1) detrital grains, mainly transported, sand-size minerals such as quartz and feldspar, (2) a detrital matrix of clay or mud, which is absent in "clean" sandstones, and (3) a cement that is chemically precipitated in crystalline form from solution and that serves to fill up original pore spaces.

The colour of a sandstone depends on its detrital grains and bonding material. An abundance of potassium feldspar often gives a pink colour; this is true of many arkoses, which are feldspar-rich sandstones. Fine-grained, dark-coloured rock fragments, such as pieces of slate, chert, or andesite, however, give a salt-and-pepper appearance to a sandstone. Iron oxide cement imparts tones of yellow, orange, brown, or red, whereas calcite cement imparts a gray colour. A sandstone consisting almost wholly of quartz grains cemented by quartz may be glassy and white. A chloritic clay matrix results in a greenish black colour and extreme hardness; such rocks are wackes.

Formation of sandstones today. Sandstones occur in strata of all geologic ages. Much scientific understanding of the depositional environment of ancient sandstones comes from detailed study of sand bodies forming at the present time. One of the clues to origin is the overall shape of the entire sand deposit. Inland desert sands today cover vast areas as a uniform blanket; some ancient sandstones in beds a few hundred metres thick but 1,600 kilometres or more in lateral extent, such as the Nubian Sandstone of North Africa, of Mesozoic age (about 245 to 66.4 million years old), also may have formed as blankets of desert sand. Deposits from alluvial fans form thick, fault-bounded prisms. River sands today form shoestring-shaped bodies, tens of metres thick, a few hundred metres wide, up to 60 kilometres or more long, and usually oriented perpendicularly to the shoreline. In meandering back and forth, a river may construct a wide swath of sand deposits, mostly accumulating on meander-point bars. Beaches, coastal dunes, and barrier bars also form "shoestring" sands, but these are parallel to the shore. Deltaic sands show a fanlike pattern of radial, thick, finger-shaped sand bodies interbedded with muddy sediments. Submarine sand bodies are diverse, reflecting the complexities of underwater topography and currents. They may form great ribbons parallel with the current; huge submarine "dunes" or "sand waves" aligned perpendicularly to the current; or irregular shoals, bars, and sheets. Some sands are deposited in deep water by the action of density currents, which flow down submarine slopes by reason of their high sediment concentrations and, hence, are called turbidity currents. These characteristically form thin beds interbedded with shales; sandstone beds often are graded from coarse grains at the base to fine grains at the top of the bed and commonly have a clay matrix.

Bedding structure. One of the most fruitful methods of deciphering the environment of deposition and direction of transport of ancient sandstones is detailed field study of the sedimentary structures.

Bedding in sandstones, expressed by layers of clays, micas, heavy minerals, pebbles, or fossils, may be tens of feet thick, but it can range downward to paper-thin laminations. Flagstone breaks in smooth, even layers a few centimetres thick and is used in paving. Thin, nearly horizontal lamination is characteristic of many ancient beach sandstones. Bedding surfaces of sandstones may be marked by ripples (almost always of subaqueous origin), by tracks and trails of organisms, and by elongated grains that are oriented by current flow (fossils, plant fragments, or even elongated sand grains). Sand-grain orientation tends to parallel direction of the current; river-channel trends in fluvial sediments, wave-backwash direction in beach sands, and wind direction in eolian sediments are examples of such orientation.

Bedding-plane markings and cross-bedding

A great variety of markings, such as flutes and scour and fill grooves, can be found on the undersides of some sandstone beds. These markings are caused by swift currents during deposition; they are particularly abundant in sandstones deposited by turbidity currents.

Within the major beds, cross-bedding is common. This structure is developed by the migration of small ripples, sand waves, tidal-channel large-scale ripples, or dunes and consists of sets of beds that are inclined to the main horizontal bedding planes. Almost all sedimentary environments produce characteristic types of cross-beds; as one example, the lee faces of sand dunes (side not facing the wind) may bear cross-beds as much as 33 metres (108 feet) high and dipping 35°.

Some sandstones contain series of graded beds. The grains at the base of a graded bed are coarse and gradually become finer upward, at which point there is a sharp change to the coarse basal layer of the overlying bed. Among the many mechanisms that can cause these changes in grain size are turbidity currents, but in general they can be caused by any cyclically repeated waning current.

After the sand is deposited, it may slide downslope or subside into soft underlying clays. This shifting gives rise to contorted or slumped bedding on a scale of centimetres to tens of metres. Generally these are characteristic of unstable areas of rapid deposition.

Local cementation may result in concretions of calcite, pyrite, barite, and other minerals. These can range from sand crystals or barite roses to spheroidal or discoidal concretions tens of metres across.

The fossil content also is a useful guide to the depositional environment of sandstones. Desert sandstones usually lack fossils. River-channel and deltaic sandstones may contain fossil wood, plant fragments, fossil footprints, or vertebrate remains. Beach and shallow marine sands contain mollusks, arthropods, crinoids, and other marine creatures, though marine sandstones are much less fossiliferous than marine limestones. Deepwater sands

are frequently devoid of skeletal fossils, although tracks and trails may be common. The fossils are not actually structures, of course, but the living organisms were able to produce them. Burrowing by organisms, for example, may cause small-scale structures, such as eyes and pods or tubules of sand.

Texture. The texture of a sandstone is the sum of such attributes as the clay matrix, the size and sorting of the detrital grains, and the roundness of these particles. To evaluate this property, a scale of textural maturity that involved four textural stages was devised in 1951 (see Figure 130). These stages are described as follows.

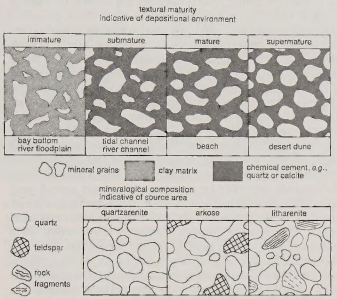

Figure 130: Textural maturity and mineralogical composition of sandstones from various environments.

Degree of textural maturity

Immature sandstones contain a clay matrix, and the sand-size grains are usually angular and poorly sorted. This means that a wide range of sand sizes is present. Such sandstones are characteristic of environments in which sediment is dumped and is not thereafter worked upon by waves or currents. These environments include stagnant areas of sluggish currents such as lagoons or bay bottoms or undisturbed seafloor below the zone of wave or current action. Immature sands also form where sediments are rapidly deposited in subaerial environments, such as river floodplains, swamps, alluvial fans, or glacial margins. Submature sandstones are created by the removal of the clay matrix by current action. The sand grains are, however, still poorly sorted in these rocks. Submature sandstones are common as river-channel sands, tidal-channel sands, and shallow submarine sands swept by unidirectional currents. Mature sandstones are clay-free, and the sand grains are subangular, but they are well sorted—that is, of nearly uniform particle size. Typically, these sandstones form in environments of current reversal and continual washing, such as beaches. Supermature sandstones are those that are clay-free and well sorted and, in addition, in which the grains are well rounded. These sandstones probably formed primarily as desert dunes, where intense eolian abrasion over a very long period of time may wear sand grains to nearly spherical shapes.

The methodology used for detailed study of siliciclastic sedimentary rock textures, particularly grain-size distribution and grain shape (angularity and sphericity) has been described above. The information that results from textural analyses is especially useful in identifying sandstone depositional environments. Dune sands in all parts of the world, for example, tend to be fine-sand-size (clast diameters from $^1/_4$ to $^1/_8$ millimetre) because sand of that dimension is most easily moved by winds. Desert (eolian) sandstones also tend to be bimodal or polymodal—*i.e.*, having two (or more) abundant grain-size classes separated by intervening, less prevalent size classes. Dune and beach sands exhibit the best sorting; river and shallow marine sands are less well sorted. River-floodplain, deltaic, and turbidity-current sand deposits show much poorer sorting. Skewness (the symmetry or asymmetry of a grain-size distribution) also varies as a function of depositional setting. Beach sands are commonly negatively skewed (they have a tail of more poorly sorted coarse grains), whereas dune and river sands tend to be positively skewed (a tail of more poorly sorted fine grains).

Shape and roundness

Careful analysis of grain roundness and grain shape also can aid in distinguishing the high-abrasion environments of beach and especially dune sands from those of fluvial or marine sands. Rounding takes place much more rapidly in sands subjected to wind action than in water-laid sands. In general, coarser sand grains are better rounded than finer grains because the coarser ones hit bottom more frequently and also hit with greater impact during transport. Sand grains may also have polished, frosted, pitted, or otherwise characteristic surfaces. These depend on the grain size, the agent of transport, and the amount of chemical attack. For example, polish can occur on medium-grained beach sands and fine-grained desert sands and can also be produced chemically by weathering processes.

Mineral composition. Mineralogical study of sandstones has proceeded along two distinct lines. One method involves cutting a thin section (0.03 millimetre thick) from the rock for examination of the mineralogy, cementation, texture, and structures with a petrographic microscope. This thin section approach was first used in the 1870s. Another method is to disaggregate the sand and place the grains in a heavy liquid such as bromoform (specific gravity about 2.9). This concentrates the heavy minerals that are present in minute amounts (0.01 to 1 or 2 percent of the rock) for detailed microscopic study. These methods offer valuable clues as to source area composition.

Although sandstones may be composed of any mineral, the most common mineral is quartz (SiO_2), which constitutes about 80 percent of the average sandstone; a few sandstones, however, lack quartz entirely, whereas others contain more than 99 percent quartz. Microscopic study reveals a great many types of quartz, recognizable by their appearance in polarized light and by inclusions of gas or liquid bubbles or other substances. Volcanic quartz, various types of metamorphic quartz, hydrothermal quartz, and other varieties are known. Other detrital minerals of common occurrence are the feldspars and micas. The abundance of these chemically less resistant silicates has been used as a climatic indicator. Sand-size fragments of older fine-grained rocks (*e.g.*, chert, slate, and basalt) are common in many sandstones. Clay matrix, if present, may consist of the minerals illite, kaolinite, montmorillonite, or clay-size micas. Some marine sandstones contain an abundance of pellets of glauconite (greensands) or phosphates in the form of bones, teeth, scales, or chemical precipitates. These sands are useful as fertilizers.

Classification of sandstones. There are many different systems of classifying sandstones, but the most commonly used schemes incorporate both texture (the presence and amount of either interstitial matrix—*i.e.*, clasts with diameters finer than 0.03 millimetre—or chemical cement) and mineralogy (the relative amount of quartz and the relative abundance of rock fragments to feldspar grains). The system presented here (Figure 131) is that of the American petrologist Robert H. Dott (1964), which is based on the concepts of P.D. Krynine and F.J. Pettijohn.

Arenites and wackes

Sandstones are first subdivided into two major textural groups, arenites and wackes. Arenites (the front triangular panel of Figure 131) consist of a sand-size framework component surrounded by pore spaces that are either empty (in the case of arenite sands) or filled with crystalline chemical cement (in the case of arenites). Wackes (the second triangular panel of Figure 131) consist of a sand-size framework component floating in a finer-grained pasty matrix of grains finer than 0.03 millimetre whose overall abundance exceeds 15 percent by volume. A third triangular panel in the background shows the natural transition from sandstones to mudrocks as the percentage of sand-size framework clasts decreases.

Further subdivision of both arenites and wackes into three specific sandstone families is based on the relative proportions of three major framework grain types: quartz (Q), feldspar (F), and rock fragments (R for rock fragment, or L for lithic fragment). For example, quartz arenites are rocks whose sand grains consist of at least 95 percent

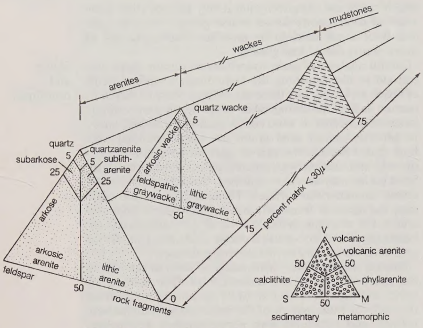

Figure 131: Classification of terrigenous sandstones.

quartz. If the sand grains consist of more than 25 percent feldspar (and feldspar grains are in excess of rock fragments), the rock is termed arkosic arenite or "arkose," although such sandstones are also somewhat loosely referred to as feldspathic sandstones. In subarkosic arenite (or subarkose), feldspar sand grains likewise exceed rock fragments but range in abundance from 5 to 15 percent. Lithic arenites (or litharenites) have rock fragments that exceed feldspar grains; the abundance of rock fragments is greater than 25 percent. Sublitharenites likewise contain more rock fragments than feldspar, but the amount of rock fragments is lower, ranging from 5 to 25 percent. Lithic arenites can be further subdivided according to the nature of the rock fragments, as shown in the smaller triangle of Figure 131. This classification scheme also recognizes three major types of wackes or graywackes that are roughly analogous with the three major arenite groups: quartz wacke, feldspathic wacke (with the subvariety arkosic wacke), and lithic wacke. The three major arenite sandstone families are separately described below, but the varieties of wacke can be conveniently considered together as a single group.

Quartz arenites. Quartz arenites are usually white, but they may be any other colour; cementation by hematite, for example, makes them red. They are usually well sorted and well rounded (supermature) and often represent ancient dune, beach, or shallow marine deposits. Characteristically, they are ripple-marked or cross-bedded and occur as widespread thin blanket sands. On chemical analysis, some are found to contain more than 99 percent SiO_2 (quartz). Most commonly they are cemented with quartz, but calcite and iron oxide frequently serve as cements as well.

St. Peter Sandstone

This type of sandstone is widespread in stable areas of continents surrounding the craton, such as central North America (St. Peter Sandstone of Ordovician age [about 505 to 438 million years old]), central Australia, or the Russian Platform, and are particularly common in Paleozoic strata (that formed from 570 to 245 million years ago). Quartz arenites have formed in the past when large areas of subcontinental dimensions were tectonically stable (not subject to uplift or deformation) and of low relief, so that extensive weathering could take place, accompanied by prolonged abrasion and sorting. This process eliminated all the unstable or readily decomposed minerals such as feldspar or rock fragments and concentrated pure quartz together with trace amounts of zircon, tourmaline, and various other resistant heavy minerals.

Quartz arenites have also accumulated to thicknesses of hundreds and even thousands of metres on the continental shelf areas produced as passive continental margins develop during the early stages of continental rifting and the opening of an ocean basin. These thick, continental margin deposits form only if source areas are sufficiently stable to permit beach abrasion and intense chemical weathering capable of destroying rock fragments and feldspars. Subsequent ocean basin closure and continental collision deforms the continental shelf and rise assemblages, incorporating clean quartz arenite units into the resulting folded and faulted mountain system, typically as major ridges. Examples include the Cambrian Chilhowee Group and Silurian Tuscarora Sandstone and Clinch Sandstone formations in the Appalachian Mountains of eastern North America and the Flathead Sandstone and Tapeats Sandstone of the Rocky Mountains in the western part of the continent. Some quartz arenites are shown in Figures 132 and 133.

Arkosic sandstones. Arkosic sandstones are of two types. The most common of these is a mixture of quartz, potash feldspar, and granitic rock fragments. Chemically, these rocks are 60–70 percent silica (or silicon dioxide) and 10–15 percent aluminum oxide (Al_2O_3), with significant amounts of potassium (K), sodium (Na), and other elements. This type of arkosic sandstone, or arkose, can form wherever block faulting of granitic rocks occurs, given rates of uplift, erosion, and deposition that are so great that chemical weathering is outweighed and feldspar can survive in a relatively unaltered state. These rocks are usually reddish, generally immature, very poorly sorted, and frequently interbedded with arkose conglomerate; alluvial fans or fluvial aprons are the main depositional environments. The Triassic Newark Group of Connecticut is a classic example of this type of arkosic sandstone. Arkose

Arkoses also form under desert (or rarely Arctic) conditions in which the rate of chemical decomposition of the parent granite or gneiss is very slow. These arkoses are generally well sorted and rounded (supermature) and show other desert features, such as eolian cross-beds, associated gypsum, and other evaporitic minerals. The Precambrian Torridonian Arkose of Great Britain is thought to be of desert origin. Basal sands deposited on a granitic-gneissic craton also are usually arkosic. Subarkose sandstones (*e.g.,* Millstone Grit from the Carboniferous of England) have a feldspar content that is diminished by more extensive weathering or abrasion or by dilution from nonigneous source rocks.

Lithic arenites. Lithic arenites occur in several subvarieties, but they are normally gray or of salt-and-pepper appearance because of the inclusion of dark-coloured rock fragments. Most commonly, fragments of metamorphic rocks such as slate, phyllite, or schist predominate, producing phyllarenite. If volcanic rock fragments such as andesite and basalt are most abundant, the rock is termed a volcanic arenite. If chert and carbonate rock fragments are predominant, the name chert or calchithite is applied.

Lithic arenites are usually rich in mica and texturally immature; the silicon dioxide content is 60–70 percent; aluminum oxide is 15 percent; and potassium, sodium, iron (Fe), calcium (Ca), and magnesium (Mg) are present in lesser amounts. Lithic arenites are very common in the geologic record, are widespread geographically, and are of all ages. They generally were formed as the result of rapid uplift, intense erosion, and high rates of deposition. Many of the classic postorogenic clastic wedge systems found in the major mountain systems of the world contain abundant lithic arenites. In the Appalachians, these include the Ordovician Juniata Formation of the Taconic clastic wedge, the Devonian Catskill Formation of the Acadian clastic wedge, and the Pocono and Mauch Chunk formations of the Alleghenian clastic wedge. Most lithic arenites are deposited as fluvial apron, deltaic, coastal plain, and shallow marine sandstones, interbedded with great thicknesses of shale and frequently with beds of coal or limestone. If they are deposited in an oxidizing environment such as a well-drained river system, they are reddish (*e.g.*, the Catskill Formation of the northeastern United States and the Devonian Old Red Sandstone of England).

Wackes. Wacke, or graywacke, is the name applied to generally dark-coloured, very strongly bonded sandstones that consist of a heterogeneous mixture of rock fragments, feldspar, and quartz of sand size, together with appreciable amounts of mud matrix. Almost all wackes originated in the sea, and many were deposited in deep water by turbidity currents.

Characteristics of wackes

Wackes typically are poorly sorted, and the grain sizes present range over three orders of magnitude—*e.g.*, from 2 to 2,000 micrometres (8×10^{-5} to 8×10^{-2} inch). Commonly, the coarsest part of a wacke bed is its base, where pebbles may be abundant. Shale fragments, which represent lumps of mud eroded from bottom sediments by the depositing current, may be concentrated elsewhere in the bed.

Many wackes contain much mud, typically 15–40 percent, and this increases as the mean grain size of the rock decreases. The particles forming the rock are typically angular. This, and the presence of the interstitial mud matrix, has led to these rocks being called "microbreccias." The fabric and texture indicate that the sediments were carried only a short distance and were subject to very little reworking by currents after deposition.

The most widespread internal structure of wackes is graded bedding (Figure 134), although some sequences display it poorly. Sets of cross strata more than three centimetres thick are rare, but thinner sets are very common. Parallel lamination is widespread, and convolute bedding is usually present. These internal structures are arranged within wacke beds in a regular sequence. They appear to result from the action of a single current flow and are related to changes in the hydraulics of the depositing current. In some beds, the upper part of the sequence of structures is missing, presumably because of erosion or nondeposition. In others, the lower part is missing. This has been attributed to change in the hydraulic properties of the depositing current as it moves away from its source and its velocity decreases to the point at which the first sediment deposited is laminated, rather than massive and graded as is the case closer to the source.

The most typical external structures of wacke beds are sole markings, which occur on their undersurfaces. Flute and groove molds (Figure 134) are the most characteristic, but many other structures have been recorded.

The upper surfaces of wacke beds are less well characterized by sedimentary structures. The most typical are current lineation and various worm tracks, particularly of the highly sinuous form *Nereites*. Apart from these trace fossils, wackes are usually sparsely fossiliferous. Where fossils occur they are generally free-floating organisms (graptolites, foraminiferans) that have settled to the bottom, or bottom-living (benthic), shallow-water organisms displaced into deeper water as part of the sediment mass.

Chemical composition

Wackes are chemically homogeneous and are generally rich in aluminum oxide (Al_2O_3), ferrous oxide (FeO) + ferric oxide (Fe_2O_3), magnesium oxide (MgO), and soda (Na_2O). The abundance of soda relative to potash (K_2O) (reflecting a typically high sodium plagioclase feldspar content) and dominance of ferrous oxide over ferric oxide (reflecting large amounts of chlorite in the matrix) chemically distinguishes wackes from the three arenite families. The bulk composition of most wackes mimics that of their source owing to a lack of chemical differentiation by weathering and sorting. The matrix component, which is by definition any clasts 30 micrometres or finer, allows wackes to be differentiated from the other major sandstones. To be characterized as a wacke, its matrix component must equal or exceed 15 percent; in some cases more than 50 percent matrix has been reported. The origin of the matrix component, however, is controversial. Even though laboratory studies demonstrate that gravity-driven, bottom-hugging turbidity currents deposit sand-size grains together with mud-size clasts, modern deep-sea fan and abyssal plain sands (turbidites) have a matrix component that seldom exceeds 10 percent. A large portion of the matrix in ancient wackes must therefore be secondary, derived either from the disaggregation of feldspar and fine-grained lithic fragments like shale, phyllite, and volcanic rocks or from the postdepositional infiltration of clay- and silt-size clasts from overlying beds.

Wackes are widespread in the geologic record and occur throughout geologic history. They typically are not found in association with sedimentary rocks that accumulate upon stable continental blocks and are instead confined either to intensely deformed mountain systems or to their modern analogues: ocean trenches, the continental slope and rise, and abyssal plain areas. Many, perhaps most, wackes are redeposited marine sands derived from source areas in which weathering, erosion, and deposition are too rapid to permit chemical differentiation and the break-

down of unstable components. Wackes of Archean age (those formed from 3.8 to 2.5 billion years ago) constitute the dominant sandstone type in the classic greenstone belts of the Precambrian shields (large areas of basement rocks in a craton that formed 3.8 billion to 570 million years ago around which younger sedimentary rocks have been deposited). They probably accumulated in rapidly subsiding trenches and ocean basins that surrounded primitive continental blocks. Proterozoic wackes (those formed from about 2.5 billion to 570 million years ago) are dominantly trench and ocean basin deposits, as are wackes of Phanerozoic age (those formed from 570 million years ago to the present day). They represent the accumulation of sand-size prisms of material that today are deposited both within ocean trenches (*e.g.,* the modern trenches off Indonesia) and as submarine fan aprons (*e.g.,* the Astoria Fan off the Pacific coast of Washington and Oregon in the United States) developed at the base of the continental slope at the mouths of submarine canyons. More distal carpets of wacke sand can extend for thousands of square kilometres across oceanic abyssal plains. Classic examples of the continental margin and ocean basin deposits include the late Precambrian Ocoee Supergroup and Ordovician Martinsburg Formation of the Appalachians, the Jurassic and Cretaceous Franciscan Formation of the Pacific Coast Ranges of California, much of the Alpine flysch (see below) of Switzerland and France, and many of the famous turbidite sands found in the Italian Apennines.

The feature common to all modern depositional sites is that they adjoin landmasses in areas of high submarine relief. The landmass may be a continent bordered by either a passive, aseismic margin (for example, the eastern margin of North America) or a seismically active margin like that found along the western coast of both North and South America. The landmass can also be an active volcanic arc such as the Aleutian Islands chain or the Japan islands arc. The critical factor is the close proximity of topographically high and emergent clastic source areas and steeply sloped submarine depositional slopes, basins, or trenches. (K.A.W.C./F.L.S.)

MUDROCKS

In terms of volume, mudrocks are by far the most important variety of sedimentary rock, probably constituting nearly 80 percent of the Earth's sedimentary rock column. Despite this abundance, the literature on mudrocks does not match in extent or detail that dealing with sandstones, carbonate rocks, and the various rarer sedimentary rock varieties like evaporite and phosphorite. This paradox reflects the difficulties inherent both in analyzing such rocks, owing to their poor exposure and fine grain size, and in interpreting any data obtained from their analysis because of the effects of diagenesis. Mudrocks include all siliciclastic sedimentary rocks composed of silt- and clay-size particles: siltstone ($^1/_{16}$ millimetre to $^1/_{256}$ millimetre diameters), claystone (less than $^1/_{256}$ millimetre), and mudstone (a mix of silt and clay). Shale refers specifically to mudrocks that regularly exhibit lamination or fissility or both. Mudrocks are also loosely referred to as both lutites and pelites and as argillaceous sedimentary rocks.

Though mudrocks are composed mainly of detritus weathered from preexisting rocks, many contain large amounts of chemically precipitated cement (either calcium carbonate or silica), as well as abundant organic material. Mudrocks produced from the alteration of volcanic lava flows and ash beds to clay and zeolite minerals are called bentonites.

General properties of shales. The properties of shales are largely determined by the fine grain size of the constituent minerals. The accumulation of fine clastic detritus generally requires a sedimentary environment of low mechanical energy (one in which wave and current actions are minimal), although some fine material may be trapped by plants or deposited as weakly coherent pellets in more agitated environments. The properties of the clay mineral constituents of lutites are particularly important, even when they do not make up the bulk of a rock.

Mineralogy and chemistry

The mineralogy of shales is highly variable. In addition to clay minerals (60 percent), the average shale contains quartz and other forms of silica, notably amorphous silica and cristobalite (30 percent), feldspars (5 percent), and the carbonate minerals calcite and dolomite (5 percent). Iron oxides and organic matter (about 0.5 and 1 percent, respectively) are also important. Older estimates greatly underestimated clay minerals because of incorrect assignment of potassium to feldspar minerals. The most abundant clay mineral is illite; montmorillonite and mixed-layer illite-montmorillonite are next in abundance, followed by kaolinite, chlorite, chlorite-montmorillonite, and vermiculite. The quartz-to-feldspar ratio generally mirrors that of associated sands. In pelagic (deep-sea) sediments, however, feldspar may be derived from local volcanic sources, whereas quartz may be introduced from the continents by wind, upsetting simple patterns. A large number of accessory minerals occur in shales. Some of these are detrital, but diagenetic or in situ varieties (*e.g.,* pyrite, siderite, and various phosphates) and volcanically derived varieties (*e.g.,* zeolites, zircon, and biotite) have been noted.

Transportation and deposition of sediments

Origin of shales. The formation of fine-grained sediments generally requires weak transporting currents and a quiet depositional basin. Water is the common transporting medium, but ice-rafted glacial flour (silt produced by glacial grinding) is a major component in high-latitude oceanic muds, and windblown dust is prominent, particularly in the open ocean at low and intermediate latitudes. Shale environments thus include the deep ocean; the continental slope and rise; the deeper and more protected parts of shelves, shallow seas, and bays; coastal lagoons; interdistributory regions of deltas, swamps, and lakes (including arid basin playas); and river floodplains. The deep-sea muds are very fine, but an orderly sequence from coarse sediments in high-energy nearshore environments to fine sediments at greater depths is rarely found. Sediments at the outer edges of present-day continental shelves are commonly sands, relict deposits of shallower Pleistocene (from about 1,600,000 to 10,000 years ago) glacial conditions, whereas muds are currently being deposited in many parts of the inner shelf. The nearshore deposition of clay minerals is enhanced by the tendency of riverborne dispersed

platelets to flocculate in saline waters (salinity greater than about four parts per thousand) and to be deposited just beyond the agitated estuarine environment as aggregates hydraulically equivalent to coarser particles. Differential flocculation leads to clay-mineral segregation, with illite and kaolinite near shore and montmorillonite farther out to sea. Advance of silty and sandy delta-slope deposits over clays also leads to complex grain-size patterns.

Shales may be deposited in environments of periodic agitation. Sediments deposited on submarine slopes are frequently mechanically unstable and may be redistributed by slumping and turbidity currents to form thick accumulations (possible present-day eugeosynclinal equivalents) on the lower continental slope and rise. Part of the shale in many wacke-shale alternations may be of turbidite origin. Fine sediment can be deposited in marshes and on tidal flats. Trapping by marsh plants and binding of muds in fecal pellets are important. Because of electrochemical interactions among fine particles, muds plastered on a tidal flat by an advancing tide are difficult to reerode on the ebb. This may lead, as in the present-day Waddenzee, in The Netherlands, to a size increase from nearshore tidal flat muds to lag sands seaward. Fine floodplain sediments may dry out to coherent shale pellets, and these, on reerosion, can be redistributed as sands and gravels.

Shales of economic value. Black shales are often of economic importance as sources of petroleum products and metals, and this importance will probably increase in the future. The lacustrine Eocene Green River Shales of Colorado, Wyoming, and Utah are potentially rich petroleum sources and are undergoing exploratory extraction. Bituminous layers of the Early Permian Irati Shales of Brazil are similarly important. These shales contain the remains of the marine reptile *Mesosaurus,* also found in South Africa, and played a prominent part in the development of the concepts of continental drift. The widespread thin Chattanooga Shale (Devonian-Mississippian) of the eastern United States has been exploited for its high (up to 250 parts per million) uranium content. The Kupferschiefer of the Permian (286 to 245 million years old) is a bituminous shale rich in metallic sulfides of primary sedimentary or early diagenetic origin; it covers a large area of central Europe as a band generally less than one metre thick, and in eastern Germany and in Poland there is sufficient enrichment in copper, lead, and zinc for its exploitation as an ore. (K.C.B./F.L.S.)

LIMESTONES AND DOLOMITES

Limestones and dolomites are collectively referred to as carbonates because they consist predominantly of the carbonate minerals calcite ($CaCO_3$) and dolomite ($CaMg[CO_3]_2$). Some limestones are shown in Figure 135. Almost all dolomites are believed to be produced by recrystallization of preexisting limestones, although the exact details of this dolomitization process continue to be debated (see above *Major rock-forming minerals: Dolomite: Origin and occurrence*). Consequently, the following discussion initially deals with limestones and dolomites as a single rock type and subsequently considers the complex process by which some limestones become dolomite.

Carbonates are by far the only volumetrically important nonsiliciclastic sedimentary rock type. Most are marine, and thick sequences of carbonate rocks occur in all the continental blocks, a surviving record of the transgressions and regressions of shallow marine (epeiric) seas that repeatedly blanketed the stable continental cratonic areas from time to time mainly during the late Precambrian, Paleozoic, and Mesozoic eras. Modern marine carbonate sediments, whose formation is favoured by warm, shallow water, are presently being deposited in a broad band straddling the Equator. The texture, sedimentary structures, composition, and organic content of carbonates provide numerous insights into the environment of deposition and regional paleogeography. Many important oil reservoirs of the world, especially those of the Middle East, occur in carbonate rocks.

Oil reservoirs

Mineralogy. Though ancient limestones and dolomites are composed of calcite and dolomite, respectively, other calcite group minerals such as magnesite ($MgCO_3$), rhodochrosite ($MnCO_3$), and siderite ($FeCO_3$) occur in limited amounts in restricted environments. Modern carbonate sediments are composed almost entirely of metastable aragonite ($CaCO_3$) and magnesium-rich calcite, both of which readily recrystallize during diagenesis to form calcite. Carbonate rocks commonly grade naturally into siliciclastic sedimentary rocks as the proportion of terrigenous grains of varying size and mineralogy increases. Such mixtures are the consequence of the infringement of a dominantly siliciclastic depositional setting (*e.g.,* a quartz arenitic beach area) into, for example, a lagoon or tidal flat in which carbonate mud accumulates.

Textural components. Carbonate minerals present in ancient limestones and dolomites occur in one of three textural forms: (1) discrete silt to sand to coarser carbonate grains, or allochems, such as oöids or skeletal fragments, (2) mud-size interstitial calcium carbonate matrix called microcrystalline calcite or micrite, and (3) interlocking, 0.02- to 0.1-millimetre-diameter crystals of clear interstitial calcium carbonate cement or spar. In a rather simplistic sense, these three carbonate rock textural components are comparable, respectively, to the three possible constituents in a sandstone: (1) the coarser rock and mineral grains, (2) interstitial matrix, and (3) interstitial chemical cement.

Several types of allochems exist: oöids, skeletal grains, carbonate clasts, and pellets. Ooids (also known as oölites or oöliths) are sand-size spheres of calcium carbonate mud concentrically laminated about some sort of nucleus grain, perhaps a fossil fragment or a silt-size detrital quartz grain. Oöids develop today on shallow shelf areas where strong bottom currents can wash the various kinds of material that form oöid nuclei back and forth in well-agitated, warm water that is supersaturated with calcium carbonate. The concentric layers of aragonite (in modern oöids) is produced by blue-green algae that affix themselves to the grain nucleus. Skeletal fragments, also known as bioclasts, can be whole fossils or broken fragments of organisms, depending on current and wave strength as well as depositional depth. The content and texture of the bioclast component in any carbonate will vary noticeably as a function of both age (due to evolution) and depositional setting (because of subsequent abrasion and transport as well as ecology). Carbonate clasts include fragments weathered from carbonate source rocks outside the depositional basin (lithoclasts) as well as fragments of carbonate sediment eroded from within the basin almost immediately after it was deposited (intraclasts). Silt- to sand-size particles of microcrystalline calcite or aragonite that lack the internal structure of oöids or bioclasts generally are called pellets or peloids. Most are fecal pellets generated by mud-ingesting organisms. Pellets can be cemented together into irregularly shaped composite grains dubbed lumpstones or grapestones.

Micrite and sparite

Microcrystalline carbonate mud (micrite) and sparry carbonate cement (sparite) are collectively referred to as orthochemical carbonate because, in contrast to allochems, neither exhibits a history of transport and deposition as clastic material. Micrite can occur either as matrix that fills or partly fills the interstitial pores between allochems or as the main component of a carbonate rock. It originates mainly as the result of organic activity: algae generate tiny needles of aragonite within their tissues, and after their death such needles fall to the depositional surface as unconsolidated mud, which soon recrystallizes to calcite. Some micrite is produced by inorganic precipitation of aragonite; grain-to-grain collision and the resulting abrasion of allochems also can generate modest amounts of micrite. Most of the coarser and clearer crystals of sparry calcite that fill interstitial pores as cement represent either recrystallized micrite or essentially a direct inorganic precipitate.

A number of carbonate classification schemes have been developed, but most modern ones subdivide and name carbonate rock types on the basis of the kinds of allochems present and the nature of the interstitial pore filling, whether it is micrite or spar. The most widely used scheme of this type is the descriptive classification devised by the American petrologist Robert L. Folk.

through the lithification of loose carbonate sediments (see Figure 136). Modern carbonate sediments are generated in a variety of environments: continental, marine, and transitional, but most are marine. The present-day Bahama banks is the best known modern carbonate setting. It is a broad submarine shelf covered by shallow, warm seawater. The Bahama shelf, or carbonate platform, mimics the setting that repeatedly prevailed across the stable cratonic areas of the major continental blocks during late Precambrian, Paleozoic, and Mesozoic time and serves as a model for explaining the various limestone types that make up such ancient carbonate successions.

The edge of the shelf is marked by a topographically sharp escarpment flanked by coarse, angular limestone breccia. Submarine channels etched into the escarpment serve as waterways down which shallow-water carbonate sediment can be transported by turbidity currents capable of redistributing them as apronlike deposits on the oceanic abyssal plain. In many areas, the fringe of the Bahama banks is marked by wave-resistant reef rocks (sometimes classified as boundstone). Abrasion of these reefs by wave activity generates abundant skeletal debris. Variations in depth and current strength control the relative amounts of micrite and sparite, the prevalence of specific organisms and their productivity, and the likelihood of generating oöids, pellets, and carbonate rock fragments. Micrite and micritic allochemical sediments accumulate in deep-water, low-energy, protected areas like lagoons and tidal flats and on the leeward side of major islands. In high-energy, shallow-water locales such as beaches, coastal dunes, and tidal channels, currents winnow out any micrite, and these become the sites of sparry allochemical sediment deposition. Pinpointing the exact depositional setting for an ancient carbonate deposit requires detailed analysis of its texture, composition, sedimentary structures, geometry, fossil content, and stratigraphic relationships with modern carbonate depositional sites.

In addition to the ancient analogues of the modern carbonate deposits described above are freshwater limestones (marls) and limestone muds (or calcilutites) of deep-water abyssal plains. Freshwater limestones of limited extent represent a spectrum of small-scale settings developed within and along the margins of lacustrine basins. Deep-water abyssal plain limestones are quite restricted in volume and age in the geologic record for a number of reasons. First of all, abyssal plain sequences are less likely to be incorporated into the orogenic belts that develop as continental margins are compressed during ocean basin closure. Second, pelagic calcareous oozes are the obvious modern analogues of ancient abyssal plain calcilutites. These oozes are produced by aragonite-secreting plankton that float near the surface (such as foraminiferans and

Calcareous oozes

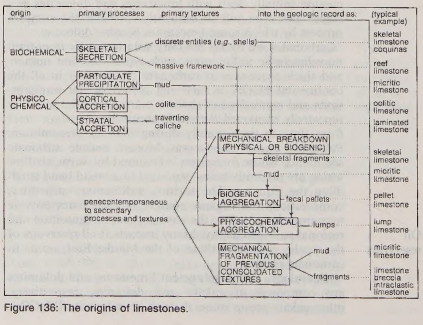

Figure 136: The origins of limestones.

coccoliths), which upon their death leave their shells, or tests, to settle slowly to the ocean bottom and accumulate. The development of such deep-sea deposits is therefore obviously dependent on the existence of calcium-secreting planktonic organisms, and these did not evolve until Mesozoic time. Finally, calcareous ooze accumulation is severely restricted both by latitude (being largely confined to a band extending 30° to 40° north and south of the Equator) and abyssal plain depth (approximately 2,000 metres). Below a depth of about 4,500 metres, which is the carbonate compensation depth (CCD), the pressure and temperature of seawater produces a rate of dissolution in excess of the rate of pelagic test accumulation.

Dolomites and dolomitization. Dolomite is produced by dolomitization, a diagenetic process in which the calcium carbonate minerals aragonite and calcite are recrystallized and converted into the mineral dolomite. Dolomitization can obscure or even obliterate all or part of the original limestone textures and structures; in the case where such original features survive, carbonate nomenclature and interpretation can still be applied to the rock with emphasis on the effects of alteration.

The exact processes by which limestones are dolomitized are not thoroughly understood, but dolomites occur widely in the geologic record. The relative proportion of dolomite to limestone progressively increases with age in carbonate rocks. This secular trend probably either reflects the earlier existence of geochemical settings that were more favourable to dolomitization or is the logical result of the fact that the likelihood for a limestone to undergo dolomitization increases proportionally with its age.

Geochemists have been unable to precipitate normal dolomite under the conditions of temperature and pressure that exist in nature; temperatures within the 200° C range are required to support precipitation. A few modern, so-called primary marine dolomite localities have been studied, but close investigation of these areas suggests that even these penecontemporaneous dolomites are produced by altering calcite or aragonite almost immediately after their initial precipitation. Dolomites generated by later alteration of older limestones are known as diagenetic dolomites.

The study of the few reported penecontemporaneous dolomite sites allows some conclusions to be formed regarding the dolomitization process. These modern dolomites develop mainly under conditions of high salinity (hypersalinity), which commonly exist in arid regions across supratidal mud flats as well as on the flat, saline plains and playa lake beds known as sabkhas. In highly saline environments, the ratio of dissolved magnesium ions to dissolved calcium ions progressively increases above the norm for seawater (5:1) as a result of the selective formation of calcium-rich evaporite minerals like gypsum and anhydrite. These magnesium-rich brines then tend to be flushed downward owing to their high density; the entire process is named evaporative reflux. Penecontemporaneous dolomites would result from the positioning of sabkhas and arid supratidal flats in a site that is in immediate contact with carbonate sediment; diagenetic dolomites would logically result when such dolomite-producing settings overlie older limestone deposits. The presence of fissures or highly permeable zones serving as channelways for downward percolation of dolomitizing fluids would also promote the alteration. Other studies have emphasized a possible role in dolomitization for dense brackish (salty) fluids formed when seawater and meteoric waters (those precipitated from the atmosphere as rain or snow) are produced along coastal zones.

Evaporative reflux

SILICEOUS ROCKS

Those siliceous rocks composed of an exceptionally high amount of crystalline siliceous material, mainly the mineral quartz (especially microcrystalline quartz and fibrous chalcedony) and amorphous opal, are most commonly known as chert. A wide variety of rock names are applied to cherty rocks reflecting their colour (flint is dark chert; jasper is usually red; prase is green) and geographic origin (novaculite of Arkansas, U.S.; silexite of France). The term chert is applied here to all fine-grained siliceous sediments and sedimentary rocks of chemical, biochemical, and organic origin.

Types of cherts. Two major varieties of chert deposits exist—namely, bedded chert and nodular chert. Bedded cherts occur in individual bands or layers ranging in thickness from one to several centimetres or even tens of metres. They are intimately associated with volcanic rocks, commonly submarine volcanic flows as well as deep-water mudrocks. Classic examples include the Miocene Monterey Formation of the Coast Ranges of California, the Permian Rex Chert of Utah and Wyoming, the Arkansas Novaculite of the Ouachita Mountains, and the Mesozoic chert deposits of the Franciscan Formation of California. Nodular cherts occur as small to large (millimetres to centimetres) knotlike and fistlike clusters of quartz, chalcedony, and opal concentrated along or parallel with bedding planes in shallow-water marine carbonate rocks as well as pelagic limestones. Individual nodules may be ovoid or semispherical in shape; masses of chert typically form an anastamosing network.

Origin of cherts. Many bedded cherts are composed almost entirely of the remains of silica-secreting organisms like diatoms and radiolarians. Such deposits are produced by compacting and recrystallizing the organically produced siliceous ooze deposits that accumulate on the present-day abyssal ocean floor. The modern oozes gather in latitudes where high organic productivity of floating planktonic radiolarians and diatoms takes place in the warm surface waters. As individual organisms die, their shells settle slowly to the abyssal floor and accumulate as unconsolidated siliceous ooze. Siliceous oozes are particularly prominent across areas of the ocean floor located far from continental blocks, where the rate of terrigenous sediment supply is low, and in deeper parts of the abyssal plain lying below the carbonate compensation depth, where the accumulation of calcareous oozes cannot occur. Some bedded cherts might not be of organic origin. They instead may be produced by precipitating silica gels derived from the same magma chambers from which the submarine basalts (pillow lava) that are intimately associated with bedded cherts are precipitated.

The origin of nodular cherts has long been debated, but most are produced by the secondary replacement of the carbonate minerals and fossils within shallow marine shelf deposits. Evidence of secondary origin includes relict structures of allochems such as skeletal fragments and oöids preserved entirely within chert nodules. Silica can be mobilized from elsewhere within a rock and transported in solution under proper conditions of temperature and geochemistry. Likely sources of silica found scattered within shallow-water shelf carbonates include siliceous sponge spicules, radiolarians or diatom shells, and windblown sand grains. The details of the process and the possible role of microscopic organisms like bacteria in dissolving, mobilizing, and reconcentrating the silica remains uncertain.

Sites of chert deposition

Finally, geysers and hot springs like those of the Yellowstone National Park area of northwestern Wyoming, U.S., are also sites of chert deposition. Encrustations of silica, known as sinter or geyserite, are volumetrically unimpressive but nevertheless are curiosities. The geyser and hot springs activity at Yellowstone is probably typical, with a subterranean body of magma as the source of silica-rich hydrothermal solutions rising periodically near or to the surface.

PHOSPHORITES

Many sedimentary rocks contain phosphate in the form of scattered bones composed of the mineral apatite (calcium phosphate), but rocks composed predominantly of phosphate are rare. Nevertheless, three principal types exist: (1) regionally extensive, crystalline nodular and bedded phosphorites, (2) localized concentrations of phosphate-rich clastic deposits (bone beds), and (3) guano deposits.

EVAPORITES

Evaporites are layered crystalline sedimentary rocks that form from brines generated in areas where the amount of water lost by evaporation exceeds the total amount of water from rainfall and influx via rivers and streams. The

mineralogy of evaporite rocks is complex, with almost 100 varieties possible, but less than a dozen species are volumetrically important. Minerals in evaporite rocks include carbonates (especially calcite, dolomite, magnesite, and aragonite), sulfates (anhydrite and gypsum), and chlorides (particularly halite, sylvite, and carnallite), as well as various borates, silicates, nitrates, and sulfocarbonates. Evaporite deposits occur in both marine and nonmarine sedimentary successions.

Minerals in evaporites

Though restricted in area, modern evaporites contribute to genetic models for explaining ancient evaporite deposits. Modern evaporites are limited to arid regions (those of high temperature and low rates of precipitation), for example, on the floors of semidry ephemeral playa lakes in the Great Basin of Nevada and California, across the coastal salt flats (sabkhas) of the Middle East, and in salt pans, estuaries, and lagoons around the Gulf of Suez. Ancient evaporates occur widely in the Phanerozoic geologic record, particularly in those of Cambrian (from 570 to 505 million years ago), Permian (from 286 to 245 million years ago), and Triassic (from 245 to 208 million years ago) age, but are rare in sedimentary sequences of Precambrian age. They tend to be closely associated with shallow marine shelf carbonates and fine (typically rich in iron oxide) mudrocks. Because evaporite sedimentation requires a specific climate and basin setting, their presence in time and space clearly constrains inferences of paleoclimatology and paleogeography. Evaporite beds tend to concentrate and facilitate major thrust fault horizons, so their presence is of particular interest to structural geologists. Evaporites also have economic significance as a source of salts and fertilizer.

All evaporite deposits result from the precipitation of brines generated by evaporation. Laboratory experiments can accurately trace the evolution of brines as various evaporite minerals crystallize. Normal seawater has a salinity of 3.5 percent (or 35,000 parts per million), with the most important dissolved constituents being sodium and chlorine. When seawater volume is reduced to one-fifth of the original, evaporite precipitation commences in an orderly fashion, with the more insoluble components (gypsum and anhydrite) forming first. When the solution reaches one-tenth the volume of the original, more soluble minerals like sylvite and halite form. Natural evaporite sequences show vertical changes in mineralogy that crudely correspond to the orderly appearance of mineralogy as a function of solubility but are less systematic.

Nonmarine environment. Evaporite deposition in the nonmarine environment occurs in closed lakes—*i.e.,* those without outlet—in arid and semiarid regions. Such lakes form in closed interior basins or shallow depressions on land where drainage is internal and runoff does not reach the sea. If water depths are shallow or, more typically, somewhat ephemeral, the term playa or playa lake is commonly used.

Water inflow into closed lakes consists principally of precipitation and surface runoff, both of which are small in amount and variable in occurrence in arid regions. Groundwater flow and discharge from springs may provide additional water input, but evaporation rates are always in excess of precipitation and surface runoff. Sporadic or seasonal storms may give rise to a sudden surge of water inflow. Because closed lakes lack outlets, they can respond to such circumstances only by deepening and expanding. Subsequent evaporation will reduce the volume of water present to prestorm or normal amount; fluctuation of closed lake levels therefore characterizes the environment.

Fluctuating lake levels

Such changing lake levels and water volumes lead to fluctuating salinity values. Variations in salinity effect equilibrium relations between the resulting brines and lead to much solution and subsequent reprecipitation of evaporites in the nonmarine environment. As a result of these complexities as well as the distinctive nature of dissolved constituents in closed lake settings, nonmarine evaporite deposits contain many minerals that are uncommon in marine evaporites—*e.g.,* borax, epsomite, trona, and mirabilite.

Shallow marine environment. Evaporite deposition in the shallow marine environment (sometimes termed the salina) occurs in desert coastal areas, particularly along the margins of such semi-restricted water bodies as the Red Sea, Persian Gulf, and Gulf of California. Restriction is, in general, one of the critical requirements for evaporite deposition, because free and unlimited mixing with the open sea would allow the bodies of water to easily overcome the high evaporation rates of arid areas and dilute these waters to near-normal salinity. This semi-restriction cannot, in fact, prevent a large amount of dilution by mixing; coastal physiography is the principal factor involved in brine production. Shallow-water evaporites, almost exclusively gypsum, anhydrite, and halite, typically interfinger with tidal flat limestone and dolomite and fine-grained mudrock.

Deep-basin environment. Most of the thick, laterally extensive evaporite deposits appear to have been produced in deep, isolated basins that developed during episodes of global aridity. The most crucial requirement for evaporite production is aridity; water must be evaporated more rapidly than it can be replenished by precipitation and inflow. In addition, the evaporite basin must somehow be isolated or at least partially isolated from the open ocean so that brines produced through evaporation are prevented from returning there. Restricting brines to such an isolated basin over a period of time enables them to be concentrated to the point where evaporite mineral precipitation occurs. Periodic breaching of the barrier, due either to crustal downwarping or to global sea-level changes, refills the basin from time to time, thereby replenishing the volume of seawater to be evaporated and making possible the inordinately thick, regionally extensive evaporite sequences visible in the geologic record.

Debate continues over the exact mechanisms for gener-

ating thick evaporite deposits. Three possible models for restricting "barred" evaporite basins are shown in Figure 137. They differ in detail, and none has garnered a consensus of support. The deep-water, deep-basin model accounts for replenishment of the basin across the barrier or sill, with slow, continual buildup of thick evaporites made possible by the seaward escape of brine that allows a constant brine concentration to be maintained. The shallow-water, shallow-basin model produces thick evaporites by continual subsidence of the basin floor. The shallow-water, deep-basin model shows the brine level in the basin beneath the level of the sea as a result of evaporation; brines are replenished by groundwater recharge from the open ocean.

IRON-RICH SEDIMENTARY ROCKS

Almost all sedimentary rocks are iron-bearing in the sense that mudrocks, sandstones, and carbonates typically have an iron content of several percent. Nevertheless, sedimentary rocks in which the proportion of iron exceeds 15 percent are separately categorized as iron-rich. Two major types of iron-rich sedimentary rocks are recognized: (1) iron formation, or banded iron formation (BIF)—regionally extensive, locally thick sequences composed of alternating thin (millimetre to centimetre thick) layers of mainly crystalline-textured iron-rich minerals and chert—and (2) ironstone—noncherty, essentially clastic-textured, iron-rich minerals of local extent.

Banded iron formation

Banded iron formations are predominantly Precambrian in age; most are 1.8 to 2.2 billion years old; none are younger than Cambrian age. The most important iron-bearing minerals in iron formations are hematite, magnetite, and greenalite. These deposits constitute the world's major source of iron ore. Classic examples are found in the Mesabi Range of Minnesota, U.S., and the Kiruna ores of Sweden.

Ironstones are principally of Phanerozoic age, mainly Early Paleozoic (roughly 440 to 570 million years old) and Jurassic (about 144 to 208 million years old), but can be as old as Middle Precambrian age (about 1.6 to 3 billion years old). They appear to be restricted to basins no larger than 150 kilometres in any direction. Major iron minerals are goethite, hematite, and chamosite.

Origin of banded iron formation. The origin of banded iron formation is not clearly understood. Banded iron formation units are typically 50 to 600 metres thick. Their complex mineralogy includes various iron oxides, iron carbonates, iron silicates, and iron sulfides. The essentially crystalline texture of these minerals together with the definitive crystalline texture of the laminated chert bands with which the iron mineral layers alternate is perplexing. At present, iron is not easily dissolved, nor can it be readily transported in solution and subsequently precipitated as crystalline-textured, iron-rich minerals, because of the presence of free atmospheric oxygen. Many sedimentary petrologists consequently conclude that banded iron formation deposition is a uniquely Precambrian occurrence made possible by, and supporting the existence of, an earlier anaerobic Earth atmosphere (one lacking free oxygen) quite unlike that in existence today. Controversy also continues over the ultimate source of iron (weathering as opposed to magmatic iron escaping from the Earth's interior) and over the possible role of microorganisms such as bacteria and algae in the precipitation of the iron.

Origin of ironstones. The origin of ironstones also is not well understood, but most appear to be derived from the erosion and redeposition of lateritic (iron-rich, red) soils. Ironstones occur as thin (a few tens of metres at most) units interbedded with shallow marine and transitional carbonates, mudrocks, and sandstones. They generally have an oölitic texture. Cross-bedding, ripple marks, and small scour and fill channels are abundant. Slight uplift and erosion of reddish soils developed in coastal regions drained by rivers that transport and deposit such material in deltas and embayments along the coast is compatible with the features and fossils found in deposits of this sort. Classical ironstone deposits include the Ordovician Wabana Formation of Newfoundland and the Silurian Clinton Group of the central and southern Appalachians.

ORGANIC-RICH SEDIMENTARY DEPOSITS

Coal, oil shale, and petroleum are not sedimentary rocks per se; they represent accumulations of undecayed organic tissue that can either make up the bulk of the material (*e.g.*, coal), or be disseminated in the pores within mudrocks, sandstones, and carbonates (*e.g.*, oil shale and petroleum). Much of the undecomposed organic matter in sediment and sedimentary rocks is humus, plant matter that accumulates in soil. Other important organic constituents include peat, humic organic matter that collects in bogs and swamps where oxidation and bacterial decay is incomplete, and sapropel, fine-grained organic material—mainly the soft organic tissue of phytoplankton and zooplankton, along with bits and pieces of higher plants—that amass subaqueously in lakes and oceans.

Fossil fuels

Organic-rich sedimentary rock deposits are collectively referred to as fossil fuels because they consist of the undecayed organic tissue of plants and animals preserved in depositional settings characterized by a lack of free oxygen. Fossil fuels constitute the major sources of energy in the industrial world, and their unequal distribution in time (exclusively Phanerozoic) and space (more than half of the proved petroleum reserves are in the Persian Gulf region of the Middle East) has a significant effect on the world's political and economic stability.

Coal. Coals are the most abundant organic-rich sedimentary rock. They consist of undecayed organic matter that either accumulated in place or was transported from elsewhere to the depositional site. The most important organic component in coal is humus. The grade or rank of coal is determined by the percentage of carbon present. The term peat is used for the uncompacted plant matter that accumulates in bogs and brackish swamps. With increasing compaction and carbon content, peat can be transformed into the various kinds of coal: initially brown coal or lignite, then soft or bituminous coal, and finally, with metamorphism, hard or anthracite coal. In the geologic record, coal occurs in beds, called seams, which are blanketlike coal deposits a few centimetres to metres or hundreds of metres thick.

Many coal seams occur within cyclothems, rhythmic successions of sandstone, mudrock, and limestone in which nonmarine units are regularly and systematically overlain by an underclay, the coal seam itself, and then various marine lithologies. The nonmarine units are thought to constitute the floor of ancient forests and swamps developed in low-lying coastal regions; the underclay is a preserved relict of the soil in which the coal-producing vegetation was rooted; and the marine units overlying the coal record the rapid transgression of the sea inland that killed the vegetation by drowning it and preventing its decomposition by rapid burial. The exact mechanism responsible for generating the rapid episodes of marine transgression and regression necessary to generate coal-bearing cyclothems is not definitively known. A combination of episodic upwarping and downwarping of the continental blocks or global (eustatic) changes in sea level or both, coupled with normal changes in the rate of sediment supply that occurs along coasts traversed by major laterally meandering river systems, may have been the cause.

In any case, coal is a rare, though widely distributed, lithology. Extensive coal deposits overall occur mainly in rocks of Devonian age (those from 408 to 360 million years old) and younger because their existence is clearly contingent on the evolution of land plants. Nevertheless, small, scattered coal deposits as old as early Proterozoic have been described. Coal-bearing cyclothem deposits are especially abundant in the middle and late Paleozoic sequences of the Appalachians and central United States and in the Carboniferous of Great Britain, probably because during this time interval global climates were warm and humid and large portions of the continental blocks were low-lying platforms located only slightly above sea level.

Oil shale. Mudrock containing high amounts of organic matter in the form of kerogen is known as oil shale or kerogen shale. Kerogen is altered, undecayed, fatty organic matter, mainly sapropel, and is very fine-grained. It can be generated in place or transported. The most famous oil shale deposit in the world, located in the United States,

is the Green River Formation of Utah, Wyoming, and Colorado of Eocene age (*i.e.*, formed 57.8 to 36.6 million years ago). This vast deposit contains fossils and sedimentary structures, suggesting rapid deposition and burial of unoxidized organic matter in shallow lakes or marine embayments. The quantity of oil entrapped in the Green River Formation is significant. The cost of extracting the oil trapped in the mudrock by heating the oil shale, however, far exceeds the cost of extracting equivalent quantities of oil, natural gas, or coal. Also, the refractory process not only requires extensive strip mining and immense volumes of water but also results in a volume expansion of the original oil shale. Despite these considerable economic and technical problems, oil shales potentially represent a significant future energy resource.

Hydrocarbons

Oil and natural gas. Natural gas refers collectively to the various gaseous hydrocarbons generated below the Earth's surface and trapped in the pores of sedimentary rocks. Major natural gas varieties, include methane, ethane, propane, and butane. These natural gases are commonly, though not invariably, intimately associated with the various liquid hydrocarbons—mainly liquid paraffins, napthenes, and aromatics that collectively constitute oil.

The exact process by which oil and natural gas are produced is not precisely known, despite the extensive efforts made to determine the mode of petroleum genesis. Crude oil is thought to form from undecomposed organic matter, principally single-celled floating phytoplankton and zooplankton that settle to the bottom of marine basins and are rapidly buried within sequences of mudrock and limestone. Natural gas and oil are generated from such source rocks only after heating and compaction. Typical petroleum formation (maturation) temperatures do not exceed 100° C, meaning that the depth of burial of source rocks cannot be greater than a few kilometres. After their formation, oil and natural gas migrate from source rocks to reservoir rocks composed of sedimentary rocks largely as a consequence of the lower density of the hydrocarbon fluids and gases. Good reservoir rocks, by implication, must possess high porosity and permeability. A high proportion of open pore spaces enhances the capacity of a reservoir to store the migrating petroleum; the interconnectedness of the pores facilitates the withdrawal of the petroleum once the reservoir rock is penetrated by drill holes.

Secular trends in the sedimentary rock record

Reexamination of the sedimentary rock record preserved within the continental blocks suggests systematic changes through time in the relative proportions of the major sedimentary rock types deposited, as summarized in Figure 138. These changes can be linked to the evolution of the atmosphere and hydrosphere and to the changing global tectonic setting. Carbonates and quartz sands, for example, require long-term source area stability as well as the existence of broad, shallow-water epeiric seas that mantle continental blocks. Marine transgressions and regressions across broad stable continental cratons occurred only in

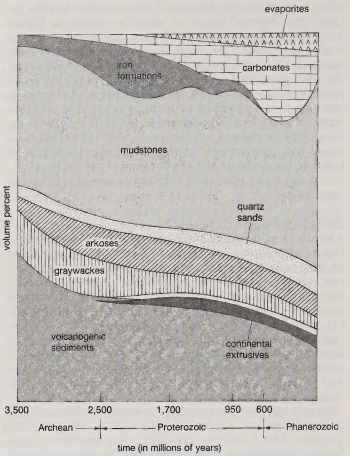

Figure 138: Changes in relative proportions of sedimentary rocks deposited on cratonic surfaces throughout geologic time.
From S.M. Stanley, *Earth and Life through Time* (1987), 2nd ed., W.H. Freeman and Co., New York

Proterozoic and Phanerozoic time; Archean continental blocks were smaller and tectonically unstable, and most likely less granitic than those of today. Consequently, the early Precambrian sedimentary rock record consists largely of volcanogenic sediments, wackes, and arkoses physically disintegrated from small, high-relief island arcs (the Archean greenstone belts of the various Precambrian shields) and microcontinental fragments. The fact that iron formations are restricted to rocks of Archean and Proterozoic time supports the conclusion that atmospheric oxygen levels in earlier stages of Earth history were lower, promoting the dissolution, transport, and precipitation of iron by chemical or biochemical means. The total lack of evaporites from the Archean record and their subsequent steady buildup probably reflects a number of factors. Such deposits can be easily destroyed by metamorphism, and presumably, given enough time, they will have been completely erased. Also, evaporite formation requires seawater with elevated salinity, a condition that is established with time. Finally, significant volumes of bedded evaporites can occur only once broad, stable continents have evolved, because the requisite restricted evaporite basins develop exclusively adjacent to cratons. (F.L.S.)

METAMORPHIC ROCKS

Metamorphic rocks are, as noted above, those rocks that have recrystallized in response to changes in pressure, temperature, and the composition of fluids percolating through them. The word metamorphism is taken from the Greek for "change of form"; metamorphic rocks are derived from igneous or sedimentary rocks that have altered their form (recrystallized) as a result of changes in their physical environment. Metamorphism comprises changes both in mineralogy and in the fabric of the original rock.

Sources of metamorphic changes

In general, these alterations are brought about either by the intrusion of hot magma into cooler surrounding rocks (contact metamorphism) or by large-scale tectonic movements of the Earth's lithospheric plates that alter the pressure-temperature conditions of the rocks (regional metamorphism; see also PLATE TECTONICS). Minerals within the original rock, or protolith, respond to the changing conditions by reacting with one another to produce a new mineral assemblage that is thermodynamically stable under the new pressure-temperature conditions. These reactions occur in the solid state but may be facilitated by the presence of a fluid phase lining the grain boundaries of the minerals. In contrast to the formation of igneous rocks, metamorphic rocks do not crystallize from a silicate melt, although high-temperature metamorphism can lead to partial melting of the host rock.

Because metamorphism represents a response to changing physical conditions, those regions of the Earth's surface where dynamic processes are most active will also be regions where metamorphic processes are most intense and easily observed. The vast region of the Pacific mar-

gin, for example, with its seismic and volcanic activity, is also an area in which materials are being buried and metamorphosed intensely. In general, the margins of continents and regions of mountain building are the regions where metamorphic processes proceed with intensity. But in relatively quiet places, where sediments accumulate at slow rates, less spectacular changes also occur in response to changes in pressure and temperature conditions. Metamorphic rocks are therefore distributed throughout the geologic column.

Because most of the Earth's mantle is solid, metamorphic processes may also occur there. Mantle rocks are seldom observed at the surface because they are too dense to rise, but occasionally a glimpse is presented by their inclusion in volcanic materials. Such rocks may represent samples from a depth of a few hundred kilometres, where pressures of about 100 kilobars (3,000,000 inches of mercury) may be operative. Experiments at high pressure have shown that few of the common minerals that occur at the surface will survive at depth within the mantle without changing to new high-density phases in which atoms are packed more closely together. Thus, the common form of SiO_2, quartz, with a density of 2.65 grams per cubic centimetre, transforms to a new phase, stishovite, with a density of 4.29 grams per cubic centimetre. Such changes are of critical significance in the geophysical interpretation of the Earth's interior.

Geotherms

In general, temperatures increase with depth within the Earth along curves referred to as geotherms. The specific shape of the geotherm beneath any location on Earth is a function of its corresponding local tectonic regime. Metamorphism can occur either when a rock moves from one position to another along a single geotherm or when the geotherm itself changes form (see Figure 139). The former can take place when a rock is buried or uplifted at a rate that permits it to maintain thermal equilibrium with its surroundings; this type of metamorphism occurs beneath slowly subsiding sedimentary basins and also in the descending oceanic plate in some subduction zones. The latter process occurs either when hot magma intrudes and alters the thermal state of a stationary rock or when the rock is rapidly transported by tectonic processes (*e.g.*, thrust faulting or large-scale folding) into a new depth-temperature regime in, for example, areas of collision between two continents. Regardless of which process occurs, the result is that a collection of minerals that are thermodynamically stable at the initial conditions are placed under a new set of conditions at which they may or may not be stable. If they are no longer in equilibrium with one another under the new conditions, the minerals will react in such a way as to approach a new equilibrium state. This may involve a complete change in mineral assemblage or simply a shift in the compositions of the preexisting mineral phases. The resultant mineral assemblage will reflect the chemical composition of the original rock and the new pressure-temperature conditions to which the rock was subjected.

The heavier lines represent paths that show (1) metamorphism during burial along a single geotherm and (2) metamorphism as a result of a change in the geotherm at a fixed depth. Because protolith compositions and the pressure-temperature conditions under which they may be placed vary widely, the diversity of metamorphic rock types is large. Many of these varieties are repeatedly associated with one another in space and time, however, reflecting a uniformity of geologic processes over hundreds of millions of years. For example, the metamorphic rock associations that developed in the Appalachian Mountains of eastern North America in response to the collision between the North American and African lithospheric plates during the Paleozoic are very similar to those developed in the Alps of south-central Europe during the Mesozoic-Cenozoic collision between the European and African plates. Likewise, the metamorphic rocks exposed in the Alps are grossly similar to metamorphic rocks of the same age in the Himalayas of Asia, which formed during the continental collision between the Indian and Eurasian plates. Metamorphic rocks produced during collisions between oceanic and continental plates from different localities around the world also show striking similarities to each other (see below *Types of metamorphism and their associated facies: Regional metamorphism*) yet are markedly different from metamorphic rocks produced during continent-continent collisions. Thus, it is often possible to reconstruct tectonic events of the past on the basis of metamorphic rock associations currently exposed at the Earth's surface.

Metamorphic variables

Metamorphism results from a complex interplay between physical and chemical processes that operate on a scale ranging from micrometres (*e.g.*, fine mineral grain sizes, thickness of intergranular fluid, diffusion distances for chemical species) to tens or hundreds of kilometres (*e.g.*, crustal thickness, width of collision zone between lithospheric plates, depth to subducting plate). Despite this wide range and the many processes involved in the recrystallization of sedimentary and igneous protoliths into metamorphic rocks, there are relatively few variables that effect metamorphic changes. Those of greatest importance are temperature, pressure, and the original chemical composition of the protolith; each is briefly discussed below.

TEMPERATURE

Temperatures at which metamorphism occurs range from the conditions of diagenesis (approximately 150°–200° C) up to the onset of melting. Rocks of different compositions begin to melt at different temperatures, with initial melting occurring at roughly 650°–750° C in rocks of granitic or shaley composition and approximately 900°–1,200° C in rocks of basaltic composition. Above these temperatures, metamorphic processes gradually give way to igneous processes. Hence, the temperature realm of metamorphism spans an interval of about 150°–1,000° C and is strongly dependent on the composition of the protolith.

Geothermal gradient

The temperature at any point within the Earth's crust is controlled by the local heat-flow regime, which is a composite function of heat flow upward from the mantle into the crust, heat generated by radioactive decay in nearby regions of the crust, heat transported into the crust by silicate melts, and tectonic transport of hot or cold rocks at rates faster than those needed to maintain thermal equilibrium with the surrounding rocks. The temperature gradient at any location in the Earth, known as the geothermal gradient, is the increase in temperature per unit distance of depth; it is given by the tangent to the local geotherm. The magnitude of the geothermal gradient thus varies with the shape of the geotherm. In regions with high surface heat flow, such as areas of active volcanism or mantle upwelling beneath thinned continental crust, geothermal gradients of 40° to 100° C (104° to 212° F) per kilometre (0.6 mile) prevail, giving rise to high temperatures at relatively shallow levels of the crust. Within the stable interiors of old continents, geothermal gradients of 25° to 35° C per kilometre are more typical, and in zones of active subduction, where the relatively cold oceanic crust is rapidly transported to great depths,

geothermal gradients range from 10° to 20° C per kilometre. These large variations in geotherms and geothermal gradients give rise to different metamorphic regimes, or combinations of pressure-temperature conditions, associated with the different tectonic provinces.

In addition to the variation of geotherms as a function of position in the Earth, individual geotherms at a single location can vary with time. Geotherms are at steady state (*i.e.*, do not change with time) in tectonically quiescent areas of the Earth, such as the middle regions of large continents, and also in areas where tectonic processes like subduction have operated at similar rates over long periods. Transient geotherms, on the other hand, are generated in tectonically active regions, such as zones of continent-continent collision or rapid uplift and erosion, in which the tectonic processes are relatively short-lived; in these areas, the temperature at a given depth in the Earth is time-dependent, and individual geotherms can have very complex shapes that with time approach smooth curves (see Figure 139). These complex geotherms can produce wide temperature fluctuations at a given depth within the Earth; rocks metamorphosed in response to these variations may show considerable textural and chemical evidence of disequilibrium, reflecting the fact that temperatures changed at rates that were more rapid than reaction rates among the constituent minerals.

PRESSURE

The pressure experienced by a rock during metamorphism is due primarily to the weight of the overlying rocks (*i.e.*, lithostatic pressure) and is generally reported in units of bars or kilobars. For typical densities of crustal rocks of two to three grams per cubic centimetre, one kilobar of lithostatic pressure is generated by a column of overlying rocks approximately 3.5 kilometres high. Typical continental crustal thicknesses are on the order of 30–40 kilometres but can be as great as 60–80 kilometres in mountain belts such as the Alps and Himalayas. Hence, metamorphism of continental crust occurs at pressures from a few hundred bars (adjacent to shallow-level intrusions) to 10–20 kilobars at the base of the crust. Oceanic crust is generally 6–10 kilometres in thickness, and metamorphic pressures within the oceanic crust are therefore considerably less than in continental regions. In subduction zones, however, oceanic and, more rarely, continental crust may be carried down to depths exceeding 100 kilometres, and metamorphism at very high pressures may occur. Metamorphic recrystallization also occurs in the mantle at pressures up to hundreds of kilobars.

Burial and uplift

Changes in lithostatic pressure experienced by a rock during metamorphism are brought about by burial or uplift of the sample. Burial can occur in response either to ongoing deposition of sediments above the sample or tectonic loading brought about, for example, by thrust-faulting or large-scale folding of the region. Uplift, or more properly unroofing, takes place when overlying rocks are stripped off by erosional processes or when the overburden is tectonically thinned.

Fluids trapped in the pores of rocks during metamorphism exert pressure on the surrounding grains. At depths greater than a few kilometres within the Earth, the magnitude of the fluid pressure is equal to the lithostatic pressure, reflecting the fact that mineral grain boundaries recrystallize in such a way as to minimize pore space and to seal off the fluid channelways by which solutions rise from depth. At shallow depths, however, interconnected pore spaces can exist, and hence the pressure within a pore is related to the weight of an overlying column of fluid rather than rock. Because metamorphic fluids (dominantly composed of water and carbon dioxide) are less dense than rocks, the fluid pressure at these conditions is lower than the lithostatic pressure.

Deformation of rocks during metamorphism occurs when the rock experiences an anisotropic stress—*i.e.*, unequal pressures operating in different directions. Anisotropic stresses rarely exceed more than a few tens or hundreds of bars but have a profound influence on the textural development of metamorphic rocks (see below *Textural features; Structural features*).

ROCK COMPOSITION

Common metamorphic rock types have essentially the same chemical composition as what must be their equally common igneous or sedimentary precursors. Common greenschists have essentially the same compositions as basalts; marbles are like limestones; slates are similar to mudstones or shales; and many gneisses are like granodiorites. In general, then, the chemical composition of a metamorphic rock will closely reflect the primary nature of the material that has been metamorphosed. If there are significant differences, they tend to affect only the most mobile (soluble) or volatile elements; water and carbon dioxide contents can change significantly, for example.

Despite the wide variety of igneous and sedimentary rock types that can recrystallize into metamorphic rocks, most metamorphic rocks can be described with reference to only four chemical systems: pelitic, calcareous, felsic, and mafic. Pelitic rocks are derived from shale protoliths and are rich in potassium (K), aluminum (Al), silicon (Si), iron (Fe), magnesium (Mg), and water (H_2O), with lesser amounts of manganese (Mn), titanium (Ti), calcium (Ca), and other constituents. Calcareous rocks are formed from a variety of chemical and detrital sediments such as limestone, dolostone, or marl and are largely composed of calcium oxide (CaO), magnesium oxide (MgO), and carbon dioxide (CO_2), with varying amounts of aluminum, silicon, iron, and water. Felsic rocks can be produced by metamorphism of both igneous and sedimentary protoliths (*e.g.*, granite and arkose, respectively) and are rich in silicon, sodium (Na), potassium, calcium, aluminum, and lesser amounts of iron and magnesium. Mafic rocks derive from basalt protoliths and some volcanogenic sediments and contain an abundance of iron, magnesium, calcium, silicon, and aluminum. Ultramafic metamorphic rocks result from the metamorphism of mantle rocks and some oceanic crust and contain dominantly magnesium, silicon, and carbon dioxide, with smaller amounts of iron, calcium, and aluminum. For the purposes of this discussion, ultramafic rocks are considered to be a subset of the mafic category.

Mafic rocks

The particular metamorphic minerals that develop in each of these four rock categories are controlled above all by the protolith chemistry. The mineral calcite ($CaCO_3$), for example, can occur only in rocks that contain sufficient quantities of calcium. The specific pressure-temperature conditions to which the rock is subjected will further influence the minerals that are produced during recrystallization; for example, at high pressures calcite will be replaced by a denser polymorph of $CaCO_3$ called aragonite. In general, increasing pressure favours denser mineral structures, whereas increasing temperature favours anhydrous and less dense mineral phases. Many of the minerals developed during metamorphism, along with their chemical compositions, are given in alphabetical order in Table 55. The most common metamorphic minerals that form in rocks of the four chemical categories described above are listed in Table 56 as a function of pressure and temperature. Although some minerals, such as quartz, calcite, plagioclase, and biotite, develop under a variety of conditions, other minerals are more restricted in occurrence; examples are lawsonite, which is produced primarily during high-pressure, low-temperature metamorphism of basaltic protoliths, and sillimanite, which develops during relatively high-temperature metamorphism of pelitic rocks.

Despite the large number of minerals listed in Table 56 for each of the four bulk compositions, the actual number of minerals present in an individual metamorphic rock is limited by the laws of thermodynamics. The number of mineral phases that can coexist stably in a metamorphic rock at a particular set of pressure-temperature conditions is given by the Gibbs phase rule: number of mineral phases = number of chemical components − number of degrees of freedom + 2, where the 2 stands for the two variables of pressure and temperature. The degrees of freedom of the system are the parameters that can be independently varied without changing the mineral assemblage of the rock. For example, a rock with no degrees of freedom can only exist at a single set of pressure-temperature conditions; if either the pressure or the temperature is

varied, the minerals will react with one another to change the assemblage. A rock with two degrees of freedom can undergo small changes in pressure or temperature or both without altering the assemblage. Most metamorphic rocks have mineral assemblages that reflect two or more degrees of freedom at the time the rock recrystallized. Thus, a typical pelitic rock made up of the six chemical components silica (SiO_2), aluminum oxide (Al_2O_3), ferrous oxide (FeO), magnesium oxide (MgO), potash (K_2O), and water would contain no more than six minerals; the identity of those minerals would be controlled by the pressure and temperature at which recrystallization occurred. In such a rock taken from the Earth's surface, the identity of the six minerals could be used to infer the approximate depth and temperature conditions that prevailed at the time of its recrystallization. Rocks that contain more mineral phases than would be predicted by the phase rule often preserve evidence of chemical disequilibrium in the form of reactions that did not go to completion. Careful examination of such samples under the microscope can often reveal the nature of these reactions and provide useful information on how pressure and temperature conditions changed during the burial and uplift history of the rock.

Metamorphic rocks only rarely exhibit a chemical composition that is characteristically "metamorphic." This statement is equivalent to saying that diffusion of materials in metamorphism is a slow process, and various chemical units do not mix on any large scale. But occasionally, particularly during contact metamorphism, diffusion may occur across a boundary of chemical dissimilarity, leading to rocks of unique composition. This process is referred to as metasomatism. If a granite is emplaced into a limestone, the contact region may be flooded with silica and other components, leading to the formation of a metasomatic rock. Often such contacts are chemically zoned. A simple example is provided by the metamorphism of magnesium-rich igneous rocks in contact with quartz-rich sediments. A zonation of the type serpentine-talc-quartz may be found such as:

$$Mg_6(Si_4O_{10})(OH)_8\text{-}Mg_3(Si_4O_{10})(OH)_2\text{-}SiO_2.$$

In this case the talc zone has grown by silica diffusion into the more silica-poor environment of the serpentine. Economic deposits are not uncommon in such situations—*e.g.*, the formation of the $CaWO_4$ (calcium tungstate) scheelite when tungstate in the form of WO_3 moves from a granite into a limestone contact. The reaction can be expressed as:

$$CaCO_3 + WO_3 \text{ (solution)} \rightarrow CaWO_4 + CO_2 \text{ (gas)}.$$

Metamorphic reactions

A very simple mineralogical system and its response to changing pressure and temperature provide a good illustration of what occurs in metamorphism. An uncomplicated sediment at the Earth's surface, a mixture of the clay mineral kaolinite [$Al_4Si_4O_{10}(OH)_8$] and the mineral quartz (SiO_2), provides a good example. Most sediments have small crystals or grain sizes but great porosity and permeability, and the pores are filled with water. As time passes, more sediments are piled on top of the surface layer, and it becomes slowly buried. Accordingly, the pressure to which the layer is subjected increases because of the load on top, known as overburden. At the same time, the temperature will increase because of radioactive heating within the sediment and heat flow from deeper levels within the Earth.

In the first stages of incremental burial and heating, few chemical reactions will occur in the sediment layer, but the porosity decreases, and the low-density pore water is squeezed out. This process will be nearly complete by the time the layer is buried by five kilometres of overburden. There will be some increase in the size of crystals; small crystals with a large surface area are more soluble and less stable than large crystals, and throughout metamorphic processes there is a tendency for crystals to grow in size with time, particularly if the temperature is rising.

Eventually, when the rock is buried to a depth at which

temperatures of about 300° C obtain, a chemical reaction sets in, and the kaolinite and quartz are transformed to pyrophyllite and water:

$$Al_4Si_4O_{10}(OH)_8 + 4SiO_2 \rightarrow 2Al_2Si_4O_{10}(OH)_2 + 2H_2O.$$

kaolinite quartz pyrophyllite water

The exact temperature at which this occurs depends on the fluid pressure in the system (see Figure 140), but in general the fluid and rock-load pressures tend to be rather similar during such reactions. The water virtually fights its way out by lifting the rocks. Thus, the first chemical reaction is a dehydration reaction leading to the formation of a new hydrate. The water released is itself a solvent for silicates and promotes the crystallization of the product phases.

A second dehydration reaction

If heating and burial continue, another dehydration sets in at about 400° C, in which the pyrophyllite is transformed to andalusite, quartz, and water:

$$Al_2Si_4O_{10}(OH)_2 \rightarrow Al_2SiO_5 + 3SiO_2 + H_2O.$$

pyrophyllite andalusite quartz water

After the water has escaped, the rock becomes virtually anhydrous, containing only traces of fluid in small inclusions in the product crystals and along grain boundaries. Both of these dehydration reactions tend to be fast, because water, a good silicate solvent, is present.

Although the mineral andalusite is indicated as the first product of dehydration of pyrophyllite, there are three minerals with the chemical composition Al_2SiO_5. Each has unique crystal structures, and each is stable under definite pressure-temperature conditions (Figure 140). Such differing forms with identical composition are called polymorphs. If pyrophyllite is dehydrated under high-pressure conditions, the polymorph of Al_2SiO_5 formed would be the mineral kyanite (the most dense polymorph). With continued heating, the original andalusite or kyanite will invert to sillimanite, the highest-temperature Al_2SiO_5 polymorph (see Figure 140):

$$Al_2SiO_5 \rightarrow Al_2SiO_5$$

andalusite or kyanite sillimanite

The kinetics of these polymorphic transformations are sufficiently sluggish, however, that kyanite or andalusite may persist well into the stability field of sillimanite.

Owing to the very simple bulk composition of the protolith in this example (a subset of the pelitic system containing only SiO_2-Al_2O_3-H_2O), no other mineralogical changes will occur with continued heating or burial. The original sediment composed of kaolinite, quartz, and water will thus have been metamorphosed into a rock composed of sillimanite and quartz, and perhaps some metastable andalusite or kyanite, depending on the details of the burial and heating history. In the case of a more typical pelite containing the additional chemical components potash, ferrous oxide, and magnesium oxide, the reaction history would be correspondingly more complex. A typical shale that undergoes burial and heating in response to continent-continent collision would develop the minerals muscovite, chlorite, biotite, garnet, staurolite, kyanite, sillimanite, and alkali feldspar, in approximately that order, before beginning to melt at about 700° C. Each of these minerals appears in response to a chemical reaction similar to those presented above. Most of these reactions are dehydration reactions, and the shale thus loses water progressively throughout the entire metamorphic event. As discussed above, the total number of minerals present in the rock is controlled by the Gibbs phase rule, and the addition of new minerals generally results from the breakdown of old minerals. For example, the following reaction,

$$\text{garnet} + \text{muscovite} + \text{chlorite} \rightarrow \text{staurolite} + \text{biotite} + \text{quartz} + \text{water},$$

occurs at temperatures of about 500°–550° C and typically consumes all the preexisting chlorite in the rock, introduces the new mineral staurolite, and adds more biotite and quartz to the biotite and quartz generated by earlier reactions. Some garnet and muscovite usually remain after the reaction, although examination of the sample under the microscope would probably reveal partial corrosion (wearing away due to chemical reactions) of the garnets resulting from their consumption.

Reactions that introduce new minerals in rocks of a specific bulk composition are referred to as mineral appearance isograds. Isograds can be mapped in the field as lines across which the metamorphic mineral assemblage changes. Caution must be exercised to note the approximate bulk composition of the rocks throughout the map area, however, because the same mineral can develop at quite different sets of pressure-temperature conditions in rocks of dissimilar chemical composition. For example, garnet generally appears at a lower temperature in pelitic rocks than it does in mafic rocks; hence, the garnet isograd in pelitic rocks will not be the same map line as that in metabasaltic (*i.e.*, metamorphosed basalt) compositions. Isograd patterns are discussed further in *Structural features* below.

Isograds

PRINCIPAL TYPES

Metamorphic reactions can be classified into two types that show different degrees of sensitivity to temperature and pressure changes: net-transfer reactions and exchange reactions. Net-transfer reactions involve the breakdown of preexisting mineral phases and corresponding nucleation and growth of new phases. (Nucleation is the process in which a crystal begins to grow from one or more points, or nuclei.) They can be either solid-solid reactions (mineral A + mineral B = mineral C + mineral D) or devolatilization reactions (hydrous mineral A = anhydrous mineral B + water), but in either case they require significant breaking of bonds and reorganization of material in the rock. They may depend most strongly on either temperature or pressure changes. In general, devolatilization reactions are temperature-sensitive, reflecting the large increase in entropy (disorder) that accompanies release of structurally bound hydroxyl groups (OH) from minerals to produce molecular water. Net-transfer reactions that

involve a significant change in density of the participating mineral phases are typically more sensitive to changes in pressure than in temperature. An example is the transformation of albite ($NaAlSi_3O_8$) to the sodic pyroxene jadeite ($NaAlSi_2O_6$) plus quartz (SiO_2); albite and quartz have similar densities of about 2.6 grams per cubic centimetre, whereas jadeite has a density of 3.3 grams per cubic centimetre. The increased density reflects the closer packing of atoms in the jadeite structure. Not surprisingly, the denser phase jadeite is produced during subduction zone (high-pressure) metamorphism. Net-transfer reactions always involve a change in mineral assemblage, and textural evidence of the reaction often remains in the sample (see below *Textural features*); isograd reactions are invariably net-transfer reactions.

Exchange reactions

In contrast to net-transfer reactions, exchange reactions involve redistribution of atoms between preexisting phases rather than nucleation and growth of new phases. The reactions result simply in compositional changes of minerals already present in the rock and do not modify the mineral assemblage. For example, the reaction

$$Fe_3Al_2Si_3O_{12} + KMg_3AlSi_3O_{10}(OH)_2 \rightarrow$$

almandine garnet magnesium-biotite

$$Mg_3Al_2Si_3O_{12} + KFe_3AlSi_3O_{10}(OH)_2$$

pyrope garnet iron-biotite

results in redistribution of iron and magnesium between garnet and biotite but creates no new phases. This reaction is limited by the rates at which iron and magnesium can diffuse through the garnet and biotite structures. Because diffusion processes are strongly controlled by temperature but are nearly unaffected by pressure, exchange reactions are typically sensitive to changes only in metamorphic temperature. Exchange reactions leave no textural record in the sample and can be determined only by detailed microanalysis of the constituent mineral phases. The compositions of minerals as controlled by exchange reactions can provide a useful record of the temperature history of a metamorphic sample.

The types of reactions cited here are typical of all metamorphic changes. Gases are lost (hydrates lose water, carbonates lose carbon dioxide), and mineral phases undergo polymorphic or other structural changes; low-volume, dense mineral species are formed by high pressures, and less dense phases are favoured by high temperatures. Considering the immense chemical and mineralogical complexity of the Earth's crust, it is clear that the number of possible reactions is vast. In any given complex column of crustal materials some chemical reaction is likely for almost any incremental change in pressure and temperature. This is a fact of immense importance in unraveling the history and mechanics of the Earth, for such changes constitute a vital record and are the primary reason for the study of metamorphic rocks.

RETROGRADE METAMORPHISM

In general, the changes in mineral assemblage and mineral composition that occur during burial and heating are referred to as prograde metamorphism, whereas those that occur during uplift and cooling of a rock represent retrograde metamorphism. If thermodynamic equilibrium were always maintained, one might expect all the reactions that occur during prograde metamorphism to be reversed during subsequent uplift of the rocks and reexposure at the Earth's surface; in this case, metamorphic rocks would never be seen in outcrop. Two factors mitigate against complete retrogression of metamorphic rocks, however, during their return to the Earth's surface. First is the efficient removal of the water and carbon dioxide released during prograde devolatilization reactions by upward migration of the fluid along grain boundaries and through fractures. Because almost all the water released during heating by reactions such as

$$Fe_5Al_6Si_3O_{20}(OH)_{16} + 4SiO_2 \rightarrow 3Fe_3Al_2Si_3O_{12} + 8H_2O$$

chlorite quartz garnet water

is removed from the site of reaction, the reaction cannot be reversed during cooling unless water is subsequently added to the rock. Thus, garnet can be preserved at the Earth's surface even though it is thermodynamically unstable at such low temperatures and pressures. The second reason that metamorphic reactions do not typically operate in reverse during cooling is that reaction rates are increased by rising temperatures. During cooling, reaction kinetics become sluggish, and metastable mineral assemblages and compositions can be preserved well outside their normal stability fields. Thus, prograde reactions are generally more efficient than retrograde reactions, and metamorphic assemblages indicative of even extremely high temperatures or pressures or both are found exposed throughout the world. It is common, however, to find at least some signs of retrogression in most metamorphic rocks. For example, garnets are often rimmed by small amounts of chlorite and quartz, indicating that limited quantities of water were available for the reverse of the reaction given above to proceed during cooling. Retrograde features such as these reaction rims can be mapped to yield information on pathways of fluid migration through the rocks during uplift and cooling. In other rocks, such as high-temperature gneisses, mineral compositions often reflect temperatures too low to be in equilibrium with the preserved mineral assemblage; in these samples, it is clear that certain exchange reactions operated in a retrograde sense even when the net-transfer reactions were frozen in during prograde metamorphism.

Textural features

The fabric of a metamorphic rock results from the combined effects of mineral reactions and deformation throughout the metamorphic event and the subsequent return of the rock to the terrestrial surface. The study of metamorphic fabrics in outcrop and under the microscope has become a highly specialized subject aimed at revealing the nature and direction of the forces acting during dynamic processes within the Earth. Much of this work is an outgrowth of a classic investigation conducted in 1930 by the Austrian geologist Bruno Sander, coupled with more recent experimental work on the pressure-temperature stabilities of metamorphic minerals and their responses to deformation.

Observations show that pressure is only rarely hydrostatic (equal in all directions) at any point within the Earth's crust. In real cases, consequently, anisotropic stresses operate that may lead to flow or fracture of materials. Such occurrences produce certain characteristic fabrics or structures in metamorphic rocks that may be observed at the scale of the orientation of small crystals in a rock or as a pattern of folds in a mountain range. One of the principal characteristics of most metamorphic rocks is that the arrangement of crystals is not isotropic, or random, but that there is a strong preferred orientation related to the direction of stress components of pressure. Such preferred orientation of crystals and mineral grains is perhaps the most striking difference between metamorphic rocks and other rock types.

The most obvious features of metamorphic rocks are certain planar features that are often termed s-surfaces. The simplest planar features may be primary bedding (akin to the layering in sedimentary rocks). As the rock crystallizes or recrystallizes under directed pressure, new crystals may grow in some preferred direction, sometimes subparallel to the primary bedding but often at new angles defining new planar structures. At the same time, folding of layers may occur, leading to folds with amplitudes on scales of kilometres or millimetres. Fabric symmetry may be represented by the nature of deformed fossils, pebbles in a conglomerate, or any objects with a known shape prior to deformation (Figure 141).

A few terms that commonly are used to describe several types of preferred orientation in metamorphic rocks include foliation, a general term describing any type of s-surface, bedding, or crystal orientation; slaty cleavage, a planar structure leading to facile cleavage that is normally caused by the preferred orientation of mica crystals; schis-

tosity, a term used to describe repetitive and pronounced foliation of the type that is present in schists; and lineation, which is any linear structure, such as the axis of the fold, grooves on a fault plane, or the direction of stretching of pebbles.

The various mineral phases of a metamorphic rock have different physical properties and symmetries. When a rock is subjected to recrystallization in a stress field, different substances will behave differently according to such physical properties and symmetries. Some minerals always tend to grow in better-formed crystals than others; rates of nucleation may differ, and this can lead to different patterns of growth of crystals—there may be a few large crystals or a mass of small crystals. Minerals can be arranged in order of their tendency to form crystals showing planar surfaces—namely, magnetite, garnet, epidote, mica, calcite, quartz, and feldspar. Minerals that have a tendency to form large single crystals (*e.g.*, garnet) are termed porphyroblasts.

Porphyroblasts

Porphyroblastic crystals may grow before, during, or after an episode of deformation (pre-, syn-, and postkinematic growth, respectively); the relative timing of mineral growth and deformation can often be determined by examining the sample under a microscope. Prekinematic porphyroblasts may be fractured by subsequent deformation; the orientation of the fractures and any offset of the grains along them provide information on the directed stresses responsible for the deformation. Prekinematic grains may also be surrounded by pressure shadows produced by minerals such as quartz that dissolve in zones of maximum compressive stress and reprecipitate in zones of lesser

compressive stress adjacent to the rigid porphyroblasts. The texture of the shadows is different from that of the host rock. Samples exhibiting asymmetric pressure shadows around porphyroblasts can yield information on the orientation of shear stresses during deformation. A spectacular example of synkinematic prophyroblast growth is provided by the so-called snowball garnets, which have spiral trails of inclusions that indicate rotation of either the garnet or the matrix foliation during garnet growth (see Figure 142). Postkinematic porphyroblasts typically overgrow all previous fabrics in the rock and may contain trails of mineral inclusions that define microfolds or an earlier schistosity.

In some samples, it is possible to use the compositions of the porphyroblasts to calculate the depth and temperature conditions at which they grew and thereby constrain the conditions at which deformation occurred. Studies of this sort add immeasurably to the understanding of crustal rheologies and the response of rocks to large-scale orogenic events. Because a particular metamorphic event may be accompanied by either several isolated episodes of deformation or a single continuum of deformation, there may be many fabric generations recorded in one sample; individual minerals may be postkinematic with respect to the earliest deformation but prekinematic relative to younger deformation in the same rock. Thus, the study of porphyroblast fabrics in metamorphic rocks can be complex but has the potential to yield important information on the structural history of metamorphic regions (see below *Structural features*).

Because changes in pressure and temperature often occur at faster rates than those of mineral reaction and recrystallization, metamorphic rocks may display fabrics that result from incomplete reactions. Such disequilibrium features provide a wealth of information on the reaction history of the sample and, by comparison with experimental studies of mineral stabilities, can also constrain the quantitative pressure-temperature history of the rock during metamorphism. An example of a reaction texture is shown in Figure 143, in which a corroded garnet is surrounded by a corona (reaction rim) of the mineral cordierite; other minerals present in the matrix include sillimanite, quartz, biotite, and alkali feldspar. The sample does not contain garnet in contact with sillimanite or quartz. These textural features suggest the following reaction relationship between garnet, sillimanite, quartz, and cordierite:

$$2Mg_3Al_2Si_3O_{12} + 4Al_2SiO_5 + 5SiO_2 \rightleftharpoons 3Mg_2Al_4Si_5O_{18}.$$

garnet sillimanite quartz cordierite

This reaction has been shown experimentally to occur at temperatures of approximately $725° \pm 50°$ C and to be very sensitive to pressure, with cordierite occurring under low-pressure conditions. The textural evidence that pre-

existing garnet was partially replaced by cordierite thus implies that the rock underwent decompression while still at high temperatures and that the decompression occurred too rapidly for the rock to recrystallize completely (*i.e.,* for garnet to be totally replaced by cordierite).

Lamination

There is also a tendency for many types of metamorphic rocks to become laminated, and the separate laminae may have distinct chemical compositions. A macroscopically rather homogeneous sediment may prove to be inhomogeneous on a minute scale. When graywackes are metamorphosed within the greenschist facies, for example, laminae rich in quartz and feldspar alternate with others rich in epidote, chlorite, and muscovite. The precise causes of this process are not well known, but it must result from a combination of extensive deformation accompanied by recrystallization. In a sense, it is a type of flow unmixing. It is important to recognize that this type of structure need have no relation to original bedding in the unmetamorphosed sediments.

Structural features

Metamorphic rocks are often intimately related to large-scale (kilometres of tens of kilometres) structural features of the Earth. Such features include folds, nappes, and faults with a wide variety of geometries. In many cases, the correlation of metamorphic isograds and their position in the structure implies a genetic relationship between the two. For example, one of the major structural features in the Himalayan mountain belt is the Main Central Thrust, a thrust fault that runs for hundreds of kilometres from east to west and was responsible for the transportation of rocks belonging to the Eurasian Plate southward over those of the Indian Plate. Along much of the length of this fault, the metamorphic rocks in the hanging wall (located above the fault) display a pattern of inverted isograds; *i.e.,* the rocks that reached the highest temperatures of metamorphism overlie rocks that record lower temperatures, implying that metamorphic temperatures decreased with depth to the fault. Several explanations have been proposed to account for this anomalous distribution of temperature with depth. One model suggests the fault transported hot Asian rocks over cooler Indian rocks, which caused cooling of the Asian rocks in the vicinity of the fault. Another model proposes that fluids circulating along the fault zone caused retrograde metamorphism and thus reset the rocks located nearest to the fault to lower temperatures. Although neither of these models provides an adequate explanation for the entire length of the Main Central Thrust, they both emphasize the significant control that structural features can exert on the development of metamorphic rocks.

Nappes

Metamorphism associated with nappes (large recumbent folds) in the Alps and the Appalachians provides strong evidence that the tectonic transport of rocks typically occurs at rates faster than those of thermal equilibration—in other words, that the nappes can transport hot rocks for large distances without significant cooling. Nappe formation is a major process of crustal thickening during continent-continent collision; emplacement of the nappes results in burial and heating of the underlying rocks. Isograd distributions associated with nappe structures can be either normal or inverted, depending on the relative rates of nappe emplacement and heat transfer.

Isograd maps can provide information on the relative timing of structural and metamorphic events in much the same way that fabric studies constrain the relative timing of deformation episodes and prophyroblast growth. For example, isograd patterns that are cut by faults clearly indicate that metamorphism predated fault displacement, whereas isograd sequences that overprint structural discontinuities imply the reverse. Isograds that parallel major structures suggest some cause-and-effect relationship between the structural and metamorphic development of the region. Since the 1980s, metamorphic petrologists and structural geologists have increasingly worked together to correlate metamorphic and tectonic events and thereby increase understanding of crustal dynamics in tectonically active regions of the Earth.

Metamorphic facies

Metamorphic petrologists studying contact metamorphism early in the 20th century introduced the idea of metamorphic facies to correlate metamorphic events. The concept was first defined in 1914 by a Finnish petrologist, Pentti Eelis Eskola, as any rock of a metamorphic formation that has attained chemical equilibrium through metamorphism at constant temperature and pressure conditions, with its mineral composition controlled only by the chemical composition. In current usage, a metamorphic facies (Figure 144) is a set of metamorphic mineral assemblages, repeatedly associated in space and time, such that there is a constant and therefore predictable relation between mineral composition and chemical composition.

The facies concept is more or less observation-based. In a single outcrop, for instance, layers of different chemical composition will display different mineral assemblages despite having all experienced the same pressure and temperature history. A pelitic layer might contain the assemblage garnet + chlorite + biotite + muscovite + quartz, whereas a basaltic horizon a few centimetres away would contain the assemblage chlorite + actinolite + albite. Both of these rocks belong to the same facies, meaning that, in another region, a geologist who observed the assemblage chlorite + actinolite + albite in a metabasalt could predict that associated pelitic rocks would contain the garnet + chlorite + biotite + muscovite + quartz assemblage.

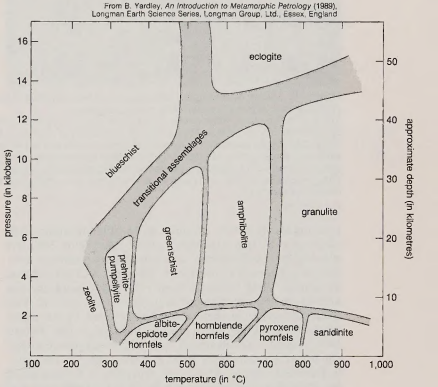

Figure 144: Approximate pressure-temperature regions of the major metamorphic facies (see text).

Experimental work on the relative stabilities of metamorphic minerals and assemblages has permitted correlation of the empirically derived facies with quantitative pressure and temperature conditions, as shown in Figure 144. The names of metamorphic facies in common usage are derived from the behaviour of a rock of basaltic bulk composition during metamorphism at various sets of pressure-temperature conditions. For example, a basalt metamorphosed during subduction to high pressures at low temperatures recrystallizes into a rock containing glaucophane, lawsonite, and albite; glaucophane is a sodic amphibole that is blue to black in hand sample and lavender to blue under the microscope (see Figure 145). Because of their distinctive bluish coloration, such samples are called blueschists. The same rock type metamorphosed at more moderate pressures and temperatures in the range of 400°–500° C would contain abundant chlorite and actinolite, minerals that are green both in hand sample and under the microscope, and would be referred to as a greenschist (see Figure 145). At somewhat higher temperatures, the rock would become an amphibolite, reflecting a mineralogy composed

The four metamorphic facies shown in the figure owe their names to differences in their appearance. (Top left) Blueschist containing glaucophanitic amphibole (blue), epidote, and albite. (Top right) Greenschist composed of green chlorite and actinolitic amphibole with albite and some epidote. (Bottom left) Amphibolite containing the amphibole hornblende (green), garnet, and plagioclase. Jane Selverstone

predominantly of the amphibole hornblende along with plagioclase and perhaps some garnet (see Figure 145). At still higher temperatures, a metabasalt recrystallizes into a rock containing hypersthene, diopside, and plagioclase; in general, these minerals form relatively equant crystals and hence do not develop a preferred orientation. The granular texture of these rocks has resulted in the name granulite for a high-temperature metabasalt (see Figure 145). A pelitic or calcareous rock will develop very different mineral assemblages from a metabasalt, yet the same facies names apply. Thus, one can refer to a greenschist facies pelitic schist, an amphibolite facies calcsilicate rock, or a granulite facies garnet gneiss.

Facies boundaries

The boundaries between the different facies are regions of pressure and temperature in which chemical reactions occur that would significantly alter the mineralogy of a rock of basaltic bulk composition. For example, the boundary between the greenschist and amphibolite facies marks a transition from amphibole of actinolitic composition to hornblende and of a sodic plagioclase into a more calcic plagioclase. The reactions that bring about these transformations depend on the specific composition of the rock and hence are denoted by broad bands rather than single lines on the pressure-temperature diagram in Figure 144.

FACIES SERIES

Different types of tectonic processes produce different associations of metamorphic facies in the field. For example, regions associated with subduction of oceanic material beneath either oceanic or continental crust are characterized by blueschist, greenschist, and eclogite facies rocks, whereas areas thought to reflect continent-continent collision are more typically distinguished by greenschist and amphibolite facies rocks. Still other regions, usually containing an abundance of intrusive igneous material, show associations of low-pressure greenschist, amphibolite, and granulite facies rocks. These observations led a Japanese petrologist, Akiho Miyashiro, working in the 1960s and '70s, to develop the concept of baric types, or metamorphic facies series. Miyashiro described the three facies associations given above as high-pressure, medium-pressure, and low-pressure facies series, respectively, and correlated the development of these characteristic series with the shape of the geotherm in different tectonic settings. Subsequent thermal modeling studies have shown that metamorphism generally occurs in response to tectonically induced perturbation of geotherms rather than along steady-state geotherms and, hence, that the facies series do not record metamorphic geotherms. Nonetheless, the concept of metamorphic facies series is a useful one in that it emphasizes the strong genetic relationship between metamorphic style and tectonic setting.

PRESSURE-TEMPERATURE-TIME PATHS

Interaction between metamorphic petrologists and geophysicists in the 1980s led to the realization that each metamorphic rock follows its own unique path through pressure- (depth-) temperature space during metamorphism and that these paths bear little or no resemblance to steady-state geotherms. The specific shape of a pressure-temperature-time (P-T-t) path depends on the tectonic setting in which the rock was metamorphosed, which in turn controls the relative rates at which burial or uplift and heating or cooling occur. For example, a rock that is uplifted rapidly from depth, perhaps in response to extensional faulting (that caused by the stretching of the Earth's crust), may transport heat with it to near-surface depths. Its P-T-t path would show a phase of nearly isothermal decompression (uplift at approximately constant temperature), reflecting the fact that uplift rates were more rapid

than those of heat transfer. In contrast, if the same rock remained at depth for a long period of time and then experienced very slow uplift, its P-T-t path would show cooling during uplift or even a phase of isobaric (constant-pressure) cooling. Rocks belonging to medium-pressure facies series generally follow P-T-t paths that are clockwise loops on a pressure-temperature diagram, reflecting rapid burial during a collisional event followed by heating and relatively rapid uplift. In contrast, low-pressure facies series rocks may follow counterclockwise P-T-t paths in response to rapid heating of the crust due to magma intrusion prior to uplift (Figure 146). P-T-t paths followed by rocks of a high-pressure facies series are less predictable and depend strongly on the mechanism by which the rocks are transferred from the subducting slab to the overlying continental crust. In general, the mineral assemblage preserved in a metamorphic rock is frozen at the highest temperature experienced during metamorphism (see above *Retrograde metamorphism*), and thus the facies and facies series to which the rock would be assigned reflect only a single point on its P-T-t path.

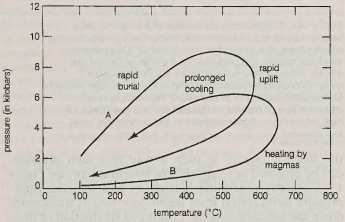

Figure 146: Examples of pressure-temperature-time paths that would be followed by rocks metamorphosed in different environments. (A) represents the rapid burial and uplift paths typical of areas of continental convergence. (B) represents heating and burial in response to regional-scale magma intrusion, followed by prolonged cooling and slow uplift.

Reconstruction of P-T-t paths

One of the principal goals of much of the work that is done on metamorphic rocks is the reconstruction of the P-T-t paths followed by rocks presently exposed at the Earth's surface. Because these paths are so strongly linked to dynamic processes, their reconstruction provides a means by which tectonic processes operative in the geologic past may be understood. Owing to the continuous recrystallization of rocks that occurs during progressive metamorphism, much of the early record of metamorphic changes within a sample is eradicated by later events. It is, therefore, not possible to determine the entire P-T-t path followed by an individual sample, but often enough disequilibrium features are preserved to permit reconstruction of a few thousand bars and a couple of hundred degrees of the path; such a portion may represent anywhere from a few million to a hundred million years of Earth history, as revealed by geochronologic determinations involving different minerals or fabric generations in the sample. Techniques for determining the pressure-temperature history of a metamorphic rock include using compositions of coexisting minerals to calculate pressures and temperatures of equilibration (geobarometry and geothermometry, respectively), comparing the mineral assemblage to experimentally determined stability fields for the phases, utilizing mineral inclusions enclosed within porphyroblasts to constrain assemblages present in the early history of the sample, and making use of the densities of small inclusions of fluids trapped within the minerals to determine possible pressures and temperatures experienced at different stages in the burial and uplift history.

Origin of metamorphic rocks: types of metamorphism

It is convenient to distinguish several general types of metamorphism in order to simplify the description of the various metamorphic phenomena. Recognized here are hydrothermal, dynamic, contact, and regional metamorphism, each of which will be described in turn.

Hydrothermal metamorphism. Changes that occur in rocks near the surface, where there is intense activity of hot water, are categorized as hydrothermal metamorphism. Such areas include Yellowstone National Park in the northwestern United States, the Salton Sea in California, and Wairakei in New Zealand. It is now generally recognized that the circulating groundwaters that often become heated by their proximity to igneous materials produce the metamorphism. Migration of chemical elements, vein formation, and other kinds of mineral concentration may be extreme on account of the large volumes of water circulated.

Dynamic metamorphism. When directed pressure or stress is the dominant agent of metamorphism, it is termed dynamic; other terms are dislocation, kinematic, and mechanical metamorphism. Mineralogical changes occurring on a fault plane provide an obvious example. In some such cases, the action may simply be a grinding up of existing grains or realignment of minerals that have nonequant crystals. If the action is intense, friction may even lead to melting.

Contact metamorphism. Whenever silicate melts (magmas, from which igneous rocks crystallize within the Earth) invade the crust at any level, they perturb the normal thermal regime and cause a heat increase in the vicinity. If a mass of basaltic liquid ascending from the upper mantle is trapped in the crust and crystallizes there, it will heat the surrounding area; the amount of heating and its duration will be a direct function of the mass and shape of the igneous material. Contact-metamorphic phenomena thus occur in the vicinity of hot igneous materials and at any depth. Under such circumstances, pressure and temperature are not simply correlated. Thermal gradients are often steep unless the igneous mass is extremely large.
