Contact aureoles—the surrounding zones of rock that become altered or metamorphosed—vary in thickness from several centimetres (around tabular bodies such as dikes and thin sills) to several kilometres (around large granitic intrusions). The contact metamorphic rocks of the aureole zone often lack any obvious schistosity or foliation.

The facies associated with contact metamorphism include the sanidinite, pyroxenite-hornfels, hornblende-hornfels, and albite-epidote-hornfels facies.

Sanidinite facies. Rocks of the sanidinite facies are represented by small fragments of aureole materials that have often been totally immersed in silicate liquids or by the aureole rocks surrounding volcanic pipes. Very high temperatures are attained, often at very low pressures. The dominant feature of the mineralogy of this facies is an almost complete lack of minerals containing water or carbon dioxide. Many of the minerals show similarity to those of igneous rocks themselves. If the duration of heating is short, adjustment to the imposed temperature is often imperfect.

Pelitic rocks (high in aluminum oxide) contain minerals such as mullite, sillimanite, sanidine, cordierite, spinel, hypersthene, anorthite, tridymite, and even glass. One of the classic localities of such rocks is the island of Mull, off the west coast of Scotland, but these rocks can be found in most regions of volcanism.

Calcareous rocks (originally impure limestones or dolomites) tend to lose nearly all their carbon dioxide, but pure calcite may survive. Typical metamorphic minerals are quartz, wollastonite, anorthite, diopside, periclase, and in some places (the classic is Scawt Hill in Northern Ireland) an array of complex calcium silicates such as spurrite, larnite, rankinite, melilite, merwinite, and monticellite. These minerals result from the addition of varying amounts of silica to impure mixtures of calcite and dolomite. In a general way the minerals of this facies are reminiscent of those of industrial slags.

Pyroxene-hornfels facies. Rocks of the pyroxene-hornfels facies are characteristically formed near larger granitic or gabbroic bodies at depths of a few kilometres or at pressures of a few hundred bars. The mineral assemblages are again largely anhydrous, but, unlike the sanidinite

facies, the minerals reflect distinctly lower temperatures. One of the classic descriptions of such rocks is from the Oslo district of Norway.

In pelitic rocks, minerals such as quartz, orthoclase, andalusite, sillimanite, cordierite, hypersthene, and plagioclase occur. Sometimes the hydrate biotite is developed. In calcareous rocks the minerals found include plagioclase, diopside, grossularite, vesuvianite (a hydrate), wollastonite, and sometimes the more complex calcium silicates monticellite, melilite, spurrite, tilleyite, and clinohumite.

Hornblende-hornfels facies. A generally deeper level of contact metamorphism where pressures of a few kilobars may be active is represented by the hornblende-hornfels facies. Hydrated phases become stable, and the transition to regional metamorphism becomes apparent. Because of the generally greater depth, this type of aureole is often superposed on a metamorphism at more normal pressure-temperature conditions, and the rocks may appear schistose and exhibit new thermally generated minerals on a preexisting assemblage. This type of metamorphism develops the classic "spotted" texture in which new porphyroblasts grow in slates and phyllites of a previous episode of metamorphism. Typically, such rocks are developed near most of the world's large granite batholiths, where these have moved to higher levels in the Earth's crust.

Typical minerals of pelitic assemblages include quartz, muscovite, biotite, andalusite, sillimanite, cordierite, plagioclase, microcline, and staurolite. Calcareous assemblages include calcite, quartz, diopside, grossularite, plagioclase, wollastonite, brucite, talc, forsterite, tremolite, and clinozoisite. Basaltic compositions include plagioclase, hornblende, diopside, quartz, biotite, and almandine garnet.

Formation of skarns

When rather pure limestone and dolomite come into direct contact with granitic rocks, elements such as silicon, iron, magnesium, and aluminum diffuse into the limestone, forming spectacular rocks termed skarns. These rocks often consist of large garnet crystals (grossularite) with green diopside and vesuvianite or epidote.

Albite-epidote-hornfels facies. Rocks of the albite-epidote-hornfels facies are characteristically found as the outer zones of contact aureoles where the thermal episode fades out and the rocks pass into their regional grade of metamorphism. The mineral assemblages are quite similar to those found in regional greenschist-facies metamorphism, except for the presence of low-pressure phases such as andalusite. Characteristic minerals include quartz, muscovite, biotite, chlorite, andalusite, actinolite, calcite, dolomite, albite, and epidote.

Regional metamorphism. Regional metamorphism is associated with the major events of Earth dynamics, and the vast majority of metamorphic rocks are so produced. They are the rocks involved in the cyclic processes of erosion, sedimentation, burial, metamorphism, and mountain building, events that are all related to major convective processes in the Earth's mantle.

Most regionally metamorphosed rocks develop primarily in response to continent-continent collision and to collision between oceanic and continental plates. As a result, young metamorphic belts aligned roughly parallel to the present-day continental margins (*e.g.*, the Pacific margin) as well as older metamorphic belts are used to infer the geometries of the continental margins at earlier periods in Earth history. Most of the world's mountain belts are at least partially composed of regionally metamorphosed rocks, with spectacular examples provided by the Alps, the Himalayas, the northern Appalachians, and the Highlands of Scotland. Although the processes that formed each of these mountain belts are broadly similar, in almost all such crustal events at different times and places, there is uniqueness as well as conformity to a general pattern. Metamorphic events in the Alps, the Urals, and the Himalayas all show specific differences: to unravel such differences and their significance is one of the major tasks of metamorphic petrology.

In areas of collision between oceanic and continental lithospheric plates such as the circum-Pacific region, the denser oceanic plate is subducted (carried into the Earth's mantle) beneath the more buoyant continental lithosphere. Rapid subduction of the cool oceanic lithosphere perturbs the thermal regime in such a way that high pressures can be obtained at relatively low temperatures (see Figure 147), thereby generating blueschists and eclogites (high-pressure facies series) from ocean-floor basalts transported down the subduction zone. Continued subduction of these rocks to great depth may eventually result in partial melting in response to rising temperatures; these melts contribute to the formation of the volcanoes that overlie subduction zones in areas such as the Andes of South America, Japan, and the Aleutian Islands. Upward migration of subduction-related magmas also contributes to the development of paired metamorphic belts, in which high-pressure, low-temperature metamorphic rocks are flanked on the continental side by a parallel belt of low-pressure, high-temperature rocks. The latter rocks are thought to reflect perturbation of the crustal thermal regime by the passage of silicate melts generated above the subducting slab. Continued intrusion of magma over a period of time would cause an increase in crustal temperatures at relatively shallow depths and produce the high-temperature rocks adjacent to the high-pressure rocks generated in the subduction zone (see Figure 147). Well-developed paired metamorphic belts are exposed in Japan, California, the Alps, and New Zealand.

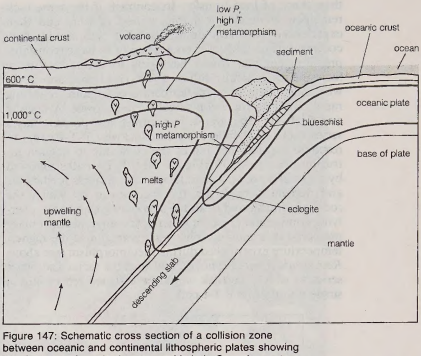

Figure 147: Schematic cross section of a collision zone between oceanic and continental lithospheric plates showing development of a paired metamorphic belt. Oceanic crust subducts rapidly and perturbs the thermal regime of the mantle. Rocks in the oceanic crust are progressively metamorphosed to blueschists and eclogites at high pressure. Subsequent melting in or above the descending crust causes a rise of magma to the surface and low-pressure, high-temperature metamorphism in the continental crust.
After A. Miyashiro, *Metamorphism and Metamorphic Belts* (1973), George Allen and Unwin, Ltd., London

Paired metamorphic belts

Data obtained from deep earthquakes in subduction zones indicate that a descending slab of oceanic lithosphere can remain intact to depths of several hundred kilometres before undergoing complete melting or fragmentation or both and being incorporated into the surrounding mantle. Clearly, the blueschists and eclogites exposed in orogenic belts around the world did not undergo such a process and were instead returned to the Earth's surface. Most of the high-pressure rocks that have been studied from Japan, California, New Caledonia, the Alps, and Scandinavia record maximum pressures of 10–20 kilobars, corresponding to subduction to depths of approximately 35–70 kilometres. A few samples have been discovered in Norway, the Alps, and China that contain the mineral coesite, a high-pressure polymorph of quartz. Experimental studies on the stability of coesite imply minimum pressures of 30 kilobars for these rocks, indicating burial or subduction to depths of approximately 100 kilometres. These pressures are particularly noteworthy in that they are recorded in rocks derived from sedimentary rather than basaltic protoliths. Because of the low density, and hence greater buoyancy, of sediments relative to basalts, many geologists have argued that sediment subduction must be

a rather limited process; the coesite-bearing metapelites (metamorphosed pelites) provide important evidence that sediment subduction can and does occur under certain circumstances.

The processes by which rocks that have been partially subducted are returned to the surface are not well understood. Models have been proposed to account for uplift and exposure of these high-pressure, high-density rocks; they include scraping material from the subducting plate against the overlying crustal lithosphere, upward flow of material in response to forced convection above the subducted slab, and removal of overlying thickened crust by low-angle extensional faulting. Testing these models requires considerable petrologic and structural work in areas where high-pressure rocks are exposed.

High-pressure rocks

Most of the high-pressure rocks that are currently displayed in metamorphic belts around the world were metamorphosed in Mesozoic or Cenozoic time (*e.g.*, the circum-Pacific belt, the Alps, the Greek Cyclades, and the Cordillera Betica in Spain). Older high-pressure rocks are known from only a few isolated occurrences in, for example, Wales, Bavaria, the Île de Groix off the coast of Brittany, and the Norwegian Caledonides (on the west coast of Norway). The general absence of high-pressure samples in the early rock record raises a number of interesting questions concerning Earth history. Some geologists have argued that the lack of well-developed Precambrian and Paleozoic high-pressure belts indicates that plate tectonic processes have changed significantly throughout geologic time. Specifically, they claim that greater heat production in Archean time (about 3.8 to 2.5 billion years ago) would have produced hotter crustal geotherms, resulting in thin, hot lithospheric plates whose mechanical behaviour may have been quite different from that of the present-day plates and hence may not have permitted formation of subduction zones. The increasing abundance of subduction-related metamorphic rocks with decreasing age in the rock record would thus reflect the gradual onset of plate tectonics as operative today. Others argue that the rock record is biased owing to preferential erosion or thermal overprinting (development of a new mineralogy that may obliterate the original one) of old blueschists and eclogites. Thermal modeling studies suggest that blueschists will generally undergo heating and be converted to greenschist assemblages if exposure at the Earth's surface does not occur within 100 million to 200 million years after high-pressure metamorphism. Early exposure at the surface also increases the chances for removal by erosion, however, resulting in a low probability for preserving blueschists greater than 100 million to 200 million years old. Geologists favouring generation of blueschists throughout Earth history but only selective preservation of these rocks also point to crustal rocks more than 2.5 billion years old that record metamorphism at depths of 25–40 kilometres; these medium-pressure facies series rocks imply that crustal thicknesses in the early Earth were similar to those of the present day and thus that modern plate tectonic processes may have operated from the early Precambrian to the present. This debate, though unresolved, emphasizes the substantial knowledge of the thermal structure of the Earth and plate tectonic processes that can be obtained from the study of metamorphic rocks.

Continent-continent collision

Depending on the original geometry of the Earth's lithospheric plates, subduction of oceanic crust beneath continental lithosphere may result in complete consumption of an ocean basin and subsequent collision between two continents. Collisions of this type have a long and complex history that may include initial formation of a paired metamorphic belt followed by extreme crustal thickening in response to the actual collision of the continents. The overthickened crust produced by the collision event will be gravitationally unstable and will undergo subsequent rapid erosion and possibly extensional faulting in order to return to a normal crustal thickness. Rocks metamorphosed in the early stages of collision may belong to a high-pressure facies series, reflecting the final stages of subduction of oceanic lithosphere, whereas the younger facies more typically belong to medium-pressure facies series. Metamorphic rocks exposed in former collision zones may thus have followed a variety of pressure-temperature-time paths, but paths showing rapid burial followed by heating and subsequent unroofing at moderate to high temperatures have been reported from many mountain belts around the world. Owing to the strong directed forces operative during collision, deformation typically accompanies metamorphism; rocks metamorphosed in response to continent-continent collision generally have fabrics showing a strong preferred orientation of mineral grains, folds on a variety of scales, and pre-, syn-, and postkinematic porphyroblasts. Examples of metamorphic belts produced in response to this type of collision include the Paleozoic Appalachian and Caledonides belts and the Mesozoic-Cenozoic Alpine and Himalayan belts.

Regionally metamorphosed rocks are also exposed in areas where the crust has been thinned by extensional faulting, such as the Basin and Range province of the western United States. In this type of occurrence, areas of medium- and low-pressure facies series rocks that measure a few tens of kilometres in diameter are juxtaposed against unmetamorphosed sediments or very low-grade metamorphic rocks along low-angle extensional faults. (Metamorphic grades refer to the degree and intensity of the metamorphism: they are determined by the pressure and temperatures to which the rock has been subjected.) Such areas are generally referred to as metamorphic core complexes. Metamorphism in these complexes may or may not be related to the extensional event. In some instances, metamorphic rocks produced during much earlier events are simply unroofed and exposed by the faulting but show little or no recrystallization related to extension. In other cases, prolonged extension has resulted in an increased crustal geotherm, and relatively high-temperature metamorphism and magmatism is thus directly related to the extensional event. Immediately adjacent to the faults, the rocks may also be affected by dynamic metamorphism.

The facies associated with regional metamorphism include, at low grade, the zeolite and prehnite-pumpellyite facies. In areas belonging to high-pressure facies series, the rocks are predominantly in the blueschist and eclogite facies. Medium- and low-pressure facies series are typified by rocks belonging to the greenschist, amphibolite, and granulite facies.

Zeolite facies. In the zeolite facies, sediments and volcanic debris show the first major response to burial. Reactions are often not complete, and typical metamorphic fabrics may be poorly developed or not developed at all. This is the facies of burial metamorphism.

The zeolite facies was first described from southern New Zealand, but similar rocks have now been described from many younger mountain regions of the Earth, particularly around the Pacific margin and the European Alps. Typically, the rocks are best developed where reactive volcanic materials (often partly glassy) are common and the characteristic minerals include zeolites, which are low-density, hydrated silicates, stable at temperatures rarely exceeding 300° C. Typical mineral assemblages include heulandite, analcite, quartz with complex clay minerals (montmorillonite), micaceous phases such as chlorite and celadonite, and the potassium feldspar, adularia. At higher grades of metamorphism, the zeolite laumonite and the feldspar albite dominate the mineral assemblage. In New Zealand these are developed in a rock column that is about 15 kilometres thick. Calcareous rocks (impure limestones) show very little response to this grade of metamorphism.

Prehnite-pumpellyite facies. Along with the zeolite facies, the prehnite-pumpellyite facies received little attention until about 1950. The first rocks of the facies were described in New Zealand and Celebes. The facies is transitional, bridging the path to the blueschist facies or the greenschist facies. It is particularly well developed in graywacke-type sediments. The two minerals prehnite and pumpellyite replace the zeolite minerals of the zeolite facies and are themselves replaced by epidote minerals in the greenschist facies and by lawsonite and pyroxenes in the blueschist facies. Typical minerals in this facies are quartz, albite, prehnite, pumpellyite, chlorite, stilpnomelane, muscovite, and actinolite. Almost all the minerals are hydrated, and, except for chlorite, they bear little re-

Transitional facies

semblance to the minerals of sediments. Again, the facies has been most described from younger mountain ranges of the Pacific margin.

Blueschist facies. Rocks of the blueschist facies represent deep metamorphism under conditions of a low thermal gradient. The characteristic locale for this type of metamorphism appears to be along a continental margin being underthrust by an oceanic plate. Regions in which blueschists are found are also regions of great seismic and volcanic activity, such as the Pacific margin. The best described examples of this class of metamorphism come from California, Japan, New Caledonia, Celebes, the Alps, and the Mediterranean region. At present there are no confirmed examples of glaucophane schists predating the Paleozoic Era. Because of the presence of the blue amphibole glaucophane and minerals such as garnet and jadeite, these schists are among the most attractive of metamorphic rocks.

Characteristic minerals of the facies include quartz, glaucophane, lawsonite, jadeite, omphacite, garnet, albite, chlorite, muscovite, paragonite, epidote, and kyanite. In calcareous rocks, calcite may be replaced by the high-pressure polymorph aragonite. In general, the facies is characterized by many high-density minerals reflecting a high pressure of formation.

Eclogite facies. The eclogite facies was initially recognized in rocks only of basaltic composition, which are transformed at the pressure-temperature conditions of the eclogite facies into spectacular red and green rocks composed of the anhydrous mineral assemblage garnet plus omphacite. The garnet is rich in the high-pressure species pyrope, and the omphacite is rich in the high-pressure pyroxene jadeite. Small amounts of minerals such as kyanite, the hydrate zoisite, and hornblende may be present. The rocks are of high density and frequently show little or no schistosity. It is now known that protoliths other than basalt also can be metamorphosed to pressures and temperatures characteristic of the eclogite facies, and a wide variety of mineral assemblages can be stable at these conditions, including several hydrous mineral phases. Minerals that have been observed in metapelites include magnesium-rich chloritoid and staurolite, kyanite, garnet, phengite (a muscovite mica with high magnesium and silicon and low aluminum content), chlorite, and talc. Experimental work shows that pelitic rocks composed primarily of talc and kyanite, which are referred to as whiteschists, can be stable from pressures of approximately 6 kilobars up to greater than 30 kilobars. Minerals observed in eclogite-facies calcareous rocks include magnesite, dolomite, zoisite or epidote, and omphacite.

Upper mantle as a source of eclogite

Because of the high density and composition, it was proposed long ago that part of the upper mantle might be made of eclogite. Such a view is supported by eclogitic intrusions in volcanic rocks and by eclogitic inclusions in diamond-bearing kimberlite, which must come from the upper mantle. Some workers also think that eclogites found in metamorphic terrains in Norway, California, U.S., and the European Alps could also come from the mantle by tectonic processes.

Early experimental work on eclogites of basaltic bulk composition suggested that eclogites could generally only be stable if water pressure was much lower than the lithostatic pressure, and the facies was thus thought to represent dry, high-pressure metamorphism of basaltic protoliths. Subsequent work on the more diverse protolith compositions reveals, however, that a wide range of water pressures are possible in the eclogite facies and that fluid compositions in equilibrium with the eclogite minerals also probably vary greatly. Indeed, fluid inclusions (tiny bubbles of fluid trapped within mineral grains) in eclogite samples provide evidence of fluids containing nitrogen, salts, and carbon dioxide in addition to water. Eclogite metamorphism is therefore not confined to dry environments but results instead from metamorphism of a variety of rock types at pressures above about 10 kilobars, corresponding to burial to approximately 35 kilometres, and at temperatures ranging from about 400° to 1,000° C. The temperatures of the eclogite facies overlap those of the greenschist, amphibolite, and granulite facies, but the higher pressures result in distinctly different mineral assemblages characterized by high-density mineral phases.

Greenschist facies. The greenschist facies was once considered the first major facies of metamorphism proper. The name comes from the abundance of the green mineral chlorite in such rocks. Because chlorite and muscovite are ubiquitous and because both exhibit a platy crystal habit, these rocks normally show a highly developed foliation and often exhibit strong metamorphic differentiation. They have been described from practically every metamorphic terrain on Earth, from earliest Precambrian to the young mountain regions. In fact, many of the Earth's oldest rocks (about three billion years old) of the continental-shield areas are in this facies, classic examples of which are in the Appalachians, the Highlands of Scotland, New Zealand, the European Alps, Japan, and Norway.

The dominant minerals of greenschists formed from silicate-rich sediments include quartz, albite, muscovite, chlorite, epidote, calcite, actinolite, magnetite, biotite, and paragonite. Minerals less common include the manganese-rich garnet spessartine, stilpnomelane, kyanite, rutile, sphene, pyrophyllite, and chloritoid. Calcareous rocks are dominated by calcite, dolomite, and quartz; the major carbonate minerals are thermally stable. It is only when large quantities of water flush away carbon dioxide or keep its partial pressure low that carbonate-silicate reactions take place and liberate carbon dioxide. The typical minerals of this facies have low water contents as compared to the zeolite facies minerals.

Amphibolite facies. The amphibolite facies is the common high-grade facies of regional metamorphism, and, like the greenschist facies, such rocks are present in all ages from all over the world. Their characteristic feature is the development of the most common amphibole, hornblende, in the presence of a plagioclase feldspar and garnet. The rocks are normally highly foliated or schistose. Many zones or isograds subdividing the facies have been recognized, and classic studies have been made in the Highlands of Scotland, New Hampshire and Vermont in the United States, Switzerland, and the Himalayas.

Hornblende, the most common amphibole

Characteristic minerals derived from pelitic rocks are quartz, muscovite, biotite, garnet, plagioclase, kyanite, sillimanite, staurolite, and orthoclase. Minerals derived from basaltic rocks include hornblende, plagioclase, garnet, epidote, and biotite. Those derived from calcareous rocks are calcite, diopside, grossularite (garnet), zoisite, actinolite (hornblende), scapolite, and phlogopite. Minerals from magnesium-rich ultrabasic rocks are chlorite, anthophyllite, and talc. In most common types, water is present in minerals only of the mica and amphibole families, and, with their water contents of only about 1 to 3 percent, dehydration is nearing its metamorphic climax.

Granulite facies. In rocks of basaltic composition, the granulite facies is an anhydrous facies that results from progressive dehydration of amphibolites at high temperature. Rocks of other bulk compositions may retain some hydrous minerals, such as biotite and hornblende, but it is likely that water pressure is lower than lithostatic pressure during most granulite facies metamorphism. Evidence for relatively low water pressures comes from fluid inclusion data indicating carbon dioxide-rich fluid compositions and from preservation of some bulk compositions that should have undergone nearly total melting at granulite temperatures if water pressure had been equal to lithostatic pressure.

Rocks of this facies frequently have a granular texture quite similar to plutonic igneous rocks. Schistosity is only weakly developed. Typical minerals of the facies are quartz, alkali feldspar, garnet, plagioclase, cordierite, sillimanite, and hypersthene. In calcareous members, dolomite, calcite, diopside, and forsterite occur; and it is in this facies that minerals of the scapolite family are best developed. Small amounts of hornblende are often present. A rare mineral occurring in this facies is sapphirine. The rock type charnockite (from Tamil Nādu, India), essentially a hypersthene granite, is normally included in this facies.

It appears from experimental studies that during ultrametamorphism, when melting starts, the basic reactions which take place are of the type

biotite + other minerals → melt + residue
hornblende + other minerals → melt + residue.

The first melts to form are partly wet granitic or granodioritic melts, and phases such as biotite and hornblende break down by producing a partly wet melt from the least refractory phases in the rocks. They would persist to much higher temperatures in other systems of their own composition. The residue in the above equations is a granulite-facies metamorphic rock containing phases such as pyroxene and sillimanite. Thus it is probable but certainly not universally proved that many granulites are formed only in the presence of a silicate liquid. This liquid may, of course, move to higher crustal levels.

The probable process of granulite formation

Large areas of granulite facies rocks are confined almost entirely to Precambrian areas of the continents (those areas that were formed more than 570 million years ago), with well-developed areas exposed in Canada, India, Africa, Antarctica, Greenland, and the Adirondack Mountains of New York in the northeastern United States. Smaller areas of granulite facies rocks occur in younger mountain belts, with Paleozoic examples in New England (U.S.) and Brittany and Tertiary examples (those formed between 66.4 and 1.6 million years ago) in British Columbia (Can.) and Timor. The apparent decrease in the volume of granulite facies rocks with decreasing age of metamorphism has led some geologists to postulate, as mentioned above, that plate tectonic processes might have changed significantly with time—specifically that steady-state continental geotherms were hotter in the Precambrian than at the present time. Some work on pressure-temperature-time paths in granulites also suggests that Precambrian granulites were metamorphosed along distinctly different paths than younger granulites, lending credence to models invoking changes in tectonic processes. An alternative hypothesis is that large volumes of granulites have been formed throughout Earth history but that they have not yet been exposed by erosion. Pressures calculated from fragments of granulite-facies metamorphic rocks carried to the surface in young volcanic eruptions suggest that the fragments were derived from the lower crust. It is likely that the lower crust is currently composed largely of granulite-facies rocks that may be exposed by future episodes of mountain building, but it is also possible that these granulites will prove to be different from their Precambrian counterparts. In order to resolve some of the controversies surrounding the origin and composition of granulites, it is necessary that considerable studies of these rocks be conducted in the future.

Distribution of metamorphic rocks

A high-grade metamorphic rock is one that formed at a depth of tens of kilometres and later returned to the surface. Hence, metamorphic regions are also regions of former or recent intense orogeny. More stable regions of the Earth's crust tend to be covered with sediments, and only deep drilling will reveal the metamorphic rocks below.

The Earth's crust is made up of two basic units, the continents and ocean basins. Exploration of ocean floors has revealed that old, thick sedimentary piles are missing. Doubtless this is related to the processes of continental drift or seafloor spreading; sediments are continuously swept up by continental motion and are added to the continents or returned to the upper mantle (see also PLATE TECTONICS). Nearly all studies of metamorphic rocks have concentrated on the continents for this reason.

There are few large areas of the Earth's crust that are not affected by some type of igneous event from time to time. Although the intensity of volcanism may be focused in certain geographic regions (*e.g.*, the Pacific margin), volcanism appears to be a rather random phenomenon, at times even occurring in the stable shield areas of the continents. In this sense, contact-metamorphic events may be found almost everywhere at almost any time on Earth. But these metamorphic events are of trivial volumetric significance compared to those of regional metamorphism.

During the past 500 million years or so of Earth history, major tectonic, seismic, igneous, and metamorphic events have been concentrated on continental margins (Figure 148). This has been a period of depression and uplift of the Earth's crust associated with the formation of the present continental distribution. The processes are still going on at dramatic rates in ocean trench environments. These modern regions of activity form immense linear belts. One such belt runs around virtually the entire Pacific margin and another through the Mediterranean and southern Asia to fuse with the circum-Pacific belt. It is in these belts that the spectacular development of zeolite facies, prehnite-pumpellyite facies, blueschist facies, and, occasionally, eclogite facies, as well as the more universal facies of regional metamorphism, have occurred. The granulite facies is almost missing.

Belts of mountain building and shield areas

The central and often dominant feature of most continents is their vast Precambrian-shield area; examples include the Canadian Shield, Brazilian Shield, African Shield, and Australian Shield. In these rocks, dating reveals ages of 1 to 3.5 billion years, and they have been little affected by tectonic events postdating the Cambrian. But

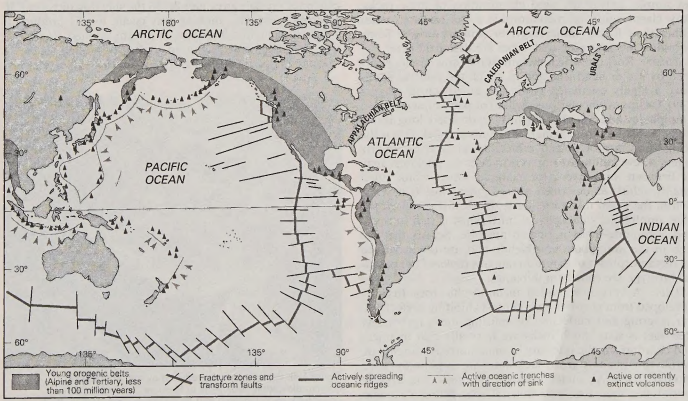

Figure 148: Tectonic units of the continents: shields and the present-day configuration of the continents and the Earth's major lithospheric plates (see text).

these shield areas are themselves complex. They consist of vast areas of granitic or granodioritic gneisses. Inside them, between them, and overlapping onto them are belts of sedimentary rocks quite like those in modern sedimentary belts of the Pacific margin or European Alps. These rocks are frequently metamorphosed in the greenschist, amphibolite, and granulite facies. Low-temperature facies and, in particular, low-temperature–high-pressure facies are missing—or have not yet been found. From marginal areas of these stable shield areas, a complex array of processes has been documented covering the past few hundred million years. The Caledonian orogeny (at the close of the Silurian Period) produced tectonic-metamorphic events along the east coast of North America, Greenland, the British Isles, Fennoscandia, Central Asia, and Australia. The Hercynian, or Variscan, orogeny followed about 300 million years ago, affecting subparallel regions and the Urals and European Alps. In fact, the shield margins appear to have been subjected to a more or less constant battering by forces both destroying and rebuilding the margins of these protocontinents. As geologists study Precambrian areas in greater detail, the number of metamorphic and orogenic events recognized on a global scale increases.

Tectonic-metamorphic events associated with the Caledonian orogeny

It is the great task and problem of those who study metamorphic rocks to deduce the record of Earth dynamics and thermal history from metamorphic rocks. Among the questions to be answered are (1) whether the pattern of facies development through time—*e.g.*, the granulite facies in the Archean to blueschist facies in the Tertiary—is a reflection of a cooling Earth and the decline of radioactivity in the crust, and (2) whether the increase in size of global tectonic-metamorphic belts through time reflects changes in convective patterns in the mantle.

As understanding of the pressure-temperature regimes of metamorphism increases, and as knowledge of rock mechanics and fluid motion during metamorphism also increases through field and laboratory studies, it may become possible to understand the details of the motion of the chemical elements during such processes and hence much of the subject of economic geology, or the search for man's essential raw materials.

Classification of metamorphic rocks

Because of the diverse chemistry, mineralogy, and primary origin of metamorphic rocks and because of the diverse fabrics or textures that may develop depending on the stresses that may operate during their formation, there is no simple, universally used classification of these rocks. Any classification of metamorphic rocks tends to stress either their fabric, mineralogy, or primary origin. Some common metamorphic rock types are described here.

Schist. Rocks in which metamorphic minerals are easily seen by eye or hand lens and in which the mineral grains have a highly orientated fabric are called schists (Figure 149). Grains of acicular (needlelike) or platy minerals (*e.g.*, amphiboles and micas) tend to lie with their long directions parallel or their planar directions parallel. Often the rocks show a pronounced mineralogical layering; quartz layers a few millimetres or centimetres in thickness may lie between mica layers, for example. Other words often qualify schist: as described above, greenschist is a schist rich in the green mineral chlorite; blueschist is rich in the blue amphibole, glaucophane; mica-schist is rich in mica; and a graphite-schist is rich in graphite. Schists that are rich in the amphibole hornblende and are often derived by metamorphism of common igneous rocks of the basalt-gabbro type are called amphibolites.

Pronounced mineralogical layering in schists

Slate. A very fine-grained metamorphic rock (usually developed from clay-rich sediments) exhibiting perfect planar layering and perfection of splitting into layers (slaty cleavage) is slate. Such rocks are normally rich in micas and chlorites. As the intensity of metamorphism increases, porphyroblasts may grow; such slates are sometimes called spotted slates. As metamorphism proceeds, the average crystal size increases, and mineral segregation develops; the rock then may be termed a phyllite.

Gneiss. A gneiss is produced by intense metamorphism,

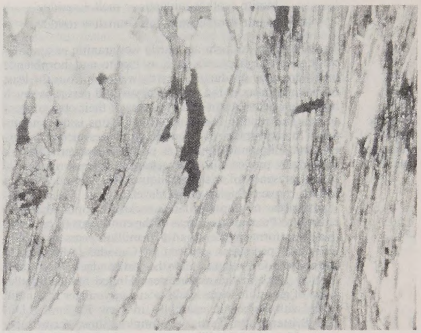

Figure 149: Photomicrograph of a staurolite-biotite schist from Scotland showing strong orientation of biotite crystals (dark) in a matrix of quartz and feldspars (magnification 50×).
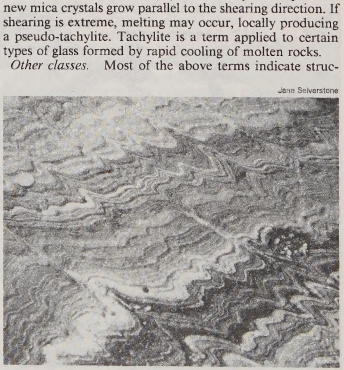
By courtesy of W.S. Fyfe

at high temperature and pressure. The grain size is coarser than that in schists, and layering is often well developed (see Figure 150); mineral orientation is less perfect than in schists, however. Very common granitic gneisses of Precambrian areas have been derived from metamorphism of granitic igneous rocks.



Hornfels. The hornfels are formed by contact metamorphism and typically show little sign of the action of directed pressure. They are fine-grained rocks in which crystals display little orientation.

Hornfels as a product of contact metamorphism

Marble. Rocks derived from the metamorphism of carbonate sediments containing calcite or dolomite are marbles. The main result of metamorphism is an increase in grain size. Because of the rather equidimensional habit of calcite and dolomite crystals, they rarely appear schistose unless they contain other minerals such as mica.

Mylonites and cataclastites. These are rocks in which the texture is the result of ductile shearing or mechanical shattering of grains. They often show only slight, if any, development of new minerals. They form on fault planes or in zones of intense shearing. If the crustal rocks have an appropriate composition, phyllonites may develop where new mica crystals grow parallel to the shearing direction. If shearing is extreme, melting may occur, locally producing a pseudo-tachylite. Tachylite is a term applied to certain types of glass formed by rapid cooling of molten rocks.

Other classes. Most of the above terms indicate struc-

tural or fabric classification of metamorphic rocks. Sometimes terms are used to indicate chemical features. Several types of schists, for example, include the following: pelitic schists contain much aluminum oxide and often are derivatives of clay-rich sediments; quartzofeldspathic schists are high in quartz and feldspars and often are derivatives of sandstones or quartz-rich igneous rocks; calcareous schists have a high content of lime (CaO) and often are derivatives of impure limestones, dolomites, or calcareous muds; and basic schists contain the elements of basic igneous rocks—namely, calcium, magnesium, and iron.

Carbonate minerals: TERENCE P. SCOFFIN, *An Introduction to Carbonate Sediments and Rocks* (1987), is a well-illustrated, easy-to-read book about limestones and dolostones. Both ALBERT V. CAROZZI, *Carbonate Rock Depositional Models: A Microfacies Approach* (1989), an extensively illustrated treatise of the author's ideas about the geneses of carbonate-rich sedimentary rocks; and RICHARD J. REEDER (ed.), *Carbonates: Mineralogy and Chemistry* (1983), a collection of summaries that deal with the carbonates, including calcite, are written at the professional level. A review article by LAURENCE A. HARDIE, "Dolomitization: A Critical View of Some Current Views," *Journal of Sedimentary Petrology*, 57(1):166–183 (1987), emphasizes the problems involved with accepting the most commonly embraced models of dolomitization and concludes that direct precipitation models (among other things) should receive more attention and study. VIJAI SHUKLA and PAUL A. BAKER, *Sedimentology and Geochemistry of Dolostones* (1988), a collection of symposium papers, covers organogenic dolomites and the geochemistry of dolomite textures. JOHN K. WARREN, *Evaporite Sedimentology* (1989), includes a chapter on dolomites and dolomitization, a good recent summary of the pertinent data and hypotheses; the bibliography includes most of the noteworthy articles published in English.

Other common rock-forming minerals: Descriptions can be found in the texts by Deer, Howie, and Zussman; by Dana; and by Berry and Mason, cited in the first two paragraphs above. Useful works at the professional level are ROGER G. BURNS *et al.*, *Marine Minerals*, corrected ed. (1981); and DOUGLAS RUMBLE III (ed.), *Oxide Minerals*, corrected ed. (1981).

(R.V.Di.)

The nature of rocks. A number of the books cited in the first paragraph above contain important information about rocks. D.H. GRIFFITHS and R.F. KING, *Applied Geophysics for Geologists and Engineers: The Elements of Geophysical Prospecting*, 2nd ed. (1981); ROBERT S. CARMICHAEL (ed.), *Handbook of Physical Properties of Rocks*, 3 vol. (1982–84), also available in a 1-vol. abridged ed., *Practical Handbook of Physical Properties of Rocks and Minerals* (1989); EDGAR W. SPENCER, *Introduction to the Structure of the Earth*, 3rd ed. (1988); and D.R. BOWES (ed.), *The Encyclopedia of Igneous and Metamorphic Petrology* (1989), may also be consulted.

(R.S.Ca.)

Igneous rocks: DANIEL S. BARKER, *Igneous Rocks* (1983); GORDON A. MACDONALD, *Volcanoes* (1972); ALEXANDER R. MCBIRNEY, *Igneous Petrology* (1984); HOWEL WILLIAMS and ALEXANDER R. MCBIRNEY, *Volcanology* (1979); and the work by Philpotts cited in the first paragraph above.

(A.M.K.)

Sedimentary rocks: SAM BOGGS, JR., *Principles of Sedimentology and Stratigraphy* (1987); RHODES W. FAIRBRIDGE and JOANNE BOURGEOIS, *The Encyclopedia of Sedimentology* (1978); ANDREW D. MIALL, *Principles of Sedimentary Basin Analysis*, 2nd ed. (1990); F.J. PETTIJOHN, *Sedimentary Rocks*, 3rd ed. (1975); F.J. PETTIJOHN, P.E. POTTER, and R. SIEVER, *Sand and Sandstone*, 2nd ed. (1987); P.E. POTTER, J. BARRY MAYNARD, and WAYNE A. PRYOR, *Sedimentology of Shale* (1980); DONALD R. PROTHERO, *Interpreting the Stratigraphic Record* (1989); J.G. READING (ed.), *Sedimentary Environments and Facies*, 2nd ed. (1985); STUART R. TAYLOR and SCOTT M. MCLENNAN, *The Continental Crust: Its Composition and Evolution* (1985); MAURICE E. TUCKER, *Sedimentary Petrology: An Introduction to the Origin of Sedimentary Rocks*, 2nd ed. (1991); JAMES L. WILSON, *Carbonate Facies in Geologic History* (1975).

(F.L.S.)

Metamorphic rocks: Standard references and basic textbooks include, in order of increasing complexity, CON GILLEN, *Metamorphic Geology: An Introduction to Tectonic and Metamorphic Processes* (1982); ROGER MASON, *Petrology of the Metamorphic Rocks*, 2nd ed. (1990); B.W.D. YARDLEY, *An Introduction to Metamorphic Geology* (1989); AKIHO MIYASHIRO, *Metamorphism and Metamorphic Belts* (1973); FRANCIS J. TURNER, *Metamorphic Petrology: Mineralogical, Field, and Tectonic Aspects*, 2nd ed. (1981); HELMUT G.F. WINKLER, *Petrogenesis of Metamorphic Rocks*, 5th ed. (1979; originally published in German, 1965); and ANTHONY R. PHILPOTTS, *Principles of Igneous and Metamorphic Petrology* (1990). Metamorphic fabric development is discussed in ALAN H. SPRY, *Metamorphic Textures* (1969); and R.H. VERNON, *Metamorphic Processes: Reactions and Microstructure Development* (1975, reissued 1983). Major techniques for studying metamorphic rocks and the metamorphic histories of many of the world's mountain belts are reviewed in J.S. DALY, R.A. CLIFF, and B.W.D. YARDLEY (eds.), *Evolution of Metamorphic Belts* (1989).

Modernization and Industrialization

Modern society is industrial society. To modernize a society is, first of all, to industrialize it. Historically, the rise of modern society has been inextricably linked with the emergence of industrial society. All the features that are associated with modernity can be shown to be related to the set of changes that, no more than two centuries ago, brought into being the industrial type of society. This suggests that the terms industrialism and industrial society imply far more than the economic and technological components that make up their core. Industrialism is a way of life that encompasses profound economic, social, political, and cultural changes. It is by undergoing the comprehensive transformation of industrialization that societies become modern.

Modernization is a continuous and open-ended process. Historically, the span of time over which it has occurred must be measured in centuries, although there are examples of accelerated modernization. In either case, modernization is not a once-and-for-all-time achievement. There seems to be a dynamic principle built into the very fabric of modern societies that does not allow them to settle, or to achieve equilibrium. Their development is always irregular and uneven. Whatever the level of development, there are always "backward" regions and "peripheral" groups. This is a persistent source of strain and conflict in modern societies. Such a condition is not confined to the internal development of individual states. It can be seen on a global scale, as modernization extends outward from its original Western base to take in the whole world. The existence of unevenly and unequally developed nations introduces a fundamental element of instability into the world system of states.

Modernization seems to have two main phases. Up to a certain point in its course, it carries the institutions and values of society along with it, in what is generally regarded as a progressive, upward movement. Initial resistance to modernization may be sharp and prolonged, but it is generally doomed to failure. Beyond some point, however, modernization begins to breed discontent on an increasing scale. This is due in part to rising expectations provoked by the early successes and dynamism of modern society. Groups tend to make escalating demands on the community, and these demands become increasingly difficult to meet. More seriously, modernization on an intensified level and on a world scale brings new social and material strains that may threaten the very growth and expansion on which modern society is founded. In this second phase, modern societies find themselves faced with an array of new problems whose solutions often seem beyond the competence of the traditional nation-state. At the same time, the world remains dominated by a system of just such sovereign nation-states of unequal strengths and conflicting interests.

Yet challenge and response are the essence of modern society. In considering its nature and development, what stands out initially at least is not so much the difficulties and dangers as the extraordinary success with which modern society has mastered the most profound and far-reaching revolution in human history.

This article discusses the processes of modernization and industrialization from a very general and primarily sociological point of view. It does so also, it should be remembered, from a position within the very processes it describes. The phenomena of industrialization and modernization that are taken to have begun some two centuries ago and that were not until much later identified as distinct and novel concepts have not yet arrived at any recognizable closure. The end of the story, if there is one, is thus not in sight, and the question of an ultimate judgment on the nature and value of this vast historical movement is unanswerable.

Becoming modern

THE REVOLUTION OF MODERNITY

If one imagines all of human social evolution charted on a 12-hour clock, then the modern industrial epoch represents the last five minutes, no more. For more than half a million years, small bands of what we may agree were human beings roamed the earth as hunters and gatherers. With simple stone tools and a social order based on kinship ties they successfully preserved the human species against predators and natural calamities. In observing contemporary Australian Aborigines, the San (Bushmen) of southern Africa, the Eskimo, the Negritos in Malaysia and the Philippines, and Pygmy groups in Africa, a glimpse may be had of the social life of the Paleolithic period (Old Stone Age)—the oldest and most enduring type of human society.

About 10,000 BC some of these hunters and gatherers took to cultivating the earth and domesticating animals. It is this process that is somewhat misleadingly called the Neolithic revolution, implying that new stone tools were at the root of this vast change. It is now generally accepted that the new technology was not the principal factor. Nevertheless what took place was undoubtedly a revolution. Mobile bands became settled village communities. The development of the plow raised the productivity of the land a thousandfold, and in response the human population of the planet increased dramatically. More significantly, herding and agriculture for the first time created a surplus of food. This allowed some members of the population to abandon subsistence activities and become artisans, merchants, priests, and bureaucrats. This division of labour took place in a newly concentrated physical environment. In the 4th millennium BC cities arose, and with them trade, markets, government, laws, and armies.

The agricultural revolution

The technology and social organization of the Neolithic revolution remained the basis of all civilization until the coming of industrialism. With remarkably few additions—the invention of the stirrup was an important one—what served ancient Mesopotamia and ancient Egypt of the

third and second millennia BC served as the foundation of all the states and empires of the ancient world, from China and India to Greece and Rome. And it served equally the European Middle Ages, which in some respects, notably in technology, actually fell back from the achievements of the ancient world. Not until the 17th and 18th centuries in Europe did humankind make another leap comparable to that of the Neolithic revolution.

It is against this very slowly evolutionary background that the revolution that underlay modernity must be seen. It is one of just two quantum jumps that human social evolution has made since the primal hunting and gathering stage of early *Homo sapiens*. The Neolithic or agricultural revolution produced, paradoxically, urban civilization; the Industrial Revolution lifted humankind onto a new plane of technological development that vastly increased the scope for transforming the material environment. In its speed and scale the change brought about by the Industrial Revolution has had, indeed, a greater impact on human life than the Neolithic revolution. Neolithic civilization remained throughout confined by a sharply limited technical and economic base; industrial civilization knows no such limits. Nevertheless, an understanding of agrarian society is essential to the analysis of industrial society, for it is largely through the contrast with its agrarian past that modern society stands out. The meaning of the modern is to be found as much in what it renounces as in what it aspires to.

THE WEST AND THE WORLD

It is not fully understood what produced the leap into modernity and why, just as some groups of hunters and gatherers gave rise to agrarian society, some agrarian societies gave rise to industrial society. What is clear is that it took place between the 16th and 18th centuries and that it began in the countries of northwestern Europe—especially England, the Netherlands, northern France, and northern Germany.

This could not have been expected. Compared to the Mediterranean, not to mention Arabic and Chinese civilizations, northwestern Europe early in the 16th century was backward, technically and culturally. In the 16th and 17th centuries it was still absorbing the commercial and artistic innovations of the Italian city-states of the Renaissance and making piratical raids, where it could, on the wealthy Spanish empire. It seemed an unlikely candidate for future economic leadership of Europe. Yet it was there that the changes took place that propelled those particular societies into the forefront of world development.

One reason advanced for this is that northwestern Europe was the origin and heartland of the Protestant Reformation of the 16th century. In his great work *The Protestant Ethic and the Spirit of Capitalism* (1904), the German sociologist Max Weber suggested that Roman Catholicism and to an even greater extent such Eastern religions as Hinduism and Buddhism were essentially otherworldly religions. They placed doctrinal emphasis on religious contemplation and the life hereafter. Protestantism, on the other hand, was predominantly a "this-worldly" religion. It broke down the distinction between the church and the world, between the monastery and the marketplace. Every man was a priest; everything he did, at work or at play, he did 'in the sight of God. Weber sought to show that Protestantism, and especially its Puritan variety, developed a particular type of character that valued frugality and hard work. Protestantism particularly promoted a work ethic. For the Protestant, all work, all occupations, were in a sense a religious vocation. Work was to be pursued with a fitting seriousness and order, in a spirit of rational enterprise that eschewed waste and frivolous adventurism. Such an attitude was admirably suited—though not intentionally—to the development of industrial capitalism. The Protestant nations, therefore, according to Weber, invented modern capitalism and so launched the world on a course that it still follows. Some later historians have disputed Weber's thesis and have adduced evidence that the early development of capitalism and of industrial organization preceded the rise of Protestantism. In either case, their mutual accommodation remains striking.

Weber's thesis

In a similarly persuasive way, the rationality of the Protestant work ethic has seemed linked to the development of modern science. This, too, took place largely in northwestern Europe in the course of the 17th century. In no other place, at no other time, was there anything like the scientific revolution of these years in England, France, and the Netherlands. It is true that the Industrial Revolution, in its early phases at least, did not depend on the theoretical science of Isaac Newton, Robert Boyle, or others of the period. What was crucial was the rationalist culture and the scientific habits of mind that this culture nurtured. Moreover, the scientific method of observation, hypothesis, experimentation, and verification could be applied not only to nature but also to society. Eventually, toward the end of the 18th century, what would later be called social science—economics and sociology especially—began to find a place alongside natural science. The scientific outlook—skeptical, autonomous, applying fixed standards of observation to continually changing phenomena, to reach conclusions that were never to be considered more than provisional—became the hallmark of modern society.

The scientific temper

Already, by the 17th century, western Europe had embarked on the course of transoceanic expansion that was to become one of its most notable features in the succeeding centuries. The colonization of America, although uneven, added a vast new domain to the West. In wealth, resources, and physical power, the West took a commanding lead over the rest of the world. From the enormous potentialities of science and industry, it acquired a momentum and a dynamism that pointed to a future immeasurably grander than anything previously achieved. For the first time, moralists and philosophers began to conceive of the possibility that the modern world might come to be the equal and even the superior of the ancient world of Greece and Rome. The idea of progress, and with it that of modernism, was born. The world was growing in power and enlightenment and, so far as anyone could see, would continue indefinitely to do so. Western society was not merely plunging ahead on its own; it was paving the way for the rest of the world. As Karl Marx said, albeit two centuries later, "The country that is more developed industrially only shows, to the less developed, the image of its own future."

THE DUAL REVOLUTION

Modern society owes its origin to two great upheavals in the 18th century, one political, the other economic. Both were part of a broader pattern of change that, since the Renaissance and Reformation, had set the West on a different path of development from that of the rest of the world. This pattern included the individualism and, in the end, the secularism, that was the Protestant legacy. It also included the rise of science, as a method and as a practice. Both of these culminated in explosive events toward the end of the 18th century. The first helped provoke political revolutions in America and France. The second, in creating an atmosphere conducive to technological innovation, was one of the chief elements in the emergence of the Industrial Revolution in Great Britain.

The American and French revolutions established the political character of modern society as constitutional and democratic, meaning not necessarily that every government thenceforward was of such character but that even those most conspicuously not so frequently claimed to be. From the time of those revolutions it became clear to practically all thinkers that no political system could now claim legitimacy that was not in some sense based on "the will of the people," constitutionally expressed. It was this message that was so brilliantly spelled out by the clear-sighted French aristocrat Alexis de Tocqueville in his works, *The Ancien Régime and the Revolution* (1856) and *Democracy in America* (1835–40).

Political origins of modern society

That the new democratic legitimation could be, and would be, claimed by popular or constitutional dictatorships such as those of Napoleon III in France or Adolf Hitler in Germany only showed how central the double ideal of democracy and constitutional justification had become. But they were not infinitely malleable. The idea

of tacit or implicit popular consent, resorted to by several old-fashioned monarchies and empires, fell before the march of modern democratic theory as developed from the American and French revolutions. In the United Kingdom this was done through a gradual extension of the franchise in the 19th century. In Russia and in eastern and central Europe, violent revolution, defeat in war, and centrifugal nationalist tendencies turned out to be the means by which autocratic intransigence was overcome.

The democratic constitutional state

But however accomplished—whether grudgingly conceded, seized in popular revolution, or imposed by modernizing elites—the democratic constitutional state has come to be accepted as in principle the only fully legitimate polity of modern society. States that deviate from the norm, as, for instance, the communist states of eastern Europe or the military dictatorships of Africa and Latin America, feel compelled to offer elaborate justifications of their conduct. These are sometimes outright denials that the regime in question is the antithesis of a constitutional democracy; generally, however, they take the form of pleading special or emergency conditions. Full democracy, at some time in the future, remains the professed goal. The doggedness with which most of this casuistry is advanced, often in the teeth of observable evidence to the contrary, is the clearest testimony to the normative strength of the democratic ideal in modern society.

Self-determination

The American Revolution added a further ingredient to the political form of modern society. It asserted the principle of self-determination. Only those states were legitimate in which a people of common culture ruled for themselves a common territory. Foreign rule, or rule by an alien elite, as in the Ottoman and Habsburg empires, was unnatural. Only nation-states were natural political entities; only they were legitimate. "National self-determination" became one of the most powerful catchphrases of the liberal and radical ideologies that largely shaped the modern states of the 19th and 20th centuries.

That self-determination could be a highly ambiguous demand, as with democracy, was shown especially in the experience of central and eastern Europe, where the question of whose presumed nationality should be the basis of the state divided ethnic groups bitterly and murderously. Who, in the extremely mixed domains of what was Austria-Hungary before 1918, was to constitute an autonomous national group—Magyars, Slovaks, Croats, Serbs, Romanians? Only force would resolve the issue, so that modern Romania ended up with substantial Magyar and Saxon minorities inside its national boundaries while Yugoslavia contained a number of ethnic groups not much less various than those of the Austro-Hungarian monarchy which in part it was created to replace. But, once again, it was not the practical difficulties that mattered. As with democracy, it was the pure ideal of nationalism that became the irresistible force. And, once invented by the West, it could not be contained there. Along with democracy, it was one of the ideals absorbed by the colonies of the Western powers, and it became a powerful factor in the dissolution of Europe's overseas empires.

If the American and French revolutions laid down the political pattern of the modern world, the Industrial Revolution in Great Britain laid down the economic pattern. The changes that took place in Britain during the 19th century became almost a prototype of industrialization. To choose to industrialize—and not so to choose meant risking backwardness and dependence—was to imitate consciously the British Industrial Revolution. Great Britain was the pioneer industrial nation of the world; there simply was no other model to fix on. Even later, when it was clear that the British method of industrialization might not be exclusively valid or universally applicable, the general form of society that emerged in the course of the Industrial Revolution was widely regarded as typical.

Industrial revolution in Britain

Certain episodes and tendencies in the British case were pointed to as characterizing industrial development as such. These included the movement from the land to the cities, the massing of workers in the new industrial towns and factories, and the rise of new distinctions between family life and work life, and between work and leisure as notions meaningful to large classes of persons. Such features, with various others, were compounded into a powerful image of industrialism as a whole and wholly new social system and way of life.

The British themselves, it should be noted, did not contribute much to the promulgation of this image of industrialism, at least insofar as it was turned into a systematic account of society. Certain powerful symbols and images of urban and industrial life were indeed picked up from such English novelists as Charles Dickens and Elizabeth Gaskell. But it was left to others, from societies only just beginning to industrialize, to blend these artistic impressions (many of them not at all celebratory) into a systematic analysis of the new society. Foreigners such as Alexis de Tocqueville, Friedrich Engels, and Karl Marx observed and reflected on the changes they saw in England. They were convinced that what was happening in Britain would be repeated, more or less exactly, in other societies as they underwent industrialization. Industrial Britain could be seen, therefore, as a social laboratory of inestimable value to those other societies. In works such as Engels' *The Condition of the Working Class in England in 1844* (1845), and Marx's *Das Kapital* (1867–1894), British experience was examined for the light it shed on the general process of industrialization and for what it suggested of future developments, there and elsewhere. Through such works, the British Industrial Revolution became the property not just of the British nation but of the whole world. All societies, it was felt, would have their "Coketowns," the generic industrial town of Dickens' *Hard Times* (1854); all would have industrializing ideologies and institutions of the kind—referred to by Germans as *Manchestertum*—that 19th-century observers came to associate with the world's leading industrial city. Manchester was indeed the symbol of the new industrial society, and hence the image of the world's future. "The age of ruins is past," declared the British politician and novelist Benjamin Disraeli in his novel *Coningsby* (1844). "Have you seen Manchester?"

Industrialization as symbol

One consequence of this tendency to generalize the British experience was that the idea of industrialism itself grew in scope and significance. It came to symbolize and to embody not just the economic and technological changes that lay at its heart, but other political, social, and cultural changes that appeared to be organically connected with it, whether as causes, concomitants, or consequences. Thus, the democratic movement triggered by the American and French revolutions was seen as the necessary political transformation that, sooner or later, must accompany all movement toward an industrial society. Similarly, changes in urban life, in family form, in individual and social values, and in intellectual outlook, were all seen as linked to industrialism. Industrial society came to stand as the epitome of modern society. And through the lens provided by industrialism, earlier developments, such as Protestant individualism and the scientific revolution, came to be seen as preconditions or presentiments of industrialism, elements incorporated into a systematic and more comprehensive movement that had its own compelling logic and momentum. Industrialism, it came to be agreed, was a package and had to be purchased as such.

The nature of modern society

GENERAL FEATURES

Modernity must be understood, in part at least, against the background of what went before. Industrial society emerged only patchily and unevenly out of agrarian society, a system that had endured 5,000 years. Industrial structures thus took much of their characteristic form and colour from the rejection, conscious or unconscious, of preindustrial ways. Industrialism certainly contained much that was new, but it remained always at least partly an idea that in both its theory and its practice was to be understood as much by what it denied as by what it affirmed. The force of the modern has always been partly a reactive force, a force that derived meaning and momentum by a comparison or contrast with, and by rejection or negation of, what went before.

Considered at the most general level, this point suggests a view of modernization as a process of individualiza-

tion, differentiation or specialization, and abstraction. Put more concretely: first, the structures of modern society take as their basic unit the individual rather than, as with agrarian or peasant society, the group or community. Second, modern institutions are assigned the performance of specific, specialized tasks in a social system with a highly developed and complex division of labour; in this they stand in the sharpest possible contrast with, for instance, the family in peasant society, which is at once the unit of production, consumption, socialization, and authoritative decision-making. Third, rather than attaching rights and prerogatives to particular groups and persons, or being guided by custom or tradition, modern institutions tend to be governed and guided by general rules and regulations that derive their legitimacy from the methods and findings of science. In principle at least, they are not the agents of particular individuals, such as a king or priest, endowed with divine or prescriptive authority, but act according to the rational and impersonal precepts formulated by "experts."

Contrasts with traditional society

These contrasts by no means complete the characterization of modern society, nor are they the only ones that might be drawn. Nevertheless, they do illustrate the dependence of the concept of modernity on past structures that form the basis of comparison and exclusion. Indeed, it is such a set of contrasts, not necessarily carefully distinguished, that most people have in mind when they speak of modern as opposed to traditional society.

With regard to the more positive features of industrialism, industrial society can best be thought of as consisting of an economic core around which other, noneconomic structures crystallize. In Marxist terminology, this is rendered in the more deterministic form of an economic base conditioning a noneconomic "superstructure." This seems unnecessarily rigid and misleading. The relation of the economic to the noneconomic realm is mutual and interactive, as can be seen by considering the impact of scientific ideas on economic and technological development. Still, it is true to say that, fundamentally, it is the economic changes that most dramatically affect industrial society.

ECONOMIC CHANGE

Economic historians and theorists have been inclined to stress economic growth as the central defining feature of an industrial as opposed to a nonindustrial economy. Thus, the British historian Edward Anthony Wrigley (b. 1931) declared that "industrialization is said to occur in a given country when real incomes per head begin to rise steadily and without apparent limit." The American economic historian W.W. Rostow (b. 1916) popularized a similar conception in suggesting that with industrialization, the economy at a certain point "takes off" into "self-sustained growth"; all the relevant statistical indexes of the economy—investment, output, growth rate, and so on—take sudden, sharp, almost vertical upward turns.

Underlying this phenomenon of growth are certain core components of the industrial system. These include technological change, whereby work is increasingly done by machines rather than by hand; the supplementing or replacement of human and animal power by inanimate sources of energy, such as coal and oil; the freeing of the labourer from feudal and customary ties and obligations, and the consequent creation of a free market in labour; the concentration of workers in single, comprehensive enterprises (the factory system); and a pivotal role for a specific social type, the entrepreneur.

Core components of the industrial system

It would be easy to vary and extend this list. Not all components are of equal importance, nor are all equally indispensable to the industrial economy. They are drawn largely from the experience of the first industrializing nations, in western Europe and North America. Later industrializers were able to dispense with some of them, or at least to try to do so. The Soviet Union, for instance, industrialized on the basis largely of forced rather than free labour and made a point of doing away with entrepreneurs, while in Japan the entrepreneur was throughout stimulated and sustained by strong state involvement in industrialization. Moreover, it should be remembered that states—as, for instance, Denmark and New Zealand—can industrialize largely through the commercialization and mechanization of agriculture. Agriculture simply becomes another industry; farms are simply rural factories.

Even in this latter case, there is no place for a distinctively rural way of life in industrial society. Mechanization brings an increase in productivity that renders a large portion of the rural labour force superfluous. Even where agriculture remains an important part of the industrial economy, the proportion of the labour force employed in agriculture drops steadily with industrialization. This is the "sectoral transformation" that is one of industrialization's clearest and most obvious effects. A majority of the work force comes to be employed in the production of manufactured goods and in services rather than in the primary sector of agriculture. In both the United Kingdom and the United States, for instance, by the mid-1970s more than 95 percent of the employed population were in manufacturing and services and less than 5 percent in agriculture. Japan, as an example of a late developer, shows the same pattern: in 1970, more than 80 percent of the employed population were in manufacturing and services, and less than 20 percent in agriculture. These figures should be compared with the normal condition of preindustrial agrarian societies, where typically 90 percent of the adult population are peasant farmers or farm workers.

Agricultural productivity and labour

The vast increase in agricultural productivity which this sectoral change in employment signals is characteristic of industrialism. Industrial society breaks through the historic limits of scarcity. In the past, the potential for economic growth was always cut short by Malthusian checks on population, by limitations of food supply, or by the shortage of easily available raw materials such as wood. Industrialization permits the creation of large food surpluses that can feed a largely urban population. The entire world, both on land and in the sea, is scoured for raw materials and further energy sources to supply industry. Science has so far proved remarkably effective at finding substitutes for those sources that have dried up and those materials that have become dangerously scarce. The British economist John Maynard Keynes suggested that, for the first time in human history, "the economic problem may be solved," and that "the economic problem is not the permanent problem of the human race." In the mid-1980s it still seemed reasonable to believe that industrialism promised growth for the foreseeable future, even that it might bring abundance to all.

POPULATION CHANGE

There have been two major population explosions in the course of human social evolution. By the end of the Paleolithic period the world's human population is estimated to have been between five and six million (an average of 0.1 person per square mile [0.04 person per square kilometre] of the Earth's land area). Following the Neolithic or agricultural revolution, the population made its first major leap, reaching over the short span of 8,000 years around 150 million by the year 1000 BC (2.6 persons per square mile). For the next two and a half thousand years there was relatively little change. World population had reached about 500 million by the middle of the 17th century. During this time any tendency for population to grow was punished by the Malthusian checks of starvation and pestilence. Only with the Industrial Revolution of the 18th century did population break out again from its Malthusian fetters.

From about 1700 there was a second and far more rapid population explosion. Since the late 1600s the world's population has increased more than eightfold, reaching 4.8 billion by the mid-1980s. On current projections it is expected to reach more than six billion by the year 2000 (which will mean an average of 42 persons per square kilometre of the Earth's land area). This gives some measure of the difference between the two population revolutions of human history: there has been a dramatic acceleration not simply in population but in the rate of increase of population since industrialization took hold. Between 1650 and 1850 the average annual rate of increase of the world's population doubled; it doubled again by the

Industrial revolution and population

1920s, and more than doubled, once more, by the 1970s.

If the time taken to double the world's population over the past 350 years is taken as a measure, then the doubling time is seen to have been shrinking fast. It took 200 years, to 1825, to double the world's population from 500 million to one billion. It took only 100 years to achieve the next doubling, bringing the total to two billion by 1930; and only 45 years to achieve yet another doubling, to four billion by 1975. There were signs of slowing in the last part of the 20th century, and clearly this accelerating pace could not last indefinitely. Even so, many experts predicted eight billion by early in the 21st century, a reduction in the doubling time to about 40 years.

It was in western Europe, with the Industrial Revolution, that the second population revolution began. Europe's population doubled during the 18th century, from roughly 100 million to almost 200 million, and doubled again during the 19th century, to about 400 million. It was in Europe, too, that the pattern first emerged that has come to be known as the "demographic transition" (see POPULATION). The populations of nonindustrial countries are normally stable (and low) because high birth rates are matched by high death rates. With industrialization, improvements in medical knowledge and public health, together with a more regular food supply, bring about a drastic reduction in the death rate but no corresponding decline in the birth rate. The result is a population explosion, as experienced in 19th-century Europe. In time, however, as European societies showed in the early 20th century, the urbanized populations of industrial societies voluntarily lower their birth rates and population growth flattens out. A new population plateau is reached. Japan, industrializing some 50 years later than the West, provided an almost textbook demonstration of the pattern of the demographic transition. Its population grew rapidly after 1870, during its industrializing phase, and leveled off equally rapidly after World War II. In an even more speeded-up form, the Soviet Union in its century of industrialization that began in the 1880s illustrated the link between industrialization and population.

Demographic transition

Does the demographic transition hold good for the developing societies known as the Third World? Nearly all of these countries experienced rapid population growth after World War II, at rates greater than had ever occurred anywhere in the West. Western aid and medical science spectacularly reduced the high death rates, often by more than 50 percent. But, unlike those in the West, the high birth rates showed little tendency to fall. Determined efforts in a few countries, such as Singapore, Sri Lanka, and China, were beginning to yield some results by the 1980s. But on the whole the attempts by national governments and international agencies to persuade non-Westerners to have smaller families had failed. One result was the persistence of predominantly youthful populations in societies that could least afford the burden of feeding and educating their nonproductive young. People under 15 made up more than 40 percent of the populations of the Third World, as compared with between 20 and 30 percent in the industrialized world.

Third World demographics

It was argued that the birth rate remained stubbornly high in these societies partly because industrialization was so slow and fragmentary in the Third World. In addition, where any significant development had taken place, as in Brazil or Malaysia, it had only really affected a small elite; the mass of the people were untouched. Thus, the reasons people in the industrialized West chose to have fewer children lacked cogency in underdeveloped countries. It remained rational for the bulk of the population to continue to have large families both to share in manual labour and to provide security for parents in their old age. Lower fertility would come, it was argued, when wealth was more evenly distributed and social security systems well established.

URBANISM AS A WAY OF LIFE

Industrialism does not simply increase numbers; it distributes them in particular ways, concentrating mass populations in cities. Modern life is unquestionably urban life.

It may be argued that it was in the cities of ancient Mesopotamia, Egypt, Greece, and Rome that a distinctively urban existence was first brought to that pitch of refinement that signifies an advanced civilization. Certainly for those fortunates who were free citizens the Athens of Pericles provided an agreeable existence. The Italian cities of the Renaissance, too, provided a distinctly urban culture.

Industrial urbanism differs from preindustrial urbanism in two ways. The first is in its quantitative reach and intensity; the second is in the new qualitative relationship it sets up between the city and society.

For all the culture and sophistication of the preindustrial city, it remained a minority experience. Full participation in urban life was available to no more than the 3 or 4 percent of the population who were city dwellers in 3rd-millennium-BC Egypt and Mesopotamia and to the 10 to 15 percent of Romans who lived in cities at the zenith of imperial Rome (but who were heavily dependent on food supplies from North Africa). These latter represent a high point of preindustrial urbanism.

Industrialization brings a growth in trade and manufactures. To serve these activities it requires centralized sites of production, distribution, exchange, and credit. It demands a regular system of communications and transport. It multiplies the demand that political authorities establish a dependable coinage, a standard system of weights and measures, a reasonable degree of protection and safety on the roads, and regular enforcement of the laws. All these developments conduce to a vast increase in urbanization. Whereas in typical agrarian societies 90 percent or more of the population are rural, in industrial societies it is not uncommon for 90 percent or more to be urban.

Demands of industrialization

The growth of cities with industrialization can be illustrated by the example of the United Kingdom. In 1801 about a fifth of its population lived in towns and cities of 10,000 or more inhabitants. By 1851 two fifths were so urbanized; and if smaller towns of 5,000 or more are included, as they were in the census of that year, more than half the population could be counted as urbanized. The world's first industrial society had become its first truly urban society as well. By 1901, the year of Queen Victoria's death, the census recorded three-quarters of the population as urban (two-thirds in cities of 10,000 or more and half in cities of 20,000 or more). In the span of a century a largely rural society had become a largely urban one.

The pattern was repeated on a European and then a world scale as industrialization proceeded. At the beginning of the 19th century, continental Europe (excluding Russia) was less than 10 percent urbanized, with respect to cities of 10,000 or more; by the end of the century it was about 30 percent urbanized (10 percent in cities with 100,000 or more), and by the mid-1980s, the urban population was more than 70 percent. In the United States in 1800, only 6 percent of the population lived in towns of 2,500 or more; in 1920 the census reported that for the first time more than half of the American people lived in cities. By the mid-1980s this had risen to nearly 75 percent—about the same as Japan's urban population—and more than two-fifths of the population lived in metropolitan areas of one million or more. Taking the world as a whole, in 1800 no more than 2.5 percent of the population lived in cities of 20,000 or more; by 1965 this had increased to 25 percent, and by 1980 to 40 percent. It is estimated that by the year 2000 about half the world's population will be urban, by this measure. At the same time there has been a great growth of very large cities, of a type virtually unknown in the preindustrial world. Cities of more than one million inhabitants numbered 16 in 1900, 67 in 1950, and 250 in 1985.

Western urbanization

As with population growth, it was in the underdeveloped nations that the fastest rates of urban growth were to be found. The rapidly expanding population of a countryside unable to support it sought the city for both escape and opportunity, though in many cases it was a perilous choice. Between 1900 and 1950, while the world's population as a whole grew by 50 percent, the urban population grew by 254 percent; but in Asia urban growth was 444 percent and in Africa 629 percent. By the mid-1980s, Africa and Asia were about 30 percent urbanized, and Latin America

Third World urbanization

nearly 70 percent so. Cities such as São Paulo (15 million), Mexico City (17 million), and Calcutta (10 million), had mushroomed to rival and even overtake in size the large cities of the developed West and Japan.

But while urbanization in the underdeveloped nations repeats some of the more distressing features of its Western counterpart—overcrowding, unsanitary conditions, and unemployment—the compensation and eventual remedy of economic growth has been largely lacking. With some partial exceptions, such as Brazil, Mexico, Singapore, and Hong Kong, the underdeveloped world has known urbanization without industrialization. The result has been the rapid growth of shantytowns on the edges of the big cities. It has been estimated that about four or five million families in Latin America live in shantytowns.

Urbanism cannot be understood simply by statistics of urban growth. It is a matter, too, of a distinctive culture and consciousness. Urbanism is a way of life, as classically analyzed by the German sociologist Georg Simmel and the American sociologist Louis Wirth. City life, with its tendency to nervous overstimulation, may lead to a bored and blasé attitude to life. It may encourage frivolous and fleeting cults and fashions. It can detach people from their traditional communal moorings, leaving them morally stranded and so inclined to harbour unreal expectations and feverish dreams. In the very number of social contacts it necessarily generates, it may compel individuals to erect barriers to protect their privacy. Individuals may be forced into an attitude of reserve and isolation. Hence, as Simmel noted, the superficial paradox that "one nowhere feels as lonely and lost as in the metropolitan crowd."

Urban culture

At the same time, cities promote diversity and creativity. They attract the best and the brightest. If anything is to be accomplished in modern society, it almost certainly will be in the city. Karl Marx spoke of "the idiocy of rural life." Only in cities, many sociologists have felt, are human beings able to realize to the full all their potentialities. Cities are the forcing house of change and growth. "Great cities," declared the French sociologist Émile Durkheim, "are the uncontested homes of progress; it is in them that ideas, fashions, customs, new needs are elaborated and then spread over the rest of the country. . . . Minds naturally are there oriented to the future."

But whether they deplored or praised urban life, most commentators have agreed that, with industrialism, the city moved into a pivotal new relation with society as a whole. Preindustrial cities were islands in an agrarian sea. They hailed each other across vast alien tracts of nonurban life, which remained largely indifferent to and unaffected by their practices. Essentially they were parasitic on the countryside and on the peasant masses whose agricultural labour sustained them. Their disappearance not only would not have mattered to the peasants but would in most cases have been welcomed.

With industrial urbanism, this relationship was reversed. The countryside now became dependent on the city. It became an integral but peripheral part of a single economic system that was centred on the cities. Largely emptied of people, the countryside was now in effect simply another theatre of industrial operations for city merchants and bankers. Political and economic power resided in the city; industrial and financial corporations became the dominant landowners, replacing individual proprietors. Except in pockets largely maintained as quaint retreats for tourists, rustic life virtually disappeared; certainly it no longer significantly affected the values and practices of the larger society. What remained of "country life" was often little more than a persuasive and nostalgic motif in the hands of advertising copywriters, preying on the fantasies of city dwellers.

The city became both the symbol and the reality of industrial society as a whole. No longer, as in the past, standing in a merely mechanical relation to other parts of society, the city took its place at the centre of an increasingly organic whole. Industrialism created a centralized web of social relationships, and the city was the node. It dictated the style and set the standard for the whole society, imposing on all its own economic, political, and cultural framework.

WORK AND THE FAMILY

In preindustrial or nonindustrial society the family is the basic unit of production. All its members engage in a cooperative set of subsistence activities. In a typical example from early 18th-century England, the man might be a weaver and his wife a spinner, with the younger children acting as assistants in the joint domestic enterprise. Mixed in with this wage or piece labour would probably be the cultivation of a small plot of land, together with access to common land to forage for fuel and to hunt small game. The family need not necessarily be very large—in northwestern Europe and North America it seems to have been relatively small—but on the whole additional members are an economic asset as the value of extra hands to work outweighs the cost of extra mouths to feed. The family is a collective enterprise; all its members regard themselves as part of that collectivity and their contributions as adding to a common store; servants or other nonfamily members, such as apprentices, are "adopted" or treated as family members, for no other binding personal relationships but family ones are recognized. The family and its members are society in miniature.

The family as the unit of production

Industrialization radically disrupts this more or less autonomous family economy. It takes away the economic function of the family, and reduces it to a unit of consumption and socialization. Production moves away from the household to the factory. The commons are enclosed, and the land commercially exploited for national and international markets. Some individuals become the owners and the managers of the new system. But the bulk of family members must become either landless agricultural labourers or, increasingly, workers in the factories of the new industrial towns. In either case, the family becomes immediately dependent for its livelihood on structures and processes external to itself. It lives by the jobs and wages of its members, and these are affected by forces which it barely comprehends, still less controls.

In the early stages of industrialization, the family will likely struggle to maintain its traditional collective unity. Its members, whether employed as farm workers in the country, industrial workers in the towns, or domestic servants in well-to-do urban homes, continue to pool their resources. They make regular visits home and continue to think of themselves as a collectivity. Their wages still contribute to a common family fund, which is used to support the nonworking young as well as temporarily unemployed members and to provide for members in sickness and old age. In the absence of a comprehensive system of social security, the family itself continues to fulfill the role. In these circumstances, as in the past, a large family can be as much an asset as a burden. For a considerable time, therefore, large families, especially among the working classes, continue to be the norm in industrializing society.

Eventually the forces of individualization, whose gross effects on the industrial economy and the society at large are so striking, also affect the family. Its members, male and female, increasingly come to think of their wages as their own, to be disposed of as they individually see fit. This attitude is encouraged by the increasing availability of attractive consumer goods. At some point it becomes economically and politically necessary for the state to step in to provide for those members unable to earn their own living, either because they are chronically unemployed, or because they are too young, too sick, or too old. The family role thus shrinks further to little more than child-rearing, and even here it has to compete with the school, peer groups, and child-care agencies. For its older members, the family becomes merely the domicile and the locus of recreation and a certain amount of sociability. Its members may spend a good deal of time at home, but their minds are formed more by influences operating outside it. Their lives are led largely outside the family, in their work and in association with nonfamily friends and colleagues. They no longer find their identity within a collective family identity. Hence the tendency of young adults to marry young, to break away from their families of origin, and to set up their own independent families.

Fragmentation of the family

Shorn of so many traditional functions, the family becomes almost exclusively the sphere of private life. It

attends to the needs of children and the emotional and sexual satisfaction of the spouses. A small unit is best suited to these tasks. The extended families of the preindustrial and early industrial periods, which sometimes included grandparents and married offspring to three or more generations, give way to the small, two-generation nuclear family of parents and dependent children only. Whether or not the nuclear family precedes industrialization—as, for instance, it seems to have done in England—in industrial society it certainly becomes the norm.

With the shrinking and privatization of the family, the importance of work grows correspondingly. It becomes the principal source of individual identity. In preindustrial society, the question of who one is is likely to be answered in terms of place of origin or family membership: I am John of Winchester, or John, Robert's son. In industrial society the question is typically answered in terms of one's occupation in the formal economy. The occupational role, as miner or machinist, clerk or cleaner, becomes the determining and defining role. It is the source of one's identity, status, and income. Work, throwing off its religious justifications, itself becomes a religion. Not to work, to be unemployed, is to be stigmatized as much in one's own eyes as in the eyes of society.

Work as identity

Work is redefined as applying almost exclusively to formal employment in the industrial economy. All other kinds of work—unpaid domestic work, voluntary work, work done for friends or family, child-rearing—are devalued and treated as marginal or "unproductive." The paradox is that the elevation of employed work is accompanied by a decisive fragmentation of work as an activity. Industrialization brings about a massive increase in the division of labour. But this involves not just, as in preindustrial urban life, a specialization of crafts and the rise of new occupations. More significant is a new kind of division of labour, what Adam Smith and Karl Marx called the "detailed" division of labour, in the work task itself. The set of tasks involved in the making of a whole product, which was previously performed by a single artisan or worker, is now broken apart and allocated to a number of different individuals. In his famous example of a pin manufactory, Adam Smith showed how, by dividing the task of pin-making into some 18 distinct operations, each performed by "distinct hands," productivity could be increased more than a thousandfold. It was this form of the division of labour that became the source of the fantastic productivity of the industrial system, especially once Henry Ford had organized it around the continuously moving assembly line and the American pioneer in scientific management Frederick W. Taylor had supplied an engineering method for the splitting of any task into its simplest operations.

Division of labour

The English social critic John Ruskin pointed to one consequence of this new division of labour when he said that "it is not, truly speaking, the labour that is divided, but the men." The problem of motivating the work force, of providing sufficient inducement to work discipline and performance when the tasks themselves were so intrinsically uninteresting, haunted all industrial societies. But the new division of labour itself pointed, rather ominously, to the likely resolution of this problem. Once tasks had been so minutely subdivided that the least skilled worker could do them, the next step was to mechanize the tasks and dispense with the human worker altogether. Full automation was in some sense implicit in the principle of the division of labour from the very start. It is ironic that a social process that had in its early stages put work at its very centre should also, in its further evolution, threaten to take it away altogether from its citizens.

SOCIAL STRUCTURE

Given the importance of economic institutions in general, and of employment in particular, it is not surprising to find that industrial society tends to produce a new principle in the ordering and ranking of individuals. Economic position and relationships become the key to social position and class membership. This is new, at least in its extent. While wealth or the lack of it were always important in determining social position, they were not usually the sole or even the central determinant. In all nonindustrial societies, attributes of tribal membership, race, religion, age, and gender are of equal and often greater importance in assigning individuals to a position in the social hierarchy. In the traditional Indian caste system, for instance, the religious eminence of even the poorest Brahman marks him out as a member of the highest and most esteemed caste.

Industrial society tends to subordinate all these preindustrial principles of ranking to the economic one. One's position in the system of production or, more generally, in the marketplace assigns one to a particular class or group. Ownership of property, level of education, and type and degree of training all affect one's market position. Karl Marx was convinced that in the course of its development capitalism—the only form of industrialism he considered—would eventually throw up only two main economic classes, the propertyless workers, or proletariat, and the capitalist owners, or bourgeoisie.

Primacy of economic status

One reason why Marx's prediction has not come to pass in any developed society is that, though perhaps dominant in the long run, economic relationships have not so sweepingly eliminated other noneconomic considerations. Older sources of identity have continued to exert considerable power. Groups based on ethnic, religious, and regional ties have overlapped with and occasionally submerged those based solely on the tie of economic interest. Thus, the working class of Northern Ireland has preferred to stress its Protestant identification over its proletarian one. Workers and capitalists in the Basque and Catalan regions of Spain have united in a long, drawn-out opposition to the central government in Madrid. In the United States, racial identity has continued to override any other based on income or occupation.

This is one way in which it is brought home that even radical changes do not necessarily disrupt all continuities. There are gainers and losers in the process of change, and the losers are apt to hark back to past ways and values. Industrialization, while making a fundamental break with earlier forms of society, does not abolish all the elements of traditional society.

SECULARIZATION AND RATIONALIZATION

At the most abstract level of analysis, modernization leads to what Max Weber called "the disenchantment of the world." It eliminates all the superhuman and supernatural forces, the gods and spirits, with which nonindustrial cultures populate the universe and to which they attribute responsibility for the phenomena of the natural and social worlds. In their place it substitutes as the sole cosmology the modern scientific interpretation of nature. Only the laws and regularities discovered by the scientific method are admitted as valid explanations of phenomena. If it rains, or does not rain, it is not because the gods are angry but because of atmospheric conditions, as measured by the barometer and photographed by satellites.

Specifically, modernization involves a process of secularization; that is, it systematically displaces religious institutions, beliefs, and practices, substituting for them those of reason and science. This process was first observable in Christian Europe toward the end of the 17th century. (It is possible that there is something inherently secularizing about Christianity, for no other religion seems to give rise spontaneously to secular beliefs.) At any rate, once invented in Europe, especially Protestant Europe, secularization was carried as part of the "package" of industrialism that was exported to the non-European world. Wherever modern European cultures have impinged, they have diffused secularizing currents into traditional religions and nonrational ideologies.

Although secularization is a general tendency or principle of development in modern societies, this does not imply that religion is driven out altogether from society. Against a deep background of tradition, it inevitably leaves many religious practices in place and may even stimulate new ones. Religious rituals, such as Christian baptism and church weddings, persist in all industrial societies; the church may, as in England and Italy, continue to play an important moral and social role. The majority of the population may hold, however insecurely, traditional religious beliefs alongside more scientific ones. There may even

Persistence of religious practice

be, as in the United States, waves of religious revivalism, involving large sections of the population.

It is nonetheless true that all such religious phenomena, real as they may be in the lives of believers, lose their centrality in the life of the society as a whole. As compared with their place in traditional society, they increasingly take on the character of marginal, even leisure-time, activities. They no longer embody that crucial legitimating power that religious activities have in all nonindustrial societies. The religious establishment is aware that to confront the modern state too openly is to risk disestablishment, as in France, or even, as in communist societies, dissolution. Baptisms and church weddings persist as much for social reasons as from belief in their religious significance.

Secularization is but one manifestation of a larger cultural process that affects all modern societies: the process of rationalization. While this process is epitomized by the rise of the scientific worldview, it encompasses many more areas than are usually associated with science. It applies, for instance, to the capitalist economy, with its rational organization of labour and its rational calculation of profit and loss. It applies also to artistic developments, such as the rational application of the geometry of perspective in painting and the development of a rational system of notation and rational harmonic principles in music. For Max Weber, the most careful student of the process, it referred above all to the establishment of a rational system of laws and administration in modern society. It was in the system of bureaucracy, seen as the impersonal and impartial rule of rationally constituted laws and formal procedures, that Weber saw the highest development of the rational principle. Bureaucracy meant a principled hostility to all traditional and "irrational" considerations of person or place, kinship or culture. It expressed the triumph of the scientific method and scientific expertise in social life. The trained official, said Weber, is "the pillar both of the modern state and of the economic life of the West."

The role of bureaucracy

Weber was aware that bureaucracy has two faces. It can also be despotic and irrational in actual operation. The triumph of the principle does not guarantee its strict performance in practice. Rationalization is a process that operates at the highest, most general level of social development. It would be surprising if its effects were to be found in every nook and cranny of modern society. Everywhere one should expect to find the persistence of nonrational and even antirational attitudes and behaviour. Superstition is one example; the occasional rise of personal, charismatic leadership breaking through the rationalized routines of bureaucracy is another. These should not be thought of simply as vestiges of traditional society. They are also the expressions of essential needs, emotional and cultural, that are in danger of being stifled in a scientific and unillusioned environment.

Weber stressed another significant point. Rationalization does not connote that the populations of modern societies are, as individuals, any more reasonable or knowledgeable than those of nonindustrial societies. What it means is that there is, in principle, scientifically validated knowledge available to modern populations, by which they may, if they choose, enlighten themselves about their world and govern their behaviour. In practice, as Weber knew, such knowledge tends to be restricted to scientifically trained elites. The mass of the population of a modern society might in their daily lives be relatively more ignorant than the most primitive savage, for the savage usually has a comprehensive and working knowledge of the tools he uses and the food he consumes, whereas modern man may well use an elevator without the slightest idea of its working principle or eat food manufactured in ways and with materials of which he is totally unaware.

SOCIAL PROBLEMS

Two faces of modernity

As with bureaucracy, so with most other features: they show the two faces of modernity. One is dynamic, forward-looking, progressive, promising unprecedented abundance, freedom, and fulfillment. The other shows the dark side of modernity, the new problems that modernity brings in its wake by virtue of the very scale and novelty of its achievements. Social progress is matched by social pathology.

Thus, the historic achievement of becoming able to feed a large population brings with it crowding, pollution, and environmental destruction. Quiet, privacy, and space become scarce and increasingly treasured commodities. Massed together in cities, seeking rest and recreation, the populations of industrial societies force open the whole world to tourism. Soon every rural haven, every sunswept coast, is turned into an administered holiday camp, each a uniform replica of the rest. The industrial principle of mass production and distribution can readily be turned from the production of goods to that of services, including those of leisure and entertainment.

Urban-industrial life offers unprecedented opportunities for individual mobility and personal freedom. It also promises the attainment of dazzling prizes, in wealth and honours, for those with the enterprise and talent to reach for them. The other side of the coin is the loneliness of the city dweller and the desolation of failure for those many who cannot win any of the prizes. As Durkheim analyzed it, the individual is placed in the pathological condition of anomie. He experiences "the malady of infinite aspirations." The decline of religion and community removes the traditional restraints on appetite, allowing it to grow morbidly and without limit. At the same time the competitive modern order that stimulates these unreal expectations provides insufficient and unequal means for their realization. The result is an increase in suicide, crime, and mental disorder.

Anomie and alienation

Industrial work, too, exacts a high price for the enormous increase in productivity brought about by the intensified division of labour. Karl Marx offered the most systematic analysis of this price under the heading of "alienation." The industrial worker feels estranged from the activity of work because his task is so fragmented, undemanding, and meaningless. He does not realize himself, his human potential, in his work. Unlike traditional craft work, for instance, it does not call on his constructive and creative faculties. The industrial worker also feels alienated from the product of his work, for he has no control over its manufacture, nor over the terms and conditions of its disposal. As the dynamic sum of its parts, the industrial system of production is phenomenally powerful; but this power is achieved at the cost of reducing one class of those parts, the human workers, to mere "hands," mere semblances of humanity. Eventually, Marx hoped, the surplus wealth produced by the industrial system would free workers altogether from the necessity of work; but until that time the degraded condition of the worker would be the most eloquent testimony to the dehumanization wrought by the system.

Marx's optimism about the future was perhaps as excessive as his pessimism about his present. But he was by no means the only one who felt that industrial society demanded too high a price of many of its members. Repeatedly, industrialism was found to have created new and apparently ineradicable pockets of poverty. Despite steady economic growth, it was the persistent finding throughout the industrial world that between 15 and 20 percent of the population remained permanently below officially defined levels of poverty. It appeared that industrialism by its very mechanism of growth created a "new poor," who for whatever reason—deprived backgrounds, low enterprise, low intelligence—were unable to compete according to the rules of the industrial order. The communal and kinship supports of the past having withered away, there was no alternative for the failed and the rejected but to become claimants and pensioners of the state.

There were other victims, too. The small nuclear family offered, to a greater extent than ever before, the opportunity for intense privacy and emotional fulfillment. But the very intensity of these relationships seemed to put an intolerable burden on it. Added to that, the family survived as the only remaining primary group in society, the only social unit where relationships remained primarily personal and face-to-face. Elsewhere bureaucratic or commercial relationships prevailed. The nuclear family was called upon to do all the work of restoration and repair of its members on their return from the impersonal, large-scale, bureaucratic world of work and, increasingly, play.

Stress of the nuclear family

Under this unprecedented pressure it began to show all the classic symptoms of distress. Adolescent alienation and teenage rebellion became accepted features of modern family life. Divorce rates soared; and when people sought to remarry—"the triumph of hope over experience"—their second marriages proved even less stable than their first. There was a steady increase in the incidence of one-parent families, usually headed by a woman.

Societal costs of modernization

Modernization, finally, put a number of new political and cultural problems on the agenda. The decline of local communities, and the great growth in the scale of all social institutions and especially the acceleration of political centralization, put a strain on civic loyalties and the willingness of people to participate in political life. As mass political parties came to monopolize civic life, individual citizens retreated increasingly into private life. Political apathy and low turnouts at elections became matters of serious concern, calling into question the democratic claims of modern liberal societies. A similar concern centred on the spread of mass communications, which in the 20th century came to dominate the cultural life of modern societies. The uniformity and conformity bred by the press, radio, and television threatened—albeit passively rather than directly—the pluralism and diversity on which liberal society prided itself and which it regarded as its chief security against totalitarian challenge.

Together, political and cultural centralization and uniformity were interpreted as evidence of the creation of a "mass society." Tocqueville had warned that individuals lacking strong intermediate institutions with which to identify would become atomized and in their anonymity and powerlessness might look to the protection of strong men and strong governments. Once more, this outcome had to be seen as a possibility, not an inevitability. Pluralism remained strong in many societies. But the rise and success of totalitarian movements in some industrial societies showed that the tendencies were real and suggested that they were present in some degree in all modern societies.

Modern society and world society

WESTERN AND NON-WESTERN ROUTES TO MODERNITY

The Western experience of industrialization was the model for world industrialization. To become modern was to become something like Western industrial society. Non-Western societies were not always given much choice in the matter. As formal colonies or informal clients of Western powers, they often found themselves being "developed" in a Western direction before they were permitted to take political control of their own destinies. Once on the way, there was no turning back. But, even where an element of choice existed, it remained the consensus that the only viable form of society in the modern world was industrial society. Only industrial societies could be active agents in the world system. All others must remain clients or dependents. Japan demonstrated this better than any other nation. From a poor nation humiliated at the hands of the West in the mid-19th century, Japan rose through industrialization to become one of the most powerful societies in the world. More pointedly, Japan showed that, by meeting the challenge of industrialization, a non-Western society could become not merely the equal but the superior of some of the strongest Western powers.

Japan confirmed what Western experience had already made clear: There are several routes to modernity. In the 19th century Britain, Belgium, France, and the United States industrialized largely on the basis of the individual entrepreneur and the free market economy. In Germany, and even more in Japan, the state and political elites played a major role, organizing credit, coordinating and planning development, and restricting foreign access to home markets in the interests of native industry. Later still came the even more centralized authoritarian model of modernization under the aegis of the one-party state. Taking their lead from the Soviet Union following the Russian Revolution of 1917, many developing countries in Asia, Africa, and Latin America sought to industrialize according to economic plans drawn up by political elites and stringently imposed on their populations. Even where, as in India, formal liberal democracy was instituted, industrialization was largely guided by a single national party—usually the one identified with the struggle for independence from colonial rule, as was the Indian National Congress party. In any case, there were plenty of socialisms to choose from. There were the African socialisms of Kwame Nkrumah's Ghana and Julius Nyerere's Tanzania, the Chinese socialism of Mao Zedong, the Cuban socialism of Fidel Castro, or the Yugoslav socialism of Josip Broz Tito. All could aspire to be models of development to Third World societies.

Socialist paths to development

Japan and the Soviet Union (until its dissolution in 1991) suggested, in their different ways, that there was a general pattern of late development appropriate to all those nations that attempted to industrialize in the shadow of already formidable industrial powers. This pattern variously involved strong protectionism, directed labour, control of unions, and central supervision of banking and credit. It also meant circumventing the sharp division between management and workers that hampered most early Western industrializers and that continued to worry them in their later industrial history. Above all, late developers put the power of the state at the centre of the modernizing effort. The state was the prime mover and guardian of the whole enterprise. Unlike Britain or the United States, where the state—at any rate in the early stage—encouraged development more or less passively, keeping the peace and enforcing the laws and perhaps arranging for some free land (as for the railroads in the United States), in countries such as Japan, the former Soviet Union, and China the state directed the industrializing process from the start and supervised it closely throughout. The state made the major decisions about investment, transport and communications, and education. It developed the media of mass communications as agencies of mass socialization. Therefore, whether or not the economy was formally nationalized, in practice economic development was placed firmly under national auspices and directed to nationalist ends.

ONE WORLD OR MANY

Japan has been, so far, the only non-Western country in the world to become fully industrialized. It may be significant that it began its industrialization in the 19th century, while the West was still itself industrializing and before it had built up a truly commanding lead. The same is true of Russia, the only other major case of industrialization outside western Europe and North America (taking South Africa and Australia as "European"). In the 20th century it has become increasingly clear that industrialization is not something that nations can decide to do or how to do entirely by themselves. They operate within a context of world industrialization, in a world system of states of decidedly unequal wealth and power.

Throughout most of the 20th century the nations of this world system were categorized according to political or economic criteria. Applying the former resulted in the familiar "West–East" divide. This was primarily an ideological division between the developed capitalist nations, such as the United States, Germany, and Japan (counted ideologically as Western), and the developed communist or state-socialist nations, such as the countries of the former East European bloc. Attached to these were, respectively, underdeveloped capitalist nations, such as Bolivia and Bangladesh, and underdeveloped communist nations, such as China and Cuba. The West–East distinction became obsolete in the early 1990s with the collapse of the Soviet Union and of communist regimes throughout Eastern Europe.

West–East and North–South

A more significant and in many ways more interesting division arises from placing primary emphasis on the level of economic development, with political or ideological differences as subsidiary matters. This approach yields the "North–South" divide. With some anomalies—South Africa, Australia—the world is seen as divided essentially between the wealthy and powerful countries of the Northern Hemisphere and the poor, less-developed countries of the Southern Hemisphere. But the North–South dichotomy, though useful in debate, is inaccurate

and misleading. A more precise economic model of the world system distinguishes among the superpowers, solely the United States at the end of the 20th century; other developed countries, such as Japan, Germany, and Britain; and the underdeveloped countries, such as China and Bolivia. We then have First, Second, and Third Worlds.

For most of the 20th century, when the U.S.S.R. was still a superpower, this model illustrated the interconnections and flow of power in the world system. It showed the global dominance of the superpowers, which, despite their usually conflicting ideological and strategic interests, shared a common interest in maintaining their world political and economic leadership. In competing with each other, the superpowers drew into their respective spheres of influence the less powerful countries of the Second and Third Worlds; but, in order to maintain the balance of power, they could in effect collude, choosing on occasion to ignore opportunities to gain at each other's expense in order to stifle political movements that sought too independent a third way.

A further refinement of the economic model looks past the level of three worlds of development to a single underlying and developing world system. Based on a historical perspective, this view, advanced especially by the American theorist Immanuel Wallerstein (b. 1930), argues that there is but a single world economy, the capitalist

The world economy

world economy, which has been expanding since the 17th century. This economy has, over the centuries, been expanding outward from its northwestern European base to take in an increasingly large portion of the globe. Even under the communist regimes, the Eastern European societies were seen as full participants in this system and were accordingly regarded not as aberrant socialist economies but as "collective capitalist firms." In this model, countries are classified according to their nearness to the centre of the system. There are "core countries," such as the United States and Japan; "semi-peripheral countries," such as Brazil, most eastern European states, and China; and "peripheral countries," such as Cuba and most of the poor countries of Africa and Asia. Depending on economic fortunes and fluctuations, as well as the logic of the developing system itself, countries can move in and out of these categories.

The plausibility and appeal of this model lie in its recognition of the growing internationalization of the industrial economy. Nation-states, whether capitalist or communist, are becoming increasingly subordinate to world economic developments. The politics of energy—oil, gas, nuclear power—are world politics (just as, for some considerable time, military strategy has been world strategy). Decisions about capital investment and growth are made in a world context and on a global scale. The giant multinational corporations are the most significant new actors on the

The role of multinationals

world stage. They have been establishing a new international division of labour. From their point of view, it makes more sense to manufacture goods in South Korea or Taiwan, where labour is still cheap and governments compliant, than in the United States or Britain, where labour is expensive and regulation stringent. Such high-level functions as central planning and research and development can be retained in their Western homelands, where there are the necessary reserves of highly trained professional and scientific personnel. Profits can be declared in those countries where taxes are lowest. In such a way do the multinationals illustrate, even embody, the interdependence of core and periphery nations.

Postmodern and postindustrial society

NEW DEVELOPMENTS IN ECONOMIC AND SOCIAL STRUCTURE

Industrialism, at least within our experience of it for more than 200 years, never reaches a point of equilibrium or a level plateau. By its very principle of operation, it ceaselessly innovates and changes. Having largely eliminated the agricultural work force, it moves on manufacturing employment by creating new automated technology that increases manufacturing productivity while displacing workers. Manufacturing, from accounting for a half or more of the employed population of industrial societies, shrinks to between a quarter and a third. Its place is filled by the service sector, which in fully industrial societies comes to employ between a half and two-thirds of the work force and to account for more than half of the gross national product. Most service occupations—in government, health, education, finance, leisure and entertainment—are white-collar. The typical industrial worker is now not the blue-collar worker but the white-collar worker.

The service economy

The move to a service society is marked by a great expansion in education, health, and other private and public welfare services. The population typically becomes not just healthier, better housed, and better fed but also better educated. Most young people complete secondary- or high-school education; between a quarter and a half of them go on to full-time higher education. Professional and scientific knowledge becomes the most marketable commodity. The "knowledge class" of professional, scientific, and technical workers becomes the fastest-growing occupational group. The link between pure science and technology, loose and uncertain in the early stages of industrialization, becomes pivotal. New industries, starting with chemicals and pharmaceuticals and later including the aeronautical, space, and nuclear industries, are created by developments in pure science and depend largely on theoretical research. Theoretical knowledge in the social sciences also comes to be widely applied, as in Keynesian management of the national economy and in complex models of technological and economic forecasting.

Struck by these changes, as compared with the classic forms of industrial society of the 19th and early 20th centuries, some theorists, notably the American sociologist Daniel Bell, have discerned a movement to a new postmodern or postindustrial society. Such conclusions may be premature. Most of the changes characterizing late industrialism can be seen as the results of long-term developments implicit in the process of industrialization from the start. The rise of service industries has emerged in part from the increase in leisure and in disposable wealth and in part from the continuing process of mechanization and technical innovation, which constantly raises manufacturing productivity by replacing human labour with machines. It can also be seen as the consequence of the growth of multinational corporations; this, too, is the result of the increase in scale and complexity of industrial organization, a clear tendency from the very start. The growth of knowledge-based industries, finally, represents no break with the past. Science has always been at the base of industrialism, and its closer union with industry and society in the 20th century is simply the fulfillment of modernization's rationalizing drive.

But, while there may be no new society, these changes do add a new dimension to modern societies. Beyond a certain point in economic development, new values and problems emerge. The activities of the multinationals seem to encourage a process of "de-industrialization" in many modern societies, a drastic decline in manufacturing output and employment as these functions shift to the Third World. While services have for the time being filled the breach, it cannot be assumed that such a balancing will continue, at least as far as employment is concerned. The new microelectronic technology, itself simply the latest wave of industrial tools, has made inroads into service employment faster than more traditional industrial machines displaced manufacturing workers. The application

Effects of the computer

of computers to information processing in a wide range of service work may threaten in turn to displace the vast mass of routine white-collar workers. Nor are the jobs of the more skilled workers necessarily much safer: Computer-aided design may take over much of the draftsman's and architect's work as computer-aided manufacturing equipment displaces skilled machinists; electronic audio-visual equipment may to a large extent take the place of the classroom teacher; and self-service diagnostic software may eliminate many tasks of the nurse and doctor.

NEW PATTERNS OF URBAN LIFE

Many features of modernity, intensified beyond a certain level, produce a reactive response. Urbanization, having

reached some practical saturation point, leads to suburbanization, the desire to live in neighbourhoods with green spaces and at least a breath of country air. As the suburbs fill up, the more prosperous citizens become exurban: they colonize the villages and small towns of the countryside within commuting distance of their work in the city. Aiding this trend is the industrial decentralization and depopulation of many cities as old manufacturing industries decline and new service industries move out to the suburbs and small towns. For the first time since the onset of industrialization, the countryside begins to gain population and the cities begin to lose it. According to the 1980 U.S. census, cities such as St. Louis, Buffalo, and Detroit lost between 35 and 47 percent of their populations over a 30-year period. London lost almost 15 percent of the population of its inner boroughs between 1961 and 1971, and Liverpool almost 25 percent of its population in the 20-year period to 1971.

But there is a deceptive aspect to this movement. The familiar forces of industrialism, here as elsewhere, continue to dominate the process. Suburbanization and exurbanization do not mean deurbanization. On the contrary, they amount to a spreading of urban life over greater and greater areas. They are simply the filling up, at lesser but still urban densities, of larger areas and regions. From the old city develops the metropolitan area, comprising a large city of about 10 million people together with a surrounding community socially and economically dependent on it. The metropolitan areas themselves tend to merge into even larger urban agglomerations, the megalopolises, which serve populations of 40 million or more. The biggest of these is "Boswash," the chain of contiguous cities and surrounding regions that stretches from Boston to Washington, D.C., along the northeastern seaboard of the United States. Others in the United States include the Chicago–Pittsburgh area around the Great Lakes and the San Francisco–San Diego region along the California coast. There are emerging megalopolises in Britain in the region between London and the Midland cities, in Germany in the industrial basin of the Ruhr, and in Japan in the Tokyo–Osaka–Kyōto complex.

The megalopolis

The Greek architect and city planner Constantinos Apostolos Doxiadis argued that this process is part of a long-term evolution that must eventually culminate in the world-city, or "Ecumenopolis." This remarkable object will incorporate areas reserved for recreation and agriculture as well as desert and wilderness conservation areas, but essentially it will be a web of interconnected cities throughout the world, all closely linked by rapid transport and electronic communication, and all contributing to a single functional unity. In Ecumenopolis the entire land surface of the globe will have become recognizably the dwelling place of urbanized humanity.

Embedded in this process is a contradictory pattern typical of late industrial life. Subjectively, individuals wish to escape from the city. They leave the congested and declining older urban centres only to find themselves cocooned by larger urban structures in the region at large. The objective structural forces of industrialism have in no way abated. But increasingly they give rise to reactions and behaviour that have a de-modernizing character.

Thus there is reaction against large-scale bureaucratic organization. "Small is beautiful," declare the protesters as they seek to reestablish communal and craft environments characteristic of the preindustrial period. Parallel with this is a movement to promote "alternative" and "intermediate" technology, which aims to design tools that restore to the human worker the potential to use and express skill and creativity.

At the political level, too, there is reaction against large scale and centralization. In many industrial societies, such as those of Britain, France, and Canada, there have been strong regional movements demanding autonomy or outright independence. Often these are areas, such as Scotland in Britain, where at least substantial minorities wish to restore historic nations that have been incorporated into larger, more centralized states. Such movements derive momentum from the internationalization of the world economy and polity, which, over the world generally, gives rise to wholly new nationalisms as well. Lacking economic and often genuine political self-government, small societies assert their cultural identity and clamour—and sometimes fight—for autonomy. This was particularly evident in the 1990s with the dissolution of the Soviet Union, the breakup of Yugoslavia, and other nationalist movements in Africa and throughout the world. In less extreme cases, new nations may emerge, although their main symbols of independence may be no more than a national anthem and an international airport.

The rise of new nationalisms

The assertion of cultural values opposed to modernity is a general characteristic of late industrialism. This may take the form of a revival of ethnicity, a claim for a culture and way of life that often harks back to older communal traditions and which denies the legitimacy of any uniform culture propagated by the large nation-state. Thus in the United States blacks, Hispanics, American Indians, and many other groups have made strong claims on behalf of a distinctive ethnic way of life that they variously seek to defend against the encroachments of the national culture. Protests against rationality and uniformity are seen, as well, in the successive waves of youth cultures and religious revivals that have marked late industrial society. Objectively, it is clear that the large-scale bureaucratic institutions of society continue to give the main direction to national life. All revolts break against their indispensability to modern society. But subjectively these institutions are incapable of satisfying the emotional and social needs of individuals. The consequence is the repeated rise of subcultures, often of bizarre mystical or hedonistic kinds, which aim in their practice to reverse the main features of modernity and which give their members a sense of participation and belonging of an almost tribal nature. Central to most of these antinomian movements and ideologies is a wholesale rejection of the scientific worldview, which is depicted as alienating and dehumanizing.

The role of subcultures

To embark on modernization is to be caught up in a whirligig. Once started, the ceaselessly spinning motion seemingly cannot be stopped or even slowed for long. A nation that modernizes is set upon a path of development that carries its own logic and an inseparable mixture of good and bad. Without question, modern society brings progress in the form of material abundance. Less certainly, it brings increasing control of the natural and social environment. But its scientific and technological achievements are bought at some cost to spiritual and emotional life. In unifying the world, modernization establishes uniform standards, albeit higher ones in many cases than previously prevailed. At the same time, it ensures that failures and disasters will also be magnified globally. There are no retreats and escape routes, except those that modern society itself invents as pastimes. The world becomes one and its fate that of all its inhabitants.

To measure the balance of gains and losses in modernity and to increase the former against the latter require forms of social accounting and social engineering that have so far largely defied the efforts of social science and government. But in practice this does not matter. No one can wait for that problem to be solved, if it ever can be. To modernize is to take everything, the bad with the good, and not to modernize is to play no part in the life of contemporary humanity. One of the unusual, and historically unprecedented, aspects of modernization is that it leaves no choice in the matter.

BIBLIOGRAPHY

General surveys of modernization: ALEXIS DE TOCQUEVILLE, *Democracy in America*, 4 vol. (1835–40; originally published in French, 1835–40), available also in many later revised editions, both of the original French edition and of Henry Reeve's translation, provides the classic statement of the "democratic revolution" in modern society, with a finely blended mixture of the author's hopes and fears. For an introduction to Marx's passionate, often indignant appraisal of modern industrial capitalist society, with suggestions of how capitalism might be superseded, see KARL MARX, *Selected Writings*, ed. by DAVID MCLELLAN (1977). ÉMILE DURKHEIM, *The Division of Labor in Society* (1984; originally published in French, 1893), is a guardedly optimistic exploration of the growth of modern society and of hopes for the future, in a new translation by W.D. HALLS. MAX WEBER, *The Protestant Ethic and the Spirit of Capitalism*

(1930, reissued 1985; originally published in German, 1904), is a classic discussion of values that underlie industrial society.

The explorations begun in these classic works continues in the writings of the second half of the 20th century: IRVING L. HOROWITZ, *Three Worlds of Development: The Theory and Practice of International Stratification*, 2nd ed. (1972), studies the impact of the West on modernization in the non-Western world; PETER L. BERGER, BRIGITTE BERGER, and HANSFRIED KELLNER, *The Homeless Mind: Modernization and Consciousness* (1973), analyzes the social tensions, pains, and conflicts that accompany modernization; SZYMON CHODAK, *Societal Development* (1973), surveys in critical detail the theories of modernization and development; PETER WORSLEY, *The Three Worlds: Culture and World Development* (1984), compares earlier Western modernization with that taking place in the rest of the world today; RICHARD L. RUBENSTEIN (ed.), *Modernization: The Humanist Response to Its Promise and Problems*, new ed. (1985), offers scholarly essays examining religious and philosophical aspects of modernization; and THEODORE H. VON LAUE, *The World Revolution of Westernization: The Twentieth Century in Global Perspective* (1987), explores modernization and development as adaptation to Western influences.

Industrialization as economic change and development: CARLO M. CIPOLLA, *Before the Industrial Revolution: European Society and Economy, 1000–1700*, 2nd ed. (1980; originally published in Italian, 1974), offers a historical survey focusing on the economic conditions of preindustrial Europe; W.W. ROSTOW, *How It All Began: Origins of the Modern Economy* (1975), surveys economic history from the beginning of the 17th to the end of the 19th century; DAVID S. LANDES, *The Unbound Prometheus: Technological Change and Industrial Development in Western Europe from 1750 to the Present* (1969), discusses the first Industrial Revolution and its spread throughout Europe and the wider world; SIDNEY POLLARD, *Peaceful Conquest: The Industrialization of Europe, 1760–1970* (1981), examines the original act of European industrialization and its further progress since. Patterns of industrialization in their historical development throughout the world are compared in TOM KEMP, *Industrialization in Nineteenth-Century Europe*, 2nd ed. (1985). *Historical Patterns of Industrialization* (1978), and *Industrialization in the Non-Western World* (1983). Philosophical and political aspects of industrialization as reflected in traditional understanding of market behaviour and economic laws are analyzed in GREGORY CLAEYS, *Machinery, Money, and the Millennium: From Moral Economy to Socialism, 1815–1860* (1987). KARL POLANYI, *The Great Transformation* (1944, reprinted 1985), explores the novelty of the modern market economy and the social and political problems arising from it; IMMANUEL WALLERSTEIN, *The Capitalist World-Economy* (1979), presents modernization as the growth of a capitalist world economy, dominated by the powerful capitalist nations; HENRY BERNSTEIN (comp.), *Underdevelopment and Development: The Third World Today* (1973), offers a collection of theoretical and empirical essays with a Marxist and neo-Marxist slant; and DAVID GOODMAN, BERNARDO SORJ, and JOHN WILKINSON, *From Farming to Biotechnology: A Theory of Agro-Industrial Development* (1987), studies the impact of modernization and industrialization on agriculture.

Demographic change: ROBERT I. ROTBERG and THEODORE K. RABB (eds.), *Population and Economy: Population and History from the Traditional to the Modern World* (1986), is a collection of excellent scholarship, exploring demographic dynamics of preindustrial society; H.J. HABAKKUK, *Population Growth and Economic Development Since 1750* (1971), is a monographic history covering both Europe and developing countries; JAMES C. RILEY, *Population Thought in the Age of the Demographic Revolution* (1985), discusses, in a somewhat technical style, the influence of demographic ideas on social policies and choices; R.K. KELSALL, *Population*, 4th ed. (1979), presents a sociological survey; PAULA ENGLAND and GEORGE FARKAS, *Households, Employment, and Gender: A Social, Economic, and Demographic View* (1986), provides an interdisciplinary explanation of the influence of main demographic trends on modern and postmodern society; MICHAEL S. TEITELBAUM and JAY M. WINTER, *The Fear of Population Decline* (1985), is a readable examination of demographic and political aspects of negative growth of population in developed economies at the end of the 19th and beginning of the 20th centuries; and WILLIAM ALONSO (ed.), *Population in an Interacting World* (1987), is a collection of contemporary studies on the connection between population development and social change.

Urbanization as a way of life: PAUL M. HOHENBERG and LYNN HOLLEN LEES, *The Making of Urban Europe, 1000–1950* (1985); offers a well-illustrated socioeconomic history of urbanization, modernization, and industrialization. Collections of shorter writings on urban history, sociology, culture, and economics, sampling both classic works and contemporary studies, include RICHARD SENNETT (comp.), *Classic Essays on the Culture of Cities* (1969); PHILIP ABRAMS and E.A. WRIGLEY (eds.), *Towns in Societies: Essays in Economic History and Historical Sociology* (1978); FUAD BAALI and JOSEPH S. VANDIVER (eds.), *Urban Sociology* (1970); and GINO GERMANI (ed.), *Modernization, Urbanization, and the Urban Crisis* (1973). JANE JACOBS, *Cities and the Wealth of Nations: Principles of Economic Life* (1984), explores the role of cities in economic development. Theories explaining the relationship between urbanization and modernization are surveyed in R.J. HOLTON, *Cities, Capitalism, and Civilization* (1986). E.A. WRIGLEY, *People, Cities, and Wealth: The Transformation of Traditional Society* (1987), examines major issues of change from rural into urban society. Sociological studies of urbanization include BRIAN J.L. BERRY, *The Human Consequences of Urbanization: Divergent Paths in the Urban Experience of the Twentieth Century* (1973); R.E. PAHL, R. FLYNN, and N.H. BUCK, *Structures and Processes of Urban Life*, 2nd ed. (1983); and EDWARD KRUPAT, *People in Cities: The Urban Environment and Its Effects* (1985).

The nature of work: CLARK KERR *et al.*, *Industrialism and Industrial Man: The Problems of Labour and Management in Economic Growth*, 2nd ed. (1973), sees the apparatus of production as an all-conquering world system, with its own inner logic and dynamism. Development of society where work for industrial production or related service is an issue of survival is studied in KRISHAN KUMAR, *Prophecy and Progress: The Sociology of Industrial and Post-Industrial Society* (1978); KENNETH THOMPSON (ed.), *Work, Employment, and Unemployment: Perspectives on Work and Society* (1984); REINHARD BENDIX, *Work and Authority in Industry: Ideologies of Management in the Course of Industrialization* (1956, reprinted with a new introduction, 1974); HERBERT G. GUTMAN, *Work, Culture, and Society in Industrializing America: Essays in American Working-Class and Social History* (1977); and HARRY BRAVERMAN, *Labor and Monopoly Capital: The Degradation of Work in the Twentieth Century* (1975). ARNE L. KALLEBERG and IVAR BERG, *Work and Industry: Structures, Markets, and Processes* (1987), is an interdisciplinary examination of the role of work in economic development; and PATRICK JOYCE (ed.), *The Historical Meaning of Work* (1987), offers observations on historical and social changes in cultural and ideological dimensions of work in the West during the last two centuries.

Family in industrial society: FRANCES GIES and JOSEPH GIES, *Marriage and the Family in the Middle Ages* (1987), looks at one thousand years of family history to the end of the preindustrial period; PETER LASLETT, *The World We Have Lost: Further Explored*, 3rd ed. (1984), examines the English household of the preindustrial period; and LLOYD BONFIELD, RICHARD M. SMITH, and KEITH WRIGHTSON (eds.), *The World We Have Gained: Histories of Population and Social Structure* (1986), is a collection of essays on family history from the 14th to the 20th century. The modern family is treated in EDWARD SHORTER, *The Making of the Modern Family* (1975); and MICHAEL YOUNG and PETER WILLMOTT, *The Symmetrical Family* (1974, reissued 1984). SYLVIA ANN HEWLETT, ALICE S. ILCHMAN, and JOHN J. SWEENEY (eds.), *Family and Work: Bridging the Gap* (1986), analyzes the complex evolutionary relationship between these two social institutions. Specific features of family in industrialized states are surveyed in JAMES DICKINSON and BOB RUSSELL (eds.), *Family, Economy & State: The Social Reproduction Process Under Capitalism* (1986).

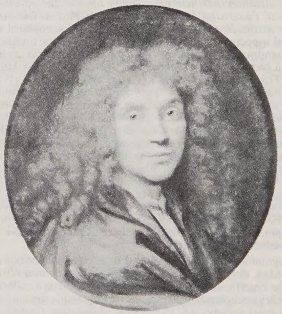
Changes in social structure and understanding of social problems: S.N. EISENSTADT (ed.), *Readings in Social Evolution and Development* (1970), gathers together classic essays of 19th- and 20th-century authors; BERT F. HOSELITZ and WILBERT E. MOORE (eds.), *Industrialization and Society* (1963), analyzes the general impact of modernization on social structure and social institutions; JASON L. FINKLE and RICHARD W. GABLE (eds.), *Political Development and Social Change*, 2nd ed. (1971), studies the political consequences of development, particularly in Third World societies; and EMANUEL DE KADT and GAVIN WILLIAMS (eds.), *Sociology and Development* (1974), emphasizes the interrelationship of the developed and developing societies. Contemporary social structures are discussed in SALVADOR GINER and MARGARET SCOTFORD ARCHER (eds.), *Contemporary Europe: Social Structures and Cultural Patterns* (1978); ANTHONY GIDDENS, *The Class Structure of the Advanced Societies*, 2nd ed. (1981); and JACQUES ELLUL, *The Technological Society* (1964; originally published in French, 1954). Dilemmas and problems posed for societies by modernization are outlined in REINHARD BENDIX, *Embattled Reason: Essays on Social Knowledge*, 2 vol.: vol. 1, 2nd rev. ed. (1988), vol. 2 (1989); FRED HIRSCH, *Social Limits to Growth* (1976); ADRIAN ELLIS and KRISHAN KUMAR (eds.), *Dilemmas of Liberal Democracies: Studies in Fred Hirsch's 'Social Limits to Growth'* (1983); and WILLIAM LEISS, *The Limits to Satisfaction: On Needs and Commodities*, rev. ed. (1978).

(Kr.K.)

Molière

Although the sacred and secular authorities of 17th-century France often combined against him, the comic genius of Jean-Baptiste Poquelin, known as Molière, emerged finally to win him eventual acclaim as the greatest of all French writers. Comedy had a long history before Molière, who employed most of its traditional forms, but he succeeded in inventing a new style that was based on a double vision of normal and abnormal seen in relation to each other—the comedy of the true opposed to the specious, the intelligent seen alongside the pedantic. An actor himself, Molière seems to have been incapable of visualizing any situation without animating and dramatizing it, often beyond the limits of probability; though living in an age of reason, his own good sense led him not to proselytize but rather to animate the absurd, as in such masterpieces as *Tartuffe, L'École des femmes, Le Misanthrope,* and many others. It is testimony to the freshness of his vision that the greatest comic artists working centuries later in other media, such as Charlie Chaplin, are still compared to Molière.

Beginnings in theatre. Molière was born (and died) in the heart of Paris. The registers showed that he was baptized on January 15, 1622, as Jean-Baptiste Poquelin. His mother died when he was 10 years old; his father, one of the appointed furnishers of the royal household, gave him a good education at the Collège de Clermont (the school that, as the Lycée Louis-le-Grand, was to train so many brilliant Frenchmen, including Voltaire). Although his father clearly intended him to take over his royal appointment, the young man renounced it in 1643, apparently determined to break with tradition and seek a living on the stage. That year he joined with nine others to produce and play comedy as a company under the name of the Illustre-Théâtre. His stage name, Molière, is first found in a document dated June 28, 1644. He was to give himself entirely to the theatre for 30 years and to die exhausted at the age of 51.



A talented actress, Madeleine Béjart, persuaded Molière to establish a theatre, but she could not keep the young company alive and solvent. In 1645 Molière was twice sent to prison for debts on the building and properties. The number of theatregoers in 17th-century Paris was small, and the city already had two established theatres, so that a continued existence must have seemed impossible to a young company. From the end of 1645, for no fewer than 13 years, the troupe sought a living touring the provinces. No history of these years is possible, though municipal registers and church records show the company emerging here and there: in Nantes in 1648, in Toulouse in 1649, and so on. They were in Lyon intermittently from the end of 1652 to the summer of 1655 and again in 1657, at Montpellier in 1654 and 1655, and at Béziers in 1656. Clearly they had their ups as well as downs. These unchronicled years must have been of crucial importance to Molière's career, forming as they did a rigorous apprenticeship to his later work as actor-manager and teaching him how to deal with authors, colleagues, audiences, and authorities. His rapid success and persistence against opposition when he finally got back to Paris is inexplicable without these years of training. His first two known plays date from this time: *L'Étourdi ou les contretemps* (*The Blunderer,* 1762), performed at Lyon in 1655, and *Le Dépit amoureux* (*The Amorous Quarrel,* 1762), performed at Béziers in 1656.

First success

The path to fame opened for him on the afternoon of October 24, 1658, when, in the guardroom of the Louvre and on an improvised stage, the company presented Corneille's *Nicomède* before the king, Louis XIV, and followed it with what Molière described as one of those little entertainments which had won him some reputation with provincial audiences. This was *Le Docteur amoureux* ("The Amorous Doctor"); whether it was in the form still extant is doubtful. It apparently was a success and secured the favour of the King's brother Philippe, duc d'Orléans. It is difficult to know the extent of the Duc's patronage, which lasted seven years, until the King himself took over the company known as "Troupe du roi." No doubt the company gained a certain celebrity and prestige, invitations to great houses, and subsidies (usually unpaid) to actors, but not much more.

From the time of his return to Paris in 1658, all the reliable facts about Molière's life have to do with his activity as author, actor, and manager. Some French biographers have done their best to read his personal life into his works, but at the cost of misconstruing what might have happened as what did happen. The truth is that there is little information except legend and satire. The fact that authors like Montaigne, Plutarch, Julius Caesar, and Seneca may have been in his library (according to a legal inventory of 1708), for example, does not mean that his plays should be read with the doctrines of such authors in mind.

Although unquestionably a great writer, Molière was not an author in the usual sense: he wrote little that could be called literature or even that was meant to be published—some poems and a translation of the ancient Latin writings of Lucretius, incomplete. His plays were made for the stage, and his early prefaces complain that he had to publish to avoid exploitation. (Two of them were in fact pirated.) He left seven of his plays unpublished, never issued any collected edition, and never (so far as is known) read proofs or took care with his text. Comedies, in his view, were made to be acted. This fact was forgotten in the 19th century. It took such 20th-century actors as Louis Jouvet, Charles Dullin, Jean-Louis Barrault, and Jean Vilar to present a new and exact sense of his dramatic genius.

Nor was he at all a classical author, with leisure to plan and write as he would. Competition, the fight for existence, was the keynote of Molière's whole career. To keep his actors and his audiences was an unremitting struggle against other theatres. He won this contest almost single-handed. He held his company together by his technical competence and force of personality.

Molière's first Paris play, *Les Précieuses ridicules* (*The Affected Young Ladies*), prefigured what was to come. It centres on two provincial girls who are exposed by valets masquerading as masters in scenes that contrast, on the

one hand, the girls' desire for elegance coupled with a lack of common sense and, on the other, the valets' plain speech seasoned with cultural clichés. The girls' fatuities, which they consider the height of wit, suggest their warped view of culture in which material things are of no account. The fun at the expense of these affected people is still refreshing and must have been even more so for the first spectators.

Molière's Paris theatres

Les Précieuses, as well as *Sganarelle* (first performed in October, 1660), probably had its premiere at the Théâtre du Petit-Bourbon, a great house adjacent to the Louvre. The Petit-Bourbon was demolished (apparently without notice), and the company moved early in 1661 to a hall in the Palais-Royal, built as a theatre by Richelieu. Here it was that all Molière's "Paris" plays were staged, starting with *Dom Garcie de Navarre, ou le prince jaloux* in February 1661, a heroic comedy of which much was hoped; it failed on the stage and succeeded only in inspiring Molière to work on *Le Misanthrope*. Such failures were rare and eclipsed by successes greater than the Paris theatre had known.

Scandals and successes. The first night of *L'École des femmes* (*The School for Wives*), December 26, 1662, caused a scandal as if people suspected that here was an emergence of a comic genius that regarded nothing as sacrosanct. Some good judges have thought this to be Molière's masterpiece, as pure comedy as he ever attained. Based on Paul Scarron's version (*La Précaution inutile*, 1655) of a Spanish story, it presents a pedant, Arnolphe, who is so frightened of femininity that he decides to marry a girl entirely unacquainted with the ways of the world. The delicate portrayal in this girl of an awakening temperament, all the stronger for its absence of convention, is a marvel of comedy. Molière crowns his fantasy by showing his pedant falling in love with her, and his elephantine gropings toward lovers' talk are both his punishment and the audience's delight.

From 1662 onward the Palais-Royal theatre was shared by Italian actors, each company taking three playing days in each week. Molière also wrote plays that were privately commissioned and thus first performed elsewhere: *Les Fâcheux* (*The Impertinents*, 1732) at Vaux in August 1661; the first version of *Tartuffe* at Versailles in 1664; *Le Bourgeois Gentilhomme* at Chambord in 1670; and *Psyché* in the Tuileries Palace in 1671.

Marriage to Armande Béjart

On February 20, 1662, Molière married Armande Béjart. It is not certain whether she was Madeleine's sister, as the documents state, or her daughter, as some contemporaries suggest. There were three children of the marriage; only a daughter survived to maturity. It was not a happy marriage; flirtations of Armande are indicated in hostile pamphlets, but there is almost no reliable information.

Molière cleverly turned the outcry produced by *L'École des femmes* to the credit of the company by replying to his critics on the stage. *La Critique de L'École des femmes* in June 1663 and *L'Impromptu de Versailles* in October were both single-act discussion plays. In *La Critique* Molière allowed himself to express some principles of his new style of comedy, and in the other play he made theatre history by reproducing with astonishing realism the actual greenroom, or actors' lounge, of the company and the backchat involved in rehearsal.

The quarrel of *L'École des femmes* was itself outrun in violence and scandal by the presentation of the first version of *Tartuffe* in May 1664. The history of this great play sheds much light on the conditions in which Molière had to work and bears a quite remarkable testimony to his persistence and capacity to show fight. He had to wait five years and risk the livelihood of his actors before his reward, which proved to be the greatest success of his career. Most men would surely have given up the struggle: from the time of the first performance of what was probably the first three acts of the play as it is now known, many must have feared that the Roman Catholic Church would never allow its public performance.

Undeterred, Molière made matters worse by staging a version of *Dom Juan, ou le festin de Pierre* with a spectacular ending in which an atheist is committed to hell—but only after he had amused and scandalized the audience. *Dom Juan* was meant to be a quick money raiser, but it was a costly failure, mysteriously removed after 15 performances and never performed again or published by Molière. It is a priceless example of his art. The central character, Dom Juan, carries the aristocratic principle to its extreme by disclaiming all types of obligation, either to parents or doctors or tradesmen or God. Yet he assumes that others will fulfill their obligations to him. His servant, Sganarelle, is imagined as his opposite in every point, earthy, timorous, superstitious. These two form the perfect French counterpart to Don Quixote and Sancho.

Setbacks and harassment by the authorities

While engaged in his battles against the authorities, Molière continued to hold his company together single-handedly. He made up for lack of authors by writing more plays himself. He could never be sure either of actors or authors. In 1664 he put on the first play of Jean Racine, *La Thébaïde*, but the next year Racine transferred his second play, *Alexandre le Grand*, to a longer established theatre while Molière's actors were actually performing it. He was constantly harassed by the authorities. These setbacks may have been offset in part by the royal favour conferred upon Molière, but royal favour was capricious. Pensions were often promised and not paid. The court wanted more light plays than great works. The receipts of his theatre were uncertain and fluctuating. In his 14 years in Paris, Molière wrote 31 of the 95 plays that were presented on his stage. To meet the cumulative misfortunes of his own illness, the closing of the theatre for seven weeks upon the death of the Queen Mother, and the proscription of *Tartuffe* and *Dom Juan*, he wrote five plays in one season (1666–67). Of the five, only one, *Le Médecin malgré lui* (*The Doctor in Spite of Himself*, 1914), was a success.

In the preceding season, however, *Le Misanthrope*, almost from the start, was treated as a masterpiece by discerning playgoers, if not by the entire public. It is a drawing-room comedy, without known sources, constructed from the elements of Molière's own company. Molière himself played the role of Alceste, a fool of a new kind, with high principles and rigid standards, yet by nature a blind critic of everybody else. Alceste is in love with Célimène (played by Molière's wife, Armande), a superb comic creation, equal to any and every occasion, the incarnate spirit of society. The structure of the play is as simple as it is poetic. Alceste storms moodily through the play, finding no "honest" men to agree with him, always ready to see the mote in another's eye, blind to the beam in his own, as ignorant of his real nature as a Tartuffe.

The church nearly won its battle against Molière: it prevented public performance, both of *Tartuffe* for five years and of *Dom Juan* for the whole of Molière's life. A five-act version of *Tartuffe* was played in 1667, but once only: it was banned by the President of Police and by the Archbishop on pain of excommunication. Molière's reply was to lobby the King repeatedly, even in a military camp, and to publish a defense of his play called *Lettre sur la comédie de l'Imposteur*. He kept his company together through 1668 with *Amphitryon* (January 13), *George Dandin* (Versailles, July 18), and *L'Avare* (September 9). Sooner or later so original an author of comedy as Molière was bound to attempt a modern sketch of the ancient comic figure of the miser. The last of his three 1668 plays, *L'Avare*, is composed in prose that reads like verse; the stock situations are all recast, but the spirit is different from Molière's other works and not to everyone's taste. His miser is a living paradox, inhuman in his worship of money, all too human in his need of respect and affection. In breathtaking scenes his mania is made to suggest cruelty, pathological loneliness, even insanity. The play is too stark for those who expect laughter from comedy; Goethe started the dubious fashion of calling it tragic. Yet, as before, forces of mind and will are made to serve inhuman ends and are opposed by instinct and a very "human" nature. The basic comic suggestion is one of absurdity and incongruity rather than of gaiety.

His second play of 1668, *George Dandin*, often dismissed as a farce, may be one of Molière's greatest creations. It centres on a fool, who admits his folly while suggesting that wisdom would not help him because, if things in fact go against us, it is pointless to be wise. As it happens he

is in the right, but he can never prove it. The subject of the play is trivial, the suggestion is limitless; it sketches a new range of comedy altogether. In 1669, permission was somehow obtained, and the long run of *Tartuffe* at last began. More than 60 performances were given that year alone. The theme for this play, which brought Molière more trouble than any other, may have come to him when a local hypocrite seduced his landlady. Of the three versions of the play, only the last has survived; the first (presented in three acts played before the King in 1664) probably portrayed a pious crook so firmly established in a bourgeois household that the master promises him his daughter and disinherits his son. At the time it was common for lay directors of conscience to be placed in families to reprove and reform conduct. When this "holy" man is caught making love to his employer's wife, he recovers by masterly self-reproach and persuades the master not only to pardon him but also to urge him to see as much of his wife as possible. Molière must have seen even greater comic possibilities in this theme, for he made five acts out of it. The final version contains two seduction scenes and a shift of interest to the comic paradox in Tartuffe himself, posing as an inhuman ascetic while by nature he is an all-too-human lecher. It is difficult to think of a theme more likely to offend pious minds. Like Arnolphe in *L'École des femmes,* Tartuffe seems to have come to grief because he trusted in wit and forgot instinct.

The long run of *Tartuffe*

Last plays. The struggle over *Tartuffe* probably exhausted Molière to the point that he was unable to stave off repeated illness and supply new plays; he had, in fact, just four years more to live. Yet he produced in 1669 *Monsieur de Pourceaugnac* for the King at Chambord and in 1670 *Le Bourgeois Gentilhomme.*

Le Bourgeois Gentilhomme treated a contemporary theme—social climbing among the bourgeois, or upper middle class—but it is perhaps the least dated of all his comedies. The protagonist Jourdain, rather than being an unpleasant sycophant, is as delightful as he is fatuous, as genuine as he is naïve; his folly is embedded in a bountiful disposition, which he of course despises. This is comedy in Molière's happiest vein: the fatuity of the masculine master is offset by the common sense of wife and servant.

Continuing to write despite his illness, he produced *Psyché* and *Les Fourberies de Scapin* (*The Cheats of Scapin,* 1677) in 1671. *Les Femmes savantes* (*The Blue-Stockings,* 1927) followed in 1672; in rougher hands this subject would have been (as some have thought it) a satire on bluestockings, but Molière has imagined a sensible bourgeois who goes in fear of his masterful and learned wife. *Le Malade imaginaire* (first performed 1673; Eng. trans., *The Imaginary Invalid*), about a hypochondriac who fears death and doctors, was Molière's last play. It is a powerful play in its delineation of medical jargon and professionalism, in the fatuity of a would-be doctor with learning and no sense, in the normality of the young and sensible lovers, as opposed to the superstition, greed, and charlatanry of other characters. During the fourth performance of the play, on February 17, 1673, Molière collapsed on stage and was carried back to his house in the rue de Richelieu to die. As he had not been given the sacraments or the opportunity of formally renouncing the actor's profession, he was buried without ceremony and after sunset on February 21.

Molière's collapse on stage and death

Molière as actor and as playwright. Molière's acting had been both his disappointment and his glory. He aspired to be a tragic actor, but contemporary taste was against him. His public seemed to favour a tragic style that was pompous, with ranting and roaring, strutting and chanting. Molière had the build, the elasticity, the india-rubber face, as it has been called, of the born comedian. Offstage he was neither a great talker nor particularly merry, but he would mime and copy speech to the life. He had the tireless energy of the actor. He was always ready to make a scene out of an incident, to put himself on a stage. He gave one of his characters his own cough and another his own moods, and he made a play out of actual rehearsals. The characters of his greatest plays are like the members of his company. It was quite appropriate that he should die while playing the part of the sick man that he really was.

The actor in him influenced his writing, since he wrote (at speed) what he could most naturally act. He gave himself choleric parts, servants' parts, a henpecked husband, a foolish bourgeois, and a superstitious old man who cursed "that fellow Molière." (The comparison with Charlie Chaplin recurs constantly.) Something more than animal energy and a talent for mime was at work in him, a quality that can only be called intensity of dramatic vision. Here again actors have helped to recover an aspect of his genius that the scholars had missed, his stage violence. To take his plays as arguments in favour of reason is to miss their vitality. His sense of reason leads him to animate the absurd. His characters are imagined as excitable and excited to the point of incoherence. He sacrifices plot to drama, vivacity, a sense of life. He is a classical writer, yet he is ready to defy all rules of writing.

To think of Molière as a cool apostle of reason, sharing the views of the more rational men of his plays, is a heresy that dies hard; but careful scrutiny of the milieu in which Molière had to work makes it impossible to believe. The comedies are not sermons; such doctrine as may be extracted from them is incidental and at the opposite pole from didacticism. Ideas are expressed to please a public, not to propagate the author's view. If asked what he thought of hypocrisy or atheism, he would have marvelled at the question and evaded it with the observation that the theatre is not the place for "views." There is no documentary evidence that Molière ever tried to convey his own opinions on marriage, on the church, on hell, or on class distinctions. Strictly speaking, his views of these things are unknown. All that is known is that he worked for and in the theatre and used his amazing power of dramatic suggestion to vivify any imagined scene. If he has left a sympathetic picture of an atheist, it was not to recommend free thought: his picture of the earthy serving man is no less vivid, no less sympathetic. Scholars who have tried to make his plays prove things or to convey lessons have made little sense of his work and have been blind to its inherent fantasy and imaginative power.

The heresy of Molière as a propagandist

Since the power of Molière's writing seems to lie in its creative vigour of language, the traditional divisions of his works into comedies of manners, comedies of character, and farce are not helpful: he does not appear to have set out in any instance to write a certain kind of play. He starts from an occasion in *Le Mariage forcé* (1664; *The Forced Marriage,* 1762) from doubts about marriage expressed by Rabelais's character Panurge, and in *Le Médecin malgré lui* he starts from a medieval fable, or *fabliau,* of a woodcutter who, to avoid a beating, pretends he is a doctor. On such skeleton themes Molière animates figures or arranges discussion in which one character exposes another or the roles are first expressed and then reversed. It is intellectual rhythm rather than what happens, the discussion more than the story, that conveys the charm, so that to recount the plot may be to omit the essential.

His unique sense of the comic. The attacks on Molière gave him the chance in his responses to state some aesthetic home truths. Thus, in *La Critique de L'École des femmes,* he states that tragedy might be heroic, but comedy must hold the mirror up to nature: "You haven't achieved anything in comedy unless your portraits can be seen to be living types . . . making decent people laugh is a strange business." And as for the rules that some were anxious to impose on writers: "I wonder if the golden rule is not to give pleasure and if a successful play is not on the right track."

The attacks on *L'École des femmes* were child's play in comparison with the storm raised by *Tartuffe* and *Dom Juan.* The attacks on them also drew from the poet a valuable statement of artistic principle. On *Dom Juan* he made no public reply since it was never officially condemned. The documents in defense of *Tartuffe* are two placets, or petitions, to the King, the preface to the first edition of 1669 (all these published over Molière's own name), and the *Lettre sur la comédie de l'Imposteur* of 1667. The placets and preface are aesthetically disappointing, since Molière was forced to fight on ground chosen by

Concept of comedy

his opponents and to admit that comedy must be didactic. (There is no other evidence that Molière thought this, so it is not unfair to assume that he used the argument only when forced.) The *Lettre* is much more important. It expresses in a few pregnant lines the aesthetic basis not only of *Tartuffe* but of Molière's new concept of comedy:

> The comic is the outward and visible form that nature's bounty has attached to everything unreasonable, so that we should see, and avoid, it. To know the comic we must know the rational, of which it denotes the absence and we must see wherein the rational consists . . . incongruity is the heart of the comic . . . it follows that all lying, disguise, cheating, dissimulation, all outward show different from the reality, all contradiction in fact between actions that proceed from a single source, all this is in essence comic.

Molière seems here to put his finger on what was new in his notion of what is comic: a comedy, only incidentally funny, that is based on a constant double vision of wise and foolish, right and wrong seen together, side by side. This is his invention and his glory.

A main feature of Molière's technique is a mixing of registers, or of contexts. Characters are made to play a part, then forget it, speak out of turn, overplay their role, so that those who watch this byplay constantly have the suggestion of mixed registers. The starting point of *Le Médecin malgré lui,* the idea of beating a man to make him pretend he is a doctor, is certainly not subtle, but Molière plays with the idea, makes his woodcutter enjoy his new experience, master the jargon, and then not know what to do with it. He utters inanities about Hippocrates, is overjoyed to find a patient ignorant of Latin, so that he need not bother about meaning. He looks for the heart on the wrong side and, undeterred by having his error recognized, sweeps aside the protest with the immortal: "We have changed all that." The miser robbed of his money is pathetic, but he does not arouse emotions because his language leads him to the absurd " . . . it's all over . . . I'm dying, I'm dead, I'm buried." He demands justice with such intemperance that his language exceeds all reason and he threatens to put the courts in the court. Molière's *Misanthrope* is even more suggestive in his confusion of justice as an ideal and as a social institution: "I have justice on my side and I lose my case!" What to him is a scandal of world order is to others just proof that he is wrongheaded. Such concision does Molière's dramatic speech achieve.

A French genius. When Voltaire described Molière as "the painter of France," he suggested the range of French attitudes found in the plays, and this may explain why the French have developed a proprietary interest in a writer whom they seem to regard in a special sense as their own. They stress aspects of his work that others tend to overlook. Three of these are noteworthy.

First, formality permeates all his works. He never gives realism—life as it is—alone, but always within a pattern and a form that fuse light and movement, music and dance and speech. Modern productions that omit the interludes in his plays stray far from the original effect. Characters are grouped, scenes and even speeches are arranged, comic repartee is rounded off in defiance of realism.

Second, the French stress the poetry where foreigners see psychology. They take the plays not as studies of social mania but as patterns of fantasy that take up ideas, only to drop them when a point has been made. *Le Misanthrope* is not considered as a case study or a French *Hamlet* but as a subtly arranged chorus of voices and attitudes that convey a critique of individualism. The play charms by its successive evocations of its central theme. The tendency to speak one's mind is seen to be many things: idealistic or backbiting or rude or spiteful or just fatuous. It is in this fantasy playing on the mystery of self-centredness in society that Molière is in the eyes of his own people unsurpassed.

A third quality admired in France is his intellectual penetration in distinguishing the parts of a man from the whole man. Montaigne, the 16th-century essayist who deeply influenced Molière, divided qualities that are acquired, such as learning or politeness or skills, from those that are natural, such as humanity or animality, what might be called "human nature" without other attributes. Molière delighted in opposing his characters in this way; often in his plays a social veneer peels off, revealing a real man. Many of his dialogues start with politeness and end in open insults.

Molière opposed wit to nature in many forms. His comedy embraces things within the mind and beyond it; reason and fact seldom meet. As the beaten servant in *Amphitryon* observes: "That conflicts with common sense. But it is so, for all that." (W.G.Mo./Ed.)

MAJOR WORKS

Les Précieuses ridicules (first performed 1659, published 1660; trans. by B.H. Clark, *The Affected Young Ladies,* 1915); *L'École des femmes* (1663; trans. by the Earl of Longford, *The School for Wives,* 1948; and by M. Malleson, 1954); *Le Tartuffe, ou l'imposteur* (first version 1664, present version 1669; trans. by M. Malleson, *The Imposter,* 1950); *Dom Juan, ou le festin de Pierre* (1665; trans. by J. Ozell as *Don John: or, The Libertine,* 1665 and rev. and augmented by O. Mandell, 1963); *Le Misanthrope* (first performed 1666, 1667; adapted by W. Wycherly, *The Plain-Dealer,* 1677; trans. by M. Malleson, 1955); *L'Avare* (1669; trans. by H. Fielding as *The Miser,* 1733; by M. Malleson, 1950; and by K. Cartledge, 1962, with the same title); *Le Bourgeois gentilhomme* (1670; trans. by M. Down, *The Blue-Stockings,* 1927); *Le Malade imaginaire* (1674; trans. as *The Imaginary Invalid* by B.H. Clark, 1925; by M. Malleson, 1959; and B. Briscoe, 1967; and as *The Hypochondriac* by H. Baker and J. Miller, 1961).

BIBLIOGRAPHY

Editions: Collected editions of Molière's works include those by C. VARLET DE LA GRANGE, 8 vol. (1682); by M.A. JOLLY, 6 vol. (1734); by EUGÈNE DESPOIS and PAUL MESNARD in the "Grands Écrivains de la France Series," 13 vol. (1873–1900); by RENÉ BRAY in the "Belles Lettres Series," 8 vol. (1935–52); by GUSTAVE MICHAUT, 11 vol. (1949); by ROBERT JOUANNY in the "Garnier Series," 2 vol. (1962); and by GEORGES COUTON in the "Pléiade Series," 2 vol. (1971). Among editions of particular plays those of *L'Avare* by CHARLES DULLIN (1946), of *Le Malade imaginaire* by PIERRE VALDE (1946), of *Tartuffe* by FERNAND LEDOUX (1953), and of *Le Misanthrope* by GUSTAVE RUDLER (1947) deserve special mention.

Biography: Earlier literature is superseded by GUSTAVE MICHAUT, *La Jeunesse de Molière* (1922, reprinted 1968), *Les Débuts de Molière à Paris* (1923, reissued 1968), and *Les Luttes de Molière* (1925, reissued 1968). See also JOHN L. PALMER, *Molière: His Life and Works* (1930, reprinted 1970); GUSTAVE MICHAUT (ed.), *Molière: raconté par ceux qui l'ont vu* (1932); GEORGES MONGRÉDIEN, *La Vie privée de Molière* (1950); GERTRUD MANDER, *Molière* (1973; originally published in German, 1967); and RENÉ BRAY, *Molière, homme de théâtre,* new ed. (1963, reissued 1972). Official documents have been collected in MADELEINE JURGENS and ELIZABETH MAXFIELD-MILLER, *Cent Ans de recherches sur Molière, sur sa famille et sur les comédiens de sa troupe* (1963).

Theatrical history: HENRY C. LANCASTER, *A History of French Dramatic Literature in the Seventeenth Century,* pt. 3 (1936, reprinted 1966); ANTOINE ADAM, *Historie de la littérature française au XVIIe siècle,* vol. 3 (1956); PIERRE MÉLÈSE, *Le Théâtre et le public à Paris sous Louis XIV* (1934, reprinted 1976); THEODORE VAN VREE, *Les Pamphlets et libelles littéraires contre Molière* (1933); and BURT E. and GRACE P. YOUNG (eds.), *Le Registre de La Grange,* 2 vol. (1947, reprinted 1977). On particular plays, see ANTOINE ADAM, "La Genèse des 'Précieuses ridicules,'" *Revue d'histoire de la philosophie et d'histoire générale de la civilisation,* 14–16 (January–March 1939); JACQUES ARNAVON, *Le Misanthrope de Molière* (1930, reprinted 1970), and *L'École des femmes de Molière* (1936); and RENÉ JASINKI, *Molière et le Misanthrope* (1951, reissued 1970).

General criticism: PAUL F. SAINTONGE and R.W. CHRIST, *Fifty Years of Molière Studies: A Bibliography, 1892–1941* (1942, reissued 1977); ROGER JOHNSON, EDITHA S. NEUMANN, and GUY T. TRAIL (eds.), *Molière and the Commonwealth of Letters* (1975), a study that includes Paul Saintonge's "Thirty Years of Molière Studies: A Bibliography, 1942–1971"; LAURENCE ROMERO, *Molière: Traditions in Criticism, 1900–1970* (1974); WILL G. MOORE, *Molière: A New Criticism* (1949, reprinted 1973); JACQUES GUICHARNAUD, *Molière, une aventure théâtrale. Tartuffe, Dom Juan, Le Misanthrope* (1963); HAROLD C. KNUTSON, *Molière: An Archetypal Approach* (1976); and NICHOLAS GRENE, *Shakespeare, Jonson, Molière: The Comic Contract* (1980), a comparative study.

Mollusks

The phylum Mollusca (mollusks) is one of the most numerous groups in the animal kingdom after the insects and vertebrates. Each class includes an ecologically and structurally immense variety of forms (Figure 1): the shell-less Caudofoveata; the narrow-footed gliders (Solenogastres); the serially valved chitons (Placophora or Polyplacophora); the cap-shaped neopilinids (Tryblidia); the limpets, snails, and slugs (Gastropoda); the clams, mussels, scallops, oysters, and cockles (Bivalvia); the tubiform to barrel-shaped tusk shells (Scaphopoda); and the nautiluses, cuttlefishes, squids, and octopuses (Cephalopoda).

In this article the biology and classification of mollusks are first considered in general terms; more detailed information on the three major classes (Gastropoda, Bivalvia, and Cephalopoda) follows.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 313, and the *Index*.

MOLLUSKS: THE PHYLUM MOLLUSCA

GENERAL FEATURES

Size range and diversity of structure. The range in size and structure is an adaptation to the environment. Typical molluscan features may be altered, or even lost, depending on the subgroup. Among the cephalopods the giant squids (*Architeuthis*), the largest living invertebrates, attain a body length of eight metres (more than 26 feet); with the tentacle arms extended, the total length reaches to 22 metres. Other cephalopods exceed a length of one metre. Many of the remaining molluscan classes show a large variation in size: among bivalves the giant clam (*Tridacna*) ranges up to 135 centimetres (four feet) and the pen shell (*Pinna*) from 40 to 80 centimetres; among gastropods the sea hares (*Aplysia*) grow from 40 to 100 centimetres and the Australian trumpet, or baler (*Syrinx*), up to 60 centimetres; among placophores the gumshoe, or gumboot chiton (*Cryptochiton*), achieves a length up to 30 to 43 centimetres; and, among solenogasters, *Epimenia* reaches a length of 15 to 30 centimetres. Finally, gastropods of the family Entoconchidae, which are parasitic in echinoderm sea cucumbers, may reach a size of almost 1.3 metres. In contrast, there are minute members, less than one millimetre (0.04 inch) in size, among the solenogasters and gastropods.

Adaptations

Distribution and abundance. The mollusks have adapted to all habitats except air. Although basically marine, bivalves and gastropods include freshwater species. Gastropods have also adapted to land, where the almost 17,500 species occupy most existing niches. Found on rocky, sandy, and muddy bottoms or substrates, mollusks burrow, become cemented to the surface, or are free-swimming.

Mollusks are of worldwide distribution, but there is a preponderance of some groups in certain areas of the world. The close association of many molluscan groups with their food source—whether by direct dependence on a specific food supply (*e.g.*, plant-eating, or herbivores) or by involvement in food chains—limits their geographic distribution; for example, bivalves of the family Teredinidae (shipworms) are associated with driftwood. In general, cold-water regions support fewer species.

Importance to humans. Mollusks are of general importance within food chains and as members of ecosystems. Certain species are of direct or indirect commercial and even medical importance to humans. Most bivalves contribute to the organic turnover in the intertidal (littoral) zones of marine and fresh water because, as filter feeders, they filter up to 40 litres (10 gallons) of water per hour. This filtering activity, however, may also seriously interfere with the various populations of invertebrate larvae (plankton) found suspended and free-swimming in the water.

Conchifera (a subphylum including the tryblids, gastropods, scaphopods, bivalves, and cephalopods) are a source of food for many cultures and therefore play an important role in the fishing industries of many countries. Conchifera also are used in the fabrication of ornaments and in pearl and mother-of-pearl industries.

NATURAL HISTORY

Reproduction and life cycles. Mollusks are primarily of separate sexes, and the reproductive organs (gonads) are simple. Reproduction via an unfertilized gamete (parthenogenesis) is also found among gastropods of the subclass Prosobranchia. Most reproduction is by sexual means: eggs and sperm are released into the water, where fertilization takes place; in prosobranch gastropods, water currents may cause a simple internal fertilization within the mantle cavity. Both male and female reproductive organs may be present in one individual (hermaphroditism) in some classes, and various groups exhibit different adaptations to this body form. For example, in bivalves and prosobranch gastropods, male and female gonads are functional at separate times and in rhythmic and consecutive patterns (successive hermaphroditism). Conversely, male and female gonads are functional at the same time

Methods of reproduction

(simultaneous hermaphroditism) in solenogasters and the gastropod subclass Euthyneura.

Fertilization by transfer of capsules containing sperm (spermatophores) typically occurs in cephalopods and some gastropods. In cephalopods, transfer of spermatophores is usually combined with copulation by a modified arm, or hectocotylus. Copulation in solenogasters, often by means of a special genital cone, may be supported by copulatory stylets. Various penis formations, in part with copulatory stylets, or darts, are widely found in gastropods.

Eggs are laid singly, in heaps, or as spawn, generally on some hard surface and often within capsules. Squids of the suborder Oegopsida and some gastropods have eggs that are suspended in the water. Fertilized eggs commonly undergo spiral cleavage. The eggs of cephalopods, on the other hand, possess a large amount of yolk, which displaces the dividing cells and causes a characteristic type of development.

Larvae (Figure 2) are originally free-swimming and lecithotrophic. The resulting larva in primitive forms is a pericalymma (test cell) larva in which the embryo is protected below a covering (test) of cells provided with one to four girdles of cilia, at the apex of which is a sensory plate of ciliated cells. After the developing juvenile has grown out apically of the test (which then is lost), the animal settles and develops into an adult. The test in other lecithotrophic larvae is restricted to a preoral girdle of ciliated cells (the prototrochus) and is called the pseudotrochophore larva. In more advanced mollusks the pseudotrochophore larva develops into a veliger larva (in marine gastropods) or into a rotiger larva (in bivalves). In these planktotrophic larvae, the girdle of ciliated cells widens to form a velum that entraps food. As the larva continues to develop, the shell, mantle cavity, and foot begin to appear; in case of planktotrophy, a characteristic larval shell interconnects the embryonic and adult shells. After a specific amount of time, the larva metamorphoses into an adult.

Development

Secondary (newly evolved) larvae are developed among freshwater bivalves and in some cephalopods. Maternal protection of the developing eggs (brood) is not unexceptional behaviour in solenogasters, bivalves, and certain gastropod adults. Direct development without a larval stage or the bearing of live young from a yolky egg, or both, are typical in cephalopods and most nonmarine gastropods. Many species go through two breeding seasons per year, whereas in cephalopods mating or egg laying appears to be rapidly followed by death effected by hormones.

Habitats, feeding habits, and associations. Caudofoveates burrow in muddy sediments at depths of 10 to more than 7,000 metres (33 to 23,000 feet) and consume microorganisms and loose organic material (detritus). In contrast, solenogasters prey on some members of the class Cnidaria (*e.g.,* hydroids and corals) in five to 6,850 metres of water, on clay or muddy sand, or directly upon hydroid or coral colonies. Placophores cling to hard bottoms of the intertidal zone, scraping algae from the rock surfaces by using their strong rasping teeth (radula); several members of the placophore family Lepidopleuridae

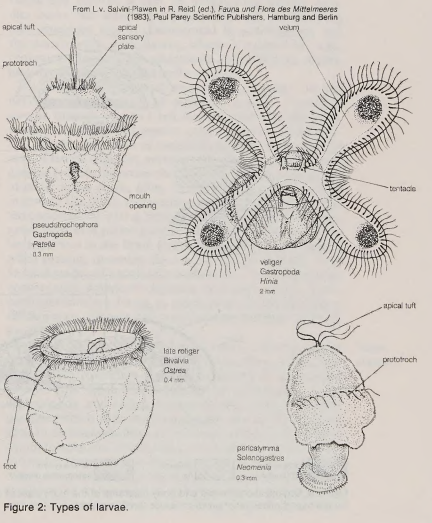

Figure 2: Types of larvae.

consume detritus found at depths down to 7,000 metres, and Hanleyidae as well as Hopaliidae even depend on animal food. The few extant members of the class Tryblidia inhabit secondary hard bottoms at depths of 175 to 6,500 metres and capture detritus by means of head appendages (velum) around the mouth. The scaphopods dwell in sand or sandy mud down to 7,000 metres and nourish themselves on protozoa, crustaceans, or small mollusks captured by the filamentous head tentacles (captacula). Except for the carnivorous septibranch anomalodermata, all bivalves are ciliary suspension feeders, using food-sorting organs near the mouth (labial palps) and respiratory gills modified to assist in feeding (ctenidia). Found in marine and fresh water, bivalves burrow into sediments to depths of 10,700 metres or attach themselves to hard surfaces by means of tough threads secreted by the byssus gland in the foot. Cephalopods are generally carnivores, feeding on crustaceans and fishes, but some have adapted a microvorous diet of detritus and microscopic organisms and plants. Some cephalopods are offshore (pelagic) jet swimmers, moving from the surface to depths of 5,400 metres, while others dwell near the bottom (benthic) at depths of 8,100 metres.

Gastropod diversity

The greatest ecological diversity is shown by the gastropods. The marine members are found from the springtide line to deep-sea trenches (10,500 metres deep) and inhabit nearly all possible substrata, even floating weeds. Both shelled and naked gastropods have pelagic members; others penetrate marine hot vents or interstices between sand grains. Some gastropods are parasitic, while others are predatory. Freshwater snails also are found in groundwaters and may inhabit hot springs. Widely distributed throughout all terrestrial habitats, various members of the gastropod order Stylommatophora are adapted to certain regions.

Some littoral bivalves, such as *Tridacna*, as well as some sea slugs, such as *Aeolidia*, share an obligatory symbiosis with zooxanthellae (a group of algae). Another metabolic association exists between certain bacteria and several bivalves and gastropods of deep-sea hot vents or other sulfide systems. There are several parasitic mollusks.

Locomotion. Mollusks have a wide range of locomotory patterns. Solenogasters and various smaller gastropods glide upon cilia that beat rapidly against a pathway of mucus secretions. This pattern of movement is supported or replaced in larger mollusks by the propulsive waves that run along the surface of the foot and are initiated by the actions of the dorsoventral musculature (Figure 3). Burrowing occurs as an interaction between musculature and the hydrostatic skeleton (see below *Internal features*);

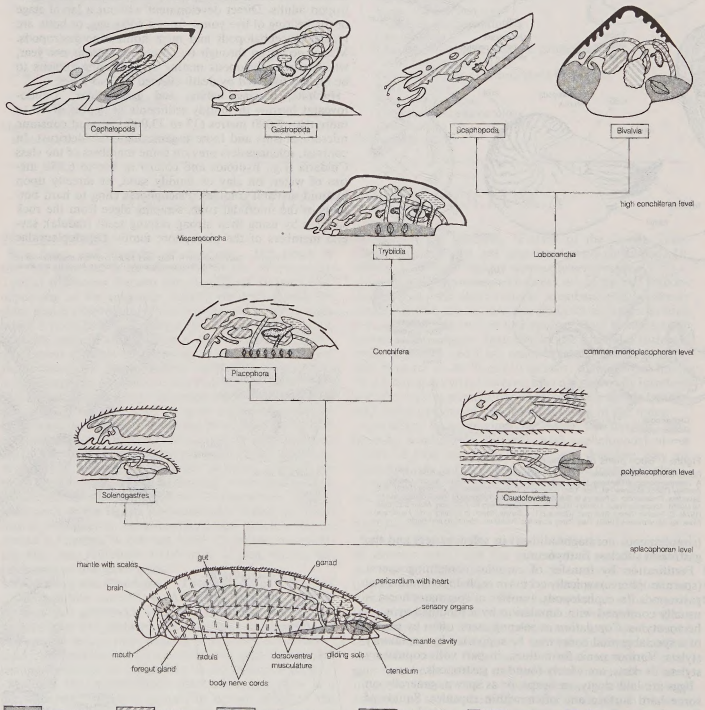

Figure 3: Organizational levels and body diagrams of the eight classes of mollusks evolved from a hypothetical generalized ancestor (archi-mollusk).

it is performed in caudofoveates and several sea slugs by the whole anterior body but is restricted to the foot in scaphopods, bivalves, and some specialized gastropods.

Various bivalves (*e.g.,* cockles) and snails may perform rapid twists or jumps through violent flexion of the foot. Buoyancy floating and jet propulsion are found in cephalopods; floating is also known in gastropods, and swimming of a different kind is practiced in gastropods of the subclass Opisthobranchia as well as in scallops and related bivalves. Octopods use their arms to crawl or even to swim or float with the help of the body skin interconnecting the arms (interbrachiate web). Some bivalve groups bore into hard surfaces by secreting strong chemicals that dissolve the substrate or by drilling, using the shell and radula. A sedentary (sessile) way of life has been adopted by many bivalves and some wormlike internal parasites of gastropods.

Features of defense. The external cover that extends over the mantle may consist of a hardened epithelial layer called a cuticle, separate calcareous plates, or a shell. The mantle cover is one of the most important protective devices, the key characteristics of which were already present at the beginning of molluscan evolution. Another defense includes the ability of most solenogasters and chitons to roll the body up. Chitons, neopilinids, and limpets can adhere firmly to the substrate by a powerful suction pad foot. Protection is also afforded if the animal is able to withdraw into its shell; a snail has the added advantage of having a hardened plate (operculum) on the foot that covers the shell opening (auricle) once the animal has withdrawn. Burrowing by caudofoveates, scaphopods, many bivalves, and some gastropods is a protective behaviour when used to escape predators.

Chemicals, poisons, and camouflage

In many gastropods, slippery mucus is secreted from mantle extensions, or parapodia, as a defense against larger predators, such as the echinoderm starfish. In scaphopods, mucus is secreted against an aggressor from the anterior mantle. Certain molluscan subgroups secrete noxious chemicals either as a poisonous secretion of the salivary glands or as distasteful acids in mantle cells. Glandular secretions by solenogasters or the gastropod superfamily Eolidacea prevent the stinging nettle capsules (nematocysts) of cnidarians, when consumed, from expulsing the stingers; moreover, the gastropods are able to store and then use the capsules when attacked by a predator. Some mollusks secrete fluids to divert or frighten a predator, to provide camouflage, or to inhibit the predator's sense of smell. For example, the ink in cephalopods, the luminous cloud secreted by some deep-sea squids, and the purple fluid from the sea hare (*Aplysia:* a gastropod of the subclass Opisthobranchia) distract and confuse the predator and conceal the prey. Camouflage or frightening coloration are effective in protecting cuttlefishes, octopuses, and sea slugs, as well as other gastropods.

FORM AND FUNCTION

The highly varied evolutionary development of basic molluscan features has left only a few characters that may be taken as typical. As a result, molluscan form varies much among levels and subgroups (Figure 3).

External features. The most obvious external molluscan features are the dorsal epidermis called the mantle (or pallium), the foot, the head (except in bivalves), and the mantle cavity. The mantle in caudofoveates and solenogasters is covered by cuticle that contains scales or minute, spinelike, hard bodies (spicules), or both (aplacophoran level). The placophores develop a series of eight plates or valves still surrounded by a girdle of cuticle with spicules; in all other mollusks (the Conchifera), the mantle secretes an initially homogeneous shell (monoplacophoran level). The mantle and shell are laterally compressed in scaphopods and bivalves; in gastropods and cephalopods the head is free of the mantle and shell. In bivalves a dorsal hinge ligament joins two valves, which are further held together by two adductor muscles with attachment points on the inner aspect of each valve.

The body

The body of the mollusk, containing all the visceral elements, such as the alimentary tract, gonads, and heart, is connected to the mantle by dorsoventral musculature. The head, when present, has tentacles called captacula in scaphopods, labial palps in bivalves, head tentacles in gastropods, and arms in cephalopods. The primitive ciliary gliding surface with forward pedal and sole glands is reduced in caudofoveats and some gastropods, as well as in some bivalves, and it is narrowed to a ridged tract in solenogasters as well as some members of the placophore genus *Cryptoplax.* The foot forms an anteriorly elongated and slendered burrowing organ in scaphopods, is ax-shaped to vermiform in bivalves, and is modified to a siphon or funnel in cephalopods. Among gastropods of the subclass opisthobranchia the foot may be extended laterally to form swimming lobes (parapodia).

The mantle, or pallial, cavity is found between the mantle rim and the body. The pallial complex is a collection of structures at the roof of the mantle cavity and typically contains at least one pair of lamellate gills (ctenidia), a thick layer of glandular epithelium called mucus tracts or hypobranchial glands, and the outlets for the digestive, excretory, and reproductive systems. A loss of the ctenidia (along with the mucus tracts) is seen in scaphopods, advanced gastropods, septibranch bivalves, and solenogasters. Placophores, tryblids, nautilid cephalopods, and some gastropods have a multiple number of ctenidia.

Internal features. *Muscles and tissues.* The internal molluscan organization is almost entirely soft-bodied. The body cavity is filled with fibrous tissue or fluid-filled spaces (hemocoel), or both. The tissues, hemocoel, and body wall act as a hydrostatic skeleton for shape and support; when filled with fluid, the hemocoel expands against the body wall and fibrous tissues, providing a rigid framework. This same framework provides a structure against which the animal can exert internal pressure when protruding the foot from the shell during burrowing. Conversely, extrusion of the head and foot from the shell in the supraclass Visceroconcha (gastropods and cephalopods), shell elevation in gastropods, and the rapid expansion and contraction of the mantle required for jet propulsion in cephalopods of the subclass Coleoidea are the result of a more complicated system carried out by the antagonistic actions of muscles working in opposition to other muscles.

Hydrostatic skeleton

The basic sets of muscle systems, fully retained only in solenogasters, include the subintegumental musculature below the mantle; a pair of longitudinal muscle bundles below the mantle margins, which roll the body up and which are almost disintegrated in conchiferans; and the dorsoventral musculature, which is reduced in caudofoveates and shell-less gastropods and which in shelled gastropods forms the columellar muscles.

The nervous system and organs of sensation. In the nervous system typical of mollusks, a pair of cerebral ganglia (masses of nerve cell bodies) innervate the head, mouth, and associated sense organs. From the dorsal cerebral ganglia, two pairs of longitudinal nerve cords arise: a pair of lateral (pleural) nerve cords, often forming pleural ganglia (which innervate the mantle), and a ventral pair of pedal nerve cords, often forming pedal ganglia (which innervate the foot). In primitive forms both cords are interconnected by lateral branches of nerve fibres. A buccal nerve loop with paired ganglia generally supplies the radular apparatus in the head. Posterior paired visceral ganglia, when present, innervate the viscera. Other mollusks have various grades of ganglia formations, all of which may be concentrated anteriorly. Because of torsion, special nerve configurations are found in gastropods; in cephalopods a cartilaginous capsule encloses the concentrated mass of ganglia.

Sense organs

Supplied by the most posterior aspect of the lateral nerve cords, a paired chemoreceptive sense organ (the osphradium) monitors the water currents of the mantle cavity. This organ has regressed in scaphopods, some cephalopods, and higher gastropods. Pluricellular mantle papillae, which penetrate the cuticle, the valves, and the shell in some conchifers, are differentiated in placophores as photoreceptors. Aside from the cerebral eyes in Visceroconcha, there are photoreceptors on the mantle margins of autobranch bivalves. Orientation in different gastropods is evidenced by reaction to polarized light, which in part serves for homing. Homing in other gastropods and in the

placophores that flee from light appears to be performed by chemoreception along their mucus trails.

The digestive system. The primitive alimentary tract is straight, and the foregut contains glands and chitinized teeth, called the radula, upon a tough membrane or ribbon underlain by a mass of compact tissue as a support and operated by musculature. In bivalves and some other mollusks the whole radular apparatus is reduced. The radula is used to bite, tear, and scrape various food materials. The different structural aspects of the radula in caudofoveates, solenogasters, and gastropods serve in classification. The differentiation of a more flexible radular structure, called the flexoglossate type, among the primitive subclass Archaeogastropoda subsequently enabled successful radiation into diverse habitats. Jaw formation is characteristic for conchifers.

The midgut and digestion

The midgut in caudofoveates divides into a hindgut and a large ventral sac for enzyme production. In contrast, the midgut in placophores and conchifers is subdivided into a slender esophagus with a pair of glandular pouches, a distinct stomach with a pair of digestive glands, and a slender, often looped intestine. In primitive conchifers the stomach is of the so-called style sac type. The esophagus opens into an anterior elaboration of the stomach into which the enzymes from the style sac, an area separated by ridges, also are released; the tapered end of the stomach leads to the intestine. Cilia that line the style sac churn the stomach contents and form a long food-laden mucous mass called a protostyle, which abuts a chitinous area of epithelium in the stomach. Usually found within the style sac is a rod, called the crystalline style. The protostyle or the crystalline style are fully retained in the bivalves and gastropods that subsist on small microorganisms and detritus. The protostyle or crystalline style may vary in form among the bivalves. Digestion in primitive forms appears to have been both intracellular and extracellular, such as is still the case in solenogasters, many bivalves, and most gastropods. In advanced levels either intracellular or extracellular digestion appears to be exclusively elaborated—*e.g.*, advanced crystalline style and intracellular.

Open circulatory system

The circulatory system. Mollusks possess an open circulatory system in which body fluid (hemolymph) is transported largely within sinuses devoid of distinct epithelial walls. The posteriodorsal heart enclosed in a pericardium typically consists of a ventricle and two posterior auricles. Hemolymph is drained from ctenidia, gills, or other specialized respiratory epithelia into the respective auricles. The ventricle pumps the hemolymph through a middorsal sinus (in solenogasters and scaphopods) or vessel (aorta) into the body tissues. Hemolymph drains from the tissues into the gills, whence it returns to the auricles.

The respiratory pigment is commonly dissolved in the fluid, either as hemoglobin (as is especially the case in bivalves) or more generally as hemocyanin; in more-advanced forms, hemoglobin is bound to blood cells. In placophores and conchifers (but not in the caudofoveates and the solenogasters) the heart is also the site of the purifying ultrafiltration, and the waste products are then discharged into the pericardium and via a pair of pericardial outlets modified to excretory organs (emunctoria, such as false kidneys or nephridia).

The reproductive system. In adult cephalopods and some other representatives the paired dorsal gonad retains the developmental connection with the pericardium. In caudofoveates and solenogasters, eggs or sperm are discharged into the pericardial cavity, and from there the pericardial outlets transport them to the environment, where fertilization takes place. In more-advanced mollusks there are usually separate ducts to transport the gametes (gonoducts): a pair of gonoducts, called oviducts for the female gametes and spermiducts, or vasa deferentia, for the male gametes, leads the egg and sperm, respectively, to the mantle cavity. Glands to secrete protective coatings around the egg may be present. In gastropods the left gonad is reduced, and after torsion only the right gonad is operational, leaving the internal body asymmetrical; similar asymmetries also may be found in other molluscan subgroups.

Hormones

The endocrine system. Hormone production is not well documented in mollusks other than gastropods and cephalopods. Antagonistic neurohormonal control of reproductive activity and metabolic processes is performed in the gastropods through cerebral dorsal bodies and lateral lobes or juxtaposed organs and in the cephalopods through optic glands. In cephalopods, the hormones also effect death by starvation after the mollusk has deposited its eggs or has mated. Neurosecretions by cells outside the nerve cell bodies (ganglia) have been described in gastropods and cephalopods, the released hormones diffusing through the tissues rather than being concentrated in special organs.

Heart rate in mollusks plays a crucial role in many metabolic processes, including excretion; hormones that affect the heart are released from the wall of veins in cephalopods or, in gastropods, from the subesophageal ganglia, the junction between the auricles and the ventricle. Insulin-like hormones shed from gastropods and bivalves by certain midgut cells control the amount of glucogen (a storage form of sugar) kept as a reserve nutrient.

EVOLUTION AND PALEONTOLOGY

There are no known fossil records of caudofoveates and solenogasters. Both placophores and conchifers date from the earliest Cambrian time (some 570 to 550 million years ago). These records exclude the scaphopods and cephalopods but include the extinct Merismoconchia, Helcionellida, and Rostroconchia. Most of these fossils represent fairly small organisms of about one to five millimetres (0.04 to 0.2 inch), which metabolically parallel the primitive lecithotrophic, rather than planktotrophic, larval development. The oldest known cephalopods are of the Late Cambrian epoch (which ended some 505 million years ago) and subsequently had a remarkable radiation, including the dominant Ammonites (predominantly spirally coiled cephalopods with complicated sutures between chambers and shell—some 10,000 fossil forms—until the Cretaceous (about 100 million years ago). Extinct bivalves (about 15,000 forms) exceed in number the recent fauna. Scaphopods have not been recorded before the Middle Ordovician (some 450 million years ago).

The fossil record gives little clue as to how the mollusks originated and how the eight classes differentiated in Precambrian times. The evolutionary pathway must thus be largely inferred from comparative anatomy and development. The common archimolluscan base, in spite of the large number of fossils of the ancestors of gastropods and bivalves, was probably of shell-less (aplacophoran) organization; that in turn appears to have been differentiated from some flatwormlike organization that adapted the mantle cover rather than from a coelomate segmented construction. Most obvious is the subsequent elaboration of the mantle cover defining the aplacophoran, the placophoran, and (by fusion) the conchiferan (monoplacophoran) level of organization. The realization that the organization of the mantle and mantle cavity in caudofoveates and solenogasters reflects two separate evolutionary lines also discloses conservative molluscan characters. The solenogasters appear to be linked by developmental characters with the placophores; they have retained, however, the most primitive alimentary tract (in that the radular membrane is poorly elaborated, and no midgut gland is separated). The latter was reorganized at the placophore level and overtaken in the conchifers. The subradular organ, the arrangement of the dorsoventral musculature, the three-layered shell structure with enclosed mantle papillae, and the excretory system also demonstrate the placophore heritage in the tryblids, which are the more primitive of the conchifera. Subsequently this radiated into two branches called subclades: the supraclass Loboconcha (or Diasoma), including the suspension-feeding bivalves, and the infaunal scaphopods, sharing a common ancestor in the fossil class Rostroconchia. These groups have a mantle with the shell enlarged in width to envelop the soft body as well as an anterior elongated foot to live on the bottoms of mobile particles (sand, mud). In contrast, a free head with cerebral eyes is set off from the mantle and shell in the supraclass Visceroconcha, including the gastropods and the cephalopods; both share a posterior mantle cavity,

lateral (or pleural) nerve cords medial to the dorsoventral musculature, and an antagonistic muscle system (see above *Internal features: Muscles and tissues*). The relation of the fossil order Bellerophontacea is controversial.

CLASSIFICATION

This classification is a consensus of recent views mainly of Luitfried v. Salvini-Plawen and Gerhard Haszprunar, generally based on those of Kenneth J. Boss.

Annotated classification.

PHYLUM MOLLUSCA

Unsegmented, soft-bodied metazoans with mantle (or pallium) covered by cuticular or calcareous secretions, or both; ventral body with head region; and ciliar to muscular locomotion organ; lamellate gills (ctenidia); paired chemoreceptive sense organ (osphridia); nervous system tetraneurous with cerebral ganglia, buccal loop, and 2 pairs of longitudinal body cords, though often concentrated; pronounced dorsoventral musculature; pharyngeal teeth (radula); hemocoelic body cavity with coelomatic pericardium and gonosacs; originally the sexes are separate; development includes spiral cleavage and a primitively lecithotrophic trochus larva; about 50,000 marine, limnic, and terrestrial species.

Class Caudofoveata (Aplacophora partim, or **Chaetodermatida;** mudmoles)

Worm-shaped; covered by cuticle and aragonitic scales; ventral gliding area reduced; mantle cavity terminal with 1 pair of ctenidia; midgut with ventrally separated sac; adapted to burrowing habits in mud; marine in 10–7,000 m; 2 mm to 14 cm; about 100 species in 3 families.

Class Solenogastres (Aplacophora partim, **Ventroplicida,** or **Neomeniidea;** narrow-footed gliders)

Narrowed body and gliding sole (foot); mantle with cuticle and aragonitic scales or spicules, or both; mantle cavity modified; no true ctenidia; radular membrane rudimentary; midgut straight without separate glands; hermaphroditic; epibenthic predators of or epizoic on Cnidaria; marine in 5–6,850 m; 0.8 mm to 30 cm; about 200 species in 4 orders.

Class Placophora (Polyplacophora or **Loricata;** chitons)

Generally flattened body and broad foot; mantle covered with cuticle and spicules; 8 middorsal serial shell plates (valves) enclosing photoreceptive papillae (aesthetes); mantle cavity peripedal with multiple pairs of ctenidia; marine; mainly algae-scraping on hard bottoms in 0–7,000 m; 3 mm to 43 cm; about 600 species in 3 orders.

Class Tryblidia (Monoplacophora or **Galeroconcha** partim; neopilinids)

Cap-shaped shell; head with 2 pairs of appendages; mantle cavity peripedal with 5–6 pairs of modified ctenidia; 5–6 pairs of excretory organs; 2 pairs of heart auricles and gonads; marine detritus feeders in 175–6,500 m; 1.5 to 37 mm; 12–15 species in 1 family.

Class Bivalvia (Pelecypoda, Acephala, or **Lamellibranchiata;** clams, mussels, oysters, scallops, and cockles)

Laterally compressed body; 2 middorsally hinged valves; posterior mantle often extended to form siphons; head with labial palps, foot ax-shaped to vermiform; peripedal mantle cavity with 1 pair of ctenidia mostly modified to large plates of lamellae; buccal mass (jaws and radula) reduced; predominantly ciliary suspension feeders burrowing in soft sediments or attached by byssus gland of foot on hard substrata in 0–10,700 m; 1 mm to 1.35 m; 3 subclasses: Ctenidiobranchia (Nuculida), Palaeobranchia (Solemyida), Autobranchia (lamellibranch and septibranch bivalves); about 6,000 marine and 2,000 limnic species.

Class Scaphopoda (Solenoconcha; tusk shells)

Midventrally fused mantle and tubiform to barrel-shaped shell; head with tubular snout and 2 bunches of slender tentacles (captacula); foot pointed and cylindrical; no ctenidia and distinct blood vessels; no heart auricles; radula strong; microcarnivores; marine burrowers in soft sediments, in 0–7,000 m; 2 to 150 mm; about 350 species in 2 orders.

Class Gastropoda (limpets, snails, and slugs)

Mantle cavity undergoes torsion and often secondarily "detorsion"; shell mostly coiled with operculum; head free with paired eyes; left reproductive organs reduced; immense ecological and structural variability; 0.3 mm to more than 1 m; about 40,000 marine, limnic, and terrestrial species.

Subclass Streptoneura

Mostly marine limpets or operculate snails; 3 ganglia at visceral loop; orders include Archaeogastropoda (long cerebropleural connectives) and Apogastropoda (bifurcate tentacle nerves, 2 pedal commissures).

Subclass Euthyneura

Marine, limnic, or terrestrial snails and slugs without operculum; visceral loop with additional parietal ganglia; hermaphroditic; supraorders include Opisthobranchia (marine with Hancock's organs or derivates) and Aeropneusta (mostly limnic and terrestrial with procerebrum/cerebral glands) with orders Gymnomorpha and Pulmonata.

Class Cephalopoda (Siphonopoda; nautiluses, cuttlefishes, squids, and octopuses)

Dorsoventrally elongated body; shell straight, coiled, or almost highly regressive, originally chambered and piercing by a siphuncular tube; head free with paired eyes and 1 or 2 circles of 8–10, or about 90, tentacles (perioral arms); foot modified as a funnel for jet locomotion; mantle cavity restricted to posterior body with 2 ctenidia; alimentary tract with strong jaws and predominantly with a rectal ink sac; nervous system extremely concentrated; about 600 recent species (some 10,000 fossil forms) of 1 cm to 8 m (+14 m arms) in size; basically pelagic marine carnivores from the surface to 5,400 m depth or benthic to 8,100 m; 4 subclasses are Palcephalopoda (Orthoceroida; fossils); Nautiloida (fossil groups and 3–5 recent species); Ammonoida (fossils); and Coleoida (fossils and 4 recent orders).

Critical appraisal. The long-standing classification of Caudofoveata and Solenogastres within one class (Aplacophora) is not tenable. The configuration of the mantle cavity in each group clearly contradicts the derivation of one from the other, and neither possesses a single commonly derived character that would demonstrate closer relationship other than in an archimolluscan ancestry. A similar condition refers to the bivalve subclasses Ctenidiobranchia and Archaeobranchia, often united below one single taxon (Protobranchia).

The term Amphineura, formerly comprising the Polyplacophora (placophores) and Aplacophora (caudofoveates and solenogasters) within one subphylum (side by side with the subphylum Conchifera), is misleading and out-of-date; it may be replaced by the more appropriate term Aculifera.

The term Monoplacophora is not used here because evolutionarily it equalizes the conchiferan level (in contrast to the polyplacophore and aplacophore levels), and classificatorily it is a junior synonym of Tryblidiacea. Moreover, as is the taxon Galeroconcha, it is in part also taken to include several fossil groups (*e.g.,* Bellerophontacea) of still uncertain relationships.

The familiar three divisions of the Gastropoda into Prosobranchia, Opisthobranchia, and Pulmonata is no more satisfying and, according to the nervous system, is generally replaced by Streptonra and Euthyneura.

The popular term Cephalopoda ("head-footed" mollusks) is a misnomer scientifically since the innervation evidences the siphon, or funnel, with its pedal–funnel gland (rather than the perioral arms) as the equivalent of the foot. Siphonopoda is often preferred. (L.v.S.-P.)

MAJOR MOLLUSK GROUPS

Gastropods (snails and slugs)

Gastropod, which means "belly-footed," refers to the broad tapered foot on which these animals glide. The class comprises the snails, which have a shell into which the animal can withdraw, and the slugs—snails whose shells have been reduced to an internal fragment or completely lost in the course of evolution. Gastropods are among the few groups of animals to have successfully radiated in the ocean, fresh waters, and on land. Because of the challenges presented by these diverse habitats, gastropods are very difficult to characterize. A few are used as food, a very few transmit animal diseases (only a fraction of these have been found to carry the agents of human and animal disease), and the shells of some are used as ornaments or in making jewelry. The main role of gastropods is as scavengers, feeding on dead plant or animal matter, or as predators.

GENERAL FEATURES

Size range and diversity of structure. Some adult marine snails (*Homalogyra*) and forest-litter snails (*Stenopylis, Punctum*) are less than one millimetre (0.04 inch) in diameter. At the other extreme, the largest land snail, the African *Achatina achatina,* is almost 20 centimetres (eight inches) long. The largest freshwater snails, *Pomacea* from South America, reach nearly 10 centimetres in diameter, and the largest marine snail, the Australian *Syrinx aruanus,* occasionally grows to more than 0.6 metre (two feet). The longest snail probably is *Parenteroxenos doglieli,* which lives as a parasite in the body cavity of a sea cucumber; it grows to be almost 130 centimetres (50 inches) in length, although it is only 0.5 centimetre (0.2 inch) in diameter. Most snails are much smaller, and probably 90 percent of all adult snails are less than one inch in maximum dimension.

Variations in shape

Snails show a tremendous variety of shapes, based primarily upon the logarithmic spiral (Figure 4). They can be coiled flatly in one plane, as in *Planorbis;* become globose with the whorls increasing rapidly in size, as in *Pomacea;* have the whorls become elongate and rapidly larger, as in *Conus* and *Scaphella;* have a few flatly coiled whorls that massively increase in width, as in *Haliotis;* become elongated spike-shaped, as in *Turritella;* or adopt a limpet shape, as in *Fissurella.* Often a number of such shapes can be found within a single family, but such marine families as the Terebridae, Conidae, and Cypraeidae are conservative in shape.

Traditionally, the three main gastropod groups are the prosobranchs, the opisthobranchs, and the pulmonates. The prosobranchs generally secrete a massive shell into which the animal can withdraw. The operculum, an often calcified disk situated on the rear part of the foot, fills the shell aperture when the snail is inside the shell, protecting the animal against predation and dessication. The body structure shows relatively minor variations. The opisthobranchs are marine species that often have a reduced or absent shell and very colourful bodies. The pulmonates are snails and slugs that lack an operculum but show complex and highly varied body structures. They have a "lung" or pulmonary cavity that serves also as a water reservoir. It long has been recognized that these groups probably represent similar morphology derived independently several times in the more than 400 million years since the origin of the gastropods.

Distribution and abundance. Of the probable 65,000 species, 30,000 are marine, 5,000 live in fresh water, and 30,000 live on land. In general, oceanic gastropods are most diverse in number of species and in structure in tropical areas; several hundred species (most of which are comparatively rare) can be found in a complex coral reef habitat. This is in contrast with Arctic or subarctic coasts, where the few species that are present are common. A

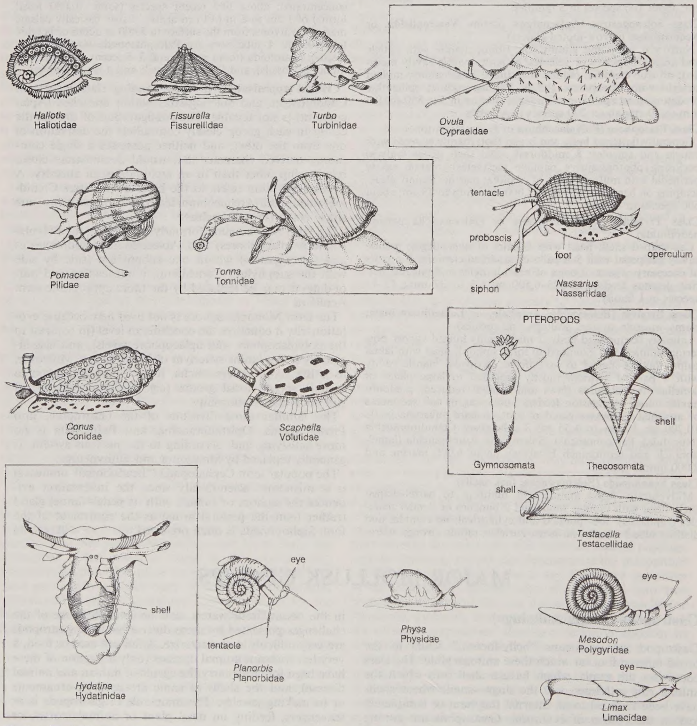

Figure 4: Diversity among gastropods.

number of deep-sea species are known, and a significant snail fauna is associated with hydrothermal vents. Most marine species have relatively large ranges.

Freshwater snails are common in ponds, streams, marshes, and lakes. Usually only a few species are found at one place, but each species will have a rather wide range. Most species are common and feed on algae or dead plant matter. In a few relatively old river systems and lakes—in particular, Baikal in Siberia, Titicaca in South America, Ohrid in Macedonia, the Mekong basin in Southeast Asia, and the African Rift lakes—extensive and complex radiations of snails have occurred in comparatively recent geologic time, producing a large number of species.

Adaptations to terrestrial life

Land snails are marginally, but very successfully, terrestrial. When actively moving, they continuously lose water. During periods when water is unavailable, they retreat into their shells and remain inactive until conditions improve. They hibernate during winter periods, when water is locked into snow or ice, and estivate during periods of summer drought. Land snails have been found above the snow line; species of *Vitrina* crawl on snowbanks in Alpine meadows. Other species inhabit barren deserts where they must remain inactive for years between rains.

Only in such favourable areas as New Zealand, Jamaica, northeastern India, and the wet forests of Queensland (Australia) 30 to 40 different species can be found together; in some parts of western Europe 20 species can be found together, while in most of North America fewer than 10 species live together. In many desert regions, only one or two species are found, and they have significant feeding specializations.

The actual local abundance of snails and slugs can be spectacular. Millions of some brackish-water and freshwater species can live on small mud flats. An acre of British farmland may hold 250,000 slugs, and a Panamanian montane forest was estimated to have 7,500,000 land snails per acre. Despite this abundance, snails and slugs often pass unobserved. Land and freshwater species often stay hidden during the day and are active at night. Most marine species as well are nocturnal, and the shells of many of these species are so heavily covered with algae and other encrusting organisms that they may be mistaken for bits of rock.

Importance to humans. From earliest times, humans have used many species of snails as food. Periwinkles (*Littorina*) in Europe and South Africa, queen conchs (*Strombus gigas*) in the West Indies, abalones (*Haliotis*) in California and Japan, and turban shells (*Turbo*) in the Pacific are the most frequently eaten marine snails. Occasionally limpets and whelks are used for food, but they are more commonly used as fish bait. Freshwater snails rarely are eaten. Land snails of the family Helicidae have been eaten in the Middle East and Europe since prehistoric times. Today many tons of the European edible snails *Helix aspersa* and *H. pomatia* are raised on snail farms or collected wild. Several species of *Otala* and *Eobania* from Morocco and Algeria are exported for food.

In some places, introductions of *Achatina* and *Helix* have resulted in damage to crops and gardens by these rapidly multiplying snails. California orange groves are plagued by *H. aspersa*. Many slugs accidentally introduced from Europe to both the West Coastal and the Eastern to Midwestern United States are a continual nuisance in home gardens. Freshwater snails of the family Bythinidae sometimes become so numerous that they clog the filter systems of pumping stations.

Shells of certain snails are highly prized by collectors. The operculum of some *Turbo* species is used in making earrings; cameos are cut from the shell of the Red Sea snail *Cassis rufa*. Abalone shells are used in many cultures for decorative purposes; the shell of the golden cowrie (*Cypraea aurantium*) served at one time as a badge of a chief in Fiji. Strings of shells have been used as money.

Intermediate hosts of disease organisms

More serious effects are caused by the few freshwater snails (*Pomatiopsis, Bulinus, Biomphalaria*) that serve as intermediate hosts for worms parasitic of humans. Schistosomiasis is a disease caused by minute blood flukes (schistosomes). Both snails and flukes are most common in areas where fields are irrigated. Schistosomes also parasitize birds and mammals. A skin rash called swimmer's itch results from bird schistosomes trying, only partly successfully, to penetrate human skin. They die in the upper skin layers, and their decomposition causes local infection. Other health problems are caused by several snails and slugs (*e.g., Bradybaena, Angustipes, Veronicella*) that serve as intermediate hosts for the rat lungworm. If an infected land snail or slug is accidentally chopped up in a salad and eaten, the worm can migrate to the brain and encyst, causing moderate to severe damage.

Most gastropods, however, are useful to humans in that they help decompose dead plants and animals into substances that can be used by plants to manufacture new organic compounds. In both field and forest, as in ponds, rivers, and oceans, gastropods are an important part of the decomposer community, and some are significant predators.

NATURAL HISTORY

The colonization of freshwater and terrestrial habitats by gastropods is due to the plasticity of their body and considerable alteration in both structure and function of specific organ systems. Most major groups of organisms primarily inhabit one of the three great biospheres (ocean, fresh water, or land); the gastropods are successful in all three.

Reproduction and life cycles. Gastropods originated in the oceans, and relics of this fact are preserved in the early life history of freshwater and land species. Only in the most primitive prosobranchs are the gametes released into the water for fertilization to take place outside the female. The fertilized egg hatches into a free-swimming form (trochophore larva). Upon the expansion of the ciliary girdle of the trochophore larva into large, heavily ciliated swimming lobes (vela), the larva, called a veliger, undergoes torsion, a 180° rotation of the fleshy organs from a posterior to an anterior position behind the head. Torsion is an embryological distinction of the gastropods (see Figure 5).

Torsion

From J.E. Morton. *Molluscs*. 4th ed. (1967); Hutchinson Publishing Group Ltd.

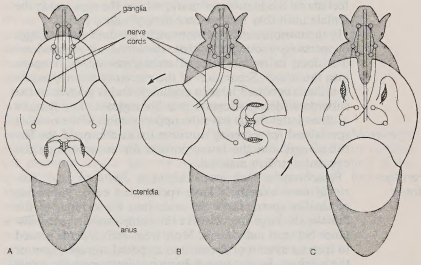

Figure 5: *Torsion.*
(A) Before torsion. (B) 90° rotation. (C) Torsion completed (180° rotation).

In some species the veliger stage may persist for a long period of larval life. The veliger has a small shell into which the velar lobes and head can be withdrawn and a larval heart that seems to exist solely to provide circulation in the velar lobes. Food consists of diatoms (an algae group) and small plankton collected by ciliary currents of the velum and channeled by the currents into the mouth. Special excretory cells located on either side of the mouth and the larval heart disappear when the veliger settles to the bottom and changes into a crawling snail. Upon settling, the snail starts a typical pattern of rapid growth until sexual maturity, at which point growth either ceases or is greatly slowed because energy is being diverted to the production of the next generation. In opisthobranchs and many pulmonates, the life span is about one year, although there are notable exceptions. Prosobranchs in general seem to have a much longer life span, with some species of the freshwater *Vivipara* having lived 20 years

Life span

in captivity. Some Sonoran Desert snails from California have been revived after eight years in estivation. Such desert species may have a life span of 20 to 50 years.

Several trends are evident in gastropod evolution from this basic pattern. First, there is a tendency toward the development of structures to permit internal fertilization. Pallial reproductive tubes of male and female become closed tubes, and a male copulatory organ develops on the right side of the head for transmission of sperm to the female. Second, the trochophore and veliger stages tend to be passed within an egg capsule provided with a food supply, rather than as free-swimming immature organisms that must find their own food. At first, provision of nutriment for the young probably involved laying eggs in a mucous mass. As evolution progressed, capsules containing yolk and with a protective cover might have been laid singly or in masses. Still later forms may have provided parental care of the eggs or egg mass. Finally the eggs are retained inside a brood pouch or the uterus until the young are ready to hatch (ovoviviparity). Third, there are tendencies toward sex reversal and the development of hermaphroditism—the presence of both male and female sex organs in one animal; nearly all opisthobranchs and pulmonates are hermaphrodites.

Such changes occurred more than once during gastropod evolution, and there is no clear pattern of changes that would suggest relationships. The differences correlate with habitat and frequently are seen within species of one genus. *Littorina,* on the English coasts, is a classic example: *L. neritoides* lives in crevices of exposed rocks above normal high water but releases floating (pelagic) egg capsules during fortnightly high tides or storms; *L. littorea,* on the lower half of the shore, also has pelagic egg capsules, which hatch six days later into veligers; *L. littoralis,* which lives on seaweeds that are rarely exposed by the tides, deposits gelatinous egg masses on the seaweeds, and the larvae pass through the veliger stage in the egg mass, emerging in two to three weeks as crawling young; and *L. saxatilis,* which extends from midtide level to several feet above the high-water mark, retains the eggs inside the female until they hatch as crawling young.

In the most primitive prosobranchs the duct carrying eggs or sperm (gonoduct) opens into the kidney or renopericardial duct; in more-advanced archaeogastropods it opens into the ureter. Separation of the excretory and reproductive ducts occurred later in evolution and is evident in the suborders Mesogastropoda and Stenoglossa. The females of these latter forms have the upper portion of the oviduct specialized for secreting nutritive material around the fertilized eggs and the lower portion for encapsulating the egg and nutritive material.

Fertilization

Prosobranchs such as *Cerithiopsis, Janthina,* and *Turritella* have extremely large sperm that carry thousands of smaller sperm from the male into the oviduct of the female; the large sperm swim the comparatively great distance between individuals. More frequently a penis is used to insert a stream of sperm into a special storage organ or the oviduct. In the opisthobranch *Limapontia* the penis stylet injects sperm through the body wall into a storage organ (bursa) of the mate.

Internal fertilization is necessary for land gastropods. The more primitive species directly transfer a stream or gelatinous mass of sperm by insertion of the penis. One individual can act as a male and the other as a female, or copulation can be reciprocal. During evolution, loosely adherent masses of sperm gave rise to enclosed packets of sperm and then to horny or calcareous sperm bundles (spermatophores) with elaborately ornamented exteriors. It is not uncommon for there to be as many as 12 such spermatophores inside the bursa of a female. Closely related species show clear differences in the number and spacing of exterior spikes. Undoubtedly, this difference provides a method of species recognition among these snails. Other pulmonates depend on explicit courtship patterns (such as the slugs from the family Limacidae) or structural differences in the penis (as in the land snails of the family Endodontidae) to distinguish close relatives.

Sex reversal

Most members of the prosobranch family Calyptraeidae begin life as fully functional males but, after a transitional phase, spend their remaining life span as females. *Crepidula* species normally attach to one spot when young and rarely move again. Other members of the species frequently attach to the shell surface of a settled individual, forming piles of as many as 19 specimens. The younger ones on top are male, the old ones on the bottom female, and those in the middle are intermediate in sex. Isolated young individuals function as males for only a week or two, but young males in a pile remain male for a longer period, through some unidentified influence of the larger females underneath. Some limpets also undergo sex reversal.

Egg production is correlated with the degree of care given the eggs or young. The extremes are the production of enormous numbers of eggs, which receive no care and hence suffer mass mortality (a fraction of 1 percent surviving), and the production of only one or two eggs, which receive intensive care. There are many gradations between the extremes. Many members of the suborders Mesogastropoda and Stenoglossa produce egg capsules that may contain from one to more than 1,000 eggs. In *Busycon,* for example, each capsule may contain up to 1,000 eggs, but extensive cannibalization occurs among the early hatched young and upon unhatched eggs in the capsule. *Strombus* can lay a tubular string of eggs 23 metres (75 feet) long, with up to 460,000 eggs. Many *Conus* cement up to 1.5 million eggs in capsules on the undersides of rocks. Opisthobranchs weave delicate ribbons of eggs in colourful sheets—sometimes up to 50 millimetres (two inches) of ribbon per hour—that contain many millions of eggs. In these cases, the eggs hatch into swimming veligers. Freshwater snails frequently deposit eggs in capsules on plant leaves or rocks, but the number of eggs is much less than in the marine gastropods.

Parental care of eggs

Direct care of the eggs is given in different ways. A small trochid, *Clanculus bertheloti,* deposits its eggs in grooves on the shell surface and covers them with a sheet of mucus to hold them in place; many *Neptunea* simply cement the egg capsules to their shell surface. Many *Crepidula* deposit a mass of 5,000 to 20,000 eggs under the shell edge just in front of the female's foot, brooding them until they hatch as veligers. Freshwater viviparids and thiarids have either uterine or neck brood pouches, in which the fertilized eggs develop to a crawling stage. The vermetid *Stephopoma* and the acmaeid *Acmaea rubella* brood their young in the mantle cavity between the fleshy body and the shell. A number of endodontid land snails on Pacific islands deposit their eggs in the umbilicus, an opening in the shell base. In one species, *Libera fratercula,* the young gnaw their way out through the apex of the maternal shell. One pteropod, *Hydromeles,* has an internal brood chamber that apparently ruptures, freeing the young into the body cavity of the parent; it is suspected that the escape of the young results in the parent's death.

Even without direct care of the eggs, land snails generally lay fewer than 200 eggs at a time. This reflects the different problems encountered on land and the lower mortality of larvae that are protected within the egg coverings. Many slugs and some snails bury egg masses in soil or under moist pieces of bark. Others, such as *Discus,* scatter their eggs singly over bark and decaying wood. One tropical genus (*Amphidromus*) rolls a leaf into a tube, seals one end with mucus, and lays its eggs in the cylinder thus formed. The South American *Strophocheilus* lays one large egg about four centimetres (1.5 inches) long. Among the many ways in which land snails minimize losses from drying is the adoption of ovoviviparity, or the hatching of eggs within the parent's body.

The evolutionary trend from the simple release of eggs and sperm toward the provision of a large quantity of nutritive materials and protective encapsulation of each fertilized egg has resulted in an increase in the size of the organs that provide these abilities as well as a reduction in the sizes of the ovary and testis. The shift to direct transfer of sperm masses has led to evolution of both complex structures for species recognition and complicated behaviour to assure species identity.

Ecology and habitats. Although all levels of the ocean are inhabited by snails, they are in greatest abundance in

and just below the tidal zones, where the most abundant quantities of food may be found. The extent of their effect on a coastline is indicated by the estimate that an average population of 860 million *Littorina* on one square mile of rocky shore ingests 2,200 tons of material each year, only about 55 tons of which is organic matter. Limpets of all types are even more influential in such habitats, browsing and grazing on the algae and sessile animals. One interesting characteristic of limpets is that of homing. Numerous species have the tendency to settle on one spot and to feed on regular pathways radiating from this home base, to which they return for rest or under stressful conditions.

Snail damage to rocky coasts

Some larger prosobranchs are selective herbivores, cutting off one- to two-centimetre (0.4- to 0.8-inch) strips of seaweed for swallowing. More characteristic of the sand and mud flats are scavengers that indiscriminately take in surface debris; scavengers are found in various groups, including limpets, strombids, and nassariids. Carnivores include both surface hunters and burrowing forms such as the naticids. As an adaptation to sedentary life, several families have adopted mucociliary feeding by collecting food particles from water currents. Sensory reception to detect prey is highly developed in many carnivores.

Janthina builds a float of air bubbles in mucus; the float is attached to the middle part of the foot. Heteropods swim either by undulations of the foot or by the action of fleshy fins. Pelagic opisthobranchs show almost every conceivable type of swimming mechanism and are at times extremely abundant on the ocean surface. Many opisthobranchs and most small freshwater pulmonates can glide on the underside of the surface film of the water but are not able to swim.

Diversity of mollusks in the ocean has resulted from specialization in food resources. Temperature and salinity are the prime physical factors limiting range extensions, usually by preventing successful breeding rather than by preventing settlement and growth of young.

Adaptations to fresh water and land

Migration of the snails into fresh water and onto land required a number of new adaptations. Snails had extra problems to solve, relating to their basic feeding and reproductive patterns. In the ocean, dispersal can take place by way of a veliger stage transported passively by currents and waves. In streams and rivers such a means of dispersal would result in downstream spread only. Because of this, the veliger stage was suppressed; instead, many freshwater prosobranchs brood the young inside the female, and pulmonates attach egg capsules to rocks, to vegetation, or to other snail shells. This essentially restricts snail dispersal to individual movement. In prosobranchs with separate sexes, the freshwater distributions closely follow drainage systems, because, in order to colonize a new body of water, either a pregnant female must be transported or both a male and a female must arrive at about the same time. The majority of pulmonates in fresh water are hermaphrodites and are capable of self-fertilization as well as cross-fertilization with other individuals. As a result, any pulmonate entering a new body of water can establish a considerable population of that species in a short time. For this reason, isolated ponds often have several species of pulmonates but only rarely prosobranch gastropods. In crawling over waterweeds, the pulmonates frequently come in contact with the feet or feathers of wading birds, to which they adhere accidentally by mucus secretion and are carried to a new pond.

Land snails avoid dessication in several ways. Prosobranchs retreat into their shells, and the operculum effectively seals the opening against the exterior. In the tropics, land operculates have developed elaborate breathing tubes to allow gas exchange during dry periods and yet minimize water loss. Pulmonates lack an operculum, but a great number of the forms secrete either simple mucous coverings (epiphragms) across the shell aperture or, in some of the more arid areas, a calcium-impregnated seal that can be almost as thick as the shell itself. Most land snails, however, have adjusted to life on land primarily through behaviour patterns. They stay in areas of high moisture or retreat into damp niches during short dry spells. A few burrow into soil. *Sonorella* species survive by remaining dormant during the years between rains; the genital structures of many individuals are reduced or lost to minimize use of energy in reproductive activities.

Tree snails

Only in the wet and warm tropics have tree snails been able to develop. These species have brightly coloured shells that usually are much thinner than those of their terrestrial counterparts. In the humid mountain regions of the world, where a constant supply of moisture is available throughout the year, there has been a marked tendency toward reduction of the shell and the evolution of slugs. This tendency probably results from two different selective pressures that reinforce each other. The shell, which is useful primarily in providing protection against dessication, is no longer needed when moisture is plentiful. Secondly, construction of the shell requires that a large quantity of calcium be readily available; calcium is generally in short supply on the slopes of volcanic mountains. With the need for the shell lessened and the primary constituent in short supply, any mutation favouring shell reduction is advantageous. Although most species of slugs seem to have evolved in mountain areas, their spread into lowlands has been greatly aided by crop irrigation and garden watering.

By far the majority of land snails occupy the surface litter and upper soil zone. This microhabitat is generally moist, and food is plentiful in the form of decaying animals and plants as well as fungi. Most land snails have shells that are drab in colour and inconspicuous. Frequently, the shell surface is highly sculpted. The minute species (less than three millimetres [0.1 inch] in diameter) face a problem of predation by small arthropods. The normal instinct of a snail to withdraw into its shell is of no help, since the predator simply follows the snail into its shell. Elaborate barriers that narrow the shell opening and tiny spines along the opening must provide some protection, since this construction occurs in more than 12 pulmonate families.

Most land snails feed directly on decaying plant matter, which is a simple shift in feeding behaviour from the primitive browsing of their marine ancestors. The carnivorous habit probably evolved through a transition period of carrion eaters. Many slugs feed on dead animal matter as well as plants. Pursuit and capture of other snails or earthworms demand increased sensory equipment and more rapid motion. Most carnivores, such as *Euglandina,* have greatly elongated bodies for reaching further into the shells of their victims.

Locomotion. The foot is the organ of locomotion in land gastropods. In swimming and sessile forms, however, the foot is greatly reduced and in many groups greatly modified. The normal progression of a snail is by muscular action, with a series of contraction waves proceeding from the posterior to the anterior end of the gliding portion of the foot. This type of progression is called monotaxic locomotion. A few groups have the foot divided into right and left halves, with separate waves moving on each side, a condition termed ditaxic locomotion. Certain species move by the beating action of cilia of the foot on the mucous sheet secreted by the anterior part of the foot. When the foot is narrow, as in *Strombus* and *Aporrhais,* the animal moves in fits and starts, tumbling along by a digging action of the foot and the pointed operculum. Most prosobranchs are relatively slow-moving, with a speed of less than eight centimetres (about three inches) per minute, although *Haliotis* has been reported to move at almost 10 times that rate.

Movement by contraction of the foot

Many opisthobranchs employ monotaxic locomotion; some can glide on the underside of water-surface films through ciliary action. Swimming has been achieved in a number of ways. Body undulations propel such large snails as *Dendronotus* and *Melibe.* Pteropods, *Gastropteron, Akera,* and others move foot flaps (parapodia) to provide motion. The sea hare, *Aplysia,* uses an inchwormlike progression, and some nudibranchs swim by beating accessory breathing organs (cerata).

Freshwater pulmonates use ciliary action on a bed of mucus secreted by the snail. Many snails, especially *Physa,* can form a cord of mucus from the water surface to the bottom.

Land pulmonates depend upon a combination of muscular action and cilia for locomotion. In many of these

species the foot is divided longitudinally into three parts, with locomotor activity being confined to the central section, which glides on a mucous track. An additional use of slime by slugs is in the act of mating. A slime rope is secreted from which the mating pair of slugs are able to suspend themselves. If irritated, slugs can secrete copious quantities of slime. This reaction is the basis for one of the most effective methods of controlling slugs: spreading enough ashes in slug-infested areas causes exhaustion and death of the animals through the overproduction of slime.

Some of the small, tropical, brightly coloured sluglike species will, when disturbed, travel at a very high rate of speed with the anterior half of the foot lifted off the ground. They can continue moving at this pace for a distance of almost a metre at a rate faster than one metre per minute in snails less than two to three centimetres (or about one inch) in body length. Large species, such as *Achatina* or *Strophocheilus,* are much slower, although carnivores are usually relatively fast-moving.

The odontophore: a rasping organ

Food and feeding. As in all molluscan groups except the bivalves, gastropods have an odontophore at the anterior end of the digestive tract. Generally, this organ forms a broad ribbon (radula) covered with a few to many thousand "teeth" (denticles). The radula is used in feeding: muscles extrude the radula from the mouth, spread it out, and then pull it back into the mouth, carrying particles or pieces of food and debris into the esophagus. Although attached at both ends, the radula grows continuously during the gastropod's life, with new rows of denticles being formed posteriorly to replace the worn denticles cast off at the anterior end. Both form and number of denticles vary greatly among species—the differences correlating with food and habitat changes. Radular denticles are shown in Figure 6.

Evidently, the most primitive type of gastropod feeding involved browsing and grazing of algae from rocks. Some species of the order Archaeogastropoda still retain the basic rhipidoglossan radula, in which many slender marginal teeth are arranged in transverse rows. During use, the outer, or marginal, denticles swing outward, and the radula is curled under the anterior end of the odontophore. The latter is pressed against the feeding surface, and, one row at a time, the denticles are erected and scrape across the surface, removing fine particles as the odontophore is withdrawn into the mouth. As the marginals swing inward, food particles are carried toward the midline of the radula and collected into a mucous mass. By folding the teeth inward, damage to the mouth lining is avoided and food particles are concentrated. Mucous-bound food particles are then passed through the esophagus and into the gut for sorting and digestion.

From this basic pattern, numerous specializations have developed, including docoglossate, taenioglossate, rachiglossate, and toxoglossate radulae. Many limpets, which scrape algae directly from rock surfaces, have a docoglossate radula, with the marginals greatly reduced in number. When the radula is extruded, in *Patella,* for example, several rows of denticles on the lower odontophoral margin are pressed against the surface. There is no elevation of single rows and no lateral movement of the few marginals. Consequently, wear against the rock surface is great, and, although the denticles are heavily impregnated with mineral salts, tooth damage and loss is extensive. In rock-grazing species, replacement and growth are relatively rapid, and the radula is very long in relation to shell size.

Wear and replacement of teeth

Mesogastropods have a taenioglossate radula, in which a central tooth is flanked on either side by three laterals, for a total of seven denticles. This highly flexible pattern has allowed great diversity in feeding by alteration of cusp and tooth size. Often members of a genus may show striking differences. The limpetlike *Hipponyx antiquatus* attaches permanently in rock crevices or on clamshells and feeds on the organic debris that can accumulate. Other limpetlike, or burrowing, mesogastropods collect food particles off the gill and pass them into the mouth by cilia. *Hipponyx* and *Aporrhais* grasp the trapped particles with the radular teeth, whereas in *Crepidula* a food-laden mucous cord is formed, bits of which are torn off by the radula.

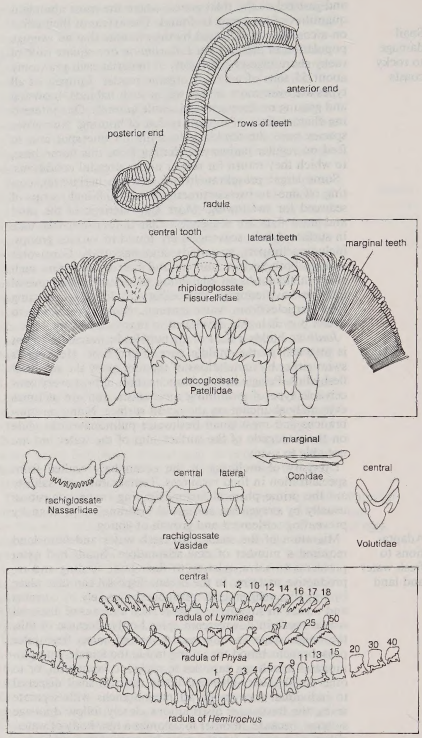

Figure 6: Gastropod radulae and types of teeth.

Gastropods that feed on sessile animals have evolved an extensible proboscis capable of reaching into narrow openings. Such minute sponge feeders as *Triphora* extend the slender proboscis into the openings of a sponge to reach delicate fleshy cells. Similarly, many cowries feed on sea squirts (ascidians). Numerous mesogastropods and prosobranch-opisthobranch transition groups are external parasites (ectoparasites) on larger animals. A few are internal parasites (endoparasites) of echinoderms.

Floating snails

Floating snails such as *Janthina* drift along until they contact prey. Certain mesogastropods are active swimmers; one, *Pterotrachea,* has the foot modified into a small sucker for holding prey. Mesogastropods of the families Naticidae and Doliidae feed upon bivalves and echinoderms. The naticids use their large foot to hold the prey while they drill through the bivalve shell. A combination of mechanical rasping by the radula and chemical loosening of the calcium by secretions produces a hole in the bivalve shell through which the proboscis is inserted to enable the naticid to feed upon the soft tissues.

In stenoglossans the basic radular type is rachiglossate, with only three denticles—a central and two laterals. Families such as the Buccinidae and Nassariidae include carnivores and scavengers. Members of the family Muricidae are predators that may use either a secretion to bore holes into shells or the physical force of their proboscis to

pry into shelled prey. Many genera (*e.g., Busycon, Fasciolaria,* some *Murex*) use part of their shell to wedge open a clam for feeding.

Finally, the toxoglossate radula has only two teeth, which are formed and used alternately. Most toxoglossate gastropods inject a poison via the functional tooth. Prey selection usually is highly specific. Although many cones hunt polychaete worms, others prey on gastropods or fishes, using the radular tooth as a harpoon, with poison being injected into the prey through the hollow shaft of the tooth. Several of the large fish-eating cones, which produce a potent nerve poison, have been known to kill humans.

Opisthobranch gastropods show less clearly defined types of radular structure. Anaspideans such as *Dolabella* may have as many as 460 teeth per row with a total of 25,000 denticles; sacoglossans have only one longitudinal row of teeth. In terms of feeding, opisthobranchs are extremely varied. Besides the algae-sucking sacoglossans, *Aplysia* cuts up strips of seaweed for swallowing, and a number of the more primitive species feed on algae encrusted on rocks. Perhaps the majority of opisthobranchs, including the sea slugs, are predators on sessile animals, ascidians and coelenterates being especially favoured. Pyramidellids are ectoparasites on a variety of organisms. Some of the pteropods are ciliary feeders on microorganisms.

Pulmonate modifications for feeding

Pulmonate gastropods are predominantly herbivores, with only a few scavenging and predatory species. Basically, on the radula there is a central tooth flanked by a few to many denticles, which may be differentiated into laterals and marginals. The central tooth may be reduced in size or lost, whereas the other teeth show modifications correlated with diet. Primitively, the pulmonate radular tooth has three raised points, or cusps (*i.e.,* is tricuspid), but modifications involving splitting of cusps or reductions to one cusp are numerous. With each successive appearance of a carnivorous type during evolution, however, the teeth have been reduced in number, each tooth usually having one long, sickle-shaped cusp.

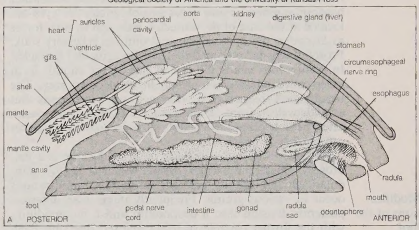
Much of the diversity achieved by the gastropods relates to the evolutionary shifts in radular structure, which have led to exploitation of a variety of food sources. Predators capable of swimming, surface crawling, and burrowing to capture prey have evolved among the prosobranchs and opisthobranchs; predators that produce chemical substances for entering the shells of their prey have evolved among the mesogastropods (family Naticidae and superfamily Tonnacea), stenoglossans (family Muricidae), and a nudibranch opisthobranch (*Okadaia*); and, in the pulmonates, predation and thus a carnivorous diet have evolved at least 12 times.

FORM AND FUNCTION

Gastropods present such a variety of structures and adaptations that few all-encompassing characteristics can be presented. A detailed presentation on the radula and reproductive changes, which are keys to understanding gastropod diversification, has been given above. The following survey focuses on the external shell and the body.

The shell. The typical snail has a calcareous shell coiled in a spiral pattern around a central axis called the columella. Generally, the coils, or whorls, added later in life are larger than those added when the snail is young. At the end of the last whorl is the aperture, or opening. The shell is secreted along the outer lip of the aperture by the fleshy part of the animal called the mantle, first by outward additions to the shell lip and then by secretion of inner thickening layers. The outer layer, or periostracum, is a mixture of proteins known as conchin. Inner layers of calcium carbonate interlace with a network of conchin and are impregnated with a variety of mineral salts. The calcium usually is in the form of calcite crystals in marine species and aragonite crystals in terrestrial species, but mixtures of crystal types do occur.

Shell ornamentation



Modifications and ornamentations of the basic shell are widely variable. Frequently, the shell is altered into a non-spiral cap or a cup-shaped limpet form as an adaptation to life in swift currents (the freshwater family Ancylidae) or amid pounding waves on rocks (the marine families Acmaeidae, Patellidae, Fissurellidae, and Calyptraeidae). In many groups, such as the abalones (the family Haliotidae), only traces of spiral coiling are evident, because the rate of successive whorl widths is so large that the last, or body, whorl occupies more than 90 percent of the shell volume. Elaborate surface sculpture, including knobs and spines, develop as protection against predation. In a few species of the genera *Leucozonia* and *Acanthina,* a spine on the lip edge is used to wedge open clam valves so that the snail can feed. As implied earlier, land gastropods in dry regions tend to have very thick shells; on the other hand, those in very humid mountain situations have thin shells or none at all. Many carnivorous snails have the calcareous part of the shell greatly reduced.

The body. The gastropod body consists of four main parts: visceral hump, mantle, head, and foot. The body is attached to the shell either by one columellar muscle or by a series of muscles. Typical snails can withdraw the head and foot into the shell, but numerous species have shells so reduced in size as to be unable to contain the body; slugs, of course, have either an internal shell vestige or no shell at all.

The visceral hump. The visceral hump of gastropods is always contained within the shell; it generally holds the bulk of the digestive, reproductive, excretory, and respiratory systems (Figure 7). A significant part of the visceral hump consists of the mantle, or pallial, cavity. In both prosobranchs and shelled opisthobranchs this is a cavity completely open anteriorly; in pulmonates it is closed except for a narrow pore. The upper surface of the mantle cavity serves a respiratory function. In marine species the ciliated lining of the mantle cavity produces a water current that passes posteriorly across the gill, or

The mantle cavity

From (B) *Treatise on Invertebrate Paleontology,* courtesy of the Geological Society of America and the University of Kansas Press

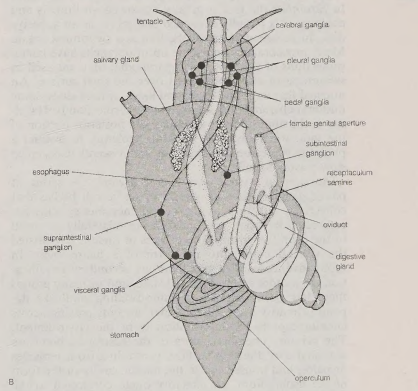


Figure 7: *Adult gastropod structure.*
(A) Primitive. (B) Advanced.

ctenidium, and the osphradium, which is thought to be a sensory receptor that can detect chemical changes in the environment. Both organs lie on the left anterior side of the cavity. The water current sweeps across the posterior part of the mantle cavity, where the nephridiopore, or kidney opening, lies; the water current then passes anteriorly along the right margin past the anus, through which undigested particles of food are eliminated, and usually moves past the gonopore, through which sexual products are released.

The mantle cavity serves as a space for the head and foot when these organs are retracted. Many land pulmonates apparently also use the mantle cavity to retain water.

Operculum

Prosobranchs use the operculum, the horny or calcareous disk located on the back of the foot at the posterior end, to seal the shell opening after the head and body have been retracted.

The mantle. The mantle is the fleshy lining of the outer wall of the shell; it roofs the mantle cavity. At its anterior end lie glandular tissues that deposit the various shell layers. In terrestrial forms with reduced shells, various lobes and laps extend anteriorly over the neck and head or are reflected back over the shell surface. These are highly vascularized and probably serve both in respiration and in water balance of the body. Many marine forms have the mantle collar extended forward and rolled into a siphon, which functions in both food location and chemoreception.

The head. Generally, the head is bilaterally symmetrical, bearing one or two pairs of tentacles, often with accessory palps, and the mouth in the middle of the ventral margin. In stylommatophoran land snails the upper tentacles, or ommatophores, are invaginable (capable of being rolled in), and the eyes are borne at the tips. In freshwater basommatophorans and most prosobranchs the eyes are located at the base of the tentacles, although in such forms as *Strombus* the eyes are elevated onto an accessory stalk. Prosobranchs have contractile (not invaginable) tentacles. In carnivorous snails the lateral lips of the mouth form lobes called labial palps, which help to locate prey. The mouth itself frequently is prolonged into a proboscis that extends well in front of the tentacles. Carnivorous species often have a proboscis capable of great extension, either invaginable or contractile.

The foot. Although the basic form of the foot is a flat, broadly tapered, muscular organ, which is highly glandularized and usually ciliated, numerous modifications occur in various groups. Frequently there is an anterior-posterior division into a propodium and a metapodium, with the former capable of being reflexed over the shell. In *Strombus* the foot is greatly narrowed; in limpets and abalones it is broadly expanded and serves as an adhesive disk. In pelagic gastropods the foot is a swimming organ. Many prosobranchs and some opisthobranchs have lateral projections of the foot called parapodia; they are used in swimming or else are reflexed over the shell surface. An unusual feature found in several kinds of land slugs, some nudibranchs, and the stenoglossan marine family Harpidae is the ability to self-amputate the posterior portion of the foot, which remains wriggling violently to distract a predator while the anterior foot and visceral mass creep slowly away to safety.

Modifications of the foot

The nervous system and sense organs. A series of paired ganglia (knotlike masses of nerve cell bodies that collectively function as the central nervous system) are connected by nerve cords, which are bilaterally arranged in the primitive forms. The process of torsion has twisted the visceral cords into the form of a figure eight. In more-advanced gastropods there are secondary modifications to a more nearly bilateral state, and in many groups there has been detorsion. Water-dwelling mollusks depend primarily upon ciliary water currents passing across chemoreceptors for information from the environment. The primary chemoreceptors in the gastropod body are scattered over the skin surface, protruding from tentacles or palps, and housed inside the mantle cavity in the form of the osphradium, an olfactory organ connected to the respiratory system. Sense organs are more highly developed in carnivores than in herbivores. Eyespots, located at the base (most gastropods) or tip (land pulmonates) of the eye tentacles, are primarily light-sensitive rather than image-forming. A pair of statocysts, thought to be balancing organs, is present in nonsessile taxa.

Digestive system. The radular motion conveys food particles into the mouth, and ciliary currents move the food through the tract, except in carnivores, where muscular action plays an important role. Various salivary and digestive glands secrete enzymes into either or both the buccal cavity and the stomach, where digestion takes place. The apical digestive gland, or "liver," can store digested food for use during periods of inactivity.

The excretory system. There are two kidneys, or nephridia, in only the primitive gastropods, such as the archaeogastropods, while, in the advanced forms, one kidney is small or lost. The kidney plays different roles, depending upon the environment in which the snail lives. Most marine gastropods have the same total concentrations of solutes as in the surrounding seawater, and thus a small osmotic differential (*i.e.,* an equilibrium) exists between the water leaving and that entering the cell. Little energy is needed therefore to prevent the cells from losing or gaining too much water. Freshwater gastropods, however, have a higher total solute concentration than that of the surrounding water. The kidney must expend energy to control water balance (osmoregulation). The flow of water through the mantle cavity is restricted in freshwater species by the closure of the mantle cavity by the mantle collar. Land prosobranchs have an open mantle cavity and, in order to conserve water, secrete nearly crystalline urine. Land pulmonates have a ureteric groove or closed ureter that resorbs water from the urine. In both marine and freshwater species, ciliary water currents sweep the excreted matter out of the mantle cavity.

Respiration. In marine and freshwater gastropods, respiration takes place as water currents pass across the gill surfaces within the mantle cavity in most species with spiral shells, across gill elements along the sides of the bodies in most limpets, or through projections from the body surface in sea slugs or taxa with reduced shells. The upper surface of the mantle cavity is heavily vascularized in land snails, which use muscular contractions to pump air in and out of the small respiratory pore at the anterior edge of the mantle cavity. In some land slugs or tropical snails with reduced shells, respiratory functions have shifted either to external projections from the mantle collar or to the skin as the area of mantle roof available for respiration has decreased in size.

The reproductive system. The primitive archaeogastropods retain two nephridia; the right nephridium provides the passage for eggs or sperm from the ovary or testis to the mantle cavity. The sexes are separate in nearly all prosobranchs, although in a few taxa, such as *Crepidula,* an animal begins life as a male and then changes to a female later. Both the opisthobranchs and pulmonates are hermaphroditic, often protandrous (male gonads maturing first), but many taxa when fully adult become simultaneous hermaphrodites (male and female gonads are functional at the same time). Internal fertilization is common in the more advanced marine taxa but mandatory in the freshwater and terrestrial groups. A very few gastropods are parthenogenetic (gametes developing without fertilization).

Features of defense. Warning coloration is found in some of the brilliantly coloured shells and bodies of carnivorous marine snails that possess highly toxic poisons. Similar bright colours characterize some land snails and slugs that secrete noxious chemicals and thus will be sampled only once by a predator. Camouflage coloration provides partial protection against predation by some European land snails.

EVOLUTION AND PALEONTOLOGY

The basic trends in snail evolution involve changing from a herbivorous to a carnivorous diet, shifting from the ocean to freshwater and terrestrial life, and adopting a sluglike form through reduction or loss of the shell and visceral hump. Each change has occurred independently several times in the course of gastropod evolution.

Prosobranch gastropods are the most primitive. One group, the Diotocardia, which retains two sets of mantle organs, is nearest the generalized gastropod in structure. Gradual loss of the right set of mantle organs occurs in the primitive archaeogastropod superfamilies Trochacea and Neritacea, thus providing a transition to the more highly developed order Monotocardia, with only one set of mantle organs. Among the numerous changes in the Monotocardia are fewer radular teeth and a shift from grazing on algae and fungi to predation and the consumption of larger sessile organisms. The two main divisions of the Monotocardia show different evolutionary patterns. Although most mesogastropods have remained coastal marine, several families moved into fresh water. Others crossed to land directly from the tidal zone, rather than passing through a freshwater transitional period. At the peak of prosobranch evolution is the predatory suborder Stenoglossa, all marine inhabitants, with highly modified radular teeth and often well-developed poison glands to aid in capturing prey. Reduction and loss of the right mantle organs are correlated with more efficient respiration and sensory apparatuses, in which a water current crosses over the sensory organs and gills on the left side, then out on the right side, together with excretory and fecal deposits.

Opisthobranchs probably arose from an unknown group of primitive prosobranchs and have evolved extensively into different lines showing a reduction of the visceral hump and shell. In certain forms the foot is shortened, and external cerata develop to provide a respiratory surface to replace the lost mantle-cavity surface. Such opisthobranch groups as the order Pyramidellacea contain a mixture of prosobranch and opisthobranch characteristics.

Pulmonates show varying degrees of adjustment to freshwater and land life, with increasing union of the male and female gonoducts characterizing the more advanced groups. Similarly, the highly advanced suborder Holopoda and superfamily Limacacea show complex accessory organs on the genitalia and a more sophisticated means of water conservation through development of a closed secondary ureter and resorption of water from the excretory products. More than a dozen different groups of pulmonates have become predators, usually upon other snails or earthworms.

The earliest gastropods

Fossil gastropods are known from Cambrian deposits. Since the shell is often very similar in unrelated families, fossil gastropods more than 350 million years old are not usually placed in the classification outlined below but instead are treated separately. Most stenoglossan prosobranchs appeared near the end of the Mesozoic (66.4 million years ago), and many groups of land snails are known from Eocene formations (57.8 to 36.6 million years old). Snails had their adaptive radiation early in geologic history. Living genera of marine, freshwater, and land snail families are known from Oligocene to Miocene deposits (36.6 to 5.3 million years old). Unlike mammals, who have undergone great evolutionary change in the last 50 million years, gastropods have shown little progressive evolution during that time.

CLASSIFICATION

Since the 1980s, gastropod classification has been the subject of extensive debate. Major revisions based on detailed information about traditional anatomy and shell features have been challenged by cladistic attempts to identify changes that have taken place once in the evolutionary history of a group and thus derive phylogenetic schemes, attempts to delineate the geneology of groups based primarily on neurological structures. Both traditional and cladistic classification schemes are being tested by data from molecular studies. Given the antiquity of the gastropods as a group, however, it is perhaps realistic to expect that most changes have occurred more than once. Graham gave an excellent review of anatomic and functional trends, concluding that many of the groups historically recognized as advanced are grades reached by several taxa independently, not monophyletic clades (groups with the same ancestor).

A conservative classification is presented below, basically using concepts from Vera Fretter and Alistair Graham (1962) for the prosobranchs, Louise Schmekel (1985) for the opisthobranchs, and Alan Solem (1978) for the pulmonates, with minor modifications from a number of sources. The remarkable radiation of primitive limpets associated with the hydrothermal vents was still under analysis in the late 1980s and is not included.

The pattern of change in the respiratory and nervous systems and in the mantle complex is fundamental. Among the major trends are the change from a streptoneurus (twisted) to a euthyneurus (straight) nerve loop, the progressive loss of the right part of the primitively paired mantle organs, the increasing sophistication of hermaphroditism, the tendency toward the reduction of the visceral hump and shell, the multiple changes from a herbivorous to a carnivorous diet, the shifts from marine to freshwater or land environments and occasionally the return from the land to the ocean, and the shifts in locomotor mechanics.

CLASS GASTROPODA (snails and slugs)

Snails typically with a calcareous shell, slugs with greatly reduced shell; length ranges from about 1 mm to 130 cm; about 65,000 species widely distributed in marine, freshwater, and land regions.

Subclass Prosobranchia

Streptoneurous (twisted) gastropods with an anteriorly located mantle cavity (space lined with epidermis); operculum (protective cover) generally present; sexes separate; shell can usually hold entire animal; primarily marine, several freshwater and terrestrial groups; about 33,000 species.

Order Diotocardia (*Archaeogastropoda*)

Heart usually with 2 auricles; 1 or 2 internal gills; no penis, siphon (organ used in food location), or proboscis (feeding organ); nervous system not concentrated; sex cells discharged by way of the right nephridium (kidney); about 3,000 species.

Superfamily Zeugobranchia (*Pleurotomariacea*). Slit shells (Pleurotomariidae) in deep ocean waters; abalones (Haliotidae) in shallow waters along rocky shores of western North America, Japan, Australia, and South Africa; keyhole limpets (Fissurellidae) in intertidal rocky areas.

Superfamily Patellacea (*Docoglossa*). Conical-shelled limpets, without slits or holes, found in rocky shallow waters (Acmaeidae and Patellidae).

Superfamily Trochacea. Small to large spiral shells in shallow to deep ocean waters, often brightly coloured, with or without heavy shell ornamentation; Trochidae (top shells), Turbinidae (turban shells), and Phasianellidae (pheasant shells).

Superfamily Neritacea. Small, generally intertidal marine shells (Neritidae), with some freshwater dwellers, particularly in Indonesia and the Philippines (Neritidae), and 2 groups of land dwellers: 1 sparsely distributed in the Old World (Hydrocenidae) and 1 widely distributed in both Old and New World tropics (Helicinidae).

Order Monotocardia

Heart with 1 auricle; 1 gill, often modified; siphon and chemoreception osphradium (sensory receptor) progressively more complex; penis present; head frequently modified into a proboscis; nervous system progressively more concentrated; about 30,000 species.

Suborder Mesogastropoda (*Taenioglossa*). Radula taenioglossate (with 7 denticles, or teeth) or reduced; most taxa herbivorous; a few families parasites or predators.

Superfamily Cyclophoracea. Land snails; particularly abundant in the West Indies and southern Asia to Melanesia.

Superfamily Viviparacea. Large, 2.5- to 5-cm globular pond and river snails of the Northern Hemisphere (Viviparidae) and tropical regions (Ampullariidae); frequently used in freshwater aquariums with tropical fish.

Superfamily Littorinacea. Periwinkles, on rocky shores (Littorinidae) of all oceans; land snails of the West Indies, part of Africa, and Europe (Pomatiasidae).

Superfamily Rissoacea. Small to minute, generally cylindrical, marine, freshwater and land snails found in most tropical and warm temperate regions of the world; about 17 families.

Superfamily Cerithiacea. Minute to large, generally elaborately sculptured shells, common in mud flats and mangroves, many species sand dwellers, with 1 group of families (Thiaridae, Pleuroceridae, Melanopsidae) especially abundant and varied in the Tennessee and Alabama river systems; 13 marine families, including worm shells (Vermetidae), horn shells (Potamididae), and button shells (Modulidae).

Superfamily Strombacea. Foot and operculum greatly modified and move with a lurching motion; feed on algae and plants; some species used for human food; conchs (Strombidae) of tropical oceans and the pelican's foot shells (Aporrhaidae) of near Arctic waters.

Superfamily Calyptraeacea. Cap shells (Capulidae) and slipper shells (Calyptraeidae) are limpets with irregularly shaped shells with a small internal cup or shelf; many species show sex reversal, becoming males early in life, then changing into females during old age; common on rocks and clamshells and in dead large snail shells in most oceans.

Superfamily Cypraeacea. Cowrie shells (Cypraeidae) and egg shells (Ovulidae) have highly polished and brilliantly coloured shells; mantle, which may cover the shell, is a totally different colour pattern; if touched, members of group suddenly withdraw, the change in colour serving to confuse predators; common in shallow tropical oceans, some species in cooler waters.

Superfamily Naticacea. Moon shells (Naticidae) medium-sized, globular predators on burrowing bivalves; bore a hole in the clamshell using acid secretions, then insert the radula to feed; common in most oceans.

Superfamily Ptenoglossa (Scalacea). Wentletraps (Epitoniidae) live in shallow to deep ocean waters; purple snails (Janthinidae) float on the ocean surface after building a raft of bubbles; large numbers of bubble shells occasionally blow ashore.

Superfamily Aglossa. Parasitic or predatory snails either with a reduced radula or with none, jaws often modified into a stylet-shaped structure; many occur on echinoderms; consists of several poorly known families.

Superfamily Doliacea (Tonnacea). Generally tropical predators on echinoderms; often burrow in sand; includes helmet shells (Cassidae), tun shells (Doliidae), frog shells (Bursidae), triton shells (Cymatiidae), and fig shells (Ficidae); frog and triton shells often live in rocky areas; most species large in size.

Suborder Stenoglossa (Neogastropoda). Carnivorous or scavengers with rachiglossate (with 3 denticles) or taxoglossate (with 2 denticles) radula; shell often with long siphonal canal; proboscis well developed and often extensible; shells generally large; all marine.

Superfamily Muricacea. Murex shells (Muricidae), rock shells (Purpuridae), and coral shells (Coralliophilidae) are common predators, often boring into shells of their prey; rock shells common in cooler waters, others mostly tropical.

Superfamily Buccinacea. Scavengers that have lost the mechanisms for boring; dove shells (Columbellidae), mud snails (Nassariidae), tulip shells (Fasciolariidae), whelks (Buccinidae), and crown conchs (Galeodidae) mainly cool-water species; but dove and tulip shells have many tropical representatives.

Superfamily Volutacea. Harp shells (Harpidae), olive shells (Olividae), mitre shells (Mitridae), volute shells (Volutidae), nutmeg shells (Cancellariidae), and marginellas (Marginellidae) generally have operculum reduced or lacking; most are tropical ocean dwellers, active predators or scavengers; many olive, volute, and marginella shells are highly polished and colourful.

Superfamily Toxoglossa. Auger shells (Terebridae), cone shells (Conidae) and turrid shells (Turridae) are carnivorous marine snails with poison glands attached to highly modified radular teeth; several cone shells have caused human deaths through poisoning and can catch and kill fish.

Subclass Opisthobranchia

Shell reduced or lacking, usually too small for withdrawal of animal; mantle cavity often lost, rotated to right side and facing anteriorly; hermaphroditic; operculum generally lost; nerve ganglia (clusters) very concentrated; marine except for 4 species; about 4,000 species.

Order Cephalaspidea

Shell present, often capable of containing whole body; head shield developed; Acteonidae with operculum; 14 families.

Order Pyramidellacea

Spiral shell; operculum present; gill and radula absent; long proboscis with stylet; ectoparasitic; in warm oceanic areas, generally minute.

Order Acochlidacea

Three families with visceral mass longer than foot; 4 species in fresh water; a few with sexes in separate animals; size minute.

Order Philinoglossacea

No head appendages; gill lacking; no external shell; 2 families.

Order Anaspidea

Shell reduced to flat plate; feed on large seaweed rather than microscopic algae; sea hares (Aplysiidae); 1 other small family.

Order Notaspidea

Shell and gill usually present; no parapodia (extensions of foot); sperm groove open; shell prominent, reduced, or hidden by mantle; 2 families.

Order Sacoglossa

One file of radular teeth; sperm duct a closed tube; shell reduced to bivalved (Julidae); many feed by sucking juices out of algae; several families with uncertain limits.

Order Thecosomata

Shell present; pelagic ciliary feeders; no gill; 6 families.

Order Gymnosomata

Shell absent; no mantle cavity; complicated feeding mechanisms; pelagic carnivores; 7 families.

Order Nudibranchia

Sea slugs without shell, mantle cavity, osphradium, or internal gill; many feed on sessile animals; few swimmers (family Tethyidae); highly colourful, often conspicuous.

Subclass Pulmonata

Mantle cavity altered into a pulmonary sac; no gills or operculum; 1 auricle of heart anterior to ventricle; hermaphroditic; shell spiral to limpetlike, often reduced to a fragment hidden by mantle; mainly terrestrial or freshwater, few marine; about 28,000 species.

Superorder Systellommatophora

Mantle cavity absent; anal and usually nephridial opening at posterior; male gonopore behind right tentacle; female gonopore middle of right side; sole of foot narrow; no shell; 2 pairs of retractile, or invaginable, tentacles; marine (Onchidiidae), terrestrial and herbivorous (Veronicellidae), or terrestrial and carnivorous (Rathouisiidae); about 200 species.

Superorder Basommatophora

Mantle cavity present; eyes at base of 1 pair of tentacles; male and female gonopore separate, usually on right side of body; shell conical to patelliform; mostly freshwater but a few land and marine taxa; about 1,000 species. (No agreement exists concerning suprafamilial classification of the Basommatophora. The following superfamilies, though not grouped into formal orders and suborders, are listed in order of increasing specialization.)

Superfamily Patelliformia. Brackish water or marine limpets with (Siphonariidae) gill-like structures or with a lung (Gadinidae).

Superfamily Amphibolacea. Operculum present; shell conical; with pulmonary cavity; brackish water; burrow in sand; 1 family.

Superfamily Ellobiacea. Conical shells; pulmonary chamber, in tidal zone or salt flats, under rocks in spray zone, or completely terrestrial; 2 families.

Superfamily Lymnaeacea. Small to large, spiral-shelled snails of ponds, lakes, and rivers; 1 limpet group (Lancidae) and larger typical group (Lymnaeidae).

Superfamily Ancylacea. Limpets (Ancylidae), ramshorns (Planorbidae), and pond snails (Physidae); all restricted to freshwater habitats.

Superorder Stylommatophora

Mantle cavity a pulmonary sac; gonopores with common opening on right side or at most narrowly separated; shell conical to vestigial, heavily to weakly calcified; eyes at tips of upper (usually) tentacles; terrestrial; about 26,800 species.

Order Orthurethra

Pore of ureter opening into mantle cavity (part of the viscera) near anterior margin of lung after ureter passes forward from anterior kidney margin; about 6,000 species.

Superfamily Achatinellacea. Minute to medium-sized Pacific land snails with multicuspid radular denticles; many Hawaiian species highly coloured and variable.

Superfamilies Cionellacea and Pupillacea. Minute leaf-litter to arboreal snails, occasionally (Enidae) large; shells often with denticles in the aperture; 10 families.

Superfamily Partulacea. Small, generally arboreal snails found on high volcanic islands of Polynesia and Micronesia, a few in Melanesia.

Order Mesurethra

Ureter represented by lateral opening of very short kidney, pore of ureter opening near or behind middle of mantle cavity; about 1,500 species.

Superfamily Clausiliacea. Elongated shells of West Indian shore salt-spray zone (Cerionidae) or Andean mountains of South America and Eurasia (Clausiliidae).

Superfamily Strophocheilacea. Large helicoidal to elongated shells of South America (Strophocheilidae) or southwestern Africa (Dorcasiidae).

Order Sigmurethra

Ureter originates near anterior margin of kidney, follows backward to posterior end, then reflexes forward along hindgut to open alongside anus; position greatly altered in sluglike forms; about 18,000 species.

Suborder Holopodopes. A group of 4 superfamilies.

Superfamily Achatinacea. Besides the giant African snail, 4

families, including many species spread by commerce throughout the world.

Superfamilies Streptaxacea and Rhytidacea. Carnivorous snails and slugs (4 families) in most tropical areas, plus the herbivorous Acavidae of Australia, Sri Lanka, and Madagascar.

Superfamily Bulimulacea. Large, often arboreal snails of Melanesia and Neotropica (Bulimulidae); long, cylindrical snails of West Indies and Central America (Urocoptidae).

Suborder Aulacopoda. A group of 3 superfamilies.

Superfamily Succineacea. A problematic group including amber snails (Succineidae), which inhabit swamps and damp areas, and peculiar slugs from the South Pacific (Athoracophoridae).

Superfamily Arionacea. A group possessing marginal teeth of radula with squarish basal plates and 1 to several cusps; small litter or tree snails mainly in Southern Hemisphere (Endodontidae); slugs (Arionidae and Philomycidae) in the Northern Hemisphere.

Superfamily Limacacea. Marginal teeth of radula with narrow, lengthened basal plates, usually unicuspid; zonitid snails with smooth shells and many sluglike species, common in wet, tropical areas and in temperate regions; about 12 families, including limacid and milacid slugs.

Suborder Holopoda. A group of 3 superfamilies.

Superfamily Polygyracea. Common woodland snails of eastern North America (Polygyridae), plus a Neotropical group (Thysanophoridae) and a relict group of Asia (Corillidae).

Superfamily Oleacinacea. Carnivorous (Oleaciniidae) and herbivorous (Sagdidae) snails of the Neotropical region.

Superfamily Helicacea. Land snails without (Oreohelicidae and Camaenidae) or with (Bradybaenidae, Helminthoglyptidae, and Helicidae) accessory glands on the genitalia; dominant land snails in most regions, including the edible snails of Europe (Helicidae). (G.A.So.)

Bivalves (clams, oysters, mussels, and relatives)

The class Bivalvia, sometimes called Pelecypoda, is characterized by a shell that is divided from front to back into left and right valves. Enclosure in a shell has resulted in loss of the head. Similarly, the adoption of deposit-feeding using labial palps and, later, suspension feeding utilizing the respiratory gills modified into organs of filtration called ctenidia have resulted in loss of the radula from the mouth.

GENERAL FEATURES

Size range and diversity of structure. Bivalves range in size from about one millimetre (0.04 inch) in length to the giant clam of South Pacific coral reefs, *Tridacna gigas,* which may be more than 137 centimetres (54 inches) in length and weigh 264 kilograms (582 pounds). Such an animal may have a life span of about 40 years.

The shell forms are used in classification. In most surface-burrowing species (the hypothetical ancestral habit) the shells are small, spherical or oval, with equal left and right valves (Figure 8). In deeper-burrowing species the shells are laterally compressed, permitting more rapid movement through the sediments. The shells of the most efficient burrowers, the razor clams *Ensis* and *Solen,* are laterally compressed, smooth, and elongated. Surface-burrowing species may have an external shell sculpture of radial ribs and concentric lines, with projections that strengthen the shell against predators and damage.

From (Cerastoderma) W. de Haas and F. Knorr, *The Young Specialist Looks at Marine Life* (1968), Burke Publishing Co., London

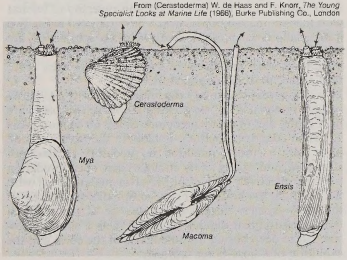

Figure 8: *Shallow- and deep-burrowing dimyarian bivalves. Cerastoderma* lives close to the sediment surface and has limited burrowing powers. When disturbed, *Mya* retracts its long siphons as does *Macoma,* but *Macoma* and *Ensis* can also dig deeper into the sediment using the muscular foot. Arrows indicate direction of current flow into the mantle cavity via the inhalant and exhalant siphons.

A triangular form, ventral flattening, and secure attachment to firm substrates by byssal threads (byssus; chitinous threads secreted by the foot) have allowed certain bivalves to colonize hard surfaces. This form, referred to as epibyssate for its byssal attachment to surfaces, has been adopted by many groups, most importantly the true mussels (family Mytilidae) of marine and estuarine shores and the family Dreissenidae of fresh and estuarine waters. Such a shell form and habit evolved first within sediments (endobyssate), where the byssus serves for anchorage and protection when formed into an enclosing nest. The byssus is a larval feature retained by some bivalve groups into adult life. The significance of this is crucial to an understanding of how bivalves have radiated. In addition to the triangular form, other bivalves have used the byssus to attach securely within crevices and thus to assume a laterally flattened, circular shape. The best example of this is the windowpane shell *Placuna.* This form has allowed the close attachment of one valve to a hard surface, and although some groups still retain byssal attachment (family Anomiidae), others have forsaken this for cementation, as in the true oysters (family Ostreidae), where the left valve is cemented to estuarine hard surfaces. Some scallops (family Pectinidae) are also cemented, but others lie on soft sediments in coastal waters and at abyssal depths. By limiting shell thickness to reduce weight, smoothing the shell contours to reduce drag, and assuming an aerofoil-like leading edge, such scallops can swim many metres.

Endobyssate and epibyssate

Shell form in the bivalves is thus intimately related to habitat and the relative degree of exposure to predation. From the simple burrowing, equivalve ancestor, the various bivalve groups have repeatedly evolved an elongated, triangular or circular shell; thus, similar body adaptations have been responses to similar modes of life.

Distribution and abundance. Most bivalves are marine and occur at all depths in or upon virtually all substrates. In shallow seas, bivalves are often dominant on rocky and sandy coasts and are also important in offshore sediments. They occur at abyssal and hadal depths, either burrowing or surface-dwelling, and are important elements of the midoceanic rift fauna. In addition, bivalves bore into soft shales and compacted muds but may be important also in the bioerosion of corals. Bivalves thus occur at all latitudes and depths, although none are planktonic. There are also estuarine bivalves, and two important families, the Unionidae and Corbiculidae, are predominantly freshwater with complicated reproductive cycles. There are no terrestrial bivalves, although some high-intertidal and freshwater species can withstand drought conditions.

To be expected within a class comprising more than 8,000 living species, abundance varies considerably. Commensal and parasitic species are small, often highly host-specific, and comprise some of the rarest animals. Others, such as cockles and clams on soft shores and mussels and oysters on rocky coasts, can occur in densities high enough that they dominate entire habitats and assume important roles in nutrient cycles.

Importance. The total marine catch of mollusks is twice that of crustaceans, and the great majority of this is bivalve. Some three million metric tons (6,615,000,000 pounds) of bivalves are harvested throughout the world each year. Virtually all bivalves, with the possible exception of the thorny oyster *Spondylus,* are edible and fall into the main categories of oysters, mussels, scallops, and clams.

Economic importance

The most important edible oysters are representatives of the genus *Crassostrea,* notably *C. gigas* in the western Pacific, *C. virginica* in North America, and *C. angulata* in Portugal. Most mussels are cultivated on ropes suspended from floats. The European mussel *Mytilus edulis* has been introduced into the northern Pacific, and the

practice now flourishes widely in Japan and China. Most scallops, *Pecten, Placopecten,* and *Amusium,* are caught by offshore trawlers, although cultivation is being attempted. A wide variety of clams are cultivated—*e.g., Mya arenaria* and *Mercenaria mercenaria* in the North Atlantic and *Venerupis japonica* and *Tapes philippinarum* in the Pacific. In some parts of the world, red tides, caused by large numbers of toxic protozoan dinoflagellates, are lethal to fish and certain invertebrates. Bivalves, by virtue of their filter-feeding apparatus, concentrate the toxin and, if eaten by humans, can cause paralysis or death.

Pearls

Bivalves of the genera *Pinctada* and *Pteria* have been collected in many tropical seas for the natural pearls they may contain, although in many countries, most notably Japan, pearl oyster fisheries have been developed. The windowpane oyster, *Placuna placenta,* has flat translucent valves that are used, primarily in the Philippines, in the manufacture of lampshades, trays, mats, and bowls, collectively called *tapis.* In developing countries, many kinds of bivalve shells are used in the manufacture of jewelry and ornaments.

Bivalves are important agents in bioerosion, most notably of calcium carbonate rocks and wood in the sea. Piddocks (family Pholadidae) bore into concrete jetties (particularly where the source of obtained lime is coral), timber, and plastics. Shipworms (family Teredinidae) bore softer woods. Date mussels (*Lithophaga*) bore into rocks and corals. Marine mussels (family Mytilidae) foul ships, buoys, and wharves; they may also block seawater intakes into the cooling systems of power stations.

Few bivalves are host to human parasitic infections. Industrial and agricultural effluents—notably trace metals, chlorophenothane (DDT), and chlorinated hydrocarbons—have contaminated bivalves, with subsequent concern over human health.

NATURAL HISTORY

Reproduction and life cycles. Although most bivalves are either male or female (dioecious), some produce both sperm and eggs (hermaphroditic); sexual dimorphism is rare. In dioecious species there is usually an equal division of the sexes. Some groups of bivalves, typically those occupying specialized habitats, have adopted hermaphroditism as a reproductive strategy, although expression of this condition may take various forms (simultaneous, consecutive, rhythmical consecutive, and alternative hemaphroditism). Simultaneous hermaphroditism occurs when sperm-producing tubules and egg-producing follicles intermingle in the gonads (as in the family Tridacnidae), or the gonads may be developed into a separate ovary and testis, as in all representatives of the subclass Anomalodesmata. In consecutive hermaphroditism, one sex develops first. Typically, this is the male phase (protandry), but in a few cases it is the female (protogyny). This is most clearly seen in the wood-boring family Teredinidae, where a young male becomes a female as it ages. Rhythmical consecutive hermaphroditism is best known in the European oyster, *Ostrea edulis,* in which each individual undergoes periodic changes of sex. Alternative hermaphroditism is characteristic of oysters of the genus *Crassostrea,* in which most young individuals are male. Later the sex ratio becomes about equal, and finally most older individuals become female.

Hermaphroditism

Bivalve sperm have two flagellae. Most eggs are small, and synchronized spawning results in the discharge of both types of gametes into the sea for external fertilization. Hermaphrodites either inhale sperm from another individual or fertilize their own eggs within the ctenidia; the eggs are then brooded, typically also within the ctenidia. There, the fertilized eggs, well endowed with yolk, develop directly (without a larval stage), and the young are released as miniature adults. Although ctenidial incubation is most common, there are other patterns: egg capsules are produced by *Turtonia minuta;* a brood chamber is plastered to the shell of the palaeotaxodont *Nucula delphinodonta;* and in members of the Carditidae the female shell is modified into a brood pouch.

Larval stage

For most marine species, however, the fertilized egg undergoes indirect development first into a swimming trochophore larva and then into a veliger larva in which the embryonic shell and rudiments of other organs are established. The veliger has a ciliated velum for swimming and also for trapping minute particles of food. Following a period in the plankton, the veliger settles to the seafloor, where metamorphosis into the adult takes place: the velum is lost, the foot develops and usually secretes one or two byssal threads for secure attachment, and the ctenidia develop.

In the freshwater Unionidae the released larva, called a glochidium, often has sharp spines projecting inward from each valve. The larva is attracted to fish and attaches to either their gills or fins, where it encysts, is temporarily parasitic, and eventually ruptures the cyst wall and falls to the lake floor. There it metamorphoses into an adult.

Ecology and habitats. The division and lateral compression of the shell into two valves is clearly related to the adoption of a burrowing mode of life, which is achieved by a muscular foot. Primitive forms were detritivorous, whereas modern bivalves are filter feeders that have modified the respiratory gills into complex structures called ctenidia. The burrowing, filter-feeding mode of life restricts bivalves to aquatic environments.

Retention of the larval anchoring byssus into adult life has freed many bivalves from soft substrates, allowing them to colonize hard surfaces. This has also been achieved by cementation, as, for example, in oysters.

Movement

There are no pelagic bivalves, except for *Planktomya hensoni,* which is still benthic as an adult but has an unusually long planktonic larval stage. Some bivalves can swim, albeit weakly, when removed from the sediment, as can some file shells. True swimming is, however, seen only in the family Pectinidae but is used mostly as an escape reaction.

Many representatives of the superfamily Galeommatoidea are commensal, a few are parasitic, and both have thus become miniaturized. Most bivalves are found in coastal seas, but their diversity is greatest on continental landmasses, where large rivers create suitable deltaic habitats and the continental shelf is broad. Except on tropical ones with coral reefs, few bivalves are found on islands.

Of the various subclasses, two are most important ecologically: the Heterodonta, which are modern burrowers that feed primarily on suspended material, and the Pteriomorphia, an older group that is epibyssate and dominates hard substrates. Some of their older representatives are endobyssate, exposing their evolutionary history. Most of these two classes occupy a wide diversity of subhabitats, with simple reproductive strategies, external fertilization, and planktonic larvae to effect wide dispersion. They apportion the shallow-water marine domain virtually everywhere. The Palaeoheterodonta are exclusively fresh water and infaunal although a few in South America are epifaunal, but all have significantly more complicated life cycles.

The Palaeotaxodonta are coastal and deepwater detrivores, always infaunal. They share this diversity of habitat with the Anomalodesmata, which have radiated along two lines: shallow-water species that are highly specialized, are hermaphroditic, occupy narrow niches, and have a short planktonic stage and deep-sea species that are even more specialized, most being predators.

Most bivalves are primary consumers, typically exploiting organic material. The two dominant bivalve subclasses are high in the diet of many predators. Some 60 million years ago great adaptive radiation, notably in the Bivalvia, took place with a similar radiation in predatory crustaceans, starfishes, and snails. It is thought that such predation pressure effectively drove the Bivalvia underground with the resultant evolution of many antipredation devices on the shell—spines, ridges, and teeth—or of the habit of burrowing to great depths. On coral reefs a similar pressure led to deep boring into the fabric of the coral and the evolution of a host–borer intimacy.

Locomotion. Unlike in other molluscan groups, locomotion in bivalves is used only when dislodgement occurs or as a means to escape predation.

The bivalve foot, unlike that of gastropods, does not have a flat creeping sole but is bladelike (laterally compressed) and pointed for digging. The muscles mainly responsible

for movement of the foot are the anterior and posterior pedal retractors. They retract the foot and effect back-and-forth movements. The foot is extended as blood is pumped into it, and it is prevented from overinflating by concentric rings of circular, oblique, and longitudinal muscle fibres, which also help to direct pedal extension and permit fine mobility.

Burrowing

During burrowing, the foot is greatly extended anteriorly from between parted shell valves. Taking a grip on the substratum, typically by dilation of the tip, the pedal retractors pull the shell downward. This is accompanied by sharp adduction of the shell valves, forcing water out of the mantle cavity into the burrow, helping to fluidize the sediment, and making movement through it more efficient. So effective is this mechanism that fast burrowers, when removed from the sediment, can swim.

Food and feeding. The primitive bivalve was almost certainly a detritivore (consumer of loose organic materials), and the modern palaeotaxodonts still pursue this mode of life. The posterior leaflike gills serve principally for respiration; feeding is carried out by the palp proboscides, which collect surface detritus.

The vast majority of other bivalves feed on the plant detritus, bacteria, and algae that characterize the sediment surface or cloud coastal and fresh waters. The gills have gradually become adapted as filtering devices called ctenidia. The primitive posterior respiratory gills have enlarged and moved to lie lateral to the body as paired folds, or demibranchs. Further increases in surface area have been achieved by folding the platelike gill lamellae into plicae. Each lamella comprises vertical rows of filaments upon the outer head of which are complex arrays of cilia that create a flow of water through the gill, form a filtration barrier, and transport retained particles to food grooves in the dorsal axes or ventral margins of the ctenidia. Bound in mucus, the food is transported to the mouth via the labial palps, where further selection occurs (see below *Internal features*).

Evolution of the ctenidia

Two groups of bivalves have exploited other food sources. These are the shipworms (family Teredinidae) and giant clams (family Tridacnidae). Shipworms are wood borers and are both protected and nourished by the wood they inhabit. They possess ctenidia and are capable of filtering food from the sea. When elongating the burrow, they digest the wood as well. In the Tridacnidae, symbiotic zooxanthellae (minute algal cells) are contained within the inhalant siphon. The relationship between clam and algae is probably mutually beneficial, the algae having access to the dissolved waste products of the clam and the clam benefiting from the nutritional value of either culled zooxanthellae or their metabolic products.

A few bivalves are parasitic—*e.g.*, species of *Entovalva*, which live either in the esophagus or upon the body of sea cucumbers (Holothuroidea), and the larvae of freshwater Unionidae, which parasitize fish.

The most exotic adaptations of the basic bivalve feeding plan are found in two groups of deepwater bivalves. These are scallops of the genus *Propeamussium* and the various deepwater families of the Anomalodesmata. In *Propeamussium* what appear to be typical ctenidia are present in the mantle cavity, but on closer examination these prove to be wholly atypical in that the filament heads are internal. The ctenidia are incapable of filtering. The gut is minute, and detected prey is sucked into the mantle cavity by an inrush of water when the valves open. The food is then pushed into the mouth with the foot.

Many deepwater Anomalodesmata have modified the typical bivalve ctenidium into a septum—the "septibranch" ctenidium—that creates pressure changes within the mantle cavity and produces sudden inrushes of water, carrying prey into a funnellike inhalant siphon (*Cuspidaria*). Food is then pushed into the mouth by the palps and foot. Others evert the inhalant siphon, like a hood, over the prey (*Poromya* and *Lyonsiella*). Prey items include small bottom-dwelling crustaceans, polychaete worms, and larvae of other benthic animals.

Adaptations

Associations. The greatest affinity of bivalves is with coral reefs. Indo-Pacific, but not Caribbean, reefs are the habitat of giant clams, *Tridacna*. Dead corals are bored by representatives of the Gastrochaenidae, living corals by species of *Lithophaga*. A greater degree of intimacy between living coral and bivalve borer is now known, some species associating with a single coral.

Similarly with wood borers: piddocks (Pholadidae) are more common in hardwoods, while shipworms (Teredinidae) favour softwoods. In the degradation of wood in the sea, a variety of species may colonize it with time and with depth.

One group of bivalves, the superfamily Galeommatoidea, form highly intimate relationships with other marine invertebrates, particularly on soft shores and coral reefs. Typically less than 10 millimetres (0.4 inch) long, most are commensal; *i.e.*, they form an association in which there is no detriment to the host and exploit it for protection, food, and respiratory currents. On soft shores they share the burrows of polychaete worms and crustaceans, sometimes attaching to the body of the host.

FORM AND FUNCTION

General features. The bivalve body comprises a dorsal visceral mass and a ventral foot, which is enclosed within a thin mantle, or pallium. The mantle secretes from its outer surface a shell divided into left and right valves. Between the body and mantle is the mantle cavity, within which hang the left and right gills, or ctenidia. The ctenidia are divided into two demibranchs, inner and outer, each in turn comprising inner and outer lamellae. Anteriorly, the ctenidia unite with paired (left and right) labial palps, which are food-sorting organs. The mantle margin can be fused at various places leaving medial apertures anteriorly for the extension and retraction of the locomotory foot and, in most bivalves, posteriorly to create inhalant and exhalant apertures that may be formed into siphons of variable length according to habitat. Foot and siphons can be withdrawn between the shell valves into the mantle cavity for protection.

External features. The bivalves occupy a wide variety of habitats and, as a consequence, deviate widely from the basic body plan. The shell form is an obvious adaptation to the environment. Shells of many modern burrowers are ornamented and coloured, and those of near-surface-dwelling cockles are thick and radially ribbed. These adaptations stabilize the animal in the substrate and may confer some degree of protection against predators. Such bivalves are slow burrowers. In contrast, the shells of deep-burrowing species are thin and nonornamented. They are often brightly coloured, as in the Tellinidae. The shell is laterally compressed and thus more bladelike, but the adductor muscles are still of similar size (the isomyarian form). Such structural features adapt the animal for rapid movement through the sand; long siphons project to the surface above. Deep burrowing has been achieved by a different mechanism in the razor shells (e.g., the family Solenidae), where the anterior region of the shell is reduced and the posterior enormously elongate. Because of their short siphons, *Ensis* and *Solen* live close to the sediment surface, but, with the lateral compression of their polished shells, they are among the most proficient burrowers. Other bivalves—*e.g.*, *Mya* (family Myidae)—live at great depths but do not burrow rapidly. The shell is largely unornamented and wider to accommodate the greatly elongated siphons, which can be retracted deeply within its borders.

The shell

Rock and wood boring are also specialized consequences of burrowing—the evolution of borers proceeded from the habitation of stiff muds or from nestling within crevices. Mechanical borers tunnel anterior end first; that face of the shell having a sculpture of spines. Borers derived from a nestling epibyssate ancestor are chemical borers that produce a calcium carbonate chelating secretion from the mantle margin. In such cases the shell is typically smooth, although calcareous encrustations on the posterior shell protect the borer from aperture-attacking predators. Reduction of the anterior adductor (the anisomyarian form) creates a triangular-shaped shell, as in the buried fan shell *Pinna* (Pinnidae) and the mussels (Mytilidae) of rocky coasts. Although such bivalves lack ornamentation, the shell is typically thick and dark.

Mechanical versus chemical borers

Figure 9: *Anisomyarian and monomyarian bivalves, with sketches of the internal gill and muscle arrangements.*
Arrows indicate inhalant and exhalant water currents. (A) *Pinna*, endobyssate with reduction of the anterior, and enlargement of the posterior, adductor. (B) *Geukensia*, endobyssate with reduction of the anterior, and enlargement of the posterior, adductor. (C) *Mytilus*, epibyssate with reduction of the anterior, and enlargement of the posterior, adductor. (D) *Pinctada*, epibyssate, laterally flattened, with loss of the anterior adductor. (E) *Lima*, epibyssate and monomyarian, with long tentacles and capable of limited swimming. (F) *Pecten*, with loss of the anterior adductor, byssus, foot, and associated musculature and capable of swimming. (G) *Ostrea*, cemented and with loss of the anterior adductor, byssus, foot, and associated musculature.

From (Geukensia) S.M. Stanley, *Relation of Shell Form to Life Habits of the Bivalvia (Mollusca)*, Geological Society of America Memoir no. 125 (1970); (*Mytilus, Pinctada, Lima*) R.C. Moore (ed.), *Treatise on Invertebrate Paleontology: Mollusca 6* (1969), Geological Society of America and University of Kansas Press; (Ostrea) W. de Haas and F. Krivor, *The Young Specialist Looks at Marine Life* (1966), Burke Publishing Co., London

Loss of the anterior adductor creates a shell with a circular outline, left and right valves being either equal or unequal. In some, lateral flattening and byssal attachment allows occupation of narrow crevices. Cementation by either valve is a further consequence of the loss of the anterior adductor muscle (the monomyarian form). Subsequent freedom from attachment, as in the scallops (Pectinidae), is associated with an almost circular outline, flat upper and cup-shaped lower valves, a deep radial sculpture, and, typically, bright coloration (*Pecten*).

Internal features. The general classification of the bivalves is typically based on shell structure and hinge and ligament organization (Figure 9). The internal anatomy is also a tool in classification, particularly the organs of the mantle cavity, the pattern of water movement through it, and the structure and functioning of the ctenidia and labial palps. Early anatomists established a correlation between shell and gill structure that is still often used as a basis for classification but which is now relegated to defining the evolutionary sequence from a deposit-feeding to a filter-feeding mode of life.

The primitive bivalve form

Nucula, from the subclass Protobranchia, reflects the primitive bivalve ancestor. Burrowing close to the sediment surface, *Nucula* is equivalve, anteriorly and posteriorly symmetrical, and isomyarian. The medial foot is wide. There are no mantle fusions ventrally, and the aerating water current passes through the mantle cavity from front to back, a feature not typical of most modern bivalves. The structure of the small gills (Figure 10), located posteriorly, is interpreted as being similar to the earliest mollusks—hence the name protobranch, or "first gills." The paired gills, separated by a central axis, are suspended from the mantle roof. Individual short gill filaments extend outward from either side of the axis, and cilia on their surfaces create an upward respiratory water current that passes from the mantle cavity below the gill (the

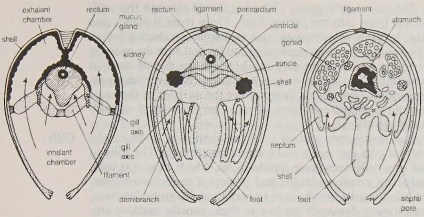

Figure 10: Transverse sections through the bodies of (A) *Nucula*, with a protobranch gill, (B) *Spisula*, with a lamellibranch gill, and (C) *Poromya*, with a septibranch gill. Arrows indicate the water currents through the gill for respiration but also for filter feeding in *Spisula*.

infrabranchial, or inhalant, chamber) to that area above it (the suprabranchial, or exhalant, chamber). The anus and the urogenital pores also open into the exhalant chamber so that all waste products exit the animal in the exhalant stream. The paired labial palps in the mantle cavity are used in feeding. The outer palp on each side bears a long, extensible proboscis with a ciliated groove that collects organic material, which is then sorted by the inner pair and outer pair of palps. Certain particles are transferred to the mouth by the ciliary currents of the inner pair of palps, while the remaining particles are sent by the outer palps into the mantle cavity as a mucus-bound mass known as pseudofeces, which are ejected by periodic contractions of the adductor muscles.

An important event in the evolution of the modern bivalve from the more primitive form illustrated above was the reorientation of the anterior inhalant stream to the posterior below the exhalant stream so that water both enters and exits the mantle cavity posteriorly. For burrowing bivalves, such a body organization allows deep burrowing in a vertical (head down) orientation, and thus escape from the sediment surface. These changes generally are associated with changes in the method of feeding and, as a consequence, the selective fusion of left and right mantle margins to exclude sediment from the mantle cavity.

Evolution of a new gill structure

The burrowing *Spisula* illustrates these changes. It, like *Nucula*, is equivalve and anteriorly and posteriorly symmetrical (isomyarian). The mantle margin is fused ventrally, allowing the foot to extend through an anterior pedal gape. The posterior inhalant and exhalant orifices are formed into tentacle-fringed siphons. The gills are here positioned on either side of the visceral mass. Gill filaments are greatly elongated and folded (forming the shape of a W) to increase their surface area. The central axis of the W joins it to the body, and the outermost arms unite with the visceral body on one side and the mantle on the other. A complex arrangement of cilia on the apex of each filament constituting the gill lamellae draws a water current through the gill, which provides oxygen, but more importantly now sieves food from this current and transfers such material along tracts in the gill axes or their ventral margins (bound in mucus) toward the labial palps. The palps process this food and eliminate the pseudofeces as in *Nucula*.

The modified gill is called a ctenidium, and its structure is best explained by the term lamellibranch. The lamellibranch structure may be further qualified as filibranch, pseudolamellibranch, or eulamellibranch. In filibranchs the filaments are only weakly united by cilia, and often the ctenidium retains some inherent sorting mechanism. Collection and sorting of potential food has not yet been definitively ascribed to gills and labial palps, respectively. In the pseudolamellibranch ctenidium, filaments and lamellae are more securely united, and an inherent sorting mechanism still exists in some. In many, however, the filaments are vertically aggregated into folds, or plicae, that greatly increase the total surface area. In the eulamellibranch ctenidium the filaments and lamellae are closely united, the selection function is lost, and gill structure varies widely. Most modern bivalves are filter feeders, and except in a few members the siphons suck in particles suspended in the water column.

In the deep seas, modification of the lamellibranch ctenidium has allowed the adoption of carnivory. The predatory bivalves of the subclass Anomalodesmata have an inhalant siphon that can be everted rapidly to form a capacious hood beneath which small crustaceans are trapped and brought into the mantle cavity. The eversion of the siphon is assisted by a horizontal septum across the mantle cavity, which is derived from the mantle and the greatly reduced ctenidium. This is the septibranch ctenidium.

Importance of the byssus

The release from a burrowing mode of life has been facilitated by the retention of a larval structure (the byssus) into adult life. The byssus, secreted by a gland in the foot, secures the animal to a hard surface in preparation for burrowing. Its retention and enlargement in the adult has provided a secure means of attachment to the open surfaces of rocks in the intertidal, estuarine, and fresh waters.

In the triangular mussels (Mytilidae) of such habitats the anterior is reduced, and the body and organs of the mantle cavity are contained in the expanded posterior regions of the shell. The reduction of the anterior adductor muscle is matched by a reduction in the size of the anterior pedal retractor muscles (and enlargement of the posterior equivalents). Since such muscles are less concerned with locomotion and more with pulling the shell down against the substrate, they are more correctly redefined as byssal retractors. The ctenidia and palps fulfil the same role as they do in burrowing lamellibranch bivalves, but, because of the triangular cross section of the shell, they come to lie largely underneath the visceral mass instead of beside it.

Further reduction of the anterior adductor, leading to its eventual loss, creates what is called the monomyarian condition. In bivalves with such a configuration, the anterior shell and mantle are confined to a small area; the foot, where present, is always greatly reduced and positioned anteriorly. The visceral mass and organs of the mantle cavity are arranged around the central posterior adductor muscle, and there is extreme reduction or loss of the anterior pedal/byssal retractor muscles. Shell valves may be so compressed that the space between them, as in *Placuna*, the windowpane oyster, is very narrow. Alternatively, as in oysters and scallops, one valve is cup-shaped, with the other fitting against it like a lid. In such a case, the body occupies the former valve, the left in oysters and generally the right in all others, such as the scallops. In these bivalves the bilateral symmetry of the shell and mantle is replaced by a radial symmetry from the midpoint of the hinge line. In these bivalves, too, the adductor muscle is more clearly demarcated into "quick" (striated) and "slow" (smooth) components for rapid and sustained adduction respectively. The capacity for work of the greatly enlarged quick component of the scallop muscle permits rapid adduction that facilitates swimming by directing jets of water out of the mantle cavity to each side of the hinge line characterized by shell auricles.

Shell structure

The shell. The bivalve shell is made of calcium carbonate embedded in an organic matrix secreted by the mantle. The periostracum, the outermost organic layer, is secreted by the inner surface of the outer mantle fold at the mantle margin. It is a substrate upon which calcium carbonate can be deposited by the outer surface of the outer mantle fold. The number of calcareous layers in the shell (in addition to the periostracum), the composition of those layers (aragonite or aragonite and calcite), and the arrangement of these deposits (*e.g.*, in sheets, or foliate) is characteristic for different groups of bivalves. Middorsally an elastic ligament creates the opening thrust that operates against the closing action of the adductor muscles. The ligament typically develops either externally (parivincular) or internally (alivincular) but comprises outer lamellar, and inner fibrous, layers secreted by the mantle crest. The ligament type is generally characteristic of each bivalve group. The hinge plate with ligament also possesses interlocking teeth to enforce valve alignment and locking, when closed, to prevent shear. Many variations in teeth structure occur.

The mantle and musculature. The mantle lobes secrete the shell valves; the mantle crest secretes the ligament and hinge teeth. Growth takes place at the margins, although increases in thickness take place everywhere. The mantle is withdrawn between the shell valves by mantle retractor muscles; their point of attachment to the shell being called the pallial line.

Musculature

The musculature comprises two (dimyarian) primitively equal (isomyarian) adductor muscles; the anterior and the posterior. The anterior of these may be reduced (anisomyarian; heteromyarian) or lost (monomyarian). Only very rarely is the posterior lost and the anterior retained.

Internal to the adductors are paired anterior and posterior pedal retractor muscles. Where the anterior adductor muscle is reduced, so are the anterior pedal retractors. In highly active burrowers, paired anterior pedal protractors and pedal elevator muscles occur—for example, the family Trigonioidea.

In byssally attached bivalves, pedal retractors are reduced and byssal retractors serve to pull the animal down in closer opposition to the rock surface. In oysters, commensurate with the extreme reduction of the foot, pedal retractors are lost. This is also the case in swimming scallops.

The nervous system and organs of sensation. The nervous system is simple, reflecting the sedentary habit. In primitive bivalves (*e.g.,* Palaeotaxodonta) there are four pairs of ganglia—cerebral, pleural, pedal, and visceral. In all other bivalves the cerebral and pleural ganglia are fused into two cerebropleural ganglia, located above and on either side of the esophagus. The pedal ganglia are in the base of the foot, and the visceral ganglia are located under the posterior adductor muscle. Nerve fibres arising from the cerebropleural ganglia extend to the pedal and visceral ganglia. In some bivalves with long siphons, there are accessory siphonal ganglia, and in many swimming bivalves the visceral ganglia are much enlarged, presumably to coordinate complex swimming actions.

Again reflecting the sedentary life, sensory functions are largely taken over by the posterior mantle margins and typically comprise tentacles developed from the middle mantle folds that are mechanoreceptors and chemoreceptors. Scallops (family Pectinidae) have complex eyes with a lens and retina. In other bivalves, eyes are simple ciliated cups, although some variation is possible. In the predatory deepwater septibranchs the inhalant siphon, which captures food, is surrounded by tentacles that have vibration-sensitive papillae for detecting the movements of prey.

Statocysts

Situated close to the pedal ganglia but with direct connections to the cerebropleural ganglia are a pair of statocysts, which comprise a capsule of ciliated sense cells. In the lumen is either a single statolith or numerous crystalline statoconia. Their points of contact with the surrounding cilia yield information about the animal's orientation. Additionally, most bivalves with or without eyes have light-sensitive cells that respond to shadows. Below the posterior adductor muscle an osphradium has been identified in some bivalves that may monitor water flow and quality.

The digestive system and nutrition. The bivalve digestive system comprises a complex stomach and associated structures but an otherwise simple intestine. The various types of stomach have been used to erect an alternative classification. Digestion typically takes place in two phases: extracellular in the stomach and intracellular in the digestive diverticula, opening laterally from the stomach wall. Transport of food particles is effected by cilia, creating an array of tracts and sorting areas within the stomach. The principal organ of extracellular digestion is the crystalline style. It is rotated in its sac by cilia; the head, projecting into the stomach, grinds against a part of the stomach wall lined by a chitinous gastric shield. As it rotates, it dissolves, releasing enzymes and initiating primary extracellular digestion of the mucus-bound food. Products of this process are passed in a fluid suspension into large embayments and thence into the digestive diverticula, where intracellular digestion takes place. Waste material is consolidated in the midgut and rectum and expelled as firm fecal pellets from an anus opening into the exhalant stream. Feeding and digestion are highly coordinated, typically regulated by tidal and diurnal cycles.

The excretory system. Blood is forced through the walls of the heart into the pericardium. From there it passes into the kidneys where wastes are removed, producing urine. The paired kidneys (nephridia) are looped with an opening into the pericardium and another into the suprabranchial chamber. The kidneys may be united. Bivalves also possess pericardial glands lining either the auricles of the heart or the pericardium; they serve as an additional ultrafiltration device.

Gills

The respiratory system. In the primitive bivalves the paired gills are small and located posteriorly. The gills in all other bivalves (save septibranchs, which have lost their gills) are greatly enlarged and possess a huge surface area. While the gills are thought to serve a respiratory function, respiratory demands are low in these mostly inactive animals, and, since the body and mantle are both bathed in water, respiration probably takes place across these surfaces as well. Such a mechanism has been demonstrated for a few bivalves, most notably freshwater species that are exposed to occasional drought. In such species, drying induces slight shell gaping posteriorly, the mantle margins exposing themselves to air. For most intertidal bivalves (which are alternately exposed to wetting and drying), respiration all but ceases during the drying phase.

The vascular system. The heart, enclosed in a pericardium, comprises a medial ventricle with left and right auricles arising from it. Blood oxygenated within the ctenidia flows to the auricles and from there to the ventricle, where it is pumped into anterior and posterior aortas. The blood then enters hemocoelic spaces in the mantle and visceral mass and returns to the heart via the ctenidia or the kidneys. The blood serves both to transport oxygen and metabolic products to tissues deep within the body and as a hydrostatic skeleton (for example, in the extension of the foot during locomotion and siphons during feeding). There are amoeboid corpuscles but, except in a few bivalves, no respiratory pigment.

The reproductive system. The reproductive system is simple and comprises paired gonads. These gonads discharge into the renal duct in primitive bivalves but open by separate gonopores into the suprabranchial chamber in more modern bivalves. Typically, the sexes are separate, but various grades of hermaphroditism are not uncommon. Eggs and sperm are shed into the sea for external fertilization in most bivalves, but inhalation of sperm by a female permits a type of internal fertilization and brooding of young, usually within the ctenidia.

Significant adaptations

Features of defense and aggression. The most significant adaptation is the earliest division of the shell into two valves within which the animal was wholly contained. Slow components of the adductor muscle permit sustained adduction, while the interlocking hinge teeth prevent shear. In addition, the shell may be strongly ridged, forming an interlocking shell margin, and it may be concentrically ringed with spines or sharp ridges projecting outward. Posterior sense organs, including photophores and eyes, are developed around the siphons and mantle margins. Detection leads to withdrawal deep into the sediment by burrowing species. In such animals the shell is smooth and compressed. Scallops respond to predation by swimming; shallow-burrowing cockles can leap using the foot. In the razor clams the siphons can break off (autotomize) when bitten, to be regenerated later. Similarly, noxious secretions are produced by the similarly autotomizing long tentacles of the Limidae (file shells). The unique pallial organ of fan shells (family Pinnidae) produces a secretion of sulfuric acid when bitten.

Only the deepwater subclass Anomalodesmata (families Verticordiidae, Poromyidae, and Cuspidariidae) and the scallops are predators. Prey is captured either in the sudden rush of water into the mantle cavity or by the rapid eversion of the inhalant siphon.

EVOLUTION AND PALEONTOLOGY

Oldest bivalve

The oldest known bivalves are generally believed to be *Fordilla troyensis,* which is best preserved in the late Early Cambrian rocks of New York (about 550 million years ago), and *Pojetaia runnegari* from the Cambrian rocks of Australia. *Fordilla* is perhaps ancestral to the pterio-

morph order Mytiloida, *Pojetaia* to the Palaeotazodonta order Nuculoida.

By the Ordovician period (505 to 438 million years ago) most modern subclasses were represented by definable ancestors. The oldest Ordovician bivalves are, however, the subclass Palaeotaxodonta, which are thought to have given rise to the Cryptodonta by elongation. Modern assessment of their shell structure and body form, notably with the possession of posterior protobranch gills and with palp proboscides for deposit feeding in the Palaeotaxodonta, generally supports this view. An extinct subclass Actinodontia also arose in the Ordovician period and may be represented today by the superfamily Trigonioidea (placed in the subclass Palaeoheterodonta), which are an aberrant group of the subclass Pteriomorphia. The remaining, more typical, members of the Pteriomorphia also arose at this time and persist today, still characteristically occupying a range of substrate types but with byssal attachment and a trend toward loss of the anterior adductor muscle. The common mussels (family Mytilidae) are thought to be derived from an extinct group, the family Modiomorphidae. The subclass Orthonotia also arose in the Ordovician period and are the probable ancestors of the deep-burrowing razor shells (Solenoidea). The origins of the subclass Anomalodesmata are less clear, but they too arose in the Ordovician period and may have links to the order Myoida, which presently includes deep-burrowing forms and borers. Representatives of the superfamily Lucinoidea are very different from all other bivalves, with an exhalant siphon only and an anterior inhalant stream. Some of these deposit feeders also possess, like the subclass Cryptodonta, sulfur-oxidizing bacteria in the ctenidia and are thought to have ancient origins, represented by the fossil *Babinka. Babinka* is itself interesting and is closely related either to *Fordilla,* one of the oldest bivalves or to the ancestors of the molluscan class Tryblidia. Today the superfamily Lucinoidea is generally placed within the subclass Heterodonta, which is a younger group that traces back to the Paleozoic era, when the first radiation of all bivalves took place.

The stamp of modernity was placed upon the Bivalvia in the Mesozoic era (245 to 66.4 million years ago), when virtually all families currently recognized were present. Throughout time, the fortunes of the subclasses have waxed and waned, with repeated modification of form allowing repeated diversification into different habitats. Similarity of habitat is matched by similarity in structure and form, allowing for various interpretations of the fossil record. It is clear, however, that most modern bivalves can trace their ancestry back a long way and that the inherent plasticity of the bivalve form is responsible for the success of a molluscan experiment in lateral compression of the shell.

CLASSIFICATION

No system of classification erected for the Bivalvia has been accepted by all. Paleontologists interpret bivalves on the basis of shell features, notably shell and ligament structure, arrangement of hinge teeth, and body form as interpreted from internal muscle scars.

Investigators of Recent (Holocene; 10,000 years ago to the present) forms use other anatomic features, such as adductor muscle arrangement, the ctenidia and their junction with the labial palps, the extent and complexity of mantle fusion, and stomach structure. Cluster analysis using many morphological features is effective with lower taxa but less so with higher taxonomic categories because of the many examples of parallel evolution from the basic bivalve plan. The triangular mussel form, for example, has evolved in representatives of virtually every subclass, resulting in similar morphologies. Shell microstructure and mineralogy evidence generally support paleontological conclusions that the class Bivalvia comprises six subclasses, recognizing, however, that some of these taxa may have more than one first ancestor (polyphyletic). In a group with a fossil history extending back to the Cambrian period and occupying a wide range of aquatic habitats, this is not unexpected, particularly since the basic bivalved form permits repeated modification.

Annotated classification.

CLASS BIVALVIA

Laterally symmetrical; left and right calcareous shell valves; dorsal elastic hinge ligament; anterior and posterior adductor muscles; lateral paired filtering ctenidia surrounding the visceral mass; primitively burrowing by means of a muscular foot, but some crawl, some attach to rocks by byssal threads from the foot, some are cemented, and some bore into soft rocks, corals, and wood; some commensal, a few parasitic, and some deepwater species predatory; microphagous feeding; mostly marine, at all depths, also estuarine and freshwater; about 8,000 extant species.

Subclass Palaeotaxodonta

Numerous similar teeth along the hinge plate; isomyarian; unique shell microstructure of aragonitic composite prisms and internal nacre; posterior ctenidia comprising 2 divergent rows of flat, short, filaments; protobranch respiratory gill; food collected by labial palps; mostly near-surface-dwelling marine detritivores; considered to be the most primitive of living bivalves, if not the most ancient.

Order Nuculoida

Equal shell valves with taxodont hinge teeth; isomyarian; posterior protobranch ctenidia; large labial palps usually with palp proboscides, which effect feeding; foot with flat sole; marine; unattached; infaunal.

Subclass Cryptodonta

Hinge either weakly taxodont or edentulous; distinctive shell structure of aragonitic simple prisms and nacre internally; large posterior protobranch ctenidia; small labial palps; of primitive and ancient lineage; marine; unattached; infaunal.

Order Solemyoida

Shell valves equal and elongate, lacking hinge teeth, covered by a shiny periostracum; dimyarian or monomyarian; some with protobranch ctenidia containing symbiotic sulfur-oxidizing bacteria; minute palps; minute or absent gut; foot with flat sole; marginally papillate; marine; deep-burrowing; infaunal.

Subclass Pteriomorphia

Highly variable shell form and structure; dimyarian, anisomyarian, or monomyarian; variable hinge dentition; lateral filibranch ctenidia comprise paired demibranchs of weakly united filaments; mostly marine; some cemented; most epibyssate; some infaunal; representative of the earliest filter-feeding bivalves.

Order Arcoida

Shell solid, elongate or circular-oval, often heavily ribbed; fibrous periostracum with simple crossed-lamellar outer layer and inner complex crossed-lamellar layer, thereby differing from all other pteriomorphs; dimyarian; hinge with vertical denticulations; ctenidia filibranch; mantle margin with uniquely divided outer fold; foot often byssate; marine; epibyssate; infaunal.

Order Trigonioida

Shell valves equal, trigonally oval, strongly ribbed; shell with outer aragonitic prismatic layer and inner nacre layers; strong hinge teeth transversely grooved; typically isomyarian, with pedal elevator and protractor muscles as well as retractors; ctenidia filibranch, without mantle fusions; powerful foot; marine; infaunal; living species confined to Australia.

Order Mytiloida (common mussels)

Shell equivalve, rounded, elongate or triangular depending on habits; anisomyarian tending toward monomyarian; hinge edentulous; shell microstructure of outer calcitic fibrous prisms and inner nacre; ctenidia filibranch; mantle margin lacking fusions; foot creeping; typically byssate; marine, estuarine, rarely freshwater; endobyssate and epibyssate.

Order Pterioida (pearl oysters and fan shells)

Shell equivalve, variably shaped; anisomyarian but often monomyarian; shell structure of outer simple calcitic prisms and inner nacre; ctenidia pseudolamellibranch, often plicate (deeply folded); mantle margin lacking fusions; foot reduced; marine; endobyssate or epibyssate.

Order Limoida

Shell equivalve, ovally elongate, ribbed, often thin and transparent, with outer foliated calcite and inner crossed-lamellar aragonitic layers; hinge short and edentulous; monomyarian; ctenidia pseudolamellibranch, encircling the adductor; palps small and lips of mouth variably fused; mantle margins unfused and often red, with long autotomizing tentacles; some swim weakly; marine; epibyssate with byssus sometimes formed into a nest.

Order Ostreoida (oysters and scallops)

Shell valves unequal, variable, typically lacking hinge teeth; shell structure of foliated calcite, upper valve with outer pris-

matic calcite; most scallops with inner crossed-lamellar layers; dimyarian but most monomyarian; ctenidia pseudolamellibranch; mantle fusions lacking; foot often lost in adult; scallops capable of swimming; some deepwater scallops predatory; marine; epibyssate; cemented by lower or left valve or free.

Subclass Palaeoheterodonta

Characterized by equal shell valves with a variable hinge dentition; aragonitic shell with outer prismatic and inner layers of nacre; most approximately isomyarian; ctenidia eulamellibranch; mantle fusions lacking, especially ventrally; complicated life cycles; wholly freshwater; nonbyssate; infaunal.

Order Unionoida

Large, equivalve, varying from round to elongate and with equally variable sculpture; shell of outer prismatic layer and inner layers of nacre; hinge schizodont; dimyarian; ctenidia eulamellibranch with either 1 or both demibranchs functioning as an incubatory marsupium; ovoviviparous; parasitically larviparous; freshwater; some cemented and oysterlike; mostly infaunal.

Subclass Heterodonta

Shell highly variable; hinge plate teeth may be reduced or absent; shell comprises crossed-lamellar, complex crossed-lamellar, or prismatic layers, but never nacreous; primitively isomyarian but with wide range of adductor muscle configurations; ctenidia eulamellibranch; mantle margins extensively fused, particularly posteriorly, often to form long inhalant and exhalant siphons; mostly marine but also estuarine and freshwater; some epibyssate, some bore soft rocks and wood; generally infaunal.

Order Veneroida

Shell typically equivalve and of outer crossed-lamellar and inner complex crossed-lamellar layers; hinge comprises radiating cardinal and lateral teeth, often weakly developed; adductor muscles of varying proportions according to habit; ctenidia eulamellibranch, mantle margins extensively fused, often developed into long siphons; most are active burrowers with a large foot; some epibyssate; mostly marine, some estuarine and freshwater; includes the poorly known miniature commensals and parasites; widely divergent, accounting for 50 percent of the extant bivalves.

Order Myoida

Shell typically thin, equivalve, comprising either 2 or 3 layers; hinge plate with cardinal dentition, often degenerate; approximately isomyarian but with much variation; boring forms develop accessory shell plates; ctenidia eulamellibranch, mantle margins extensively fused and covered in periostracum; small foot; marine deep burrowers with long siphons but also rock- and wood-boring.

Subclass Anomalodesmata

Characterized by highly variable shell, either equivalve or inequivalve, often gaping either posteriorly or anteriorly; hinge plate thickened and enrolled but generally edentulous; shell of two or three layers, the inner nacreous; typically isomyarian but with wide variation; ctenidia either eulamellibranch and plicate or septibranch; mantle margins extensively fused, often covered in periostracum; foot reduced; siphons of variable length; consistently hermaphroditic; marine; mostly burrowing; some epibyssate or cemented.

Order Pholadomyoida

Shell more or less equivalve but of widely divergent form; shell comprises aragonitic prisms and nacre or homogeneous structures; typically isomyarian; ctenidia eulamellibranch and plicate but many deepwater species are septibranch; extensive mantle fusions, reduced foot and pedal gape; siphons of variable length; shallow-water forms are burrowing, nestling, epibyssate, or cemented suspension feeders; some deepwater forms are predators with exotic modifications to the bivalve plan.

Critical appraisal. Generally, the classification scheme is accepted up to the level of family and even superfamily. The arrangement of higher categories is, however, still debated. Some authors, for example, combine the subclasses Palaeotaxodonta and Cryptodonta into a single group of primitive detrivores with protobranch gills. Differences in shell structure, however, argue against this. Similarly, the order Arcoida is separated by some from the subclass Pteriomorphia; shell structure again supports this, but other anatomic features do not. The order Trigonioida traditionally has been located within the subclass Palaeoheterodonta, but this has also been disputed, anatomic features suggesting instead an affinity with the subclass Pteriomorphia. This means that the subclass Palaeoheterodonta comprises only the order Unionoida, which has come to occupy the freshwater domain exclusively. Some authors would prefer to relocate the order Myoida from the subclass Heterodonta into the subclass Anomalodesmata, arguing that the edentulous shell, extensive mantle fusions, and deep-burrowing habit are characteristics shared with early ancestors of the order Pholadomyoida. The subclass Anomalodesmata, however, is itself possibly too narrowly demarcated, and some authorities would, for example, separate the deepwater carnivorous septibranchs from the shallow-water pholadomyoids into their own order, the Septibranchoida.

This lack of classificatory agreement is not unusual with regard to a group that has adopted a simple sedentary, filter-feeding mode of life. Simplification and parallel evolution will lead to similarity in form, structure, and function. Debate in creating classificatory trees and reconstructing the historical record is thus about the relative significance of the fossil shell record, as there is little information on tissue morphology, and the importance of morphological data obtained from living representatives. (Br.M.)

Cephalopods (octopuses, squids, cuttlefishes, and nautiluses)

Cephalopoda is a small class of highly advanced and organized, exclusively marine mollusks, of which the octopus, squid, cuttlefish, and chambered nautilus are familiar representatives. The extinct forms outnumber the living, the class having attained great diversity in late Paleozoic and Mesozoic times. The extinct cephalopods are the ammonites, belemnites, and nautiloids, except five living species of *Nautilus*.

GENERAL FEATURES AND IMPORTANCE TO HUMANS

The cephalopods agree with the rest of the Mollusca in basic structure, and the ancestors appear to have the closest affinity with the ancestors of the class Gastropoda. The best-known feature of the cephalopods is the possession of arms and tentacles, eight or 10 in most forms but about 90 in *Nautilus*. Except for the nautilus, all living members of the class show great modification and reduction of the characteristic molluscan shell.

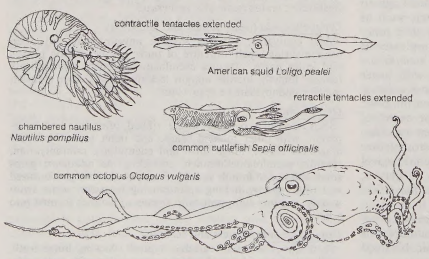

Figure 11: Body plans of typical cephalopods.

Size range

Cephalopods range greatly in size. The giant squids (*Architeuthis* species) are the largest living invertebrates; *A. dux* attains a length of more than 20 metres (60 feet), including the extended tentacles. The smallest cephalopod is the squid *Idiosepius*, rarely an inch in length. The average octopus usually has arms no longer than 30 centimetres (12 inches) and rarely longer than a metre (39 inches). But arm spans of up to nine metres (30 feet) have been reported in *Octopus dofleini*. The shell of the fossil ammonite *Pachydiscus seppenradensis* from the Cretaceous measures 205 centimetres (6 feet 8 inches) in diameter; it is considered to have been the largest shelled mollusk.

Cephalopods occur in large numbers and form one of the greatest potential food resources of the oceans. They are eaten in most parts of the world and have been accepted as part of the general diet in North America and northern Europe. They also are indirectly important to humans since they furnish a large part of the diet of sperm whales and smaller whales, seals, fishes, and seabirds.

NATURAL HISTORY

Reproduction and life cycles. The sexes are usually separate in the Cephalopoda. Sexual dimorphism is usually expressed in slight differences of size and in the proportions of various parts. In the argonaut and the blanket octopus (*Tremoctopus*) the males differ in appearance and size from the females.

Reproductive systems

The female reproductive system is simple, consisting of the posterior ovary and paired oviducts. Nidamental glands exist in species that lay eggs encased in heavy gelatinous capsules.

In males the reproductive system contains a series of chambers or sacs along the course of the vas deferens, which produce long tubes (spermatophores) to contain the spermatozoa. The final sac (Needham's organ) is used for storage of spermatophores. The spermatophores are complicated, containing sperm reservoir, cement body, cap, and a delicate triggering mechanism for releasing the tube and cementing it to the female's body, where the sperm are released when the eggs are mature and ready to be laid. Since spermatophores vary in appearance from species to species, they are important taxonomic characters.

During courtship the male deposits spermatophores in the female, either within the mantle cavity or on a pad below the mouth, by means of a specially modified arm, the hectocotylus. The hectocotylized arm of *Octopus* bears a deep groove on one side, ending in a spoonlike terminal organ. In *Argonauta* and *Tremoctopus* the arm is highly modified and in mating is autotomized (self-amputated) and left within the mantle cavity of the female. In the squids a much larger section of the arm may be modified; often the suckers are degenerate and the distal half of the arm bears rows of slender papillae, although special pouches and flaps may often be found. The modified arm of *Nautilus* is termed the spadix.

Cephalopod mating habits

Little is known about the mating habits of most cephalopods. In the common octopus the male and female remain some distance apart while the male caresses the female with the tip of the hectocotylized arm. The male then inserts the tip of the arm into the mantle cavity of the female, where it remains for more than an hour, during which time the spermatophores travel down the spermatophoral groove of the arm. In the cuttlefish (*Sepia*), according to the Dutch zoologist L. Tinbergen, the pair swims side by side, the male indulging in some courtship behaviour with its arms. Eventually, mating takes place by the pair intertwining their arms and remaining together while the spermatophores are placed on the inner side of the female's mouth membrane. In loliginid squids a somewhat similar type of mating occurs, except that it takes place en masse in schools of thousands of individuals.

Eggs may be laid shortly after mating or after a prolonged period of maturation during which time the sperm remain viable. In loliginids they are fertilized as they are ejected and before being fixed in the egg capsule. In the octopods they may be fertilized as they pass through oviductal glands near the end of the oviduct. In cuttlefishes the eggs are fertilized before the heavy capsule is formed. Egg laying in octopods is accomplished by the female individually fixing the eggs singly or in festoons by a short stalk or thread. In loliginids the eggs in fingerlike capsules often form immense moplike patches, the result of the communal spawning of perhaps hundreds of individuals. Spawning of oceanic squids is very poorly known. The number of eggs laid during a spawning period varies greatly; it may range from only a few dozen in octopuses with large eggs to more than 100,000 in the common octopus, laid over a period of about two weeks. In cuttlefishes the number of eggs is smaller, about 200 to 300 being laid in a season. In loliginids several thousand eggs may be laid by a single female, and the egg mop of the European common squid, resulting from the efforts of many individuals, may contain more than 40,000 eggs.

Egg laying

The eggs of most cephalopods are enclosed within a capsule that may be gelatinous and transparent (the squids of the genus *Loligo*) or opaque and leathery (*Octopus* and cuttlefishes). The eggs of oceanic species may be laid in large sausagelike gelatinous masses or singly. The eggs of most coastal species are laid inshore and are attached singly or in clusters, primarily to rocks and shells on the bottom. Parental care is exhibited by some octopuses, in which the female broods over the eggs in the den, and in the argonaut (*Argonauta*), in which the eggs are carried in a special shell secreted by the female. In most squids and cuttlefishes the eggs are left uncared-for. Squids that attach their eggs to the bottom engulf them in a gelatinous mass that protects them from disease and deters predators. Cuttlefishes squirt their eggs with ink when they are laid to camouflage the otherwise white eggs.

All cephalopod eggs have a remarkable amount of yolk, unlike that in the rest of the Mollusca, so that segmentation is incomplete and restricted to one end of the egg, where the embryo develops. The embryo of a cuttlefish (*Sepia*), squid (*Loligo*), or octopus (*Octopus*) has a yolk sac. In certain presumably archaic Teuthoidea there is less yolk, and the yolk sac is nearly absent. Development of the embryo is direct, without the distinctive larval stages and metamorphoses that occur in other mollusks.

Development

Incubation time varies, but in *Octopus* young hatch in about 50 days and in *Loligo* in about 40 days. At hatching, the young may closely resemble the adult and assume the adult habitat or they may differ from the adult and spend a considerable time in the plankton as part of the drifting life. The juveniles of many cephalopods were described as distinct genera before their juvenile status was discovered. In octopods with small eggs (*e.g., Octopus vulgaris*) the juveniles are planktonic, spending several weeks in the plankton; the "*Macrotritopus*" stage of *Scaeurgus* may greatly prolong its juvenile life until a favourable bottom substrate is found. In octopods with large eggs (*e.g., Octopus briareus*) the young resemble the adult and immediately assume a bottom-dwelling mode of life.

In the order Sepioidea (cuttlefishes and bottle-tailed squids) the young closely resemble the adults and are only briefly planktonic. In the Teuthoidea (squids), especially the Oegopsida, the larvae may differ widely from the adult and the juvenile period may be quite long.

Life span

Little is known about the life span of cephalopods. Studies have shown that in *Octopus joubini* raised from the egg in aquariums, sexual maturity and spawning were reached in five months; in a loliginid squid (*Sepioteuthis sepioidea*), likewise raised from the egg, sexual maturity and full growth were also attained in five months. It thus appears that the smaller inshore species may have a life span of no more than one year or, exceptionally, two or three. Nothing is known of the life span of the large oceanic squids, but it is presumed that giants such as *Architeuthis* attain their bulk only after a period of perhaps four to five years. In the smaller octopuses and squids, observational data indicate that many of the males die after mating and females after the first major spawning.

Behaviour. Cephalopods are unique among the invertebrates in the degree of cephalization and cerebralization attained. The uniting of the major ganglionic centres of the central nervous system constitutes a brain of considerable complexity. Studies undertaken at the Zoological Station in Naples by the British zoologists J.Z. Young, Martin J. Wells, and others have demonstrated that *Octopus* is

capable of learning and has considerable intelligence. The behaviour of squids and octopuses differs considerably because of their different modes of life. Laboratory behavioral studies have dealt mainly with learning processes and have centred around food acceptance, reward and punishment, maze work, and shape discrimination. By means of surgical techniques it has been possible to determine the various functional centres of the brain of *Octopus* and the transmission and receiving pathways.

Research of a detailed nature has been concerned with colour change. Most cephalopods possess colour pigment cells (chromatophores) and reflecting cells (iridocytes) in the skin. The chromatophores are expanded by nerves controlled by the brain, and the colours are exposed (brown, black, red, yellow, or orange red). Colours and colour patterns are exhibited according to specific behavioral conditions—*e.g.,* attack on prey, camouflage, rest, and alarm or defense. Alarm patterns are the most readily recognized, consisting of strong contrasting light and dark areas, bars and peripheral dark outlines, or vivid displays of spots, like huge eyes.

Other behavioral patterns are found in changes in skin texture, including the erection of branched or spikelike papillae and curling of the arms. These actions often are attempts by cephalopods to conceal or camouflage themselves through imitating bottom objects such as sand, coral, or seaweed.

Discharge of ink

The ink of cephalopods is used for both defense and escape. In *Octopus* under attack by a moray eel, the cloud of ink seems to paralyze for some time the eel's senses of sight and smell. In squids the ink is ejected as a spindle-shaped mass about the size of the squid itself, the ink coagulating in the water. With this "dummy" left behind, the squid contracts its chromatophores, becomes nearly transparent, and jets away.

Many cephalopods (but not *Nautilus* and *Octopus*) possess special light organs (photophores), which emit chemical light or bioluminescence. Light is produced by the enzymatic reaction of luciferin and luciferase or, in bottle-tailed squids (sepiolids), indirectly, through cultures of luminescent bacteria. Photophores distributed over the body are employed at night or in the mid depths in various ways: mating play, recognition of the sexes, aid in schooling, attracting prey, defense, and camouflage. The light organs of the squid *Histioteuthis* are highly complicated, consisting of reflector, light source, directive muscles, lens, diaphragm, window, and colour screens.

Octopuses, squids, and cuttlefishes display considerable skill and cunning in hunting, stalking patiently, or luring prey within reach of their arms or tentacles. Both cuttlefishes and octopuses may use the tips of their arms as wormlike lures to attract small fishes, and octopuses have been reported to thrust stones between the valves of clams to prevent their closing. This has not been verified by later observers, but such intelligence is not beyond belief.

Locomotion. Cephalopods move by crawling, swimming, or jet propulsion, mainly the latter. The mantle, which has a passive role in the majority of mollusks, has become involved in locomotion in cephalopods, having almost entirely lost its rigid shell and become highly muscular. Its expansion and contraction produce a locomotory water current by drawing water into the mantle cavity and expelling it through the funnel. The rapid ejection of this jet of water enables the animal to execute quick backward and forward movements.

Jet propulsion

Water is drawn into the mantle cavity by the relaxation of the circular muscles and resultant expansion of the mantle. It enters around the neck region or aperture of the mantle (through the funnel in some deep-sea octopuses). In the oceanic squids the system is more efficient, with a nonreturn valve that prevents water from entering the wrong way through the funnel. When the mantle is contracted the aperture is closed by locking mechanisms and contraction of the anterior ring muscle, and the water is forced out through the funnel. This flexible tube is constructed similarly to a jet nozzle and may be turned in any direction, giving the animal great flexibility of motion for steering.

Squids also possess terminal or lateral fins used in slow movement or hovering. Locomotion is by the rapid undulation of the outer edges of the fins. Movement through the water is aided by lateral expansions (swimming keels) on the outer surface of the third pair of arms. Some squids (*Onychoteuthis, Thysanoteuthis*) are able to "fly" for several hundred feet, driven into the air by powerful thrusts from their jets and gliding on their expanded fins and arm keels. This normally occurs when the squids are pursued by predatory fishes and dolphins. When the squid jets rapidly through the water, the fins are often curled tightly around the mantle. Cuttlefishes, because of the large cuttlebone, are less active animals and spend most of their life lying on or hovering slightly above the bottom. Both jet and fins are used, the latter more frequently.

The benthic octopods are bottom crawlers, gliding about the bottom and in and out of crannies with amazing agility through the use of their eight arms and hundreds of suckers. Because of the extraordinary flexibility of the body, they are able to pass through openings hardly larger than the diameter of one eye. When disturbed, octopods swim rapidly by jet propulsion. Mass swimming migrations have been reported.

The finned octopods and the bottle-tailed squids have paddle-shaped fins that probably are most useful for hovering and slow swimming. The female argonaut (*Argonauta*) propels herself by jet propulsion while encased in her paper-thin shell. The chambered nautilus (*Nautilus*) is a less active swimmer, partly due to the inefficient funnel, which is composed of two flaps instead of a single fused tube, and to a reduced mantle cavity.

The active swimmers and most bottom dwellers apparently possess no hydrostatic organ. The cuttlefish, however, which swims or hovers above the bottom or rests on the bottom, adjusts its buoyancy through the amount of gases contained in the porous cuttlebone. *Nautilus,* which swims slowly above the bottom or in midwater, accomplishes this similarly, adjusting the gases in the chambered shell. Inactive oceanic squids, such as some cranchiids, concentrate ions lighter than seawater in the body chamber, while others, such as *Bathyteuthis,* concentrate buoyant oil in the chambers associated with the digestive gland.

Distribution

Ecology. The Cephalopoda are exclusively marine animals. There are numerous littoral species, but few have been reported from brackish water except for the squid *Lolliguncula brevis,* which occurs along the Florida coast in bays where the salinity is as low as 8.5 parts per thousand (about one-fourth that of the open ocean). Cephalopods are excluded from the Baltic Sea by lower salinities but have been found in areas of the Suez Canal where salinities are higher than in the oceans. There is some evidence that in parts of the open sea that differ only slightly in salinity there may be a varying cephalopod fauna. Grace E. Pickford, an American zoologist, has found that the vertical distribution of young in *Vampyroteuthis* is governed by water density, and, according to the American zoologist Clyde F.E. Roper, a similar situation exists in the deep-sea squid *Bathyteuthis.*

The Coleoidea are carnivorous and live principally on other cephalopods, crustaceans, mollusks, and small fishes. In the food cycle of the squid *Illex,* in which the adults feed upon young mackerel and the adult mackerel feed upon young squid. Squids also are cannibalistic. *Octopus* feeds upon bivalve mollusks and on decapod crustaceans, sometimes causing severe losses to the lobster fishery by entering the traps and eating the captive lobsters. The smaller oceanic squids probably feed primarily upon small fish, copepods, heteropods, and caridean shrimp. The Cirrata, which have reduced musculature and radula, indicating reduced activity and masticatory power, probably feed on bottom dwellers or small plankton.

The Cephalopoda are fed upon by many marine mammals, large fish, and seabirds. Sperm whales and other toothed whales feed primarily on squids.

Associations

The 19th-century French naturalist Alcide d'Orbigny asserted that the Cephalopoda are in general sociable, and this statement is certainly true of *Nautilus,* which are found together in large numbers. Some authorities, studying the Mediterranean cephalopods, have concluded that only certain pelagic cephalopods are gregarious (*Todaro-*

des, Ocythoe). Schools of the large oceanic squid *Thysanoteuthis rhombis* have been reported at Madeira. Although there is no proof that numbers constitute gregariousness, octopus colonies have been reported.

The breeding season has a marked effect on the local distribution of certain cephalopods. The common cuttlefish comes into shallow water in the spring and summer to breed, and similar migrations have been observed in some squids (*Loligo, Alloteuthis, Illex*).

The geographic distribution of cephalopods is incompletely known. Some open-ocean pelagic and bathypelagic forms are cosmopolitan in warm and temperate waters (*Onychoteuthis banksi, Cranchia scabra*). Others may be limited by genera to particular oceans or to continental waters. Even some species of bathypelagic habitat are limited to one ocean. The Octopoda, as a result of their bottom-dwelling habits, show stronger restrictions in their distribution, but *Octopus vulgaris* and *O. macropus*, both species with planktonic larvae, have gained worldwide distribution. In general, the pelagic and planktonic cephalopods conform in their distribution to other pelagic animals.

The vertical distribution is also incompletely known. *Nautilus* moves vertically through the water, living near the bottom, and has been obtained at a depth of about 550 metres (1,800 feet). It is fished in the Philippines when it comes into shallow water. Of the cuttlefishes, the Sepiidae are littoral, whereas the Sepiolidae dwell on or near the bottom, down to considerable depths. Among the squids the Myopsida are coastal forms, whereas the Oegopsida are oceanic, living from the surface to depths in excess of 5,000 metres (16,400 feet). The Octopoda occur from the surface of the open ocean (*Tremoctopus*) to the ocean floor (*Pareledone, Bentheledone, Cirroteuthis*) in excess of 5,000 metres (16,400 feet); most are bottom-dwelling forms restricted to the continental shelf and its slope.

FORM AND FUNCTION

Cephalopods vary from elongate, streamlined oceanic organisms to saccular, slow-moving bottom and drifting forms. Their body plan is indicative in many ways of the habitat in which they dwell and their mode of life.

The viscera of a generalized cephalopod are covered by a dome-shaped or elongated sheath of muscle, the mantle, which is connected with the head anteriorly. Ventrally, the mantle is free and encloses the mantle cavity, the space into which the gills project and the excretory and reproductive systems open.

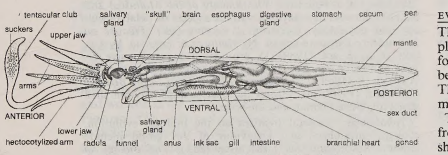

Figure 12: Internal structure of squid (*Loligo*). Left side of body, with four arms and one tentacle removed.

Number of arms and tentacles

Anterior to the mantle is the head-foot, which bears a ventral muscular tube, the funnel. Surrounding the mouth are eight long, prehensile arms, provided with suckers in octopuses and argonauts (order Octopoda), or eight arms and two tentacles, equipped with horny ringed suckers bearing teeth or hooks in squids and cuttlefishes (orders Teuthoidea and Sepioidea). The primitive *Nautilus* has about 90 small suckerless appendages.

The fossil nautiloids and ammonites (represented today only by *Nautilus*) were primitive, less-specialized forms, probably leading a rather inactive sluggish life. The modern octopuses, squids, and cuttlefishes have acquired an active, vigorous life that has led to marked departures in structure and function from the type represented by *Nautilus*. Modern forms are divided into three basic life-styles: the sluggish life in the great depths of the sea, a floating life in the midwaters, and a more active, aggressive existence near the surface. The nautiloids and ammonites were probably shallow-water animals living near the bottom and, like the slow-moving *Nautilus*, relied for protection on a coiled or curved calcareous external shell.

All cephalopods have an internal cartilaginous covering of the consolidated ganglia of the nervous system. In all except ammonites and nautiloids, it constitutes a cranium. Various other skeletal supports are found at the base of the fins and in the "neck," gills, and arms.

The alimentary system consists of a buccal mass with a pair of jaws (mandibles) and a rasping tongue (radula), esophagus, salivary glands, stomach, cecum, digestive gland ("liver"), intestine, and anus. In the Octopoda the esophagus may be expanded to form a crop, while in the deep-sea Cirrata the radula may be degenerate or lacking. Except in *Nautilus* and certain deep-sea Octopoda there is an ink sac located near the anus. This secretes a dark fluid, the sepia or ink, which is forcibly ejected through the funnel.

All members of the Coleoidea (octopuses, squids, and cuttlefishes) possess a closed circulatory system of blood vessels; in *Nautilus* it is partly lacunar (*i.e.,* made up of sinuses). The blood contains a blue respiratory pigment, hemocyanin (a copper compound), dissolved in the plasma. There are three hearts, the main systemic heart and the two branchial hearts, one at the base of each gill. The rhythmical contractions and expansions of the mantle cause a circulation of water over the gills where gas exchange takes place between the seawater and blood. The featherlike gills, consisting of a central axis with a row of lamellae on either side, are suspended in the mantle cavity from the mantle wall.

The excretion of nitrogenous wastes is carried out exclusively by the kidneys. There are four kidneys in *Nautilus* and two in the coleoids.

The central nervous system is highly developed, the major ganglionic centres being concentrated in the head. In some of the cuttlefishes (Sepioidea) the cerebral centres are subdivided for specialization, with the pedal ganglia divided into brachial and epipodal elements that innervate the arms and funnel respectively. In active squids the mantle is innervated by giant paired dorsal axons. Much of the present knowledge of mechanisms of nerve impulse conduction has come from the study of these giant axons. The sense organs of the cephalopods are eyes, rhinophores (olfactory organs), statocysts (organs of equilibrium), and tactile organs. In *Nautilus* the eyes are open pits without lenses. In the Coleoidea the eyes are complex and approach those of some lower vertebrates in efficiency.

EVOLUTION AND PALEONTOLOGY

The first cephalopods were probably provided with a simple, caplike shell. With elongation of the shell and the formation of septa or partitions, the nautiloid shell could be formed (Late Cambrian, 523 to 505 million years ago). The primitive elongate shell of *Orthoceras* became unmanageable and coiling resulted, as in the Gastropoda.

The Ammonoidea are usually considered to have evolved from Devonian (408 to 360 million years ago) straight-shelled forms (*Bactrites*) with certain nautiloid traits. Coiled ammonites appeared in the Late Devonian epoch (*Goniatites*). The subclass became extinct in the Cretaceous.

The shell

Modern cephalopods possess an internal and partly degenerate shell, straight except in *Spirula*. The state of the shell in modern forms is due to the progressive overgrowth of it by the mantle, probably accompanying the evolution of an active swimming life. The first evidence of the modification of the shell is in *Aulococeras* in the Triassic period (245 to 208 million years ago). The belemnites, with their modified, internal shell, gave rise to *Spirula* (coiled shell), to cuttlefishes (calcified phragmoconal septa, forming a thick shell), and to the squids (only the proostracum as a horny "pen"). These forms appeared in the Jurassic period (208 to 144 million years ago) and were probably derived from belemnite-like ancestors.

In the Octopoda the shell persists as cartilaginous stylets or fin supports. *Palaeoctopus newboldi,* the oldest known octopod, from the Cretaceous of Syria, was already too advanced to provide a clue to the derivation of the Octopoda. The Vampyromorpha are considered to be a possible connecting link between the Teuthoidea and the Octopoda.

CLASSIFICATION

Distinguishing taxonomic features. In fossil cephalopods, reliance is placed upon shell details (general shape, type of coiling, external sculpture, and sutures). In living forms, except for the Sepioidea, the shell is strongly degenerate or missing and the characters used consist of details of the soft parts: presence or absence of an eyelid, tentacles retractile or contractile or both, shape and size of fins, number of arms, number of sucker rows, presence or absence of teeth and hooks on arm and tentacular suckers, radular dentition, structure of funnel organ, spermatophores, details of the hectocotyles, number of gill lamellae, and the presence, patterns, and types of photophores.

Annotated classification. The following classification has gained considerable acceptance among modern specialists. Groups indicated by a dagger (†) are known only as fossils.

CLASS CEPHALOPODA

Mollusks in which typical molluscan foot surrounds head and forms arms and tentacles; mantle surrounds mantle cavity and is part of locomotory system; central nervous system highly developed, forming true brain encased in cartilaginous cranium; mouth contains pair of parrotlike jaws (or beak); body usually somewhat streamlined; eyes highly developed, most closely resembling in acuity those of some vertebrates; about 650 living species.

Subclass Nautiloidea (nautiloids)

Cambrian to present; now living only in the Indo-Pacific region, particularly East Indies; external coiled or straight chambered shell present, chambers connected by median siphuncle; smooth septa; sutures simple, little or no external sculpture; tentacles suckerless, adhesive; living and supposedly fossil forms with 4 gills; funnel formed of 2 nonfused flaps; about 5 living species, in genus *Nautilus*.

†Subclass Ammonoidea (ammonites)

Devonian to Cretaceous; fossils only; external, coiled or straight chambered shell with marginal siphuncle, last chamber protected by single horny plate or 2 calcareous plates; septa wrinkled; complex sutures; external sculpture.

Subclass Coleoidea (octopuses, squids, belemnites, cuttlefishes)

Triassic to present; shell internal, reduced, vestigial, or lacking; 2 sets of gills; 8 or 10 arms, having suckers or hooks.

†Order Belemnoidea (belemnites)

Triassic to Tertiary; fossils only; shell consisting of solid rostrum, small chambered phragmocone and anterior, broad proostracum; 6 to 10 arms bearing hooks in 1 or 2 rows; total length 5 to 210 cm.

Order Sepioidea (cuttlefishes and bottle-tailed squids)

Tertiary to present; worldwide with family exceptions; shell coiled and chambered (Spirulidae), straight with vestigial chambering (Sepiidae), vestigial, or lacking; eyes covered with transparent membrane; 8 sucker-bearing arms and 2 tentacles retractile into pockets; total length 2.5–90 cm.

Order Teuthoidea (squids)

Tertiary to present; shell thin, horny gladius; 8 arms, 2 tentacles, which are contractile only; worldwide; total length 1.5 to at least 1,800 cm (0.75 in. to 60+ ft).

Suborder Myopsida. Eye covered by transparent membrane; neritic, inshore animals.

Suborder Oegopsida. Eye open to water, completely surrounded by free eyelid; open-ocean animals living from the surface down to at least 3,000 m.

Order Vampyromorpha

Purplish-black gelatinous animals with 1 or 2 pairs of paddle-shaped fins at various stages of growth; 8 arms and 2 small retractile filaments not homologous with tentacles; deep web between the arms; worldwide; 1 species.

Order Octopoda (octopuses)

Cretaceous to present; shell lacking or vestigial, nonhomologous shell or egg case in female argonautids; fins absent or present; body generally saccular, with 8 mobile, highly contractile sucker-bearing arms; worldwide; total length 5–540 cm (2 in. to 18 ft); maximum arm spread to about 900 cm (30 ft).

Suborder Palaeoctopoda (finned octopod). Cretaceous, some living.

Suborder Cirrata (*Cirromorpha*). Holocene; soft-bodied, deep-webbed forms with cirri on arms and small to large paddle-shaped fins; primarily deep-sea.

Suborder Incirrata (common octopus). Holocene; compact, saccular to round bodied, finless forms with muscular, contractile arms; somewhat secretive; pelagic to deep-sea and shallow waters.

Critical appraisal. The elucidation of higher classification of the cephalopods is fraught with difficulties. Early specialists divided the living cephalopods into Octopoda and Decapoda without relation to their internal structure; these were both placed in the Dibranchia, in contrast to all fossil forms, which were considered as Tetrabranchia because *Nautilus* has four gills rather than two. This unnatural classification, accepted by the French zoologist Alcide d'Orbigny in 1838, was gradually modified through the efforts of the Swiss zoologist Adolph Naef and the German zoologist Georg Grimpe and later workers to the form given above. Phylogenetic linkages are still highly theoretical, but, with X-ray techniques that reveal soft parts in fossils and with new paleontological finds, the unfolding of the evolutionary history is in sight.

Monet

Claude Monet was the initiator, leader, and unswerving advocate of the Impressionist style. In his mature works, he developed his method of producing repeated studies of the same motif in series, changing canvases with the light or as his interest shifted. These series were frequently exhibited in groups—for example, his images of wheat stacks (1891) and the Rouen Cathedral (1894). At his home in Giverny, France, Monet created the water-lily pond that served as inspiration for his last series of paintings. His popularity soared posthumously in the second half of the 20th century, when his works traveled the world in museum exhibitions that attracted record-breaking crowds and marketed popular commercial items featuring imagery from his art.

Childhood and early works. Oscar-Claude Monet, the eldest son of Adolphe Monet, a grocer, was born on Nov. 14, 1840, in Paris. When he was five years old, the family moved to the Normandy coast, near Le Havre. This event has more than biographical significance, for it was Monet's childhood, spent along the beaches, and the intimate knowledge he gained of the sea and the rapidly shifting Norman weather, that would one day give rise to his fresh vision of nature. Monet's first success as an artist came when he was 15, with the sale of caricatures that were carefully observed and well drawn. In these early years he also executed pencil sketches of sailing ships, which were almost technical in their clear descriptiveness. Monet studied drawing with a local artist, but his life as a painter did not begin until he was befriended by Eugène Boudin, who introduced the somewhat arrogant student to the practice—then uncommon—of painting in the open air. The experience set the direction for Monet, who for more than 60 years would concentrate on visible phenomena and on the innovation of effective methods to transform perception into pigment.

Painting outdoors

Although oil landscapes had been painted at least since the 16th century, they usually were produced in the studio—recollections of observations, rather than direct impressions, of nature. The English painters John Constable and J.M.W. Turner made small oil sketches out-of-doors before 1810, but it is unlikely that Monet knew these studies. He first visited Paris in 1859–60, where he was impressed by the work of the Barbizon-school painters Charles Daubigny and Constant Troyon. To his family's annoyance, he refused to enroll in the École des Beaux-Arts. Instead, he frequented the haunts of advanced artists and worked at the Académie Suisse, where he met Camille Pissarro. This informal training was interrupted by a call to military service; he served from 1861 to 1862 in Algeria, where he was excited by the African light and colour. Monet's choice of Algeria for service was perhaps a result of his admiration for the Romantic painter Eugène Delacroix, whose colouristic work had been influenced by a visit to Morocco in 1832.

In 1862 Monet returned to Le Havre, perhaps because of illness, and again painted the sea with Boudin, while also meeting the Dutch marine painter Johan Barthold Jongkind. Later that year he continued to study in Paris, this time with the academician Charles Gleyre, in whose atelier he met the artists Frédéric Bazille, Alfred Sisley, and Pierre-Auguste Renoir. After disagreements with their master, the group departed for the village of Chailly-en-Bière, near Barbizon in the forest of Fontainebleau. It was also during this period—or at least before 1872—that Monet discovered Japanese prints, the decorativeness and flatness of which were to have a strong influence on the development of modern painting in France.

The exceptional achievements of Monet's prolific youthful period can be measured in works completed between 1865 and 1870, before he had begun to fragment his brushstrokes into the characteristic broken touches that were to become the hallmark of Impressionist style. One of the most ambitious of these early works (which was never finished, supposedly because of negative comments by Gustave Courbet) was "Déjeuner sur l'Herbe" (1865–66; "Luncheon on the Grass"), named after Édouard Manet's notorious painting shown in the Salon des Refusés in 1863. In contrast to Manet's masterpiece, which was a shocking adaptation of a Renaissance visual idea to a contemporary setting, Monet's painting, about 15 feet (4½ metres) high by 20 feet (6 metres) wide, was an utterly contemporary yet unprovocative representation of a group of fashionably dressed picnickers in the forest of Fontainebleau. Monet did share with Manet, however, a concern for representing actual scenes of modern life rather than contrived historical, romantic, or fanciful subjects. Thus, Monet's "Déjeuner" was an extension, by virtue of a more immediate empiricism, of the realism of Courbet.

"Déjeuner sur l'Herbe"

Impressionism, broadly viewed, was a celebration of the pleasures of middle-class life; indeed, Monet's subject matter from this period often involved domestic scenes featuring his wife, son, and garden. Yet, painting *la vie moderne* ("modern life") was not to be the primary aim of Monet's art. Of more significance in his case was his ceaseless search for painterly means to implement his radical view of nature. More so than his ambitious figure paintings, such works as "The River" (1868) or "The Beach at Sainte-Adresse" (1867) give a clear accounting of Monet's advance toward the Impressionist style. In the beach and sea pictures of 1865–67 Monet was plainly not trying to reproduce faithfully the scene before him as examined in detail but rather attempting to record on the spot the impression that relaxed, momentary vision might receive—what is seen rather than what is known, with all its vitality and movement. Boats, buildings, incidental figures, and the pebble beach are swiftly brushed in as flat colour patterns, with little attention paid to their weight or solidity.

First Impressionist paintings. Monet's life during the 1860s was precarious and itinerant, and he sold almost nothing; but several works were accepted for exhibition in the yearly Salons, most notably, and with great success, a fine but not yet Impressionist portrait of his future wife, Camille. Having already painted in Paris, Le Havre, Chailly, Honfleur, Trouville, and Fécamp and at other stations between Paris and the sea, Monet ended the 1860s at the Seine River resort known as La Grenouillère, at Bougival, where he and Renoir worked together for the first time. In canvases almost identical in style, they made rapid notations of pleasure-seekers and bathers, rowboats bobbing in the foreground, and the scintillating reflections in the lapping water. Regarded by Monet as "bad sketches," they were precursors of the Impressionist style. Both artists' Bougival studies interpret the light and movement of outdoor life in strong, abbreviating strokes, improvised at the moment of perception, that serve as equivalents for visual experiences never before committed to canvas in such a direct manner. In 1870 at Trouville, in broad, assured gestures, Monet painted a study of Camille on the beach. It is as animated an example of visual realism as had ever been painted: grains of sand remain embedded in the pigment.

Bougival

As the 1870s began, Monet continued his pursuit of natural phenomena. In order to avoid the Franco-German War, he left his son and Camille, whom he had just married, and traveled to London. There, with Pissarro, he was introduced by Daubigny to Paul Durand-Ruel, who was to become his dealer. In 1871 and 1872 he painted canals, boats, and windmills in The Netherlands and worked again at Le Havre. On his return, Monet rented a house at Argenteuil, on the Seine near Paris. The years he lived there mark the height of the Impressionist movement. He helped organize an independent exhibition, apart from the official

Salon, of the Impressionists' work in 1874. "Impression: Sunrise" (1872), one of Monet's works at the exhibition, inspired the journalist Louis Leroy to give the group their name.

Later Impressionism. Monet's celebrated method of producing works in series, each representing the same motif under different light and weather conditions, was not fully implemented until the 1890s, but what is usually regarded as the first series was executed in or around the Gare Saint-Lazare in Paris during the winter of 1876–77. A total break with the customary Impressionist subjects, these works portray the train engines belching smoke and steam in the great shed, recalling J.M.W. Turner's "Rain, Steam, and Speed—The Great Western Railway" of 1844 and prefiguring the mechanical subjects painted by Italian Futurists after 1909. Monet's life was less happy after he moved to Vétheuil, farther from Paris. In 1876 a liaison began between Monet and Alice Hoschedé, the wife of a department-store owner and collector. Monet had incurred a burden of debts in Argenteuil, and Camille was pregnant and ill. At Vétheuil the Monets were joined by Hoschedé, who had left her husband, and six of her children. Using funds from her dowry, she assumed Monet's debts and cared for Camille, who died in September 1879.

Early series

By 1881 the original Impressionist group had begun to disintegrate, although it was still to hold two more exhibitions—the eighth and last (in which Monet did not show) in 1886, after the advent of Neo-Impressionism. Only Monet continued with the same fervour to carry on the scrutiny of nature. Among the sites he chose during the 1880s were Pourville, Étretat, Fécamp, and Varangéville in Normandy; the rugged and isolated Breton island of Belle-Île; the wild Creuse River valley; Menton and Antibes in the Midi; and Bordighera in Italy. In 1886 he made a second visit to The Netherlands, to paint the tulip fields, before important sojourns at Étretat and Belle-Île.

In 1883 Monet, Hoschedé, her children, and Monet's sons, Jean and Michel, settled at Giverny, a hamlet near Vernon, 52 miles (84 km) from Paris, on the tiny Epte River. There Monet purchased a farmhouse surrounded by an orchard, which was to be his home until his death and is now a French national monument. After the travels of the 1880s, Monet spent the '90s at or near Giverny, concentrating on one series after another.

Last years. After 1900, two ambitious projects, both far from Giverny, concluded Monet's search for new motifs. The first (for which he made at least three trips to London between 1899 and 1904) was the extensive multiple series representing the River Thames, the Waterloo and Charing Cross bridges, and the Houses of Parliament. The works—with their exotic coloration and mysterious romantic mood—recall the Thames paintings of Turner and James McNeill Whistler. In these paintings it is atmosphere, more than the particularities of these structures, that is Monet's subject; buildings and bridges are less tangible than the pulsating brushstrokes that give volume to the light-filled fog and mist. The second and last of the architectural motifs Monet pursued was the canals and palaces of Venice. Monet began this series in 1908 and continued in 1909, although he worked on these subjects at Giverny until 1912. Venice was a perfect Impressionist subject, but the light, water, movement, architecture, and reflections in the water are more generalized in these works than the specific weather effects of the wheat stack and cathedral series.

Garden at Giverny

In 1893 Monet had bought a strip of marshland across the road from his house and flower garden, through which flowed a tributary of the Epte. By diverting this stream, he began to construct a water-lily garden. Soon weeping willows, iris, and bamboo grew around a free-form pool, clusters of lily pads and blossoms floated on the quiet water, and a Japanese bridge closed the composition at one end. By 1900 this unique product of Monet's imagination (for his impressionism had become more subjective) was in itself a major work of environmental art—an exotic lotus-land within which he was to meditate and paint for almost 30 years. The first canvases he created depicting lilies, water, and the Japanese bridge were only about one square yard, but their unprecedented open composition, with the large blossoms and pads suspended as if in space, and the azure water in which clouds were reflected, implied an encompassing environment beyond the frame. This concept of embracing spatiality, new to the history of painting and only implicit in the first water-lily paintings, unfolded during the years from 1915 until the artist's death into a cycle of huge murals to be installed in Paris in two 80-foot oval rooms in the Orangerie of the Tuileries. These were described in 1952 by the painter André Masson as "the Sistine Chapel of Impressionism." This crowning achievement of Monet's long, probing study of nature—his striving to render his impressions, as he said, "in the face of the most fugitive effects"—was not dedicated until after his death. The many large studies for the Orangerie murals, as well as other unprecedented and unique works painted in the water garden between 1916 and 1925, were almost unknown until the 1950s but are now distributed throughout the major private collections and museums of the world. Despite failing eyesight due to cataracts, Monet continued to paint almost until his death on Dec. 5, 1926, in his beloved Giverny.

Assessment. Although critical acclaim was slow in coming, Monet attracted the dedicated support of collectors throughout his career, most notably from Americans who discovered his work in the 1880s. His influence on other artists was wide-ranging, from his near contemporaries such as Vincent van Gogh to a diverse new generation of artists such as Émile Bernard, Pierre Bonnard, Henri Matisse, and Maurice de Vlaminck. During the years 1886 to 1914, a predominantly American colony of artists gathered around him in Giverny and regarded him as an exemplar of modern French painting. They adopted his fresh palette, subject matter, and spontaneous style, eventually introducing these elements to American art.

After his death, Monet's influence on contemporary art ebbed among the avant-garde, who favoured the more radical examples of artists such as van Gogh, Paul Cézanne, Matisse, and Marcel Duchamp. A revival of interest in his work occurred in the early 1950s. Monet's epic scale and formal innovations influenced Abstract Expressionist painters such as Mark Rothko and Jackson Pollock, and a general scholarly reassessment of his importance began to develop. Wildly popular retrospective exhibitions of his work toured the world during the last decades of the 20th century and established his unparalleled public appeal, sustaining his reputation as one of the most significant and popular figures in the modern Western painting tradition.

BIBLIOGRAPHY

Life and work: The most comprehensive analysis of Monet's long and productive career is DANIEL WILDENSTEIN, *Monet*, 4 vol. (1996; originally published in French in 5 vol., 1974–91), with a biography in English and a catalog in French, English, and German. Among the many other studies of Monet's life and career, the most thorough and accessible are PAUL HAYES TUCKER, *Claude Monet: Life and Art* (1995); and CARLA RACHMAN, *Monet* (1997). Many of Monet's contemporaries wrote about his life and work, most notably his close friends GUSTAVE GEFFROY, *Claude Monet: sa vie, son oeuvre*, 2 vol. (1924, reprinted in 1 vol., 1980); and GEORGES CLEMENCEAU, *Claude Monet: Les Nymphéas* (1928).

Themes and criticism: Focused studies of the individual phases of Monet's long career are in PAUL HAYES TUCKER, *Monet at Argenteuil* (1982, reissued 1984), and in his exhibition catalog *Monet in the '90s: The Series Paintings* (1989); and the catalog by PAUL HAYES TUCKER, GEORGE T.M. SHACKELFORD, and MARY ANNE STEVENS, *Monet in the 20th Century* (1998). Theoretical perspectives on the artist include JOHN HOUSE, *Monet: Nature into Art* (1986, reprinted 1989); and STEVEN Z. LEVINE, *Monet, Narcissus, and Self-Reflection: The Modernist Myth of the Self* (1994).

Monet's garden at Giverny has prompted many publications. Of enduring value is CLAIRE JOYES, *Claude Monet: Life at Giverny* (1985). The intriguing story of the predominantly American art colony that gathered in Giverny is recorded in WILLIAM H. GERDTS, *Monet's Giverny: An Impressionist Colony* (1993). METROPOLITAN MUSEUM OF ART, *Monet's Years at Giverny: Beyond Impressionism* (1978, reissued 1995), with an essay by DANIEL WILDENSTEIN, presents a lively anecdotal overview of the last four decades of the artist's life and work. PIERRE GEORGEL, *Claude Monet, Nymphéas* (1999), focuses on the culminating work of Monet's career, the installation of the Orangerie murals in Paris. (W.C.Se./Ed.)

Money

A commodity accepted by general consent as a medium of economic exchange. The medium in which prices and values are expressed, money circulates from person to person and country to country, thus facilitating trade, and it is the principal measure of wealth.

People accept money at face value because they know that others will do the same. This universal acceptance means that money is a social convention and one of uncommon strength that people will abide by even under extreme provocation. Yet money is not indestructible. When great variations occur in the quantity of currency—as they have during and after wars—money may be seen as no more than pieces of paper. People will then seek substitutes—like the cigarettes and cognac that for a time became the medium of exchange in Germany after World War II. New money may substitute for old under less extreme conditions than war. In countries with a history of high inflation, such as Argentina, Israel, or Russia, prices may at times be quoted in a foreign currency, such as the U.S. dollar, because its value is more stable than that of the local currency. Furthermore, the country's residents accept the foreign currency as a medium of exchange because it is well-known and offers more purchasing power than local money.

FUNCTIONS OF MONEY

The basic function of money is to enable buying to be separated from selling. If a person has something to sell and wants something else in return, it is not necessary to find someone able and willing to make the desired exchange of items. The person can sell the surplus item for general purchasing power—that is, "money"—to anyone who wants to buy it and then use the proceeds to buy the desired item from anyone who wants to sell it.

Medium of exchange

Separation of the act of sale from the act of purchase requires the existence of something that will be generally accepted in payment—this is the "medium of exchange" function of money. But there must also be something that can serve as a temporary abode of purchasing power, in which the seller holds the proceeds in the interim between the first sale and the subsequent purchase, or from which the buyer can extract the general purchasing power with which to pay for what is bought. This is the "asset" function of money.

VARIETIES OF MONEY

Anything can serve as money that habit or social convention and successful experience deem acceptable, and a variety of items have so served—from the wampum (beads made from shells) of American Indians, to cowries (brightly coloured shells) in India, to whales' teeth among the Fijians, to tobacco among early colonists in North America, to large stone disks on the Pacific island of Yap, to cigarettes and liquor in post-World War II Germany. The wide use of cattle as money in primitive times survives in the word pecuniary, which comes from the Latin *pecus*, meaning cattle.

Metallic money. The use of metals as money has occurred throughout history. As Aristotle observed, the various necessities of life are not easily carried about; hence people agreed to base their transactions on something that was intrinsically useful and transportable—for example, iron, silver, and the like. The value of the metal was at first measured by weight, but in time governments put a stamp upon it, thus saving the trouble of weighing or otherwise proving the value upon each transaction. Some of the earliest uses of metal for money can be traced back to Babylon more than 3000 years BC, but standardization and certification in the form of coinage, as referred to by Aristotle, did not occur except perhaps in isolated instances until the 7th century BC. Historians generally assign to Lydia, a state in Anatolia, priority in using coined money. The first coins were made of electrum, a natural mixture of gold and silver, and were crude, bean-shaped ingots bearing a primitive punchmark certifying to either weight or fineness, or both.

The use of coins enabled payment to be by "tale," or count, rather than weight, greatly facilitating commerce. But this in turn encouraged clipping (shaving off tiny slivers from the sides or edges of coins) and sweating (shaking a bunch of coins together and collecting the dust that was thereby knocked off) in the hope of passing on the lighter coin at its face value. Gresham's law (that "bad money drives out good" when there is a fixed rate of exchange between them) came into operation, and heavy, good coins were held for their metallic value, while light coins were passed on. The coins became lighter and lighter, and prices higher and higher. Then payment by weight would be resumed for large transactions, and there would be pressure for recoinage. These problems were largely ended by the "milling" of coins (making serrations around the circumference), which began in the late 17th century.

Gresham's law

A more serious matter was the attempt by sovereigns to benefit from the monopoly of coinage. In this respect, Greek and Roman experience offers an interesting contrast. Though Solon, on taking office in Athens in 594 BC, did institute a partial debasement of the currency, for the next four centuries, until the absorption of Greece into the Roman Empire, the Athenian *drachma* had an almost constant silver content (67 grains of fine silver until Alexander, 65 grains thereafter) and became the standard coin of trade in Greece and in much of Asia and Europe as well. Even after the Roman conquest, the *drachma* continued to be minted and widely used.

The Roman experience was very different. Not long after the silver *denarius*, patterned after the Greek *drachma*, was introduced about 212 BC, the prior copper coinage (*aes*, or *libra*) began to be debased until, by the time the empire began, its weight had been reduced from one pound to half an ounce. The silver *denarius* and the gold *aureus* (introduced about 87 BC) suffered only minor debasement until the time of Nero (AD 54), when almost continuous tampering with the coinage began. The metal content of the gold and silver coins was reduced, and the proportion of alloy was increased. Debasement in Rome was a reflection of the state's inability or unwillingness to finance its expenditures through explicit taxes. But the debasement in turn worsened Rome's economic situation and undoubtedly contributed to the collapse of the empire.

Paper money. In the late 18th and early 19th centuries, paper money and banknotes spread widely. The bulk of the money in use came to consist not of actual gold or sil-

ver but of fiduciary money—promises to pay specified amounts of gold and silver. These promises were initially issued by individuals or companies as banknotes or as the transferable book entries that came to be called deposits. But gradually the state assumed a role.

Fiat money

From fiduciary paper money promising to pay gold or silver, it is a short step to fiat paper money—that is, notes that are issued on the "fiat" of the sovereign are specified to be so many dollars or francs or yen and are legal tender, but they are not promises to pay something else. The first large-scale issue in a Western country occurred in France in the early 18th century (though there are reports of paper money in China many centuries earlier). Later, the French revolutionary government issued paper money in the form of assignats from 1789 to 1796.

Electronic money. Currency can be lost, stolen, or forged, so it is used most often for relatively small transactions or where anonymity is valued. "Electronic money" is the name given to several different means of electronic funds transfers (EFTs). Common EFT methods include automated teller machines (for transactions such as withdrawing money from a bank account), smart cards (also known as stored-value cards, used when making and receiving payments), and automated clearinghouses (commonly used for paying bills or settling other transactions), all of which increase the speed of regular payments and settlements.

STANDARDS OF VALUE

In the Middle Ages, when money consisted primarily of coins, silver and gold coins circulated simultaneously. As governments increasingly took over the coinage, and especially as fiduciary money was introduced, they tended to specify their nominal monetary units in terms of fixed weights of both silver and gold—to adopt a national bimetallic standard. Gresham's law, however, usually assured that the bimetallic standard degenerated into a monometallic standard. If one had gold (typically of greater value than silver), it was better to buy silver and bring it to be coined. Silver, the cheaper metal, "drove out" gold and became the standard. This happened in most of the countries of Europe, so that by the early 19th century all were effectively on a silver standard. In Britain, on the other hand, the ratio established in the 18th century on the advice of Sir Isaac Newton, then serving as master of the mint, overvalued gold and therefore led to an effective gold standard. In the United States a ratio of 15 ounces of silver to one ounce of gold was set in 1792. This ratio overvalued silver, so silver became the standard. In 1834, however, the ratio was altered to 16 to one, which overvalued gold, so gold became the standard.

The gold standard. The great gold discoveries in California and Australia in the 1840s and '50s produced a temporary decline in the value of gold in terms of silver. This price change, plus the dominance of Britain in international finance, led to a widespread shift from a silver standard to a gold standard. The early 20th century was the great era of the international gold standard. Gold coins circulated in most of the world; paper money, whether issued by private banks or by government, was convertible on demand into gold coins or gold bullion at an official price (with perhaps the addition of a small fee); and bank deposits were convertible into either gold coin or paper currency that was itself convertible into gold.

There was, in effect, a single world money called by different names in different countries. A U.S. dollar, for example, was defined as 23.22 grains of pure gold (25.8 grains of gold 0.9000 fineness). A British pound sterling was defined as 113.00 grains of pure gold (123.274 grains of gold 11/12th fine). Accordingly, one British pound equalled 4.8665 U.S. dollars (113.00/23.22) at the official parity. The actual exchange rate could deviate from this only by an amount that corresponded to the cost of shipping gold. If the price of the pound sterling in terms of dollars rose to a considerably higher value than this in the foreign exchange market, someone in New York City who had a debt to pay in London might find that, rather than buy the needed pounds on the market, it was cheaper to get gold for dollars at a bank or at the U.S. subtreasury, ship the gold to London, and get pounds for the gold from the Bank of England. This set an upper limit to the exchange rate. Similarly, the cost of shipping gold from Britain to the United States set a lower limit. These limits were known as the gold points.

The international gold standard

Under such an international gold standard, the quantity of money in each country was determined by the specie-flow adjustment mechanism analyzed by 19th-century economists. If the quantity of money in a country rose unduly, this would tend to raise prices in that country relative to prices in other countries; the rise in prices would then discourage exports and encourage imports. The decreased supply of foreign currency from the sale of exports plus the increased demand for foreign currency to pay for imports would tend to raise the price of foreign currency in terms of domestic currency. As soon as this price hit the upper gold point, gold would be shipped to other countries. The decline in the amount of gold would produce in turn a reduction in the total amount of money—because banks and government institutions, seeing their gold reserves decline, would want to protect themselves against further demands by reducing the claims against gold that were outstanding. This would tend to lower prices at home. The influx of gold abroad would have the opposite effect, increasing the quantity of money there and raising prices. These adjustments would continue until the gold flow ceased or was reversed.

This is precisely the mechanism that operates within a unified currency area, the mechanism that determines how much money there is in Illinois compared to how much there is in other states or how much there is in Wales compared to how much there is in other parts of the United Kingdom. In the early 20th century, most of the world was a unified currency area, so the gold standard functioned throughout the world. Its great advantage was that—if permitted to operate—it would greatly limit the power of any national government to engage in irresponsible monetary expansion. This was also its great disadvantage. In an era of big government and of full-employment policies, a real gold standard would tie the hands of governments in one of the most important areas of policy.

The dollar standard. In the wake of World War I, the international gold standard wavered, then recovered somewhat, before ending finally as a result of the Great Depression. The world's monetary system operated on a dollar standard from the end of World War II until 1971, when, in an attempt to control inflation, the United States unilaterally severed the connection between the dollar and gold. Under the dollar standard, the dollar was widely used in international trade, even in trade between countries other than the United States. Other countries maintained their "official" exchange rates by buying and selling U.S. dollars and held dollars as their primary reserve currency for that purpose. The existence of a dollar standard did not mean that other countries could not change their exchange rates—as Germany and France did in 1969—just as the gold standard did not mean that they could not "devalue" or "appreciate" in terms of gold. What it did mean was that the United States could not determine its own exchange rate or its balance of payments position. It also meant that U.S. monetary policy had a major effect on the world economy.

MODERN MONETARY SYSTEMS

Monetary systems are today very much alike in all the major countries of the world. They consist of three levels: (1) the holders of money (the "public")—individuals, businesses, governmental units; (2) commercial banks (privately or governmentally owned), which borrow from the public and make loans to individuals, firms, or governments; and (3) central banks, which have a monopoly on the issue of certain types of money, serve as the bankers for the central government and the commercial banks, and have the power to determine the quantity of money.

Public money holdings. The public holds its money as: (1) currency (including coin) and (2) bank deposits.

Currency. In many countries the bulk of the currency consists of notes issued by the central bank. In the United Kingdom these are Bank of England Notes; in the United

States, Federal Reserve Notes; and so on. It is hard to say precisely what "issued by the central bank" means. In the United States, for example, the currency bears the words "Federal Reserve Note," but these notes are not obligations of the Federal Reserve Banks in any meaningful sense. The holder who presents them to a Federal Reserve Bank has no right to anything except other pieces of paper adding up to the same face value. The situation is much the same in most other countries. Members of the European Union (EU) are adopting the euro as a standardized currency, meaning that the currencies of EU nations will eventually disappear.

Bank deposits. Bank deposits also are counted as part of the money holdings of the public. In the 19th century most economists regarded only currency and coin as "money," treating deposits only as claims to money. As deposits became more and more widely held, and as a larger fraction of transactions came to be effected by check, economists started to include not the checks, but the deposits they transferred, as money on a par with currency and coin.

The term *deposits* is highly misleading. It connotes something deposited for safekeeping, like currency in a safe-deposit box. Bank deposits are not like that. When one brings currency to a bank for "deposit," the bank does not put the currency in a vault and keep it there. It may put a small fraction of the currency in the vault as "reserves," but it will lend most of it to someone else or buy an investment—that is, a bond or some other security.

The deposits of commercial banks are assets of their holders but liabilities of the banks. The assets of the banks consist of "reserves"—currency plus deposits at other banks—and "earning assets"—loans plus investments in the form of bonds and other securities. The reserves are only a small fraction of the aggregate deposits.

Central banking. An important part of the monetary system is the central bank. The Bank of England was the first modern central bank, serving as the model for many others. It was established as a private bank in 1694 but quickly came to be largely an agency of the government. The Bank of France was established as a governmental institution by Napoleon in 1800. In the United States, the 12 Federal Reserve Banks, which, together with the Board of Governors in Washington, D.C., constitute the Federal Reserve System, are technically owned by their member commercial banks, but for all intents and purposes, the system is a governmental agency.

Open-market operations

The way in which a central bank increases or decreases the total amount of high-powered money is, typically, by making loans (discounting) or by buying and selling government securities (open-market operations). If, for example, the Federal Reserve System purchases $1,000,000 of government securities, it will pay for these securities by a check on itself, adding $1,000,000 to its assets and $1,000,000 to its liabilities. The seller can take the check to a Federal Reserve Bank, which will exchange for it $1,000,000 in Federal Reserve Notes. Or the seller may deposit the check at a commercial bank, and the bank will in turn present it to a Federal Reserve Bank, which will "pay" the check by making a book entry increasing that bank's deposits with it by $1,000,000. The bank may, in turn, transfer this sum to a borrower, who again will convert it into Federal Reserve Notes or deposit it.

The important point is that these bookkeeping operations simply record a process whereby the central bank has created, out of thin air as it were, additional high-powered money—the direct counterpart of printing Federal Reserve Notes. Similarly, if the central bank sells government securities, it destroys high-powered money. (See also GOVERNMENT FINANCE: *Monetary policy.*)

In addition to the high-powered money of the central bank, the total quantity of money at any given time depends on the preferences of the public as to the relative amounts of money it wishes to hold as currency and as deposits and on the preferences of the banks as to the ratio they wish to maintain between their reserves and their deposits. (The reserve ratio is, of course, dominated by legal reserve requirements, where they exist, but may vary somewhat as banks think it prudent to keep a larger or smaller cushion in excess of required reserves.)

It follows that a central bank can vary the total quantity of money as it wishes within broad limits. The major problem of modern monetary policy is how the central bank should use this power.

MONETARY THEORIES

The relation between money and what it will buy has always been a central issue of monetary theory. Economists have generally held that the level of prices is determined by the quantity of money. But precisely how the quantity of money affects the level of prices, and what the effects are of changes in the quantity of money, have been conceptualized in different ways at different times. From the mid-1930s to the mid-1960s, there was a widespread rejection of the quantity theory by professional economists. The following discussion of monetary theory will deal first with the quantity theory of money, as it developed before the 1930s, then with the Keynesian theory and its subsequent revisions.

The quantity theory of money. In whatever way it has been formulated, the quantity theory of money has involved a distinction between the nominal quantity of money and the real quantity of money. The nominal quantity is that expressed in whatever units are used to designate money—talents, shekels, pounds, francs, lire, drachmas, dollars, yen, and so on. The real quantity is that expressed in terms of the volume of goods and services that the money will purchase. The quantity theory assumes that what ultimately matters to holders of money is the real rather than the nominal quantity. If this is so, then—whatever factors may determine the nominal quantity of money—it is the holders of money who determine the real quantity and, in the process, the price level.

Nominal and real quantities

The following may be considered a hypothetical example. In a certain community the quantity of money in existence is $1,000,000, and the total income of the community is $10,000,000 a year. On the average, each member of the community holds an amount of money equal in value to one-tenth of a year's income, or to 5.2 weeks' income. Put differently, the income velocity of circulation is equal to 10 per year; that is, each $1 on the average is paid out 10 times a year. For the sake of simplicity there are no business enterprises; the members of the community buy and sell services from and to one another.

The quantity of money is somehow then doubled, but in such a way that no one expects the quantity to change again. Each member of the community will regard himself as better off, because each now has 10.4 weeks' income in the form of cash instead of the previous 5.2 weeks'. If everyone were to hold onto the extra cash, nothing further would happen. But people will try to spend it. One person's spending, however, is another's receipts. All the people together cannot spend more than all the people receive. The attempt of each to do so is bound to be frustrated. In the attempt to spend more than they receive, people will simultaneously try to buy more of various services from each other and to sell less. To induce others to sell, they will offer higher prices; to induce others not to buy, they will ask higher prices. Whether the quantity sold goes up or down depends on whether the attempt to buy more is stronger or weaker than the attempt to sell less. But in either case total spending is sure to go up and so are total income and prices paid. When income has doubled, to $20,000,000, the amount of money in existence will again be equal in value to 5.2 weeks' income. The community will have succeeded in reducing its real cash balances to their former level, not by reducing nominal balances but by raising incomes and prices. The process of adjustment may not be smooth; spending may go too far and leave people with real balances that are too small, requiring a subsequent fall in the price level; but the final position will tend toward a doubling of prices, and the previous real flows of services will be resumed with no one any better off than before the new money was distributed.

This simple example embodies most of the basic principles of monetary theory: (1) the central distinction between the nominal and the real quantity of money; (2) the equally crucial contrast between the alternatives open to the in-

dividual and to the community as a whole. To each individual separately (in the hypothetical example and in the real world) it looks as if income is outside personal control, but each individual can determine how much cash to hold. To the community as a whole, the total amount of cash is fixed, but it is able to determine the size of its income in dollars; (3) the importance of attempts. The attempt of people as a whole to spend more than they receive, even though doomed to frustration, has the effect of raising total nominal expenditures and receipts.

The Keynesian critique. The groundwork for the Keynesian attack on the quantity theory was laid by two historical experiences. One was the British experience after the return to the gold standard in 1925. In order to maintain the parity set for the pound in terms of gold, the Bank of England followed a consistently tight monetary policy. But prices did not move downward sufficiently, and there was persistent unemployment. This raised doubts about the allegedly classical postulate that money was only a veil, that total output was determined by real conditions, and that full employment was the "equilibrium," or normal, position. The second and even more dramatic experience was the Great Depression.

This stimulated the British economist John Maynard Keynes—who had been a highly sophisticated quantity theorist on strictly classical lines—to develop an alternative interpretation of the debacle after 1929 and an alternative prescription for policy. It also produced a sympathetic climate for his new theory, so that the Keynesian revolution swept the economics profession in a remarkably short time.

Keynes's interpretation. The basis for Keynes's critique was the quantity equation, expressed as:

$$MV = Py.$$

In this equation y represents national income in constant prices (the total value at fixed prices of all final goods and services, including additions to the stock of capital), P is a price index, M represents the amount of money, and V is the average number of times that the money is used for making income transactions (such as payments for final goods and services).

Keynes did not, of course, deny the validity of the quantity equation. What he maintained was very different: that the right-hand side—Py, or prices times output—was determined by forces largely independent of the left-hand side (quantity of money, M, and velocity of money, V). P, he argued, was largely an institutional datum, linked to customary nominal rates of wages that were very resistant to change. Real income or output, y, he argued, was determined by aggregate demand, which depended primarily on the amount of "autonomous spending"—that is, spending that was not linked directly to current income and that consisted mostly of investment expenditures by enterprises and spending by government. The rest of aggregate demand consisted mostly of consumption, which was linked closely to current income. On this view, the key factor determining the level of real income and output, and thereby the level of nominal income, was the strength of investment and of government spending.

Government spending

How then could the quantity equation hold? Keynes's answer was that V was so pliable that it would adjust to keep the two sides equal. Let autonomous spending increase without a change in the quantity of money, and V would simply increase in response; let the quantity of money increase without an increase in autonomous spending, and V would decline to offset the increase in M.

In the extreme form of this approach, the quantity of money simply did not matter at all for the course of prices or real output but only for the movement of V.

How did Keynes explain the plasticity of V? He did so by means of a very special explanation of the demand for money, to which he applied the phrase "liquidity preference." He regarded the quantity of money demanded as divided into two parts, one part, M_1, "held to satisfy the transactions and precautionary-motives," the other, M_2, "held to satisfy the speculative-motive." He regarded M_1 as a roughly constant fraction of income, and with respect to this part he accepted a rather rigid form of the quantity theory. He regarded M_2, however, as largely independent of income and as highly sensitive to current interest rates and to the expectations of future interest rates. This explained the plasticity of V.

According to Keynes, if current interest rates are above the level many holders of money expect to prevail in the future, people will prefer to hold their speculative balances in bonds instead of money—because they expect a fall in interest rates, which means a rise in bond prices. Conversely, if current interest rates are below the level expected to prevail in the future, they will prefer to hold money. Over short periods, he argued, these expectations are widely and strongly held at about the same level. In the extreme, with everyone holding the same expectations and everyone sensitive, liquidity preference will become, as he termed it, absolute. The interest rate measures the cost of holding money instead of bonds—it is the price, as Keynes put it, that the holder of money pays for retaining liquidity. If the interest rate is low, the cost of liquidity is low; hence people will hold a large fraction of their wealth in the form of money, and the fraction will be sensitive to small changes in the interest rate—liquidity preference being absolute in the long run as well as in the short run.

Liquidity and the interest rate

Keynes himself regarded absolute liquidity preference as a strictly "limiting case"; while it "might become practically important in future," he knew "of no example . . . hitherto." In practice, however, he treated velocity as if its behaviour frequently approximated this limiting case, and his disciples went much further than he did.

If liquidity preference was not absolute, then in the Keynesian view a change in the quantity of money would first affect interest rates in order to induce the community to hold the changed quantity of money. This change in interest rates might in turn affect autonomous spending—a decline encouraging investment and a rise discouraging investment—and in this way aggregate demand, income, and employment. The more sensitive is the quantity of money demanded to interest rates, and the less sensitive is investment to interest rates, the smaller will be the final effect of changes in the quantity of money, and conversely.

Changing views. The Keynesian revolution swept the economics profession in the late 1930s and early 1940s; by the 1960s Keynesian ideas had become deeply embedded in the thinking of intellectuals. Their analysis had predicted a great postwar depression if war spending was not replaced by other government spending. But government spending fell precipitously in the United States and elsewhere without ill effect. The analysis of the Keynesians had called for "cheap money" policies—that is, low interest rates—with a view to stimulating investment and thereby avoiding mass unemployment. Where they were adopted, however, these policies were consistently followed by inflation that could be restrained only by abandoning the cheap-money policies. A reexamination of the Great Depression of the 1930s demonstrated that, contrary to general belief, it had been a tragic testament to the great power of monetary policy, not to its impotence. The U.S. Federal Reserve System could have prevented the decline of one-third in the quantity of money that occurred from 1929 to 1933. Had it done so, the evidence indicates, the Depression would have been far milder and briefer. Most important of all, extensive empirical research demonstrated that the velocity of circulation of money, far from moving to offset changes in the quantity of money, has generally moved in the same direction and reinforced the effect of these changes.

The monetarist view. The result was a major change in the views of Keynesians. They now attribute far more importance to the quantity of money than they earlier did, regarding the quantity of money demanded as less elastic with respect to interest rates, and investment as more elastic, than they did in the first flush of enthusiasm. In addition, some economists waged a counterrevolution in the name of monetary policy, to which the name *monetarism* was attached. This doctrine made significant gains and has influenced considerably the views even of those who still regard themselves as Keynesians.

No counterrevolution ever produces a return to the status

quo. The monetarist doctrine has much in common with the quantity theory, but it has not expunged the Keynesian revolution. The Keynesian emphasis on the plasticity of velocity, for example, led to extensive work on the stability of the demand for money, and in particular on the exploration of time lags between monetary changes and economic changes and on the separate effects of monetary changes on prices, output, and interest rates.

Key propositions. For the long run, monetarism builds upon the earlier quantity theory by contributing a sophisticated analysis of short-run effects and a detailed set of empirical generalizations about these effects.

The key propositions of monetarism are as follows:

1. The rate of growth of the quantity of money is consistently, though not precisely, related to the rate of growth of nominal income. That is, if the quantity of money grows rapidly, so will nominal income, and conversely. The velocity of circulation, though not constant, is fairly predictable.

2. This relation is not obvious, mainly because it takes time for changes in monetary growth to affect income.

The time factor in monetarist theory

3. On the average, a change in the rate of monetary growth produces a change in the rate of growth of nominal income six to nine months later. But this is an average.

4. If the rate of monetary growth is reduced, then about six to nine months later the rate of growth of nominal income and also of physical output will decline, but the rate of price rise will be affected very little. There will be downward pressure on prices only as a gap emerges between actual and potential output.

5. The effect on prices comes on the average about a year after the effect on nominal income and output, so that the total delay between a change in monetary growth and a change in the rate of inflation averages roughly two years.

6. The above relationships are not invariable. There is many a slip between the monetary change and the income change.

7. Monetary changes affect output only in the short run—though "short run" may mean five to 10 years. Over the longer run the earlier quantity theory seems to hold, and the rate of monetary growth affects only prices. What happens to output in the long run depends on such "real" factors as the enterprise, ingenuity, and industry of the people; the extent of thrift; the structure of industry and government; the relations among nations; and so on.

8. Inflation is always and everywhere a monetary phenomenon, in the sense that it cannot occur without a more rapid increase in the quantity of money than in output. There are, of course, many possible reasons for monetary growth—gold discoveries, the manner in which government spending is financed, and even the manner in which private spending is financed.

9. Government spending may or may not be inflationary. It will be inflationary if it is financed by creating money—that is, by printing currency or creating bank deposits—and if the resultant rate of monetary growth exceeds the rate of growth of output. If it is financed by taxes or by borrowing from the public, the main effect is that the government spends the funds instead of someone else.

10. One of the most difficult things to explain is the way in which a change in the quantity of money affects income. Generally, the initial effect is not on income at all but on the prices of existing assets (bonds, equities, houses, and other physical capital). This is the liquidity effect stressed by Keynes; it occurs on the balance sheet, not on the income account. An increased rate of monetary growth raises the amount of cash people (or businesses) have relative to other assets. The holders of the excess cash will try to correct this imbalance by buying other assets. But one person's spending is another's receipts. All the people together cannot change the amount of cash all hold—only the monetary authorities can do that. Their attempts will tend, however, to raise the prices of assets and to reduce interest rates. These changes will in turn encourage spending to produce new assets. Thus the initial effect on balance sheets is translated into an effect on income and spending. In this connection the monetarists stress a far wider range of assets and interest rates than do the Keynesians; they emphasize such assets as durable consumer goods and other real property, and they regard market interest rates as only a small part of the whole complex of relevant rates.

11. One important feature of this mechanism is that a change in monetary growth affects interest rates in one direction at the outset and in the opposite direction later on. More rapid monetary growth at first tends to lower interest rates. But later on, as it raises spending and stimulates price inflation, it also produces a rise in the demand for loans that will tend to raise interest rates. Taking the opposite case, a slower rate of monetary growth at first raises interest rates, but later on, as it reduces spending and price inflation, it lowers interest rates. This inconsistent relation between the quantity of money and interest rates explains why monetarists insist that interest rates are not a good guide to monetary policy.

12. These propositions clearly imply that monetary policy is important and that what is important about monetary policy is its effect on the quantity of money, not on bank credit or total credit or interest rates. Wide swings in the rate of change of the quantity of money are evidently destabilizing and should be avoided.

Monetary prescriptions

Beyond this, different monetarists draw different conclusions. Some conclude that the monetary authorities should make deliberate changes in the rate of monetary growth in order to offset other forces making for instability; these changes should be gradual and small and make allowance for the lags involved. Others maintain that not enough is known about the relations between changes in the quantity of money and in prices and output to assure that a discretionary monetary policy will do good rather than harm. They believe that a wiser policy would be simply to have the quantity of money grow at a steady rate over time. Monetarism reached its peak of popularity in the 1970s. At that time, both the United Kingdom and the United States implemented monetarist policies. Keynesianism made a comeback in the final decades of the 20th century.

Conclusion. No other subject in economics has been studied longer or more intensively than the subject of money. The result is a vast amount of documented experience and a well-developed body of theoretical analysis. The extent to which the students of monetary problems agree in their basic conclusions is concealed by the tendency of laymen to exaggerate their differences. But even among professional economists there remain important disagreements, centring mainly on empirical judgments about the stability and form of some of the relations between money and other economic magnitudes.

Mongolia

Mongolia (Mongol: Uls) is a vast highland country of eastern Asia. This independent republic, called the People's Republic of Mongolia (Bügd Nayramdah Mongol Ard Uls, from 1924 to 1992), occupies an area of 604,000 square miles (1,565,000 square kilometres). Its shape is that of an elongated oval, measuring 1,486 miles (2,392 kilometres) from west to east and, at its maximum, 782 miles from north to south. Mongolia is bounded on the north by Russia and on the south by China.

Located deep within the interior of eastern Asia far from any ocean, Mongolia has a marked continental climate, with long, cold winters and short, cool to hot summers. Its remarkable variety of scenery consists largely of upland steppes, semideserts, and deserts, although in the west and north forested, high mountain ranges alternate with dry, lake-dotted basins. Mongolia is highland country, with an average altitude of 5,200 feet (1,585 metres) above sea level. The highest peaks are in the Mongol Altai Mountains, of which Nayramadlïn Peak (also called Hüyten Peak; 14,350 feet [4,374 metres]), at the western tip of the country, is Mongolia's highest point.

Nearly four-fifths of Mongolia's area consists of pasturelands, which support immense herds of grazing livestock; the remaining area is about equally divided between forests and barren deserts, with only a tiny fraction of the land in crops. With a total population of slightly more than two million, Mongolia has one of the lowest population densities of any country in the world. However, since the 1950s the country has had one of Asia's highest rates of natural increase.

The Mongols have a long prehistory and a most remarkable history. Their ancestors were the Huns, a people who lived in Central Asia from the 3rd to the 1st century BC. A single Mongolian feudal state eventually was formed in the early 13th century AD from nomadic tribal groupings. Its leader, Genghis Khan, and his successors in the 13th century controlled a vast empire that included much of China, Russia, and Central Asia. Because of its location between China and Russia, Mongolia subsequently was dominated first by one and then the other, but mainly by the Chinese (1691–1921). Damdiny Sühbaatar, the national hero of modern Mongolia, was profoundly influenced by the October Revolution (1917) in Russia and later, with Soviet assistance, drove out both the White Russians and the Chinese. Sühbaatar's forces achieved power on July 11, 1921, traditionally the founding date of the present state.

From its independence from China in 1921, Mongolia was closely tied to the Soviet Union until the end of the 1980s. It received technical, economic, and military assistance from the Soviet Union and generally followed Soviet guidance in political and cultural matters, both domestic and international. Symbolic of the profound changes in culture and society was the replacement in the 1940s of the traditional Mongolian alphabet with a new one based on the Cyrillic letters of the Russian alphabet. In the period 1990–92, however, Mongolia moved away from a monopoly of political power by the communist party to free multiparty elections, a coalition government, a new constitution, greater cultural and religious freedom with more emphasis on national Mongol traditions, and a neutral position in international relations, as well as toward some elements of a market economy. In the 1990s the traditional script was once again taught in schools, and store signs appeared in both Cyrillic and traditional forms. (C.D.H.)

Physical and human geography

THE LAND

Relief. Mongolia can be divided into three major topographic zones: the fingerlike mountain ridges that thrust into the northern and western areas, the basin areas that lie between and around them, and the enormous upland plateau belt that sweeps across the southern and eastern sectors. The entire country is prone to seismic movements, with some earthquakes reaching extreme limits of severity; their effects, however, are diminished by the low population density.

The mountains. The present relief of Mongolia is the result of geologically recent upheavals of the Alpine mountain-building period. There are three major mountain belts. The highest and the longest spine is the westernmost, the Altai Mountains (Mongolian: Altayn Nuruu), which sweeps in from the northwestern tip of the country and thrusts toward the southeast for 1,000 miles. The main range—the only one in the country where contemporary glaciation has developed—is the Mongolian Altai Mountains, and a lesser range splitting off to the southeast is known as the Gobi Altai Mountains. The southeastern extremities of the main range also split into a number of smaller hills, all following the same general trend, losing themselves in the expanses of the Gobi. The three major mountain belts

The Hangayn (Khangai) Mountains, also trending northwest to southeast, form a solid mountain mass near the centre of the republic, with peaks towering to more than 12,000 feet. A characteristic feature is the gentle slopes and crests, often covered with fine pastures. The higher central portions are nevertheless rugged and precipitous. To the far north, the mountains adjoin the Sayan Mountains of Siberia.

The third mountain block, the smaller and lower Hentiyn (Khentei) range, trends southwest to northeast of Ulaanbaatar; it reaches a maximum height of about 9,200 feet, but in general its elevation is between 6,000 and 8,000 feet. Ulaanbaatar lies at the southwestern base of the range. The enormous Greater Khingan Range rises along and beyond the eastern frontier with China.

The northern intermontane basins. Around and between the main ranges mentioned above lie an important series of basins. In the northwest of the country, tucked between the Altai, the Hangayn, and the mountains of the frontier with Russian Siberia, lies a scenic basin complex known as the Great Lakes region, in which are strewn more than 300 lakes. Another basin complex lies between the eastern slopes of the Hangayn Mountains and the western foothills of the Hentiyn Mountains. The southern portion (the basins of the Tuul and Orhon rivers) is a fertile region important in Mongolian history as the cradle of settled ways of life. Its landscapes are strewn with the ruins of numerous ancient communities.

Farther north, on the northern flanks of the Hangayn Mountains, lies the remarkable Khorgo region, in which as many as a dozen extinct volcanoes and numerous volcanic lakes are found in a small area. Swift and turbulent rivers have cut jagged gorges. The source stream of the Orhon River is in another volcanic region, with a cluster of lakes, deep volcanic vents, and hot springs. Near the northern border, Lake Hövsgöl is the focus of another rugged, lake-strewn region, noted for its huge subterranean caves.

The plateau and desert belt. The eastern part of Mongolia has a rolling topography of hilly steppe plains, supplanted in the extreme east by clusters of small, flat plains lying at altitudes of 2,000 to 2,300 feet. Here and there, small, stubby massifs contain the clearly discernible cones of extinct volcanoes. The Dariganga area of Mongolia's eastern tip contains some 220 such extinct volcanoes. Most of the southern part of the country is a vast rolling oasis-dotted plain, forming the northern fringe of the Gobi, which is predominantly stony. The flat relief is occasionally broken by low, heavily eroded ranges. Several spectacular natural features are found in the Gobi region. Huge, six-sided basalt columns, arranged in clusters resembling bundles of pencils, are found in the eastern and central regions. The southern Gobi contains three mountain ranges, known as the Gurvan Sayhan Mountains, and the scenic Yelyn Valley, now a national park, with deep gorges surrounded by towering rocky cliffs where condors have made their nests.

Features of the Gobi

Drainage. Mongolia lies on a continental divide: rivers in the north flow northward into the Arctic Ocean, and those in the northeast flow eastward into the Pacific. The western and southern two-thirds of the country consist of interior drainage basins, in which seasonal or intermittent streams end in salt lakes or disappear into the stones and sands of the desert. In the northern regions the turbulent mountain streams and small rivers merge into deep, well-developed rivers. In the southern areas—where there are only a few constantly flowing rivers—lakes, saltwater and freshwater springs, and wells draw on subterranean water supplies. The great divide, separating waters that flow into the oceans and into the interior basins, runs along the crest of the Hangayn Mountains. Mongolia's greatest river, the Selenge (Selenga), with its main tributary, the Orhon, drains northward across the Russian border and into Lake Baikal; the Mongolian portion of the Selenge valley is in the north-central portion of the country. Mongolia's other major rivers, the Onon and the Kerulen, run latitudinally across the eastern part of the country. The largest rivers draining into the interior are the Hovd (Kobdo), which rises from the glaciers of the Mongolian Altai Mountains, and the Dzavhan, which drains the southern slopes of the Hangayn Mountains; both flow into the Great Lakes region. A series of other rivers east of the Dzavhan run down from the southern flanks of the Hangayn, ending in salt lakes or disappearing in the Gobi expanses. Generally, the Mongolian rivers are swift and with a steep gradient, offering hydroelectric potential, as well as occasional flood dangers.

Major rivers

Mongolia has more than 3,000 lakes with areas of half a square mile or more. Many are salty, ephemeral, highly variable in area, and without outlets. The largest and deepest freshwater lake, Hövsgöl, occupies a structural depression in the northernmost part of the country. Other large lakes—all in the west—include the saline Lake Uvs, which is nearly 1,300 square miles in area, and the freshwater Lake Har Us, which drains into the saline Lake Hyargas. Many lakes are of volcanic origin, as is Lake Terhiyn Tsagaan on the Hangayn's northern slopes.

Climate. Mongolia is situated at high latitudes and high altitudes, far from the moderating influences of the ocean. As a consequence, it experiences one of the world's most pronounced continental climates with very cold winters, cool to hot summers, large annual and diurnal ranges in temperature, and generally scanty rainfall. The difference between the mean temperatures of January and July can reach 80° F (44° C), and temperature variations of as much as 55° F (30° C) can occur in a single day. Mean temperatures in the north generally are cooler than those in the south: the mean January and July temperatures for the Ulaanbaatar area are −15° F (−26° C) and 63° F (17°

The importance of latitudinal and altitudinal belts

are predominantly of the chestnut or brown type, but with considerable salinization in desert and semidesert areas. Latitudinal and altitudinal belts of vegetation are probably the most obvious feature of the local Mongolian landscape. There are four basic divisions running in latitude from north to south and in altitude from the mountains to the basins and plains: forest-steppe, steppe, semidesert, and desert. In addition, the higher mountains have bands of coniferous forest (taiga) and, higher yet, an Alpine zone. The steppes (grasslands) predominate, covering more than three-quarters of the national territory.

The mountain forest-steppe zone exhibits the richest diversity of plant and animal life. Forests grow thickest on the northern shady slopes, the most widely distributed tree being the Siberian larch, followed by the cedar, with a varying admixture of spruce, pine, and fir. Deciduous trees include the birch, aspen, and poplar. Steppe vegetation is found in the intermontane basins, the wide river valleys, and the sunny southern flanks of the mountains. These huge expanses of pastureland are covered with feather grass, couch grass, wormwood, and many fodder plant species. In summer the steppes are carpeted with a magnificent covering of bright violet, blue, red, and yellow flowers. On the highest mountain slopes the damp, dark taiga gives way to the thin grasses and occasional flowers of the Alpine zone, merging into the bare rocks and rugged glaciers of the summit zone.

Semideserts are found in the Great Lakes intermontane depression in the west and over the Gobi in the south, giving way to true desert conditions near the southern border. Vegetation is scarce there but heavy enough to feed camels, goats, and sheep. Tracts of saxaul (xerophytic vegetation adapted to very dry conditions) and groves of elm and poplars cluster around springs or other underground water sources. The Gobi is a typical hammada, or rock-floored desert with gravel cover; only the extreme east has small areas of sandy desert.

Animal life. The varied natural conditions, the interior location, and the sparse human population of Mongolia all contribute to a rich and diverse wildlife that has attracted international attention and has commercial importance. Lying on the borders of several distinct zoogeographic regions (the Tibetan, the Afghano-Turkistani, the Siberian, and the North-Chinese-Manchurian), the country has a fauna combining species from each of them. The northern forests harbour lynx, maral (Asiatic red deer), elk, roe deer, musk deer, brown bears, snow leopards, wolverines, wild boars, squirrels, and sables. The steppes are the home of, among others, the marmot—whose pelts are important economically—and the lithe Mongolian gazelle. Clustering around water holes in the semidesert and desert region may be found the wild sheep known as *argal,* Asiatic wild asses (*kulans*), wild camels (*khavtgays*), and the Gobi bear (*mazalai*); some of these species are extremely rare and found nowhere else in Asia. Domesticated animals include sheep, camels, cattle, the hairy highland yak, goats, dogs, and the famous Mongolian horses. Birdlife includes larks, partridges, cranes, pheasants, bustards, and falcons in the steppes; geese, ducks, gulls, pelicans, swans, and cormorants in the rivers and lakes; the snowy owl, the golden eagle, and the condor, which frequent some areas. The freshwater lakes and rivers harbour some 70 fish species, including salmon, trout, grayling, perch, and pike. Hunting and fishing, for sport and for commercial purposes, are important; but the government has introduced stringent hunting regulations and other conservationist measures, including the establishment of national parks and nature reserves. (D.Ba./O.Sh./C.D.H.)

Settlement patterns. Human beings have long been in evidence in this part of what is sometimes called High Asia; and the ruins of long-abandoned cities, as well as archaeological remains dating back to the earliest days of prehistory, have attracted the attention of Mongolian and international scholars. Settlement in modern Mongolia is characterized by sharp regional contrasts: in the better-watered northern basins of the Orhon and Selenga rivers, densities of population may reach 10 persons per square mile (4 per square kilometre), but some desert areas are devoid of inhabitants. The core of habitation lies in the north-central area between Ulaanbaatar and Sühbaatar. There are found the richest pastures, the main crop area, the largest cities, the most industrial establishments, and the best transportation.

Rural patterns. The huge rural areas of the country have their own charm. A feature distinctive of the countryside is the yurt, or *ger,* the traditional Mongolian dwelling. It is a cone-shaped, latticed structure, light, strong, and easy to assemble, transport, and reerect, which offers warmth in winter and coolness in summer. It is still used by herdsmen moving from pasture to pasture, and the clusters of white felt-and-canvas cones against a green background still dominate the landscape in many areas. As the nomadic population becomes more settled, however, the yurt clusters are becoming associated with cooperatives and state farms, often at centres with more permanent dwellings.

The yurt

Urban patterns. It is in the cities, however, that Mongolia presents its modern aspect. Cities grew rapidly in the second half of the 20th century, increasing their proportion of the total population from about one-quarter in 1950 to one-half by the early 1990s. The capital, Ulaanbaatar, by far the largest and most important urban centre, has a population of 500,000, one-fourth of the population of the entire country. It lies on the banks of the Tuul River in the north-central portion of Mongolia. Formerly known among Europeans as Urga, it was originally a nomadic princely residence and became settled on the present site in 1639. The old city—which numbered some 60,000 people in 1921—consisted mainly of monasteries, a few adobe structures, and clusters of yurts. By the late 20th century, however, the "city of felt" had been transformed into a modern city, with broad avenues and streets, apartment complexes, and massive governmental, cultural, and educational buildings. The yurt areas and the fenced-off small houses had become a diminishing feature of the peripheral regions. Two other important cities, Darhan and

M. Koene/H. Armstrong Roberts

Settlement of felt-and-canvas yurts, Mongolia.

Sühbaatar, lie between Ulaanbaatar and Mongolia's northern border. The city of Darhan is an example of planned urbanization. Its foundation stone was laid in 1961 in an existing settlement of about 1,500 people, and within 20 years the population exceeded 50,000. The new city became the centre of a major industrial complex, second only to Ulaanbaatar itself. Sühbaatar, founded in 1937, is a transportation and trade centre located at the confluence of the Orhon and Selenge rivers and on the Trans-Mongolian Railway near the Russian border. Other industrial centres include Choybalsan, on the Kerulen River in the northeast, and Erdenet, located west of Darhan.

THE PEOPLE

Ethnic and religious background. Anthropologically, the Mongols are quite homogeneous, belonging to the classic physical type to which they lent their name. Within Mongolia, Khalkha-speaking Mongols constitute almost four-fifths of the population. Other Mongolian groups—including Dörbed, Buryat, Bayad, and Dariganga—account for about one-eighth of the population. By tradition the Mongols have been Buddhists. Much of the rest of the population consists of Turkic-speaking peoples, mainly Kazakhs, who traditionally have been Muslims; located mainly in the western part of the country, they have been granted an autonomous area. A small but significant number of Russians live mainly in the cities. The Chinese, who were formerly important in cities, trade, and finance, have largely left the country.

The theocratic background

At the time of the founding of the modern state, the social composition was strongly influenced by the then-prevailing religious traditions of the lamas (monks), who followed tenets derived from Tibetan Buddhism, with a strong admixture of more primitive elements. Control lay in the hands of the head of the Mongolian Tibetan Buddhist Church (who was proclaimed the khan of all Mongolia) together with various local khans, hundreds of princes and noblemen, and the higher clergy. The new regime sought to replace feudal and religious structures with socialist and secular forms. During the 1930s the government closed monasteries, confiscated their livestock and landholdings, induced large numbers of monks to renounce religious life, and eliminated others. The number of Buddhist monks dropped from 100,000 in 1924 to 110 in 1990. Many aspects of the national cultural traditions are preserved in museums.

Demography. After a period of stagnation, the population of Mongolia increased rapidly in the second half of the 20th century, as birth rates climbed and death rates dropped. Improved health, sanitation, and medical facilities played a major role in reducing mortality, especially infant mortality. Also important was the government policy of encouraging families to have more children. Mongolia's rate of natural increase reached a peak in 1960 and declined slowly thereafter. Thus, by the late 20th century Mongolia's main demographic trend was toward a youthful, fast-growing population. (B.Gu./C.D.H.)

THE ECONOMY

Resources. In the early 1990s Mongolia experienced great economic difficulties as it moved from a command economy to a system with elements of a market economy. About one-third to one-half of the budget had previously come from the now-defunct Soviet Union. Mongolia's international debt was extremely high. The low national income per capita sank even lower as the population grew rapidly.

Mongolia possesses mineral resources. Geologic surveys have confirmed the existence of large deposits of coal and iron, tin, copper, gold, and silver ore and a number of lesser known minerals. Mongolia's biological resources consist largely of the great herds of livestock in the country. Overall livestock figures rose throughout most of the 20th century, providing a rich agricultural resource base that even enabled some exports of meat to be made. In addition, the northern rivers of Mongolia offer great potential for hydroelectric development, whereas the wildlife of the country offers potential for commercial exploitation.

Agriculture. Livestock raising—based on millions of head of sheep, goats, cattle, and horses and including a large number of camels—accounts for about 70 percent of the value of agricultural production. Livestock are widely distributed throughout the entire country. The number of horses and cattle reach their greatest concentrations in the wetter north-central regions, whereas goats and camels are proportionately more numerous in the drier west and south. Most of the livestock belong to agricultural cooperatives. Although the earliest cooperatives were formed in the 1930s, the main government campaign to organize the livestock herders (*arats*) into giant cooperatives took place in the years 1955–59.

Pastoral Mongols traditionally have shunned crop tillage. Furthermore, most of the country has a semiarid climate more suited to livestock production by grazing on the extensive natural grasslands than to cultivation. Less than 1 percent of the area of the country is used to grow crops. Crop production is largely limited to the moister northern parts of the country, particularly in the broad lower valleys of the Orhon and Selenge rivers but also along the Onon, Uldz, and Kerulen rivers in the northeast. Part of the cropland receives supplemental irrigation. Because of the long, cold winters only a single annual crop is possible. About four-fifths of the cropland is in grains—primarily in spring wheat but with some in barley or oats—and nearly all the rest is in fodder crops (hay). Yields are relatively low and vary greatly from year to year. Potatoes and other vegetables occupy only a tiny fraction of the crop area. About four-fifths of the cropland is in state farms, with the rest in cooperatives. The large state farms each average about 700 square miles in size and typically include some livestock production as well as crops.

Crops

Mining and industry. The chief minerals extracted are coal, primarily for domestic use, fluorite (fluorspar), and copper and molybdenum ores, both of which are exported. Some gold and tungsten deposits also are worked. The two main coal-mining districts are Sharin Gol, southeast of Darhan, and Nalayh, just southeast of Ulaanbaatar. To the southwest of Darhan lies the gigantic Erdenet copper- and molybdenum-mining complex, which began operation in the late 1970s.

Although the government has devoted a great amount of effort to industrializing the nation, much of Mongolia's industrial capacity is still engaged in processing raw materials or meeting basic domestic consumer needs. Thus, the principal manufactured products are processed foods (meat, beverages, dairy products, and flour); articles of clothing and footwear made from wool, hides, skins, and furs; and lumber, paper, matches, and furniture. Also important are the operation at Erdenet that concentrates copper and molybdenum ores for shipment and the construction industry. About half of the industrial employment is in Ulaanbaatar, which is the centre of light industry. Heavy industry is concentrated in Darhan, and forest products are processed in Sühbaatar.

Trade. During the 1980s minerals and ore concentrates became Mongolia's principal export, surpassing the traditional exports of livestock and their by-products. The main imports are machinery and equipment; fuels, minerals, and metals; and manufactures, particularly consumer goods.

More than three-fourths of Mongolia's trade was with the former Soviet Union, and much of the rest with former Comecon countries, but from the early 1990s Mongolia sought to increase trade with other nations. However, the development of a diversified international trade was hampered by various factors, notably the absence of direct access to the sea, the need to use Russian and Chinese transport and ports, the long distances and high transport costs, and the difficulties of competing in international markets.

Transportation. Mongolia's most important transportation artery is the Trans-Mongolian Railway, which runs north-south through the central part of the country; it links Mongolia to Russia and to China and provides the shortest overland route between Moscow and Peking. The railway is divided into northern and southern sections. The northern section extends from the Russian border to Ulaanbaatar, following several river valleys through the

The Trans-Mongolian Railway

mountainous terrain. It connects Mongolia's main urban and industrial centres and carries a substantial portion of the country's freight. The southern section, from Ulaanbaatar to the Chinese border, runs through rolling steppe and semidesert country. It was built in the mid-1950s, during the period of close Sino-Soviet cooperation. Another railway connects Choybalsan and other urban centres in the northeast with the Siberian rail system.

Roads provide connections between Ulaanbaatar and the *aymag* (provincial) centres and among smaller settlements. Nearly all the country's roads are unpaved. Trucks carry most of the nation's freight not carried by rail, particularly outside of the core area along the northern Trans-Mongolian Railway. Camels are still used in the sparsely populated desert areas of the south, and yaks and oxen still haul some goods in the rugged mountains of the west.

Air service is particularly suitable for passenger movement in Mongolia because distances between population centres are great, population density is low, and weather conditions generally are favourable for flying. Level, unobstructed terrain for landing strips is also widely available. Ulaanbaatar has an international airport, and the capital has regularly scheduled service to the province centres. Special medical and veterinary flights also are arranged.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. From the founding of an independent Mongolia on July 11, 1921, the country followed Soviet leadership for nearly seven decades; it was the first Soviet satellite and remained so the longest. The Soviet army became Mongolia's main defense force, and party and governmental structures closely followed the Soviet models of a one-party political system. The economy was transformed gradually into a communist command economy with governmental ownership of the means of production and with an emphasis on mining and industry.

During the 1980s the party leadership underwent change. An era of openness permitted criticism of current and past party leadership and of economic, political, and social stagnation and resulted in the elimination of the monopoly of power by the communist party (Mongolian People's Revolutionary Party [MPRP]) in March 1990, multiparty elections in July 1990, and the subsequent formation of a coalition government. A new constitution became effective on Feb. 12, 1992, with power divided among independent legislative, executive, and judicial organs, with human rights guaranteed by law, with separation and mutual noninterference of state and religion, and with the authorization of private ownership of land, except for pastures used by nomadic herders. The lands (except those given to the citizens of Mongolia for private possession), water, forests, fauna, and underground resources are the property of the state, which also regulates the economy.

The new constitution provided for a strong, directly elected president, who nominates the prime minister and who has the power to veto legislation. That he must be at least 45 years old places the position out of the reach of young reformers. The constitution also created a unicameral legislature, the State Great Hural, with 76 members elected for four-year terms. Parliament by a two-thirds vote can overturn a presidential veto. The MPRP continues to play a leading role in the government.

The country is divided administratively into 18 *aymags* (provinces), with further local subdivisions into towns and *somons* (districts). The cities of Ulaanbaatar, Darhan, and Erdenet have independent administrative status.

Justice. Justice is administered through an independent system of courts: Supreme Court, province courts (including a capital city court), and district courts. Special courts such as criminal, civil, and administrative may be formed. Matters relating to the interpretation of the constitution are decided by an independent Constitutional Court. Amendments to the constitution require a three-fourths vote of members of the Great Hural.

Armed forces. Mongolia maintains only limited military forces, consisting of infantry divisions and support aircraft. Soviet troops were withdrawn in the early 1990s. The 1992 constitution prohibits the presence of foreign troops. (C.D.H.)

Education. From the foundation of the modern state, educational development has been regarded as important. Until 1940 the main thrust was directed at eradicating illiteracy, establishing a free system of public education, and creating a trained intelligentsia. The creation of a network of schools was undertaken first. From the 1940s on, the main educational emphasis passed to establishing institutions of higher education and expanding elementary and secondary facilities. There are now several hundred general schools (offering primary and secondary education), many special vocational schools, and several institutions of higher education—the Mongolian State University (established 1942) and teachers' training, medical, and agricultural institutes.

General schools

Most children attend school for at least 8 years; those in larger urban centres receive 10 years of schooling. Illiteracy has been almost eradicated. The Academy of Sciences coordinates research institutions, experimental stations, and other scientific establishments and supervises scholarly work.

Health and welfare. Health services were similarly expanded over the republic's first half century. Medical treatment is free, and the state also maintains a network of sanatoriums and holiday rest homes.

Among other social services, the provision of housing has been greatly emphasized. The yurt remains the main traditional dwelling in the countryside. Increasing urbanization, as well as the introduction of more settled ways in the country, has necessitated the building of modern apartment blocks in the cities and an increasing number of permanent rural structures. Motor-transport mail links date from 1924, shortwave communications from 1934–36, and national radio broadcasting from 1934. A trunk telephone-telegraph link connecting Ulaanbaatar with all the province centres was established in the late 1940s. In the 1960s, satellite communication systems were used, and television broadcasts began in 1967.

(B.Sv./D.Dn./C.D.H.)

CULTURAL LIFE

Contemporary cultural life in Mongolia is a unique amalgam of traditional elements—the heritage of centuries—and a growing modern element.

Traditional elements. Mongolian literature evolved a wealth of traditional genres: heroic epics, legends, tales, *yurol* (the poetry of good wishes), and *magtaal* (the poetry of praise), as well as a host of proverbial sayings. These genres are infused by what Mongols regard as a national characteristic—a good-humoured love of life, with particular fondness for witty sayings and jokes, particularly evident in the image of Dalan Khuldalchi, the hero of humorous folktales, and in the stories about the *badarchins*, clever but wily wandering monks. The *baatar*—the popular hero of folk legend—is also a symbolic figure. *Khurchins*—folk poets and singers—carried down the oral epics and ballads; and their mime and gesture gave rise to the popular trenchant satirical vaudevilles, *Sumya Noyon* and *Dunkher Da-Lam*. The religious mysteries, *tsam* and *maidari*, were formerly staged as mass spectacles. Other folk arts include the making of *shirdeg*, richly ornamented felt carpets noted as adorning the entrances to yurts by 13th-century European travelers. The Mongolian form of chess, *shatar*, with a stern khan for king, a dog—the cattle breeder's traditional honoured friend—as queen, and a camel as a bishop, has very deep roots and has produced some finely carved chess sets. The ancient faience decoration of glazed earthenware, with exquisite motifs, has been revived. A complicated and dignified ritual still accompanies the traditional offering and acceptance of hospitality in a country where traveling is all-important, and the seating arrangements in the yurt are likewise carefully arranged. When conversing, Mongolians traditionally place the right palm on that of the left hand, a symbol of mutual esteem, and the same gesture, together with a light bow, expresses gratitude, greeting, or farewell.

The most famous celebration of traditional ways, however, is the annual Naadam festival of the Three Games of Men, beginning each year on July 11, National Day, and held in all provinces and counties. The festival has

The Naadam festival of the Three Games of Men

recorded roots going back 2,300 years or more. The first sport is wrestling, prominent in ancient times at religious festivals, and the ritual entry into the arena of several hundred participants, clad in the bright colours of a special tight-fitting costume known as the Dzodog Shudag and simulating the flight of the mythical Garudi bird, is a spectacular sight. The contests themselves also are conducted with great ceremony. Titles awarded at the national Naadam festivals are those of Titan, Lion, Elephant, and Falcon. A three-time winner becomes a Darkhan Avraga ("Invincible Titan"). The second sport is archery; and bowmen vie for the title of Merghen, or "Supermarksman," in individual and group contests, shooting at a leather-covered target with weapons of ancient design. Exceptional winners are characterized as Miraculous Archer, Most Scrupulous Archer, and similar names. The third sport, horse racing, is in many ways the most spectacular because all the competitors are children, ranging in age from 7 to 12. They are highly skilled and wear fine ornamental dresses as they race for about 20 miles across country. National horse-riding competitions for all ages are held during January and February, the Mongolian New Year, and are claimed to date back to the Bronze Age. Marco Polo, visiting in the 13th century, described a gathering of not fewer than 10,000 white horses held at the behest of the Great Khan.

Modern elements. Modern sports range from freestyle wrestling (introduced 1962) to motorcycling, rifle shooting, table tennis, boxing, and gymnastics. A growing number of economic enterprises cater to the various folk arts. The Palace Museum has a superb collection of folk art housed in the former winter palace of the khan, built in 1898. The architectural ensemble contains temples housing the famous sculptures of the goddess Tara made by the 17th-century artist Zanabazar. The State Central Museum and related exhibits portray the rich archaeological and paleontological remains of the country. Buddhist relics are exhibited in the Temple Museum, built 1903–05. The Erdene-Dzuu Monastery Museum on the site of Karakorum (Har Horin), Mongolia's ancient capital, is also noteworthy. Each province now has its own museum of regional studies. The State Public Library contains works of great variety and historical value.

In literature, the poems and short stories of Dashdorjiyn Natsagdorj became particularly significant in the 1930s. The literature of the 1940s was more varied in theme and genre, and the autobiographical "Old Scribe's Story" by G. Navaannamzhil was popular. Younger writers in the 1950s and '60s injected a more contemporary note, attempting to balance psychological and social imagery. The realistic epic novel continues in popularity.

Performing arts

The State Drama Theatre, founded in 1931, shows both Mongolian and classical works, and the State Opera and Ballet Theatre has a deserved reputation. There is a puppet theatre in the capital and internationally known song and dance companies. Practically every community has its own amateur art group, and the State Circus is also very popular. The Mongolkino film studio in the late 20th century was making an increasing impact at international festivals: its productions are assisted by the magnificent landscapes and clear air of the country, which help the production of wide-screen epics. Mass radio and television services are of importance because of the great distances in the country and are now aided by satellite links. The vast majority of households have radios, and the ownership of televisions has spread. There are about a dozen central and nearly two dozen local newspapers. The leading newspapers are *Unen* ("Truth") and *Pionyeriyn Unen* ("Pioneers' Truth"). There are also several dozen popular and specialist periodicals. (Sh.Bi./C.D.H.)

For statistical data on the land and people of Mongolia, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR.

History

The Mongols constitute one of the principal ethnographic divisions of Asian, or Oriental, peoples. Their traditional homeland is centred in Mongolia, a vast plateau in Central Asia now divided politically into an autonomous region of the People's Republic of China (Inner Mongolia) and Mongolia (Outer Mongolia), which lies at the eastern end of what was a great corridor of migration between Northeast China (Manchuria) and Hungary throughout history. It is unfortunate, because confusing, that 19th-century physical anthropologists introduced the terms Mongol and Mongolian as descriptive of racial type. The Mongols exhibit a wide range of physical characteristics and should be considered not as a race but as a group of peoples bound together by a common language and a common nomadic tradition.

The geographic origin of the Mongols themselves is the northeast corner of present-day Mongolia. To the east, the ancient tribal history is mostly that of the Tungus peoples (including the ancestors of the Manchu) and to the west, that of the Hsiung-nu, or eastern Huns, and their Turkic-speaking successors, whom the Mongols eventually displaced and in part absorbed. As a result of later wars and migrations Mongols are now found in Mongolia; southern Russia; in the Inner Mongolia Autonomous Region (which includes a large portion of Northeast China), the Hui Autonomous Region of Ningsia, the Uighur Autonomous Region of Sinkiang (Chinese Turkistan), and the northern part of the Tibet Autonomous Region of China; and in Afghanistan.

ETHNOGRAPHY AND EARLY TRIBAL HISTORY

All Mongols recognize their kinship to each other in varying degrees through legend, written history, and especially language. Dialects vary from east to west more than from north to south, but few are unintelligible to other Mongols. Historical change in the language is indicated by the fact that reading *The Secret History of the Mongols* (mid-13th century), the oldest major document written in Mongol, is for the Mongols of today like reading the work of Chaucer for the modern English. Pan-Mongolism, the desire to reunite politically all the Mongols, was always more a romantic than a practical idea, and is now a dead issue.

Nomadic tradition

The Mongols have always been nomads, though there has also always been some cultivation. However, nomadism is the seasonal movement of livestock and camps from one pasture to another, not unfettered wandering. Nomads have a clear concept of the possession of territory, though they sometimes interpret this in socially conflicting ways. Legend and folklore show that among the premodern Mongols the common people considered livestock to be private property and land to be the collective property of the tribe, while the families of ruling chiefs tried to claim the land as well as individual subjects as their property.

Traditional society was based on blood relationship traced through the common male ancestor who gave his name to the clan, though evidence exists of a more ancient system of matrilineal descent. Marriage was forbidden between members of the same clan, giving rise to complicated marriage alliances (and also feuds) among the clans. As clans grew and merged into tribes (often inventing a fictitious common ancestor), the most successful families tended to arrogate to themselves claims to "real" ancestry and, at the same time, to control of the tribal territory, while lesser families could claim ancestry only in a vaguer, tribal sense. In this process weak clans fell to a subordinate but not servile status: they owned their own cattle and had their own headmen but paid tribute to the ruling clan and moved, camped, pastured, and fought under its orders.

Political and military organization was matched to the family-clan-tribe pattern. Every man who could ride and bear arms was both a herdsman and a soldier according to the need of the moment. Raiding other tribes to capture cattle, women, and prisoners was a recognized method of property accumulation. When, however, a tribe rose to notable power, as in the time of Genghis (Chinggis) Khan in the 13th century, a decimal form of military organization was adopted, with units of 10, 100, 1,000, and 10,000. Commanders of large units were assigned territories from which they drew the tribute to the supreme khan and mustered their quotas of troops. Mongol history fluctuates between such periods of feudal concentration and those of tribal dispersion.

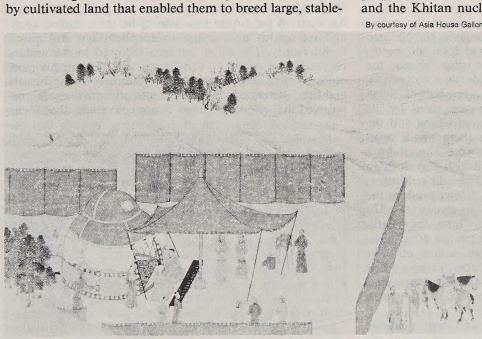
The first mention in the Chinese chronicles of tribes that can be identified with Mongolia goes back in a shadowy way to the 2nd millennium BC. The first inhabitants of whom there is certainty, however, are the Hsiung-nu, in about the 5th or 4th century BC. It was once thought that they were Turks, or at least Turkic speaking, but the opinion has grown that they spoke a paleo-Asiatic language, represented today by the Ket dialects of the Yenisey River valley in Siberia. The Hsiung-nu created a great tribal empire in Mongolia while China was being unified as an imperial state under the Ch'in (221–206 BC) and Han (206 BC–AD 220) dynasties. After several centuries of war with the Chinese, complicated by civil wars among themselves, the Hsiung-nu confederation broke up. Some of the southern tribes surrendered to the Chinese and were settled within China, where they were eventually absorbed. Some of the northern tribes migrated westward, where descendants—together with the members of other tribes—appeared in Europe in the 5th century AD as the Huns of Attila. By then, of course, these people were considerably more mixed ethnically.

The Huns

In Mongolia the Hsiung-nu were succeeded both by Turkic-speaking peoples and by others identified by some scholars as Mongols, or Mongol speakers. There is a lack of convincing archaeological or historical evidence that these groups came to Mongolia from some distant region to fill a void left by the Hsiung-nu departure. Probably they were there all the time as the subjects of the Hsiung-nu, until the breakup of that confederation gave them the opportunity to assert themselves. Among the peoples who have been considered possibly Mongol, the most important tribal names are Sienpi (Hsien-pi), who may however have been Tungus (modern Evenk) rather than Mongol, recorded in Han dynasty annals, and the Juan-juan (Joujan, or Geougen) of the 4th to 6th centuries. The latter have been identified by some scholars with the Avars, who migrated into Europe along the plains of the Danube and were nearly annihilated in Hungary by Charlemagne in the late 8th century.

According to a legend recorded by the Chinese, the Turks of Mongolia, whose name is recognizable under its Chinese transcription "T'u-chüeh," were a subject tribe ruled by the Juan-juan. The Turks overthrew their masters and soon were in control of all Mongolia, centring their power in the Orhon valley in the northern part of the country. The Orhon (Orkhon) Turks were contemporaries of the T'ang dynasty (618–907) in China, and their fortunes rose and fell in counterpoint to periods of T'ang strength and weakness. Comparison of archaeological and historical data, moreover, shows that power in Mongolia was at this time not based simply on levies of nomad horsemen. The khans and great men had fixed headquarters, surrounded by cultivated land that enabled them to breed large, stable-fed horses capable of carrying a man in armour. This situation emphasized a class distinction between the aristocrat on his charger and the herdsman-warrior-archer on his smaller horse. Agriculture also became an element in the economy, and the Uighurs, who came to power after the fall of the Orhon Turks, enter history as an oasis-centred people.

In the welter of tribes the name Mongol first appears in a tribal list recorded under the T'ang dynasty. It then vanishes, to reappear only in the 11th century, when the Khitan (Khitai, from which comes the word Cathay) ruled in Northeast and North China and controlled most of Mongolia. The Khitan, who established the Chinese dynasty of Liao (907–1125), were themselves a Mongol people, but their homeland was in Northeast China rather than in what is now Mongolia. Like other Chinese dynasties, the Liao exercised its power in Mongolia by playing off the tribes against one another. Liao sources record the existence of a rather shadowy tribal power known in Mongol tradition as Khamag Mongol Uls ("Nation of all the Mongols"), which did not, however, include all of the population who spoke the Mongol language.



When the Khitan fell, their power in China was taken over and extended by the Juchen (Jurched), a Tungus people based farther north in northeastern China. They took the Chinese name of Chin ("Golden"). In their tribal policy they switched their favour from "All the Mongols" to the Tatars (known in the West as Tartars, from a medieval pun on *tartarus*, Latin for "hell"). Although Mongols, the Tatars were not part of the tribal league of All the Mongols, centred in the Onon and Kerulen valleys in the eastern half of North Mongolia; the Tatars lived to the east and south of them.

The Tatars

On the whole, though chastened occasionally by punitive expeditions, All the Mongols had been transfrontier allies or auxiliaries of the Khitan-Liao. A contingent of 50,000 Mongols (large for that time) fought on the Khitan side in the last battles of the Khitan empire. Presumably, this was one reason why the Juchen-Chin transferred their favour to the Tatars, nearer to their frontier. Such alternations, between using the more distant and using the nearer transfrontier and frontier tribes, were frequent in the policies of dynasties in China, and this one had the desired effect of creating a feud between Mongols and Tatars.

Before the era of Genghis Khan, a defeated Khitan army had migrated westward at the fall of their Liao dynasty. It was led by a prince of the Khitan imperial line but must have included heterogeneous tribal elements. Moving westward through Mongolia, it reached what is now Kazakhstan and created a new and briefly powerful empire, the Karakitai. It ruled primarily over Turkic-speaking peoples, made up of nomads and city dwellers in the oases, and the Khitan nucleus had the opportunity to apply its

knowledge of how to deal with nomads and its ability in the administration of a bureaucracy.

THE RISE OF GENGHIS KHAN

Such was the setting in Mongolia when Genghis Khan (his given name was Temüjin) was born, about 1162 (the date accepted by contemporary Mongol scholars). Genghis was born into a clan that had a tradition of power and rule, being the great-grandson of Khabul (Qabul) Khan, who had been the greatest ruler of All the Mongols. Genghis inherited a feud against the Juchen-Chin dynasty and another against the Tatars, who had betrayed a collateral ancestor of his to the Juchen. His own father was poisoned by Tatars. He also inherited feuds among the ruling clans of All the Mongols and a feud with the powerful Merkit (Mergid) tribe, from whom his father had stolen his mother.

Genghis was even more deeply a political man than a warrior, and he resorted to war only as an extension of policy by other means. He was orphaned in his teens; his family fell on bad times, and power among the Mongols passed to other clans. Even in such apparently primitive practices as camp raiding and horse thieving, he skillfully used ancient customs: marriage alliances; putting himself under the patronage of a stronger prince; making an alliance with Jamuka (later his dangerous rival) by the oath of *anda,* under which men became as if blood brothers; and recruiting *nökhör* (the modern Mongol term for "comrade"). Unlike the institution of *anda,* which created a fictitious kinship and harboured the possibility of deadly rivalry, a man who became a *nökhör* forswore all loyalties of kinship and tribe and declared himself solely "the man" of his chosen leader. Genghis later fell out with his *anda,* but he was never betrayed by a *nökhör,* and his most brilliant generals were *nökhör.*

Genghis broke alliances and betrayed loyalties, but only when he could seem to be acting in "the common cause." By 1206 his success in tribal warfare caused him to be proclaimed ruler of All the Mongols with the rank of khan and the title of Genghis (Chinggis)—a word deriving probably ultimately from the Turkic *tengiz,* meaning "a large body of water, the ocean"; although this explanation has not convinced all Mongol scholars, it is consistent with the belief that the ocean symbolized breadth and depth of wisdom, and later the equivalent Mongol word of *ta-le* (Anglicized as "dalai") was applied to the supreme lama of Tibet. Previous nomads had invaded China, but none had yet ruled the whole of it, chiefly because they had invaded prematurely, leaving other nomads on their flanks and in their rear. Genghis, however, first united all the "dwellers in felt-walled tents" (*tuurgatan*), probing far back, away from China, to make sure that he controlled all potential nomadic rivals.

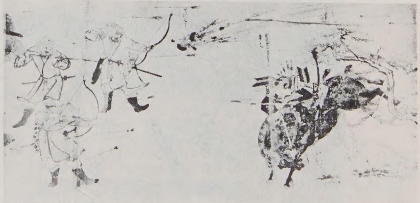
Ruler of All the Mongols

His first move was to bring under control the major tribal groups to the west of him in Mongolia, the Naiman and Kereit (Kerait) with whom he had been alternately in alliance and rivalry, as well as the tribes fringing the northern Mongolia-Siberia frontier. He then turned toward China, where at this time the eastern half of North China, south almost to the Yangtze, was ruled by the Juchen-Chin. In the northwest corner of China and the western extension of Inner Mongolia there was a small state, that of the Hsi Hsia: its rulers were Tangut from Tibet, and under them there were Turkish and Sogdian merchants who exploited the caravan trade, the cultivators of the oases being Turks and Chinese. China south of the Yangtze was ruled by the Southern Sung dynasty (1127–1279). Although they had lost North China, the Southern Sung were expanding southward toward Indochina, bringing rich new land under cultivation. Among all these states there was an interplay of diplomacy, alliances made and broken, and open warfare. The Mongols themselves, far from being ignorant barbarians, understood the game and played it skillfully.

Between 1207 and 1215 the armies of Genghis probed deep into North China. Genghis made good use of the Khitan in northern and northeastern China, whose Liao dynasty the Juchen-Chin had overthrown and who were now discontented subjects of the Chin. In 1215 the Chin capital Chung-tu (modern Peking), from which the Chin emperor had withdrawn southward, was taken and sacked. Realizing, however, that it was premature to commit his main strength to the conquest of China, Genghis withdrew to Mongolia, leaving one of his best generals, Mugali, to ravage and weaken the country. He himself turned westward. When he had defeated the Naiman, the last of the powerful tribes in Mongolia proper, the son of the last ruler of that tribe, Küchlüg, fled to Karakitai and married the daughter of its last ruler, whom he then overthrew. In that variegated kingdom, which included Semirechiya in Russian Turkistan and the Kashgarian Oases in Chinese Turkistan (Uighur Autonomous Region of Sinkiang), he favoured the Buddhist minority and persecuted Islām, the majority religion. This situation made it easy for the Mongols to defeat him. The Mongol general Jebe (Jeb) proclaimed freedom of religion and forbade massacre and plunder. This policy indicates that the Mongols did not massacre out of sheer savagery but only when they thought it necessary to break the power of an opponent.

Sack of Peking

Taking over the lands of the Karakitai opened the way for Genghis to Khwārezm, the land of the oases along the Syr Darya and Amu Darya in northern Iran. For drawing on the resources of a higher civilization this gave him an alternative to China, and it also secured him against the danger of any other nomadic power organizing, on his flank and rear, a military striking force backed by agricultural and urban resources. This done, he turned back toward China, leaving further campaigning into Russia and the eastern fringes of Europe to his generals and sons. He would not, however, commit his main forces in China until he had dealt with the wealthy Tangut state of Hsi Hsia; it was on this successful campaign in 1227 that he died.



THE SUCCESSOR STATES OF THE MONGOL EMPIRE

Genghis had already dealt with the problem of succession. Each of his four sons was to hold a vassal kingdom: Jöchi, the eldest, was given the land from the Yenisey River and the Aral Sea westward "as far as the hooves of Mongol horses have reached"—a wording attributed to Genghis himself; the second son, Chagatai (Tsagadai), received Kashgaria (now the southern part of Sinkiang) and most of Mavrannakhar between the Amu Darya and Syr Darya; the third son, Ögödei (Ogadai), received western Mongolia and the region of Tarbagatai (now the northwestern corner of Sinkiang); the youngest, Tolui, inherited the ancient Mongol homeland of eastern Mongolia. Two years later, in 1229, a great Mongol assembly confirmed the succession of Ögödei as the great khan (khagan).

Tradition of succession

These dispositions made skillful use of ancient traditions. It was the custom among prosperous families that the eldest son, on reaching manhood, was given a wife and his share of the future inheritance; he then moved away and set up his own camp, independent but still allied to his family. The other brothers followed in due order, but each one nearer to the "home camp" than his next older brother. The youngest, as "guardian of the hearth and fire," remained with his parents until their death and received the residual heritage. It was convenient that Jöchi

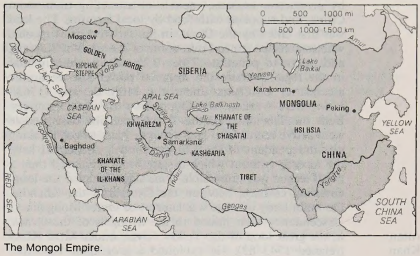
could in this way be placed at the greatest distance from the ancient homeland because he got on poorly with his brothers, who considered him illegitimate, conceived while his mother was the captive of a hostile tribe. The election of Ögödei as great khan over the head of his elder brother Chagatai (Jöchi had already died) did not do violence to nomadic tradition; it was quite acceptable in wartime for the dying ruler to nominate as his successor the son who was considered ablest and most acceptable to his brothers.



With this first division, further fission was inevitable. Under Batu, the successor of Jöchi, there began the formation of the Golden Horde, which ruled, or rather, drew tribute from the city-states of Russia. In this khanate the Mongols were greatly outnumbered by Turks; the Turkish language soon displaced Mongol, and Islām became the prevailing religion. Because its reservoir of nomad power was in the Kipchak Steppe, the Golden Horde is sometimes known as the Kipchak khanate. By its methods of collecting taxes and tribute it contributed to the rise of the grand dukes of Muscovy; and it was eventually a Moscow-led alliance that broke the power of the Mongols (by then more frequently called Tatars), at the Battle of Kulikovo in 1380. Partly by treachery and partly by guile the Golden Horde was still able to take and sack Moscow two years later, but its power soon disintegrated—an important factor being attacks by Timur (Tamerlane), coming from Turkistan.

House of Chagatai

To the east were the khanates of the House of Chagatai and the Il-Khans of Iran (Persia). Like the rulers of the Golden Horde, the rulers of the House of Chagatai considered themselves senior, in genealogy, to the House of Ögödei; they were frequently at odds with the great khan, with each other, and with the Il-Khans. On the other hand, the Il-Khans (the title itself implies subordination) accepted and supported the authority of the great khans. Like the Golden Horde, again, the House of Chagatai controlled wide pastures and therefore retained a strong nomadic base, while the Il-Khans, like the great khans (especially after Kublai [Khubilai] moved his capital into China), were directly affected by the urban influences of an old, highly developed civilization with a rich literary tradition. As in China, this situation led rather rapidly to the passage of real administrative control from Mongol hands into the hands of their subjects. The greatest of the Il-Khans was Hülegü (Khulagu, Hulagu), a brother of Kublai Khan of Mongolia and China, who began the Il-Khan tradition of supporting Peking against the House of Chagatai and the Golden Horde.

This brief review of the outer khanates helps to explain the subsequent history of the Mongols in Mongolia and the Mongol dynasty in China. As great khan, Ögödei authorized the continuation of Mongol campaigns in Russia and the west and also in China, where the disintegration of the Juchen-Chin dynasty in 1234 had brought the Mongols face to face with the surviving Sung dynasty in the Yangtze valley. Ögödei was also able to maintain a system of imperial representatives in the appanages of his imperial kinsmen in Central Asia and Iran but was less able to control the always insubordinate Golden Horde. He died in 1241 and was succeeded, after a stormy regency under his widow, Töregene, by his son Güyük (Kuyug) who had already quarreled with his cousin Batu of the Golden Horde. Güyük died at Samarkand in 1248, while preparing an attack on Batu.

A major change then occurred in the succession. At the next great assembly of the descendants of Genghis Khan, enlarged by the presence of powerful commanders and officials, the great khan chosen (again after much intrigue) was not a son of the House of Ögödei but Möngke (Mungke, Manga), a son of Tolui, the "guardian of the fire and hearth" of the Mongol homeland. This choice was favoured by Batu Khan, and Möngke responded by trying to stabilize and pacify relations among the khanates. Of his brothers he sent Kublai (later Great Khan) to continue the conquest of Sung China and Hülegü to subdue the Assassins (Nizārī Ismā'īliyūn); on this campaign Hülegü also took Baghdad, a rich and powerful city and seat of the 'Abbāsid caliphate. Möngke was aware of the desire of some of the crusaders for a Mongol alliance against the Saracens, but like Ögödei and Güyük he would not consider this except on terms of the submission of the European rulers and the pope. He himself campaigned deep into southwest China and there died of a fever in 1259.

The Mongol Empire.

The succession was then disputed between Möngke's second brother, Kublai, and his youngest brother, Arigböge (Ariböx, Arikböge). A third brother, Hülegü, supported Kublai. The dispute was more than a brawl over spoils among barbarian warriors; ideology was involved. Genghis Khan's concept of conquest and rule had been clear: the "people of the felt-walled tents" should remain in the steppes and continue their ancient warrior way of life, drawing tribute from the world of farms, cities, and caravan trade. Kublai and Hülegü, however, favoured moving into the conquered countries and there becoming the new ruling class—even if this meant mingling with the remnants of the conquered ruling class.

Kublai Khan

In this respect Arigböge was closer to the concept of Genghis than was Kublai, but Kublai prevailed and Arigböge died in honourable captivity. Kublai had himself proclaimed great khan in Mongolia in 1260. Kublai's reign has been romanticized in the West ever since Marco Polo. Kublai Khan moved the capital from Karakorum (Kharakhorum), which had been built by Ögödei (not Genghis Khan, as is often said), to a new city that he had built on the site of Chung-tu, naming it Ta-tu ("Great Capital"). He used Mongolia as his base for ascendancy over the other Mongol khanates, but drew his main revenue directly from China. He used foreigners (including Marco Polo and his family) to lessen his dependence on Chinese bureaucrats, but the administrative structure was essentially on the Chinese model; and consequently the Mongols, because they no longer held the real keys to power, lost the throne to the native Chinese Ming dynasty in 1368, only a century after the accession of Kublai and within a decade or two of the end of the Golden Horde and the Il-Khanate.

Internecine strife. Although in the first vigour of reconquest the Chinese penetrated deeply into Mongolia and destroyed Karakorum, they never succeeded in establishing control. Mongol unity was shattered, but Mongols in different regions began to recover. Mongol fission followed several lines. In western Mongolia there arose new lines of chieftains who did not claim descent from Genghis Khan. As a group, these were the Oyrat (Oirat), but at times the names of subgroups or individual tribes, such as the Dzungar (Jüüngar) or the Dörbed (Dörböd), predominated. In the centre, both in Outer and Inner Mongolia, the ruling princes claimed descent from Genghis Khan. In northeastern China were princes whose ancestor was Khasar, a brother of Genghis Khan. Because there had been bad blood between the two, these princes and the Chingiside princes were always suspicious of each other.

The Oyrat

What followed, in the renewed tribal wars and pressure on the frontiers of China in the 15th and 16th centuries, was much more than a resurgent "wave of barbarian invasions." A distinct new period was opening in which all concerned understood that in order to have real power outside the Great Wall of China it was necessary to coordinate nomadic military mobility with towns inhabited

by productive artisans, capable of attracting trade from China, and supplied with food by local farming. The lead was first taken by the Oyrat, in the far west of Mongolia, who established control over some of the oases of Sinkiang and began to penetrate Tibet. This advance meant that in the regions where the Imperial power and economic ascendancy of China under the Ming dynasty (1368–1644) were weakest, the Oyrat drew on new resources. Both the Tibetans and the Turkic-speaking oasis people were active merchants, had a literate class whose thinking was independent of the Chinese model, and could keep the records without which a state more advanced than a tribal league was impossible. This stage initiated the long-enduring cleavage between the Oyrat and the Khalkha, the main body of what was later to be Outer Mongolia.

Altan Khan

Ascendancy then passed to the Mongols of the Ordos, in the great loop of the Yellow River, under Altan Khan (reigned 1543–83). He exploited a geographic base that enabled him to develop agriculture and trade, to challenge the Oyrat in Tibet, and to pressure the Chinese. Meanwhile, the Mongols of the centre, Khalkhas in the north, and Chahars (Chakhars) in the south (there was as yet no "Outer" and "Inner" Mongolia) had lagged behind for lack of a suitably diversified geographic base. The best that they could achieve was a tribal league unification under Dayan Khan, a descendant of Kublai and grandfather of Altan Khan, who was proclaimed khan in 1470 at the age of five and died in 1543. After this, and after the death of Altan Khan, the supremacy over the Mongols of the centre passed to the south to another descendant of Dayan, Ligdan (Legdan, Lingdan) Khan of the Chahars. Using the geographic advantages of the modern Chinese frontier province of Chahar, close to the Great Wall, he tried during his reign (1604–34) to build up a power comparable to that which had been held by Altan Khan. He was too late, however, because of the rise of the Manchu.

Revival of Buddhism. During this period there was a second flowering of Buddhism among the Mongols. In the reign of Kublai, Buddhism in its Tibetan form had been fashionable at court and among some of the Mongol aristocracy, but the people as a whole had not been converted. The new entry of Buddhism was promoted by political considerations. A number of Mongol princes saw that for the kind of power that was now advantageous it was necessary to have not only a religious ethos higher than that of shamanism (whose priests used magic to cure the sick, to divine what was hidden, and to control events) but also a literate class to provide a bureaucracy. To use the Chinese language meant the risk—as had been proved under the Mongol empire in China—of the absorption of the Mongol ruling class into the Chinese ruling class. Tibet was not strong enough to dominate Mongolia, and the Tibetan monastic system had already produced able clerical bureaucrats. Moreover, Tibetan alphabetic writing was easier to use than Chinese ideographs.

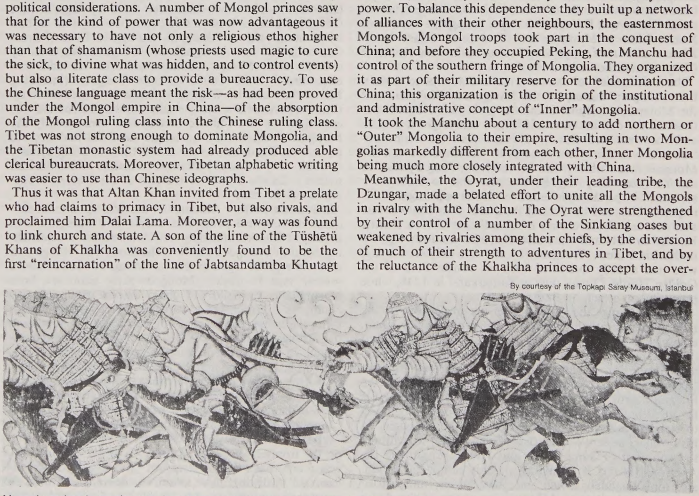
Establishment of the Dalai Lama

Thus it was that Altan Khan invited from Tibet a prelate who had claims to primacy in Tibet, but also rivals, and proclaimed him Dalai Lama. Moreover, a way was found to link church and state. A son of the line of the Tüshētü Khans of Khalkha was conveniently found to be the first "reincarnation" of the line of Jabtsandamba Khutagt (Khutukhtus) of Urga. The significance of this device is underlined by the fact that, as soon as the Manchu controlled Mongolia, they ruled that no man of the lineage of Genghis Khan could be "discovered" to be a reincarnation or "living Buddha," and also that the Khutagt of Urga must always be discovered in Tibet. In their rule of Mongolia they thus separated church and state and used them against each other.

At the beginning of the revival of Buddhism in Mongolia there was a great burst of translation of the scriptures from Tibetan (and Sanskrit) into Mongol. The Mongols wanted to use Buddhism as a unifying principle in a new nationalism. When the Manchu won control, however, they threw their support to the use of Tibetan as the "Latin" of the church, further widening the cleavage between clerical and secular authority and bureaucracy. By the end of the Manchu regime there were many monks in Mongolia who were literate in Tibetan but not in their own language.

THE ASCENDANCY OF THE MANCHU

The rise of the Ch'ing, or Manchu dynasty, which had such profound effects on the fate of Mongolia, began long before 1644, the year a Manchu emperor was first seated on the throne in Peking. In the late 16th century it was becoming clear that a new barbarian conquest of China was again possible. In competition with the various Mongol princes and tribes already mentioned, the Manchu had the advantage that in the southern part of Northeast China (Manchuria), but outside the Great Wall of China, there was a large Chinese population with a number of urban centres and a flourishing trade that, instead of passing by land through the Great Wall, went largely by sea to the Shantung Peninsula—to the rear, that is, of the rulers in Peking. These Chinese were somewhat alienated from other Chinese. They had for centuries been accustomed to trading with the barbarians and to farming under the patronage of barbarian princes, and they did not like Peking's periodic attempts to maintain a "closed frontier" along the Great Wall.



The Manchu not only subjugated these Chinese but also cultivated their loyalty and were soon heavily dependent on them, not only economically but for military manpower. To balance this dependence they built up a network of alliances with their other neighbours, the easternmost Mongols. Mongol troops took part in the conquest of China; and before they occupied Peking, the Manchu had control of the southern fringe of Mongolia. They organized it as part of their military reserve for the domination of China; this organization is the origin of the institutional and administrative concept of "Inner" Mongolia.

It took the Manchu about a century to add northern or "Outer" Mongolia to their empire, resulting in two Mongolias markedly different from each other, Inner Mongolia being much more closely integrated with China.

Attempt at Mongol revival

Meanwhile, the Oyrat, under their leading tribe, the Dzungar, made a belated effort to unite all the Mongols in rivalry with the Manchu. The Oyrat were strengthened by their control of a number of the Sinkiang oases but weakened by rivalries among their chiefs, by the diversion of much of their strength to adventures in Tibet, and by the reluctance of the Khalkha princes to accept the over-

lordship of princes not descended from Genghis Khan. Led by such warriors as Galdan (Dga'-ldan), the Oyrat made sweeping campaigns far to the east in Mongolia but were never quite able to consolidate their gains. In trying to make the Oyrat a recognizably distinct nation, the great religious leader, the Jaya Pandita, revised the Mongol alphabet, making it phonetically more accurate, and originated an independent literary tradition.

Unwilling to accept submission to the Oyrat as the price of unification, the Khalkha princes rallied more and more to the Manchu, who guaranteed their aristocratic privileges and titles in a great convention at Dolon Nor (To-lun), in Inner Mongolia, in 1691. With the added resources of Khalkha, the Manchu were then able to mount a long series of military campaigns in which they annihilated the Oyrat power with tremendous slaughter on the scale of genocide.

This conquest, however, was not completed until 1759, and it was complicated by many events, particularly a major revolt against Manchu rule in western Khalkha in the 1750s led by a noble named Chingunjav. Chingunjav was a coconspirator with an Oyrat leader named Amursana, who in turn had first submitted to the Manchu and then rebelled against them. But this was the last period of general warfare involving the Mongols, and it ended with a considerable redistribution of the tribes. Several Khalkha groups that had fled from the Oyrat into Inner Mongolia never returned; a few Chahars from Inner Mongolia were settled in Sinkiang as garrisons; numbers of the Oyrat group were included in the western part of Khalkha geographically but not within the tribal organization; some ended their migrations in Ala Shan, at the western end of Inner Mongolia, but not within the Inner Mongolian organization; and some ended theirs far away in the Kokonor-Tsaidam region of Tibet. The most distant Oyrat wanderers (mostly Torgut and Dörbed) migrated in the early 17th century from the Altai to the Volga, where they took service under the tsars and took part in the Russian conquest of the Caucasus. In 1771 about 70,000 families migrated all the way back to Sinkiang, where they were accepted under Manchu rule and allotted pastures for grazing. The descendants of those who remained on the Volga were known as the Kalmyk (Kalmuck).

Mongol dispersion

The ensuing period of peace degenerated into stagnation and economic decline. Chinese camp followers had accompanied the Manchu conquest, and from this grew Chinese control of the caravan trade and of a barter trade exploiting usurious terms of credit. Because Mongol troops were of decreasing use for the control of China, there was no incentive for the Manchu to protect, economically, this source of manpower, and the Manchu authorities relied increasingly on the potentates of the Lama Buddhist Church, who were themselves increasingly corrupt, for the control of Mongolia. Chinese colonization began to encroach on the pasturelands of Inner Mongolia, and at the end of the 19th century an attempt was made to plant a screen of Chinese colonists along the frontier between Siberia and Outer Mongolia.

THE 20TH CENTURY

In the Russo-Japanese War of 1904–05 both Russians and Japanese enlisted Mongol mercenaries as auxiliaries; from this time on there were Japanese army officers who dreamed of a new Mongol nationalism that could be used against both Russia and China. The Russians were more restrained and were satisfied with Buryatia (Buryat Mongolia). By secret treaties after the war Inner Mongolia east of the meridian of Peking was recognized by Russia as a Japanese sphere of interest.

By 1911, when the Chinese Revolution broke out, unrest was widespread in Mongolia. At the time, the Mongol language and Mongol sources being little known outside Mongolia, most observers thought of Mongolia only in terms of Russian and Japanese intrigue. But the rich documentation that later became available proved that the unrest was both social and political. The Mongols by this time identified the Manchu with the Chinese, the Chinese with usurious debt, and their own clerical and secular rulers as people who lived in luxury on Chinese loans and passed on the usurious interest to their subjects. The rulers, for their part, saw both the chance of a new government they could control and the danger that if they did not act, they would not be able to control the people.

Under the leadership of the Jabtsandamba Khutagt, the Mongols declared their independence. Uncertain of themselves in world politics, however, they sought to replace Manchu Imperial patronage with that of the tsar; but the Russians, because of the secret treaties with Japan and an understanding with Britain about Tibet and Mongolia (which, though not secret, could hardly be comprehended by the Mongols), would go no further than support of "autonomy," not "independence." This status was ratified after difficult negotiations between the Mongols, the Russians, and the new Republic of China. Union between Inner and Outer Mongolia was similarly frustrated. Some leaders in Inner Mongolia saw themselves as the future elite of a united Mongolia because they could draw on an intelligentsia with a knowledge of the language and politics of China, but for the same reason they were distrusted in Outer Mongolia as being too Chinese.

Independence

This uneasy situation endured with increasing economic distress and social unrest until the Russian Revolution. A Japanese-controlled clique in the Chinese government then sent a military expedition into Mongolia that forced the Mongols to sign a "request" to be taken over by the Chinese Republic. Almost immediately afterward, defeated anti-Bolshevik troops began to retreat into Mongolia. Their most important leader was Baron Roman von Ungern-Sternberg, known as the "Mad Baron," who defeated the Chinese occupation forces and treated the Mongols with unfeeling savagery.

In this period of terror and confusion two secret revolutionary groups, which later merged, were formed by Damdiny Sühbaatar, a former trooper and machine gunner in the Mongol forces disbanded by the Chinese, and Khorloghiyin Choibalsan, who had been a boy runaway from a monastery and later a student in Siberia. Choibalsan, though not the principal leader during the lifetime of Sühbaatar, was in touch with underground Bolsheviks—hiding there as refugees—later massacred by Ungern-Sternberg. Memoirs of the Mongol partisans enlisted by these two show that quite apart from Russian propaganda there was already in Mongolia a geographically widespread and socially embittered demand for radical social and political change. The traditional leaders had been discredited by their inability to handle either the Chinese intervention or the incursions of the antirevolutionary Russians.

The revolutionaries took the initiative in going to the Bolsheviks for help, which was quickly granted. The remnants of the Chinese warlord forces were driven out, and Ungern-Sternberg was handed over to the Bolsheviks for execution. Urga, the capital (now Ulaanbaatar), was taken by a joint Mongol-Russian column in July 1921, and this is now considered the date of the founding of the present republic, though the first measures of the revolutionary victors were surprisingly moderate. The Jabtsandamba Khutagt (the living Buddha of Urga) was continued in office, but as a "constitutional monarch," meaning he could sign only documents prepared for him by the new regime.

Sühbaatar died in 1923 and the Khutagt in 1924. In the Soviet Union Lenin also died in 1924, and in China Sun Yat-sen died in 1925. Mongolia was engaged in a revolutionary process also going forward at different rates of speed in the Soviet Union and in China. The problem of the Khutagt was easily solved; no successor was found, and on Nov. 26, 1924, Mongolia was proclaimed a People's Republic—using a wording that exactly follows the Chinese, not the Soviet, model. The government, and the controlling People's Revolutionary Party, was a coalition of conservative and nationalistic revolutionary elements. Shifts between "rightist" and "leftist" policy ensued, closely affected by the rise of Joseph Stalin in the Soviet Union and by the defeat of the Chinese communists (for the time being) by Chiang Kai-shek. Increasingly important, too, was the Japanese invasion of Northeast China (Manchuria) in 1931, followed by Japanese encroachment on Inner Mongolia and North China and all-out invasion of China in 1937.

Proclamation of the People's Republic

The uncertainty, both internal and external, engendered cliques and conspiracies—some real and others imagined—resulting in an atmosphere of suspicion and fear that cost many lives. The situation began to clear after 1939, when the Japanese, in a thrust toward Siberia, invaded the northeastern corner of Mongolia, testing the Soviet-Mongol alliance. The Mongol border troops fought ferociously, holding the heights of Nomynkhan (Nomonhan) and the line of the Khalkyn River until Soviet troops came up. The Japanese defeat was shattering, and it undoubtedly played a major part in their fateful decision not to honour the "Berlin-Tokyo Axis" with Hitler but to make their major effort in the Pacific and Southeast Asia. In Mongolia the victory dispelled fears that elements of the army might go over to the Japanese; on the contrary, many Inner Mongolian troops recruited by the Japanese went over to the Mongols. The military alliance with the Soviet Union was reconfirmed when the Mongols took part in the Soviet campaign in Inner Mongolia and Manchuria in the last two weeks of World War II.

At this time, refugees from Inner Mongolia swarmed into the Mongolian People's Republic. The Japanese had organized a puppet government of Inner Mongolia under Teh Wang (Prince Teh, Demchukdongrub). He had, however, tried to minimize Japanese control and to promote Mongol nationalism. When the Chinese communists came to power in Inner Mongolia, he was condemned as a war criminal but later released.

Under an agreement made by U.S. President Franklin D. Roosevelt at the Yalta Conference (February 1945), Chiang Kai-shek consented to a plebiscite in Mongolia after the war. The result was overwhelmingly in favour of independence over "autonomy." Full diplomatic recognition did not follow, however, because of a border dispute. Mongolian membership in the United Nations was at first sponsored by Chiang Kai-shek but later opposed by him and by the United States, and it was not until 1961 that Mongolia gained membership. In the meantime, Inner Mongolia was reorganized as an autonomous region within the People's Republic of China. (O.La.)

Foreign relations

For many years the relations of the Mongolian People's Republic with China were strained because of the former's unswerving loyalty to the Soviet alliance. Nevertheless, its long frontier with China was amicably redemarcated. Tensions eased considerably in the 1980s, leading to the establishment of diplomatic relations between the two countries in 1986. On Jan. 27, 1987, diplomatic relations also were established between the United States and the Mongolian People's Republic for the first time in the history of the two countries.

A series of events in the middle and late 1980s led to the failure of the social and economic system constructed by the Mongolian People's Revolutionary Party. The ouster from power of Yumjaagiyn Tsedenbal in 1984, and the introduction by his successor, Jambyn Batmönh, of Mongol versions of glasnost and perestroika, led to economic stagnation and demands for further social reform. Public demonstrations in December 1989 by a number of newly formed opposition groups forced the entire leadership of the MPRP to resign in 1990 and call for new elections. Prior to the elections in July 1990, the constitution was amended to provide for multiparty balloting, and the MPRP was denied its previous position as sole party and "guiding force" in Mongolia.

A new constitution put into effect in February 1992 swept away the last remaining vestiges of the previous socialist system, and the People's Republic was renamed simply Mongolia. The constitution established the single-chamber Mongolian Great Hural. Elections to the Great Hural in 1992 produced a strong majority for the MPRP. In 1993, however, the opposition candidate Punsalmaagiyn Ochirbat was elected president of Mongolia.

Laws abolishing the socialist economic system were passed in 1990, 1991, and 1992. These laws included regulations pertaining to banking, foreign investment, and privatization of state property. In order to guarantee fair access for all Mongols to available resources, every citizen was issued coupons to be used to buy at public auction any property designated for privatization. A special commission makes the determination of property to be auctioned, which to date has included pastureland, herds of animals, and factories. Collective farms have been abolished, as has party control over all state assets.

After the dissolution of the U.S.S.R. in 1991, relations between Mongolia and Russia were initially strained, as disagreements arose over the extent of Mongolia's debt to the U.S.S.R. and over the pace of withdrawal of Soviet military forces. The remaining Russian troops left in 1992, however, and the two countries signed a treaty of friendship and cooperation the following year. Mongolia concluded a similar treaty with China in 1994.

The painful process of historical reassessment of the revolutionary era has resulted in rehabilitation of some victims of past purges and the condemnation of such leaders as Tsedenbal. Continued revisions of past interpretation of the events that led to the revolution of 1921 and to the policies of the next seven decades are expected to alter the currently accepted picture of 20th-century Mongolia and its prerevolutionary past. (L.W.M./Ed.)

SECHIN JAGCHID and PAUL HYER, *Mongolia's Culture and Society* (1979), discusses the nomadic traditions, religion, arts, economy, and sociopolitical structure of the Mongols. MONGOLIAN NATIONAL COMMISSION FOR UNESCO, *Cultural Policy in the Mongolian People's Republic: A Study* (1982), is a brief discussion of contemporary practices. WALTHER HEISSIG, *The Religions of Mongolia* (1980; originally published in German, 1970), is a scholarly work covering shamanism to Tibetan Buddhism. B. ALAN J.K. SANDERS, *Mongolia: Politics, Economics, and Society* (1987), is an interdisciplinary study. Useful summaries of evolving government, economy, society, and culture appear annually in the January issue of *Asian Survey*. (C.D.H.)

History. The Mongol conquests, empire, and succession states are reviewed in *The Secret History of the Mongols*, ed. and trans. from Mongolian by FRANCIS WOODMAN CLEAVES (1982); DAVID MORGAN, *The Mongols* (1986); THOMAS T. ALLSEN, *Mongol Imperialism: The Policies of the Grand Qan Möngke in China, Russia, and the Islamic Lands, 1251–1259* (1987); MORRIS ROSSABI, *China and Inner Asia: From 1368 to the Present Day* (1975); and M. SANJDORJ, *Manchu Chinese Colonial Rule in Northern Mongolia*, trans. from Mongolian (1980). Comprehensive coverage of developments up to the 1960s is provided in B. SHIRÉNDÉV *et al.* (eds.), *History of the Mongolian People's Republic* (1976; originally published in Mongolian, 1966); ROBERT A. RUPEN, *Mongols of the Twentieth Century*, 2 vol. (1964); and C.R. BAWDEN, *The Modern History of Mongolia* (1968). Later events are analyzed by ROBERT A. RUPEN, *How Mongolia Is Really Ruled: A Political History of the Mongolian People's Republic, 1900–1978* (1979). Events which led up to the Mongolian rejection of socialism, and the move to democratization and a market economy, closely parallel the same developments in the former Soviet Union. Descriptions of these movements, as well as the environmental and social costs of the Soviet period, are presented in the brief work by MARKO MILIVOJEVIĆ, *The Mongolian Revolution of 1990* (1990). Studies of the present ecological and environmental problems, with useful analyses of the evolution of Mongolia after World War II, are *Mongolia: Restructuring for a Market Economy* (1993), published by the United Nations International Development Organization; and ROBERT L. WORDEN and ANDREA MATLES SAVADA (eds.), *Mongolia: A Country Study*, 2nd ed. (1991). LARRY WILLIAM MOSES, *The Political Role of Mongol Buddhism* (1977), analyzes the situation in the 20th century. A useful summary of the recent history of Mongolia may be found in JUDITH NORDBY (compiler), *Mongolia* (1993), a bibliography. (O.La./L.W.M.)

Montaigne

Michel Eyquem de Montaigne wrote, in his *Essais* (*Essays*), one of the most captivating and intimate self-portraits ever written, on a par with Augustine's and Rousseau's. Living, as he did, in the second half of the 16th century, he bore witness to the decline of the intellectual optimism that had marked the Renaissance. The sense of immense human possibilities, stemming from the discoveries of the New World travelers, from the rediscovery of classical antiquity, and from the opening of scholarly horizons through the works of the humanists, was shattered in France when the advent of the Calvinistic Reformation was followed closely by religious persecution and by the Wars of Religion (1562–98). These conflicts, which tore the country asunder, were in fact political and civil as well as religious wars, marked by great excesses of fanaticism and cruelty. At once deeply critical of his time and deeply involved in its preoccupations and its struggles, Montaigne chose to write about himself—"I am myself the matter of my book," he says in his opening address to the reader—in order to arrive at certain possible truths concerning man and the human condition, in a period of ideological strife and division when all possibility of truth seemed illusory and treacherous.

Montaigne, portrait by an unknown French artist, 16th century. In the Condé Museum, Chantilly, Fr.

Life. Born on Feb. 28, 1533, in the family domain of Montaigne, in Périgueux, southwestern France, Michel Eyquem spent most of his life at his château and in the city of Bordeaux, 30 miles to the west. The family fortune had been founded in commerce by Montaigne's great-grandfather, who acquired the estate and the title of nobility. His grandfather and his father expanded their activities to the realm of public service and established the family in the *noblesse de robe,* the administrative nobility of France. Montaigne's father, Pierre Eyquem, served as mayor of Bordeaux.

As a young child Montaigne was tutored at home according to his father's ideas of pedagogy, which included the creation of a cosseted ambience of gentle encouragement and the exclusive use of Latin, still the international language of educated people. As a result the boy did not learn French until he was six years old. He continued his education at the College of Guyenne, where he found the strict discipline abhorrent and the instruction only moderately interesting, and eventually at the University of Toulouse, where he studied law. Following in the public-service tradition begun by his grandfather, he entered into the magistrature, becoming a member of the Board of Excise, the new tax court of Périgueux, and, when that body was dissolved in 1557, of the Parliament of Bordeaux, one of the eight regional parliaments that constituted the French Parliament, the highest national court of justice. There, at the age of 24, he made the acquaintance of Étienne de la Boétie, a meeting that was one of the most significant events in Montaigne's life. Between the slightly older La Boétie (1530–63), an already distinguished civil servant, humanist scholar, and writer, and Montaigne an extraordinary friendship sprang up, based on a profound intellectual and emotional closeness and reciprocity. In his essay "On Friendship" Montaigne wrote in a very touching manner about his bond with La Boétie, which he called perfect and indivisible, vastly superior to all other human alliances. When La Boétie died of dysentery, he left a void in Montaigne's life that no other being was ever able to fill, and it is likely that Montaigne started on his writing career, six years after La Boétie's death, in order to fill the emptiness left by the loss of the irretrievable friend.

Étienne de la Boétie

In 1565 Montaigne was married, acting less out of love than out of a sense of familial and social duty, to Françoise de la Chassaigne, the daughter of one of his colleagues at the Parliament of Bordeaux. He fathered six daughters, five of whom died in infancy, whereas the sixth, Léonore, survived him.

In 1569 Montaigne published his first book, a French translation of the 15th-century *Natural Theology* by the Spanish monk Raymond Sebond. He had undertaken the task at the request of his father, who, however, died in 1568, before its publication, leaving to his oldest son the title and the domain of Montaigne.

In 1570 Montaigne sold his seat in the Bordeaux Parliament, signifying his departure from public life. After taking care of the posthumous publication of La Boétie's works, together with his own dedicatory letters, he retired in 1571 to the castle of Montaigne in order to devote his time to reading, meditating, and writing. His library, installed in the castle's tower, became his refuge. It was in this round room, lined with a thousand books and decorated with Greek and Latin inscriptions, that Montaigne set out to put on paper his *essais,* that is, the probings and testings of his mind. He spent the years from 1571 to 1580 composing the first two books of the *Essays,* which comprise respectively 57 and 37 chapters of greatly varying lengths; they were published in Bordeaux in 1580.

Although most of these years were dedicated to writing, Montaigne had to supervise the running of his estate as well, and he was obliged to leave his retreat from time to time, not only to travel to the court in Paris but also to intervene as mediator in several episodes of the religious conflicts in his region and beyond. Both the Roman Catholic king Henry III and the Protestant king Henry of Navarre—who as Henry IV would become king of France and convert to Roman Catholicism—honoured and respected Montaigne, but extremists on both sides criticized and harassed him.

After the 1580 publication, eager for new experiences and profoundly disgusted by the state of affairs in France, Montaigne set out to travel, and in the course of 15 months he visited areas of France, Germany, Switzerland, Austria, and Italy. Curious by nature, interested in the smallest details of dailiness, geography, and regional idiosyncrasies, Montaigne was a born traveler. He kept a record of his trip, his *Journal de voyage* (not intended for publication and not published until 1774), which is rich in picturesque episodes, encounters, evocations, and descriptions.

Journal de voyage

While still in Italy, in the fall of 1581, Montaigne received the news that he had been elected to the office his father had held, that of mayor of Bordeaux. Reluctant to accept, because of the dismal political situation in France

and because of ill health (he suffered from kidney stones, which had also plagued him on his trip), he nevertheless assumed the position at the request of Henry III and held it for two terms, until July 1585. While the beginning of his tenure was relatively tranquil, his second term was marked by an acceleration of hostilities between the warring factions, and Montaigne played a crucial role in preserving the equilibrium between the Catholic majority and the important Protestant League representation in Bordeaux. Toward the end of his term the plague broke out in Bordeaux, soon raging out of control and killing one-third of the population.

Montaigne resumed his literary work by embarking on the third book of the *Essays.* After having been interrupted again, by a renewed outbreak of the plague in the area that forced Montaigne and his family to seek refuge elsewhere, by military activity close to his estate, and by diplomatic duties, when Catherine de Médicis appealed to his abilities as a negotiator to mediate between herself and Henry of Navarre—a mission that turned out to be unsuccessful—Montaigne was able to finish the work in 1587.

The year 1588 was marked by both political and literary events. During a trip to Paris Montaigne was twice arrested and briefly imprisoned by members of the Protestant League because of his loyalty to Henry III. During the same trip he supervised the publication of the fifth edition of the *Essays,* the first to contain the 13 chapters of Book III, as well as Books I and II, enriched with many additions. He also met Marie de Gournay, an ardent and devoted young admirer of his writings. De Gournay, a writer herself, is mentioned in the *Essays* as Montaigne's "covenant daughter" and was to become his literary executrix. After the assassination of Henry III in 1589, Montaigne helped to keep Bordeaux loyal to Henry IV. He spent the last years of his life at his château, continuing to read and to reflect and to work on the *Essays,* adding new passages, which signify not so much profound changes in his ideas as further explorations of his thought and experience. Different illnesses beset him during this period, and he died after an attack of quinsy, an inflammation of the tonsils, which had deprived him of speech. His death occurred while he was hearing mass in his room, on Sept. 13, 1592.

The Essays. Montaigne saw his age as one of dissimulation, corruption, violence, and hypocrisy, and it is therefore not surprising that the point of departure of the *Essays* is situated in negativity: the negativity of Montaigne's recognition of the rule of appearances and of the loss of connection with the truth of being. Montaigne's much-discussed skepticism results from that initial negativity, as he questions the possibility of all knowing and sees the human being as a creature of weakness and failure, of inconstancy and uncertainty, of incapacity and fragmentation, or, as he wrote in the first of the essays, as "a marvelously vain, diverse, and undulating thing." His skepticism is reflected in the French title of his work, *Essais,* or "Attempts," which implies not a transmission of proven knowledge or of confident opinion but a project of trial and error, of tentative exploration. Neither a reference to an established genre (for Montaigne's book inaugurated the term essay for the short prose composition treating a given subject in a rather informal and personal manner) nor an indication of a necessary internal unity and structure within the work, the title indicates an intellectual attitude of questioning and of continuous assessment.

Skepticism

Montaigne's skepticism does not, however, preclude a belief in the existence of truth but rather constitutes a defense against the danger of locating truth in false, unexamined, and externally imposed notions. His skepticism, combined with his desire for truth, drives him to the rejection of commonly accepted ideas and to a profound distrust of generalizations and abstractions; it also shows him the way to an exploration of the only realm that promises certainty: that of concrete phenomena and primarily the basic phenomenon of his own body-and-mind self. This self, with all its imperfections, constitutes the only possible site where the search for truth can start, and it is the reason Montaigne, from the beginning to the end of the *Essays,* does not cease to affirm that "I am myself the matter of my book." He finds that his identity, his "master form" as he calls it, cannot be defined in simple terms of a constant and stable self, since it is instead a changeable and fragmented thing, and that the valorization and acceptance of these traits is the only guarantee of authenticity and integrity, the only way of remaining faithful to the truth of one's being and one's nature rather than to alien semblances.

Yet, despite his insistence that the self guard its freedom toward outside influences and the tyranny of imposed customs and opinions, Montaigne believes in the value of reaching outside the self. Indeed, throughout his writings, as he did in his private and public life, he manifests the need to entertain ties with the world of other people and of events. For this necessary coming and going between the interiority of the self and the exteriority of the world, Montaigne uses the image of the back room: human beings have their front room, facing the street, where they meet and interact with others, but they need always to be able to retreat into the back room of the most private self, where they may reaffirm the freedom and strength of intimate identity and reflect upon the vagaries of experience. Given that always-available retreat, Montaigne encourages contact with others, from which one may learn much that is useful. In order to do so, he advocates travel, reading, especially of history books, and conversations with friends. These friends, for Montaigne, are necessarily men. While none can ever replace La Boétie, it is possible to have interesting and worthwhile exchanges with men of discernment and wit. As for his relations with women, Montaigne wrote about them with a frankness unusual for his time. The only uncomplicated bond is that of marriage, which reposes, for Montaigne, on reasons of family and posterity and in which one invests little of oneself. Love, on the other hand, with its emotional and erotic demands, comports the risk of enslavement and loss of freedom. Montaigne, often designated as a misogynist, does in fact recognize that men and women are fundamentally alike in their fears, desires, and attempts to find and affirm their own identity and that only custom and adherence to an antiquated status quo establish the apparent differences between the sexes, but he does not explore the possibility of overcoming that fundamental separation and of establishing an intellectual equality.

Friendship and love

Montaigne extends his curiosity about others to the inhabitants of the New World, with whom he had become acquainted through his lively interest in oral and written travel accounts and through his meeting in 1562 with three Brazilian Indians whom the explorer Nicolas Durand de Villegagnon had brought back to France. Giving an example of cultural relativism and tolerance, rare in his time, he finds these people, in their fidelity to their own nature and in their cultural and personal dignity and sense of beauty, greatly superior to the inhabitants of western Europe, who in the conquests of the New World and in their own internal wars have shown themselves to be the true barbarians. The suffering and humiliation imposed on the New World's natives by their conquerors provoke his indignation and compassion.

Involvement in public service is also a part of interaction with the world, and it should be seen as a duty to be honourably and loyally discharged but never allowed to become a consuming and autonomy-destroying occupation.

Montaigne applies and illustrates his ideas concerning the independence and freedom of the self and the importance of social and intellectual intercourse in all his writings and in particular in his essay on the education of children. There, as elsewhere, he advocates the value of concrete experience over abstract learning and of independent judgment over an accumulation of undigested notions uncritically accepted from others. He also stresses, throughout his work, the role of the body, as in his candid descriptions of his own bodily functions and in his extensive musings on the realities of illness, of aging, and of death. The presence of death pervades the *Essays,* as Montaigne wants to familiarize himself with the inevitability of dying and so to rid himself of the tyranny of fear, and he is able to accept death as part of nature's exigencies, inherent in life's expectations and limitations.

Montaigne seems to have been a loyal if not fervent Roman Catholic all his life, but he distrusted all human pretenses to knowledge of a spiritual experience which is not attached to a concretely lived reality. He declined to speculate on a transcendence that falls beyond human ken, believing in God but refusing to invoke him in necessarily presumptuous and reductive ways.

Although Montaigne certainly knew the classical philosophers, his ideas spring less out of their teaching than out of the completely original meditation on himself, which he extends to a description of the human being and to an ethics of authenticity, self-acceptance, and tolerance. The *Essays* are the record of his thoughts, presented not in artificially organized stages but as they occurred and reoccurred to him in different shapes throughout his thinking and writing activity. They are not the record of an intellectual evolution but of a continuous accretion, and he insists on the immediacy and the authenticity of their testimony. To denote their consubstantiality with his natural self, he describes them as his children, and, in an image of startling and completely nonpejorative earthiness, as the excrements of his mind. As he refuses to impose a false unity on the spontaneous workings of his thought, so he refuses to impose a false structure on his *Essays*. "As my mind roams, so does my style," he wrote, and the multiple digressions, the wandering developments, the savory, concrete vocabulary, all denote that fidelity to the freshness and the immediacy of the living thought. Throughout the text he sprinkles anecdotes taken from ancient as well as contemporary authors and from popular lore, which reinforce his critical analysis of reality; he also peppers his writing with quotes, yet another way of interacting with others, that is, with the authors of the past who surround him in his library. Neither anecdotes nor quotes impinge upon the autonomy of his own ideas, although they may spark or reinforce a train of thought, and they become an integral part of the book's fabric.

Form of the *Essays*

Montaigne's *Essays* thus incorporate a profound skepticism concerning the human being's dangerously inflated claims to knowledge and certainty but also assert that there is no greater achievement than the ability to accept one's being without either contempt or illusion, in the full realization of its limitations and its richness.

Readership. Throughout the ages the *Essays* have been widely and variously read, and their readers have tended to look to them, and into them, for answers to their own needs. Not all his contemporaries manifested the enthusiasm of Marie de Gournay, who fainted from excitement at her first reading. She did recognize in the book the full force of an unusual mind revealing itself, but most of the intellectuals of the period preferred to find in Montaigne a safe reincarnation of stoicism. Here started a misunderstanding that was to last a long time, save in the case of the exceptional reader. The *Essays* were to be perused as an anthology of philosophical maxims, a repository of consecrated wisdom, rather than as the complete expression of a highly individual thought and experience. That Montaigne could write about his most intimate reactions and feelings, that he could describe his own physical appearance and preferences, for instance, seemed shocking and irrelevant to many, just as the apparent confusion of his writing seemed a weakness to be deplored rather than a guarantee of authenticity.

In the 17th century, when an educated nobility set the tone, he was chiefly admired for his portrayal of the *honnête homme,* the well-educated, nonpedantic man of manners, as much at home in a salon as in his study, a gentleman of smiling wisdom and elegant, discreet disenchantment. In the same period, however, religious authors such as Francis of Sales and Blaise Pascal deplored his skepticism as anti-Christian and denounced what they interpreted as an immoral self-absorption. In the pre-Revolutionary 18th century the image of a dogmatically irreligious Montaigne continued to be dominant, and Voltaire and Denis Diderot saw in him a precursor of the free thought of the Enlightenment. For Jean-Jacques Rousseau, however, the encounter with the *Essays* was differently and fundamentally important, as he rightly considered Montaigne the master and the model of the self-portrait. Rousseau inaugurated the perception of the book as the entirely personal project of a human being in search of his identity and unafraid to talk without dissimulation about his profound nature. In the 19th century some of the old misunderstandings continued, but there was a growing understanding and appreciation of Montaigne not only as a master of ideas but also as the writer of the particular, the individual, the intimate—the writer as friend and familiar. Gustave Flaubert kept the *Essays* on his bedside table and recognized in Montaigne an alter ego, as would, in the 20th century, authors such as André Gide, Michel Butor, and Roland Barthes.

The *Essays* were first translated into English by John Florio in 1603, and Anglophone readers have included Francis Bacon, John Webster, William Shakespeare, Lord Byron, William Makepeace Thackeray, Ralph Waldo Emerson, Virginia Woolf, T.S. Eliot, and Aldous Huxley.

Today Montaigne continues to be studied in all aspects of his text by great numbers of scholars and to be read by people from all corners of the earth. In an age that may seem as violent and absurd as his own, his refusal of intolerance and fanaticism and his lucid awareness of the human potential for destruction, coupled with his belief in the human capacity for self-assessment, honesty, and compassion, appeal as convincingly as ever to the many who find in him a guide and a friend.

MAJOR WORKS

ESSAYS: *Essais de messire Michel Seigneur de Montaigne,* 2 vol. in 1 (1580); *Essais de messire Michel Seigneur de Montaigne; édition seconde, revue & augmentée* (1582); and *Essais de messire Michel Seigneur de Montaigne; cinquiesme édition, augmentée d'un troisième livre et de six cens additions aux deux premiers,* 3 vol. (1588).

OTHER WORKS: *Journal de voyage* (1774).

EARLY TRANSLATIONS: *The Essays; or, Morall, Politike, and Millitarie Discourses of Lo: Michaell de Montaigne,* trans. by John Florio (1603); and *The Diary of Montaigne's Journey to Italy in 1580 and 1581,* trans. by E.J. Trechmann (1929).

COLLECTED WORKS: *Œuvres complètes de Michel de Montaigne,* ed. by A. Armaingaud, 12 vol. (1924–41); *Œuvres complètes,* ed. by Albert Thibaudet and Maurice Rat, new ed. (1967); and *Complete Works: Essays, Travel Journal, Letters,* trans. and ed. by Donald M. Frame (1957).

RECOMMENDED EDITIONS: *Complete Essays* (1958, reprinted 1973), and *Selections from the Essays* (1973), both trans. and ed. by Donald M. Frame.

BIBLIOGRAPHY. DONALD M. FRAME, *Montaigne* (1965, reprinted 1984), is a detailed biography by an authority in the field. Interpretive approaches to reading Montaigne are collected in *Montaigne: Essays in Reading* (1983). PETER BURKE, *Montaigne* (1982), offers a very readable brief survey of the historical and philosophical context of Montaigne's life and creativity. Most other critical works focus on exploring the essays and their role in shaping the intellectual tradition: R.A. SAYCE, *The Essays of Montaigne* (1972); M.A. SCREECH, *Montaigne and Melancholy: The Wisdom of the Essays* (1983); JEAN STAROBINSKI, *Montaigne in Motion* (1985; originally published in French, 1982); and DOROTHY GABE COLEMAN, *Montaigne's Essays* (1987).

(T.A.Sa.)

Montreal

Montreal (French: Montréal), the largest city of Quebec province and the second most populous metropolitan area of Canada, is uniquely situated. The present city proper occupies about one-third of Île de Montréal (Montreal Island), the largest of the 234 islands of the Hochelaga Archipelago, one of three archipelagos near the confluence of the Ottawa and St. Lawrence rivers. The city was built around and up Mont-Royal, which rises 763 feet (233 metres) above sea level (some 660 feet above the island shores). The city proper occupies an area of 61 square miles (158 square kilometres); and several independent cities and towns constitute the 1,087-square-mile metropolitan area that covers Montreal and other islands, as well as both shores of the St. Lawrence. Montreal is the major seaport on the St. Lawrence River and Seaway, lying between the navigable waters of the open Atlantic Ocean to the east and of the Great Lakes to the west.

Along with New York City and San Francisco, Montreal is one of North America's most cosmopolitan cities. It is often said to be the second largest French-speaking city in the world (after Paris), a boast that is sometimes disputed. English and French are Canada's two official languages but, in accordance with a law passed for Quebec province in 1977, the use of English in schools and in government and commercial activity is restricted. Yet, in several areas of Montreal, one must still express oneself in English to be understood fully. This phenomenon reflects decades of dominance over Montreal's economic life by the English-speaking minority. With the advent to power in 1976 of the Parti Québécois—which advocates political independence from and economic association with the rest of Canada—"normal" tensions between French- and English-speaking communities have fluctuated.

In spite of politics and unrest, Montreal remains a city of great charm, of vivacity, and of gaiety, one of the most appealing in North America, as well as one of unquestioned modernity in its physical appearance and way of life. Thus it was chosen as the site of the International World Exposition in 1967—Expo 67. No great objections were raised when the event was perpetuated for the public each summer under the title Terre des Hommes (Man and His World).

Physical and human geography

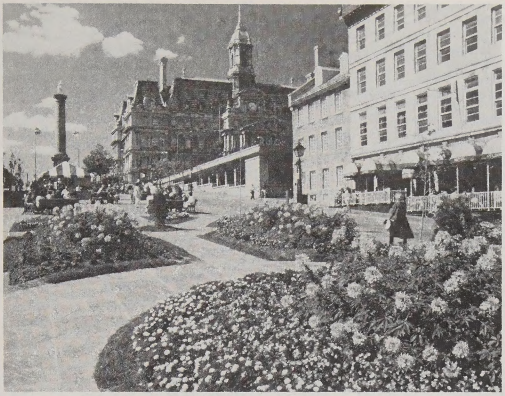
THE LANDSCAPE

The city layout. The layout of Montreal has been affected throughout its history by the river and the natural rises of the terrain from it, including the slopes of Mont-Royal. These factors produced a general southwest–northeast pattern of growth, and since its incorporation the city has been divided by Boulevard Saint-Laurent (St. Lawrence Street) into western and eastern sections. Such designations as street, avenue, and boulevard are virtually interchangeable in Montreal, and the ensuing confusion is enhanced by the use of both French and English placenames for thoroughfares and other city and suburban sites.

Modernization of the city

The city centre. Since about 1958 the centre of Montreal has been transformed significantly, abetted by post-World War II prosperity, by preparations for Expo 67 and the exposition itself, and by an administration intent upon grand designs. Built with the aid of U.S. capital and developers, Place Ville-Marie comprises a cruciform building more than 40 stories tall and many underground shops, restaurants, and theatres, linked to which are nearby skyscrapers with similar underground complexes. Together, this downtown area provides the Canadian metropolis with an answer to New York City's Rockefeller Center, with an underground commercial, culinary, and artistic life among the most advanced in the Western Hemisphere. Similar change has spread throughout the city, often obliterating historic landmarks, but the city has preserved the historic centre known as Vieux-Montréal (Old Montreal). There, seekers after nostalgia stroll amid reminiscences of the past that are in striking contrast to the city's overall momentum into the vanguard of urban modernity.

THE PEOPLE



The 1871 population of Montreal proper—about 133,000—increased 10-fold in the following century, and the pace of metropolitan planning promises ongoing growth in addition to annexation of adjacent areas. Immigration from abroad practically ceased during World War I, but a steady flow of people continued from other parts of Canada and from the United States. Although the birth rate among Canadians of French descent dropped markedly, immigration from the Continent reduced the percentage of Montrealers of British descent after World War II. French-speaking citizens account for about two-thirds of the population, with the English-speaking proportion increasingly eroded by immigrants from all over the world. Religious affiliations generally follow ethnic traditions, with Roman Catholicism by far the dominant faith.

Social and political tensions

On the other hand, newcomers to Montreal quickly learn that English is the more practical tongue, for in Montreal as in most of Canada—except Quebec city and smaller centres of Quebec province—English is the primary language of commerce and industry. The economic upper classes are mostly old Montreal-bred English-speaking families, with a sprinkling of French and others. The middle classes are more mixed, whereas the lower economic stratum continues to be made up mainly of French- and Irish-Canadians and of new immigrants. Thousands of blacks have immigrated from the United States, most of them settling in the lower part of Montréal-Ouest. The instabilities of Montreal and of Quebec province as a whole are largely the result of the continuing sociolinguistic separateness of and economic disparity between the two major ethnic groups. Majority political power has been achieved by the French community, but equivalent weight in other areas has been slower to arrive.

THE ECONOMY

Trade and industry. Montreal suffered in the 1970s from a "Go West" trend, to the benefit of Ontario and the western provinces rich in oil and natural gas. It remains, however, the headquarters of most of the largest Canadian banks, railroad lines, and insurance companies, as well as for the International Civil Aviation Organization, an agency, affiliated with the United Nations, that sets the rules and standards for international air traffic. The city is also an important shipping and industrial centre. The

Milt and Joan Mann—CAMERAMANN INTERNATIONAL

centuries-long colonial fur trade that penetrated the new continent to its westernmost territories formed the city's earliest commercial ventures, while soapmaking, brewing and distilling (among John Molson's main civic legacies), and wood and leather fabrication are longtime Montreal industries. Innumerable other products of a modern manufacturing economy emanate from the city's factories, along with millions of gallons of processed petroleum each day from Montréal-Est refineries.

Shopping areas abound throughout the city, in the more remote residential sections as well as throughout the supermodern underground city of streets and shops that has aided Montrealers to carry on in spite of the five to 10 feet of snow dumped on the city each winter. This deluge of snow from November through April is among the most significant factors in Montreal's life, costing the city millions of dollars annually to remove it from the streets.

Transportation. The perennial grumbling of Montrealers about municipal transportation is more an exercise of democratic rights than a reflection of reality. Compared with those in other large cities, bus and subway lines allow easy movement throughout the area at relatively low cost. The subway, called the Métro, has three lines running under the city and to Longueuil on the south shore of the St. Lawrence River. Each station is different in architectural design and artistic decor. Public transportation dates from 1847, and by 1868 buses mounted on sleighs replaced rail cars during the winter. By 1894 the entire system had been electrified and the last horsecars withdrawn from service. Montreal is also served by two airports (both under the same authority): Montreal International–Dorval handles domestic and U.S. flights, and Montreal International–Mirabel handles all other international flights.

The modern Métro

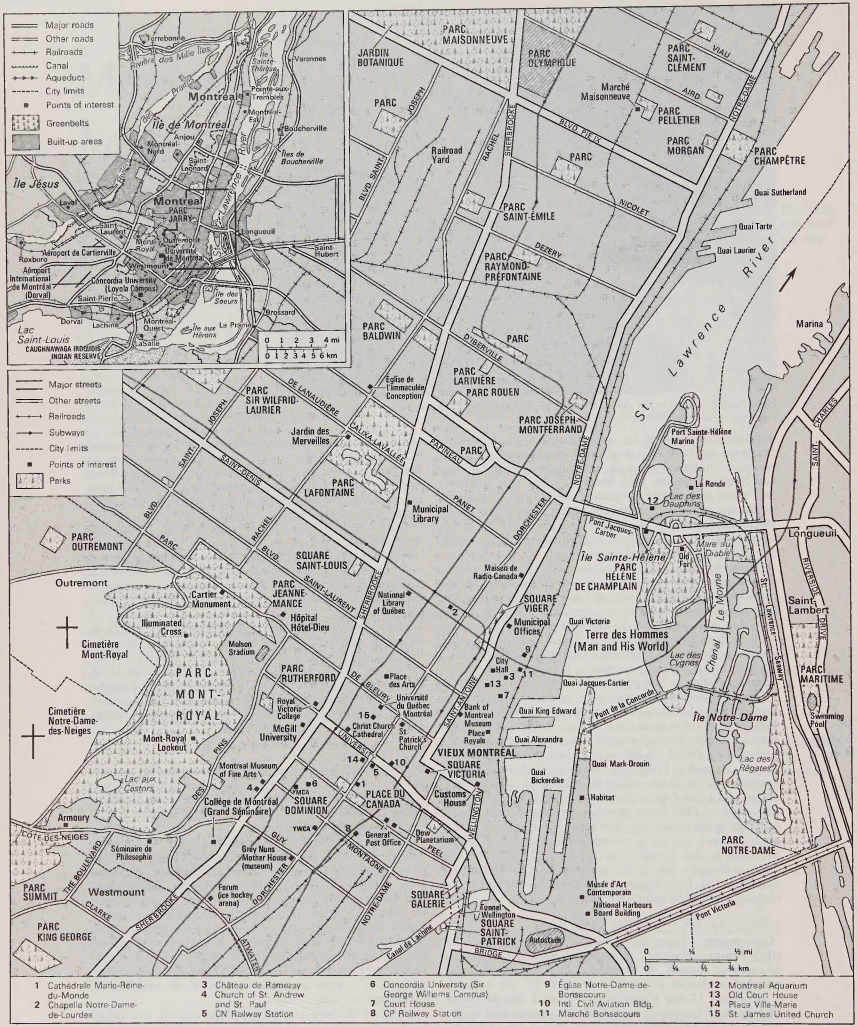
ADMINISTRATIVE AND SOCIAL CONDITIONS

Government. From the present city hall, sixth in the city's history, Montreal is governed by a mayor and a 56-member council, all elected for four years, and a six-member executive committee selected by the council. A Montreal Urban Community replaced the Montreal Metropolitan Corporation in 1969. Its responsibilities, for the whole of Montreal Island and Bizard Island to the north, include assessment and tax collection, traffic control, water and sewage services, police and fire protection, and antipollution activities. It is governed by a general council and an executive committee.

The metropolitan area embraces numerous cities (including Montreal), towns, villages, and parishes. The changes in the region's economic structure and increasing business and white-collar employment, intensified by the growing modernization of the city, have brought about some of the main administrative problems. The French-speaking majority, most of whom were relegated to blue-collar jobs for decades, reacted against this historical pattern with some success, attributable in part to legislation and to the goodwill of the more moderate elements of the two communities.

Education. As throughout Quebec, a dual school system for Roman Catholic and Protestant students is supported from the public treasury. The language of instruction—French or English, respectively—rigidly follows the religious division.

Montreal is probably the outstanding city of Canada in terms of higher education. McGill University (founded 1821) and Concordia University (1974; formed by the merger of Sir George Williams University, founded 1929, and Loyola College, founded 1899) offer mainly English-language instruction, whereas the Université de Montréal (1876) and the Université du Québec à Montréal (1968) serve the French-speaking population.



CULTURAL LIFE

With its Place des Arts, museums, public libraries, art galleries, bookshops in most European languages, symphony orchestra, publishing houses, theatre companies, and free public lectures at the universities, Montreal must be accounted a major culture centre.

The Place des Arts is a complex of concert and theatre halls in downtown Montreal. The nearby Place Desjardins is an exciting example of modern architecture; the complex, with its multilevel terraces, balconies, mezzanines, and sunken plaza, comprises three office towers, a public square, a hotel, and several restaurants and retail stores. Art instruction is given, among other places, at the Museum of Fine Arts. Besides a conservatory of music, faculties or schools of music offer instruction at the universities. The Terre des Hommes exhibition, which draws millions of visitors yearly, is the site of the Museum of Contemporary Art.

In the 1930s only a few bookshops existed, but today bookshops can be found in all districts and shopping centres; and "new Canadians," as new immigrants are called, can buy books, reviews, and magazines in their native languages. The Municipal Library has several branches, and special libraries are located throughout the city. Publishing houses, both English and French, prosper.

Montrealers are great sports enthusiasts. Hockey and baseball are foremost, but other indoor and outdoor sports

The founding fathers

the New World. More than 1,000 Indians welcomed him on the slope of the mountain that he named Mont Réal, or Mont-Royal. More than 50 years elapsed before other Frenchmen returned, this time with Samuel de Champlain, the founder of Quebec city. Hochelaga had disappeared, replaced on the shores of the St. Lawrence by a settlement that Champlain called Place Royale.

It was not until May 1642 that Paul de Chomedey, sieur de Maisonneuve, founded today's Montreal. He built dwellings, a chapel, a hospital, and other structures, protecting the settlement against Indian attack with a stockade. He named the aggregate Ville-Marie.

The community was granted its first civic charter by King Louis XIV in 1644, and Chomedey became its first governor. The first hospital, the Hôtel-Dieu, was founded in 1644 by Jeanne Mance and the first school for girls in 1653 by Marguerite Bourgeoys. Almost immediately a society of priests, Les Messieurs de Saint-Sulpice, took charge of education for boys.

The real development of Montreal began during the first half of the 18th century. Land grants were made, and farming was developed outside the original fortifications. Colonization was initiated under the French seigniorial system, in which a landowner leased portions of his holdings to numerous farming families. For many years, Montreal was a base for explorers and traders, and by the end of the 18th century outlying settlements—Saint-Henri and Lachine to the west and Longue-Pointe and Pointe-aux-Trembles to the east—had taken root, later to become part of the city or of the Montreal Urban Community.

By 1672 the population of Montreal had reached 1,500, but it did not obtain city status for another 120 years and was not incorporated until 1833. The city surrendered peacefully to British forces in 1760 and, with all of New France, became part of the British North American empire in 1763. In November 1775 Montreal was occupied by American Revolutionary forces, who retreated in the spring following the abortive siege of the city of Quebec by Benedict Arnold and thus failed to secure Canada for the new United States. In 1796 Canada's first public library was opened in Montreal, and in the following year daily postal service was established between Montreal and the United States.

EVOLUTION OF THE MODERN CITY

Sequence of civic firsts

In 1809 John Molson—entrepreneur, brewer, banker, and carrier—linked Montreal and Quebec by water with the first Canadian steamship. Canada's first bank, the Bank of Montreal, was founded in 1817, and the Lachine Canal, forerunner of the St. Lawrence Seaway, was started in 1821. In 1825 Molson, the "Montrealer par excellence," provided his city with a splendid theatre, and gas lighting appeared by 1838. A Committee of Trade, forerunner of the Board of Trade (1842), was founded in 1822, and from 1844 to 1849 Montreal was the capital of Canada. On April 25, 1849, a mob put fire to the Parliament building, possibly on the ground that it had lost its vocation. In 1847 telegraph links were made with the cities of Quebec and New York; in 1853 a shipping service between Montreal, Liverpool, and the Continent was begun; in 1856 a railroad to Toronto opened; in 1858 a transatlantic cable to Europe was laid; and in 1861 the city's first horse-drawn tramways began operation.

Fires destroyed hundreds of buildings in the early 1850s, and an economic slump provoked numerous bankruptcies in 1857. The Confederation of Canada was proclaimed in 1867, and 10 years later the city had its first labour strike and first telephone conversation with Quebec. It had its first electric lighting in 1882, electric tramways in 1892, and the first automobile along its streets and movie houses along its sidewalks in 1903.

By 1900 Montreal's population reached 270,000, and it began to annex several cities, towns, and villages on its outskirts. It purchased Île Sainte-Hélène (St. Helen's Island) in 1908, the site, with two neighbouring man-made islands, of Expo 67. Montreal's famous ice-hockey team, the Canadiens, was founded in 1909 (and has since won more world championships than any other professional team). In 1922 several mergers gave birth to the Canadian National Railways Company (CNR), which, like the Canadian Pacific in 1881, established its head office in Montreal.

The world wars gave impetus to the economic life of Montreal, as they did to most industrial centres of North America, and in January 1947 the U.S. Congress began to consider a joint venture with Canada for building the St. Lawrence Seaway. In 1959 the need for a Montreal Metropolitan Corporation was recognized by the Quebec provincial government (which, like others in Canada, has exclusive jurisdiction over municipalities). In 1960 the Metropolitan Boulevard, a throughway encircling Montreal, was opened. In 1962 construction was started on the Métro, supervised by engineers from the Paris Métro; the system was inaugurated six months before the opening of Expo 67. With the growing recognition of Montreal as a major world centre following this universally acclaimed exposition, it became the first non-U.S. city to be awarded a major-league baseball franchise. Its players first took the field in 1969 as the Montreal Expos. (C.Fe./W.J.C.)

Montreal was host of the 1976 Summer Olympic Games, a venture that was a financial disaster for the city. The high cost of building and maintaining facilities, including a stadium with a 552-foot (168-metre) tower (now the home of the Expos), placed a burden of debt on the province. Beginning in the 1960s, Quebec separatist groups engaged in occasional violence in the city, and during the 1970s and '80s many corporations that had their headquarters in Montreal moved to Toronto, partly in response to enforcement of French-language usage guidelines. In 1995 the province narrowly voted against secession from Canada.

BIBLIOGRAPHY. Firsthand accounts are the narrative journals of JACQUES CARTIER and SAMUEL DE CHAMPLAIN; and the *Histoire du Montréal* of FRANÇOIS DOLLIER DE CASSON (1672). Standard works include: WILLIAM H. ATHERTON, *Montreal,* 3 vol. (1914); STEPHEN LEACOCK, *Leacock's Montreal,* rev. ed. by JOHN CULLITON (1963); KATHLEEN JENKINS, *Montreal: Island City of the St. Lawrence* (1966); ROBERT RUMILLY, *Histoire de Montréal,* 5 vol. (1970–75); and GERALD CLARK, *Montreal: The New Cité* (1982). JOHN IRWIN COOPER, *Montreal: A Brief History* (1969), is a good summary although some interesting details are omitted. Also of interest is the article on Montreal in the *Encyclopedia Canadiana* (1977). The numerous publications of the MONTREAL ECONOMIC RESEARCH BUREAU, including the *Abridged History of Montreal,* rev. and enlarged (1970), are both informative and reliable. JEAN-CLAUDE MARSAN, *Montreal in Evolution* (1981), is a history of Montreal's architecture and urban development; and ANNICK GERMAIN and DAMARIS ROSE, *Montréal: The Quest for a Metropolis* (2000), addresses economic and social issues. (Ed.)

Moscow

One of the world's great cities, Moscow (Russian Moskva) is the capital of Russia. Since it was first mentioned in chronicles of 1147, Moscow has played a vital role in Russian history; indeed the history of the city and of the Russian nation are closely interlinked. Today Moscow is not only the political centre of Russia but also the country's leading city in population, in industrial output, and in cultural, scientific, and educational importance. For more than 600 years Moscow has been the spiritual centre of the Russian Orthodox Church.

The capital of the Union of Soviet Socialist Republics (U.S.S.R.) until its dissolution in 1991, Moscow attracted world attention as a centre of Communist power; the name of the seat of the former Soviet government and successor Russian government, the Kremlin (Russian Kreml), became a synonym for Soviet authority. The dissolution of the U.S.S.R. brought economic and political change, along with a degree of uncertainty over the future, to the city.

Moscow covers an area of about 386 square miles (1,000 square kilometres), its outer limit being roughly delineated by the Moscow Ring Road. Most of the area beyond this highway has been designated as a Forest-Park Zone, or greenbelt.

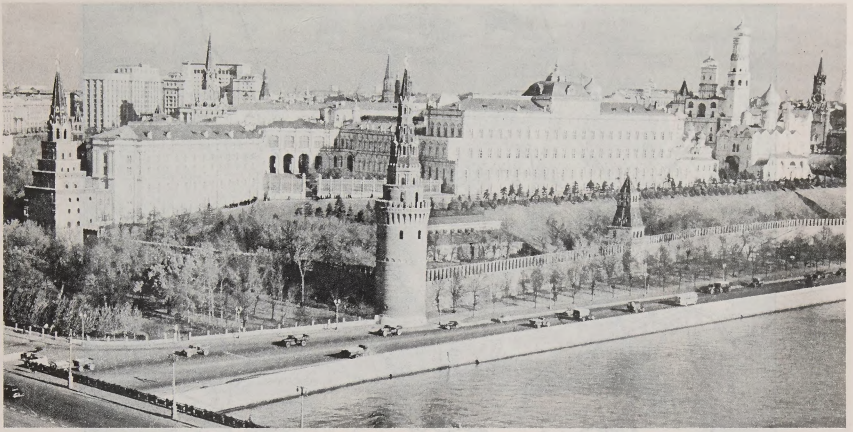
Physical and human geography

THE LANDSCAPE

Site and relief. Moscow stands on the Moskva River, a tributary of the Oka and thus of the Volga, in the centre of the vast plain of European Russia. The city and its surrounding area, the Moscow oblast (administrative region), lie in the northwest corner of the most highly developed and densely populated part of Russia. Moscow lies in the broad, extremely shallow valley of the Moskva and its tributaries. The valley itself overlies a deep syncline of the Russian Platform of very ancient crystalline rocks, a granitic basement more than a mile below the present-day surface. The trough in the platform has been filled through long geologic time by sedimentary rocks, mostly of Devonian and Carboniferous age, with Jurassic series and some Cretaceous rocks nearest the surface. Hardly anywhere is the bedrock exposed on the surface.



The advances and retreats of Pleistocene glaciers deposited a thick mantle of boulder clays and morainic sands and gravels into which the sinuous Moskva River cut its wide valley in successive stages, marked by four corresponding levels. Geologically recent alluvial deposits cover their surfaces. Beside the river itself is a narrow belt of floodplain; a few feet above this is the first terrace, which yields to the successively higher second and third levels. The last of these terraces, rising up to 100–115 feet (30–35 metres) above the river, is the most extensive, and much of Moscow is built on it. Northward the third terrace merges imperceptibly with a plain of clays and sands, which slopes up very gradually to the Klin-Dmitrov morainic ridge some 40 miles (64 kilometres) north of the city. Eastward and southeastward the surface equally gradually merges into the vast, almost completely flat and very swampy clay plain of the Meshchera Lowland, which extends far beyond the city limits.

Almost everywhere surface relief is minor. The legend that Moscow is built on seven hills is an exaggeration, although there are a few small hills in and around the city centre. Only in the southwest of the city is there an upland area on Cretaceous rocks, covered by glacial morainic material. This is the Teplostanskaya Upland, which rises more than 400 feet above the Moskva River and on which is the highest elevation within Moscow's limits, 830 feet above sea level. One of the sweeping bends of the Moskva has cut into the edge of the Teplostanskaya Upland a steep cliff, the Lenin Hills (also known as the Sparrow Hills), from the top of which there are fine panoramic views of the city.

The human imprint. Long occupation has extensively altered the natural setting. The "cultural layer," consisting of debris of buildings demolished long ago and of other materials deposited by humans, is up to 50 feet deep in some parts of central Moscow. Almost all the small rivers and streams that once flowed into the Moskva through the city area have now been put into underground conduits or filled in. The only tributaries still visible are the Yauza on the left (northern) bank and, on the right bank, the Gorodnya and Kotlovka. The Yauza, the largest of these, and the Moskva itself are controlled by stone embankments for most of their winding courses through the city. The Moskva has been diverted in places, with cuts made through the necks of its loops, and it has also been both widened and deepened; in places it is 800 feet wide. In the past the river was icebound from November to April, but a channel is now kept open throughout the winter. The Yauza receives additional water from the Volga, by way of the Moscow Canal and its branch, the Likhobory Canal. Two dams on its lower course have raised the level of the Yauza and made the lower reaches navigable.

Rivers

Part of Moscow's water supply comes from some 1,000 deep bores in the city that tap the artesian water of the underlying Carboniferous beds. Overuse has greatly lowered the levels of these underground waters, and most water needs are now met by surface sources, from the reservoirs north of the city built in connection with the Moscow Canal, in particular the Ucha Reservoir. Water is also drawn from the Moskva and pumped into underground storage reservoirs. The discharge of untreated sewage and industrial effluents had polluted the Moskva and the adjacent groundwater, until in the mid-1960s a major effort to correct it by heavy investment in antipollution and water purification measures brought great improvement. Slow but steady progress has also been made in controlling the

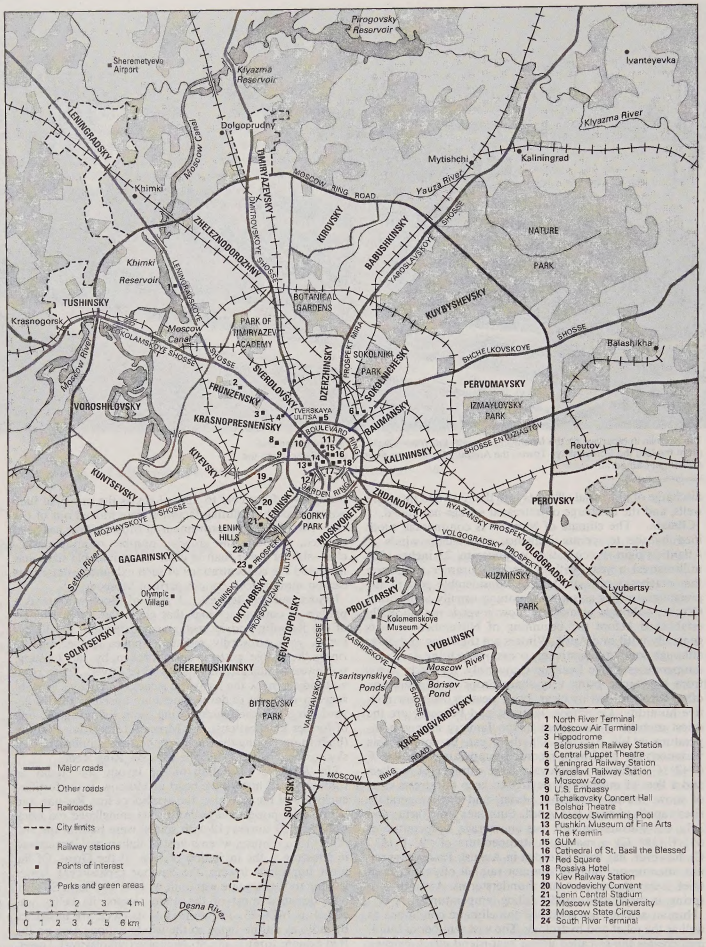
The Kremlin in Moscow, on the Moskva River, with the Water Tower in the foreground and (from the left) the Borovitskaya Tower, the Armoury Palace, the Kremlin Great Palace, and the Archangel Cathedral.
Novosti Press Agency

discharge of industrial effluents into the river and into bore wells, and the discharge of untreated sewage has ended.

Climate. The climate of Moscow is continental, modified by the temperate influence of westerly winds of Atlantic origin. Precipitation is moderate, 23 inches (581 millimetres) a year, with a marked summer maximum that reaches a peak in July. A considerable part of the precipitation falls as snow; beginning usually about mid-October—though permanent snow cover is not normally established before the beginning of November—it lasts generally until mid-April. Winters are thus long and dark, although southerly airstreams occasionally bring days with temperatures above freezing. Conversely, northerly winds from the Arctic bring very sharp drops in temperature, often accompanied by clear, brisk weather with low relative humidity. December, January, and February are the driest months. Thus, although the January average temperature is 14° F (−10° C), there can be considerable variation; the minimum recorded temperature is −44° F (−42° C). Moscow employs a large number of workers and a fleet of mechanical devices to keep the streets clear of snow. Spring is relatively brief, and the temperature rises rapidly during late April. Summers are warm, and July, the warmest month, has an average temperature of 65° F (18° C); a maximum temperature of 99° F (37° C), however, has been recorded in August. Rainy days are not uncommon, but the summer rainfall often comes in brief, heavy downpours and thunderstorms. Autumn, like spring, is short, with rapidly falling temperatures.

Urban climate

Human activity has modified the climatic conditions as well as the relief and hydrology. The vast number of buildings creates the so-called urban heat-island effect, causing the average annual temperature in the central city to be up to 3° F (2° C) higher than the temperature in open country outside the city. Plants in central parks and gardens blossom a week or more earlier than those in the outer suburbs. The temperature differential is most marked on clear winter nights, when the buildings radiate heat; it can be as much as 18° F (10° C) or more. The city centre also receives heavier rainfall than the surrounding countryside and averages about 100 hours less sunshine per year.



Until the late 1950s there was increasing air pollution in Moscow. Smog was common, often with heavy concentrations of sulfur dioxide. A major campaign to control noxious emissions was launched, assisted greatly by a changeover from coal to natural gas as the principal fuel. Some seriously polluting factories were moved out of the city. The resulting improvement in Moscow's air has been marked, although the growing number of motor vehicles—still far fewer than in cities of comparable size—has increased the concentrations of such exhaust pollutants as carbon monoxide in certain parts of Moscow.

Layout and architecture. A map of Moscow presents a pattern of concentric rings that circle the rough triangle of the Kremlin and its rectangular extension, the Kitay-gorod, with outwardly radiating spokes connecting the rings, the whole pattern being broken by the twisting, northwest–southeast-trending Moskva River. These rings and radials mark the historical stages of the city's growth: successive epochs of development are traced by the Boulevard Ring and the Garden Ring (both following the line of former fortifications), the Moscow Little Ring Railway (built in part along the line of the former Kamer-Kollezhsky customs barrier), and the Moscow Ring Road.

The Kremlin. The hub of the layout, and today as throughout its history the heart of Moscow, is the fortified enclosure of the Kremlin, the symbol of first Russian and later Soviet power and authority. Its crenellated red brick walls and 20 towers (19 with spires) were built at the end of the 15th century, when a host of Italian builders arrived in Moscow at the invitation of Ivan III the Great. Of the most important towers, the Saviour (Spasskaya) Tower leading to Red Square was built in 1491 by Pietro Solario, who designed most of the main towers; its belfry was added in 1624–25. The chimes of its clock are broadcast by radio as a time signal to the whole nation. Also on the Red Square front is the St. Nicholas (Nikolskaya) Tower, built originally in 1491 and rebuilt in 1806. The two other principal gate towers—the Trinity (Troitskaya) Tower, with a bridge and outer barbican (the Kutafya Tower), and the Borovitskaya Tower—lie on the western wall.

Kremlin gate towers

Within the Kremlin walls is one of the most striking and beautiful architectural ensembles in the world: a combination of churches and palaces, which are open to the public and are among the city's most popular tourist attractions, and the highest offices of the state, which are surrounded by strict security. Around the central Cathedral Square (Sobornaya Ploshchad) are grouped three magnificent cathedrals, superb examples of Russian church architecture at its height in the late 15th and early 16th

The city of Moscow.

centuries. These and the other churches in the Kremlin ceased functioning as places of worship after the Revolution and are now museums. The white stone Cathedral of the Assumption (Uspensky Sobor) is the oldest, built in 1475–79 in the Italianate-Byzantine style. Its pure, simple, and beautifully proportioned lines and elegant arches are crowned by five golden domes. The Orthodox metropolitans and patriarchs of the 14th to the 18th century are buried there. Across the square is the Cathedral of the Annunciation (Blagoveshchensky Sobor), built in 1484–89 by craftsmen from Pskov; though burned in 1547, it was rebuilt in 1562–64. Its cluster of chapels is topped by golden roofs and domes. Inside are a number of early 15th-century icons attributed to Theophanes the Greek and to Andrey Rublyov, considered by many to be the greatest of all Russian icon painters. The third cathedral, the Archangel (Arkhangelsky), was rebuilt in 1505–08; in it are buried the princes of Moscow and tsars of Russia (except Boris Godunov) up to the founding of St. Petersburg.

Just off the square stands the splendid, soaring white bell tower of Ivan the Great; built in the 16th century and damaged in 1812, it was restored a few years later. At its foot is the enormous Tsar Bell (Tsar-Kolokol), cast in

The Cathedral of St. Basil the Blessed (from the back) on Red Square. At the left is the State Department Store, GUM.

© Robert Houser/Comstock

1733–35 but never rung. Nearby is the Tsar Cannon (Tsar-Pushka), cast in 1586. Beside the gun are located the mid-17th-century Cathedral of the Twelve Apostles (Sobor Dvenadtsati Apostolov) and the adjoining Patriarchal Palace.

On the west of Cathedral Square is a group of palaces of various periods; the Palace of Facets (Granovitaya Palata)—so called from the exterior finish of faceted, white stone squares—was built in 1487–91. Behind it is the Terem Palace of 1635–36, which incorporates several older churches, including the Resurrection of Lazarus (Voskreseniye Lazarya), dating from 1393. Both became part of the Kremlin Great Palace, built as a royal residence in 1838–49 and formerly used for sessions of the Supreme Soviet of the U.S.S.R.; its long, yellow-washed facade dominates the riverfront. It is connected to the Armoury Palace (Oruzheynaya Palata), built in 1844–51 and now the Armoury Museum, housing a large collection of treasures of the tsars. Along the northeast wall of the Kremlin are the Arsenal (1702–36), the former Senate building (1776–88), and the School for Red Commanders (1932–34). The only other Soviet-period building within the Kremlin is the Palace of Congresses (1960–61), with a vast auditorium used for political gatherings and as a theatre.

Kremlin Great Palace

The Kitay-gorod. Along the east wall of the Kremlin lies Red Square (Krasnaya Ploshchad), the ceremonial centre of the capital and scene of holiday parades. The modest Lenin Mausoleum blends into the wall, which itself contains the graves of most of the U.S.S.R.'s past leadership. At the southern end of Red Square is the Church of the Intercession (Pokrovsky Sobor), better known as the Cathedral of St. Basil the Blessed. Built in 1554–60 to commemorate the defeat of the Tatars (Mongols) of Kazan and Astrakhan by Ivan IV the Terrible, it is a unique and magnificent architectural fantasy, each of its 10 domes differing in design and colour. Along Red Square facing the Kremlin is the State Department Store—usually called by its Russian acronym, GUM—with its long aisles, iron bridges linking the upper floors, and great skylights. The slightly earlier State Historical Museum (1875–83) closes off the northern end of the square.

GUM

Many old churches survive in the Kitay-gorod. Of particular note are the Church of the Trinity (1628–34) in Nikitniki, the 15th-century Church of St. Anne of the Conception, and the Epiphany Cathedral (1693–96). The Kitay-gorod was for centuries the commercial centre of Moscow, and its narrow, crowded streets still contain former banks, the stock-exchange building, and warehouses. Many of the old buildings near the river, however, were demolished in the 1960s to make room for the huge Rossiya Hotel. Along the northern front of the hotel is a row of preserved buildings, including the 16th-century house of the Romanov boyars and Old English Embassy and the 17th-century Monastery of the Sign.

The inner city. In the remainder of the central part of Moscow, within the Garden Ring (Sadovoye Koltso), are buildings representative of every period of Moscow's development from the 15th century to the present day. Scattered through the inner city are several fine examples of 17th-century church architecture, notably the Church of All Saints of Kulishki, built in the 1670s and '80s to replace a 14th-century edifice, and the Church of the Nativity of Putniki (1649–52). This was the period of development of the Moscow Baroque style; one of the best examples of this style, the Church of the Intercession at Fili (1693), is outside the city centre. Buildings of the classical period—beginning about the latter half of the 18th century and covering the rebuilding of Moscow after the fire of 1812—abound within the Garden Ring and the Boulevard Ring (Bulvarnoye Koltso), the latter forming a rough horseshoe north of the Moskva around the Kremlin and Kitay-gorod, and Zamoskvoreche, a largely residential district south of the Moskva. Notable examples are the old university and the former assembly of nobles with its Hall of Columns (now the House of Trade Unions), both built by Kazakov in the 1780s; the elegant Pashkov House (1785–86), now part of the Lenin State Library; the Lunin House (1818–23), now the Museum of Oriental Art; the Manezh (Riding School; 1817), which is now used as an exhibition hall; and the magnificent Bolshoi Theatre (1821–24), rebuilt in 1856 after a fire. Toward the end of the 19th century and continuing into the early 20th, buildings in the revivalist Old Russian style were built, including the State Tretyakov Gallery (1906) and—just outside of the Garden Ring—the Yaroslavl railway station (1902–04).

In the Soviet period many of the old buildings of the inner city were replaced by large office and apartment buildings. Side by side with the old appeared new buildings in the modern, functional style of the 1920s, in the ponderous, often over-ornate style of the later Stalin period (1930s to '50s), and in the high-rise concrete and glass predominant since the 1960s. Cheek by jowl with the Pashkov House stands the main building of the Lenin State Library (1927–29). Among more imaginative exam-

ples of later architecture is the Taganka Theatre (1983).

In the Soviet period much more open space was created, especially by constructing large squares such as Manezhnaya Square (formerly known as the Square of the 50th Anniversary of October). Many streets have also been widened, in particular Gorky Street (Gorkogo Ulitsa), now one of Moscow's principal radial roads, lined with large shops, hotels, and offices. The Garden Ring itself has been widened to form a broad highway with multiple lanes in each direction and with overpasses where it is intersected by the main radial routes. In the 1960s a new radial street, Prospekt Kalinina, was built through an area of older housing westward from the Kremlin to the Moskva River; it is lined by high-rise office and apartment buildings, linked at street and second-floor levels by a shopping mall. At its outer end rises a lofty, three-winged building overlooking the river that for many years housed offices of Comecon (Council for Mutual Economic Assistance, disbanded in 1991). Yet, just next to this bustling thoroughfare is Arbat Street (also called Old Arbat), one of the most picturesque streets of Moscow and now closed to vehicular traffic. Most of the historic buildings of central Moscow have been preserved—since the 1960s much careful restoration and repair work has been undertaken—but some architectural monuments disappeared in the early Soviet period. Where before the Revolution the Cathedral of the Saviour stood, near the river just above the Kremlin, there is now a vast open-air swimming pool.

Prospekt Kalinina

Inner Moscow has the functions typical of a central business district. In this area are concentrated most of the government offices and administrative headquarters of state bodies, most of the hotels and larger shops, and the principal theatres, museums, and art galleries. But its function as a residential area has not been lost; the many large apartment buildings of modern times have ensured that a large population continues to live in the centre, and there are still many quiet residential neighbourhoods within the Garden Ring.

Nikolai Ignatiev

The interior of the State Department Store, GUM.

The middle zone. Beyond the Garden Ring and approximately as far as the Moscow Little Ring Railway lies a zone mostly of late 18th- and 19th-century development. Within it are many factories and the principal railway stations and freight yards. The Likhachyov Automobile Works, with its associated housing, occupies much of the southeastern sector. Enveloped within this zone are further examples of the best of classical Moscow, such as the 18th-century palace that houses the Presidium of the Academy of Sciences of Russia on Leninsky Prospekt. Also to the southwest, on the banks of the Moskva, are the most important of the fortified monasteries, the 16th-century Novodevichy Convent, with its beautiful Smolensk Cathedral, whose tall bell tower (1690) dominates the churches and buildings within the crenellated walls and towers of the convent. The cathedral now houses the Novodevichy Convent Museum, and the complex includes a cemetery where, among other prominent figures of Soviet history, Nikita Khrushchev is buried. Just south of Novodevichy, within the large loop of the Moskva and facing the Lenin Hills, is the sports complex known as Luzhniki Park, dominated by the huge Central Lenin Stadium (1955–56).

Novodevichy Convent

The middle zone underwent the most urban renewal in Soviet times. Among the features of the present Moscow skyline are the ornate "wedding cake" skyscrapers along the Garden Ring, built in the late 1940s and early 1950s. In the same Stalin-period style are the Ukraina Hotel across the river and the gigantic building in the Moscow State University complex on the Lenin Hills. Most of the renewal that has taken place since 1960 consists of extensive neighbourhoods of wide streets lined with rows of apartment buildings. A number of areas still have narrow streets of 19th-century housing and smaller factories.

Outer Moscow. Beyond the Garden Ring is the zone of modern factory development and of extensive housing construction. Closer to the centre are the micro-regions, or neighbourhood housing units, of the Khrushchev period, typically five- to nine-story apartment buildings built predominantly of yellowish brick. Farther out, the neighbourhoods are characterized by high-rise buildings (20 or more stories), made of standardized, prefabricated concrete sections. Commonly the street levels of the buildings are occupied by shops. Streets are broad and tree-lined. Between the densely populated micro-regions are wedge-shaped areas of open land, notably the extensive Izmaylovsky Park in the east, Sokolniki Park and large forest tracts to the northeast, and on the north the grounds of the permanent Exhibition of National Economic Achievements. Nearby, in Dzerzhinsky Park at Ostankino, is the 1,758-foot television tower.

In the sea of new building, individual monuments of the past, such as the 17th-century Church of the Intercession in Medvedkovo, survive. Moscow's growth has engulfed a number of former country estates, the mansions of which date mostly from the period of classical architecture. On the east side of the city is Kuskovo, once the estate of the Sheremetyev family, its palace built in the 1770s, a church, hermitage, and Baroque grotto. To the south is the Uzkoe mansion, formerly belonging to the Trubetskoy family; to the north are the Petrovsky Palace (built by Kazakov in 1775–82) and, best known of all, the Ostankino Palace (1790–98). In the southeastern suburbs is the former village of Kolomenskoye, once a summer residence of the princes of Moscow. Its most remarkable architectural ensemble of buildings is dominated by the tower of the Church of the Ascension (1532). The Kazan Church and the gatehouse both date from the later 17th century. The surrounding park has a collection of examples of early Russian wooden architecture, brought from various parts of the country. In the nearby village of Dyakovo is the ornate Church of St. John the Baptist, built in 1557.

Beyond the newest suburbs are remaining areas of open land and forest within the Ring Road, together with the satellite industrial towns and dormitory suburbs that were included within the extended boundaries of the city of Moscow in 1960. The principal satellites are Babushkin to the north, with textile mills and a large number of

Satellite towns

commuters, Perovo to the east, with major marshaling yards and engineering and chemical factories, Lyublino to the southeast, Kuntsevo to the west, and Tushino to the northwest. In the mid-1980s several areas outside the Ring Road—including the suburban city of Solntsevo (now the Solntsevsky District [*rayon*]) to the southwest—were added to Moscow. Another part of Moscow, the new town of Zelenograd, established in 1963, is several miles north of the Ring Road.

THE PEOPLE

The inhabitants of Moscow are overwhelmingly of Russian nationality, the largest minority groups being Jews, Ukrainians, Belorussians, and Tatars. It is possible, however, to meet people on the streets of Moscow who belong to any of numerous nationalities, including Georgians and Armenians from the Caucasus Mountains and Uzbeks and Kazakhs from Central Asia.

A considerable percentage of the residents were not born in Moscow but migrated there during the rapid growth of the city. Some of the older generation have lived through the Stalinist purges and the deprivations of World War II. There is no typical Muscovite, but to some visitors the residents seem guarded in their relations with others. With the coming of summer, however, this seems less true as people shed their winter clothes and mingle more freely. Among the more common scenes are those in the courtyards of apartment buildings, where the children play while their elders gossip on benches and play chess, and young people congregate to listen to music.

The great increase in the amount of housing since the late 1950s has brought a fundamental change in the Muscovites' way of life as many have moved farther from the central city. For most of them, living in the suburbs has involved lengthier travel to and from work. The subway system has been extended to many suburban housing districts, but most working Muscovites must spend at least two hours a day commuting. The new housing pattern has also inevitably led to the breakup of the close communities that existed in the old central areas, such as the so-called intelligentsia district around Kropotkinskaya and the Arbat. The degree of change has been marked: in 1926 more than one-third of the population lived within the Garden Ring, but by 1967 fewer than 9 percent of the people lived there. The population density of central Moscow, however, is still much higher than in the suburbs.

THE ECONOMY

Since the dissolution of the Soviet Union in 1991 and the free-market reforms of the early 1990s, Moscow's economy has undergone a dramatic transformation. The manufacturing and engineering sectors that had dominated the Soviet capital's economy shrank dramatically, partly because their products could not compete on the world market and partly because rapid privatization left many industrial plants in the hands of owners who chose to invest their earnings abroad rather than in modernizing their plants to compete with foreign producers. At the same time, the city's financial and service sectors have grown rapidly to meet the demands of investors and consumers. While this transformation has brought hardship to many of the city's workers, it has also ended the retail shortages and lack of services that once characterized the city.

Moscow's labour force is one of the most highly skilled and educated in Russia, and the city's financial, engineering, and manufacturing sectors are among the country's most advanced. Women make up more than half of the workforce. They form the vast majority of workers in the textile and food-processing industries, and they predominate in the teaching and medical professions.

Industry. Despite the decline of industry in the post-Soviet period, Moscow remains the largest industrial centre of Russia. It dominates an industrial region that extends east and northeast to the Volga between Yaroslavl and Nizhny Novgorod (formerly Gorky). Moscow's industries generally rely more on the city's skilled labour force than on raw materials.

Moscow's most important industries are engineering and metalworking, which together employ more than half of the industrial workforce. There is significant production of automobiles and trucks. The largest plant in the city is the Likhachyov Automobile Works, followed by the Lenin Komsomol Automobile Plant. Closely linked with these two plants are a number of factories producing component parts, both elsewhere in Moscow and in other towns of the region. Ball bearings are manufactured both for the vehicle industry and for other purposes. The manufacture of machine tools is another major branch of engineering, particularly grinding lathes, precision cutting tools, and machinery for the textile industry.

Precision engineering

Precision engineering is highly developed and is noted for measuring and other instruments (especially at the Kalibr and Frezer factories), as well as for watches. In addition, Moscow is an important centre of electrical, electronic, and radio engineering; the wide range of items made includes transformers, computers, radio and video equipment, refrigerators, vacuum cleaners, and electric motors. Aerospace design and manufacture is one of Moscow's most important engineering sectors.

Some of the specialized, high-grade steels required by this formidable array of engineering industries are made in the city; specialized steels also come from the satellite town of Elektrostal, 36 miles east of Moscow.

Moscow is the nation's leading textile centre, and the numerous branches of its textile industry are the city's second leading employer. All types of natural and synthetic cloth are manufactured.

Chemical industry

Moscow's large chemical industry was originally geared to producing dyestuffs for the textile industry. The industry's product line has been expanded, however, to include synthetic industrial rubber and rubber tires, paints, plastics, pharmaceutical goods, and perfumes. Many of its chemical products are derived from Moscow's oil refinery, which processes petroleum piped from the Volga–Urals oil field.

Nikolai Ignatiev

Housing in southwestern Moscow.

Food processing avoided the sharp decline in output that characterized other industrial sectors and became one of the city's most developed industries in the 1990s. Its most important products include processed meat and dairy items, confectionery, and alcoholic beverages. Among the city's most successful firms is the Kristall Distillery, which produces the renowned Stolichnaya vodka.

Apart from food processing, Moscow's consumer goods sector suffered in the early 1990s when the market was opened to inexpensive, higher-quality imports. Still, the city produces a wide range of consumer goods for the city and its wider hinterland. Furniture making is part of a varied timber-processing industry, which also makes pulp and paper. Some of the timber is used in the vast construction industry, the workers of which include not only the large numbers actually employed in building but also those engaged in making building materials, such as reinforced concrete sections, glass, and bricks. Moscow's printing industry is the nation's largest supplier of books, journals, and newspapers. Many of Moscow's factories are small, long-established works that make highly specialized items.

Moscow draws on a wide area for its power supply. Electrical generating stations in the city are fired by natural gas, which is piped via a grid system from fields in Siberia and elsewhere. Large gas storage facilities have been constructed near Moscow, and a linking pipeline rings the city. Electrical power also comes from nuclear plants, the nearest of which is about 37 miles to the south, and from the hydroelectric stations on the Volga. Other sources are the large thermal stations at Konakovo to the northwest and Kashira to the south. A by-product of the power industry is hot water, which is piped from the district central stations to apartment buildings for heating and domestic use.

Services. *Commerce and finance.* As the capital and largest city of Russia, Moscow not surprisingly is the country's chief commercial and financial centre. The privatization of the Russian economy spurred the development of a substantial financial sector, including several banks and securities exchanges. Most foreign investment in the Russian economy passes through Moscow's financial institutions. As the hub of Russia's transportation network, Moscow also enjoys unchallenged supremacy as the country's centre for domestic and foreign commerce.

Moscow is Russia's leading educational and research centre, and its educational institutions furnish skilled workers for its important engineering and aerospace sectors. It is also the centre of Russia's publishing industry.

The city's retailing facilities are heavily used, not only by the inhabitants of Moscow itself and its satellite towns but also by people throughout the nation. Its shops offer a wide range of goods and are always crowded with customers. Many of the stores are fairly large, particularly the department stores (*univermagy*). The most important of the department stores are Children's World (Detsky Mir); the Central Department Store (TsUM); the Moscow (Moskovsky) Department Store, close to three main railway stations; and, best known and most heavily patronized, GUM, the direct descendant of the medieval trading rows. An important part of Moscow's retail trade is carried on at farmers' markets, where farmers and small-scale traders sell fruit, vegetables, meat, liquor, and other goods to the populace.

Tourism. As a world-renowned capital, Moscow is a principal focus for foreign visitors. Free-market reforms have encouraged the construction of new, modern hotels and the modernization of existing hotels in the city. The government also opened new tourist offices and refurbished many cultural attractions.

Moscow has thousands of eating places, many of them inexpensive cafeterias serving the city's workers. The city's more exclusive dining venues include Chinese, Indian, American, Italian, and other ethnic restaurants that opened during the 1990s.

Transportation. *Rail.* Russia is heavily dependent for freight transport on its railways. The hub of this network is the capital. Trunk lines radiate out from the city in all directions. The first in operation was the St. Petersburg (formerly Leningrad) line, opened in 1851. Others include the Savyolovo line, running north to the Volga and on as a secondary route to St. Petersburg; the Yaroslav line, which is connected by way of the Trans-Siberian route to Vladivostok; the Nizhny Novgorod line, linked to Kirov; the Kazan line, the most direct route to the Urals and Siberia; the Ryazan line, leading to Central Asia and the Caucasus; the Pavelets line, a secondary route to the European south and the Caucasus; the Kursk line, the main route south to the Crimea; the Kiev line to the southwest; the Smolensk line to Minsk, Warsaw, and Berlin; and the Riga line to the Baltic. The most heavily used of these lines are now electrified—notably those to St. Petersburg, Kiev, the Donbass, and the Trans-Siberian—as are all suburban-zone lines, which carry the heavy commuter traffic. To link the radial lines the Moscow Little Ring Railway was built in 1908 within the city; this has been supplemented by the Greater Moscow Ring Railway at a distance of some 25 to 40 miles from the city.

Waterways. Moscow is a major river port. The canalized Moskva can take only smaller craft, but the Moscow Canal, built by forced labour in 1932–37, can take ships of seagoing size. The canal runs from the Moskva, upstream of the city, northward to the Khimki and Ucha reservoirs and, continuing northward, through the Klin-Dmitrov Ridge to the Volga at Ivankovo. The Volga's various canal links open up Moscow to all the seas bordering European Russia. The capital has three large river ports mainly for freight and two terminals for passengers that are part of the urban transit system.

Moscow Canal

Air. Moscow is similarly the hub of the Russian airline network, and the number of passengers rises steadily each year. Four airports operate in the Moscow area. Sheremetyevo-2 to the north is the main airport for international flights, with direct links to most European capitals and to Havana, New York City, Montreal, Tokyo, and other foreign cities. Sheremetyevo-1 handles mostly domestic flights, as does Vnukovo, 15 miles to the southwest. Other domestic airports are Bykovo, 20 miles to the southeast, and Domodedovo, 28 miles to the south.

Intracity transport. Compared with other large cities in most developed countries, Moscow has few privately owned cars, although their number is steadily increasing. There are, however, a considerable number of officially owned cars, which have added to the increase in traffic congestion. At the same time, there is heavy reliance on public transport, and in this respect Moscow is generally well served.

The most important element in Moscow's city transport is the Metropolitan (Metro) subway. The system, begun in 1935, is renowned for the elaborate architecture of its stations, especially the older ones, which are highly decorated with marble, stained glass, statuary, and chandeliers. Trains usually arrive at three-minute intervals, although the interval is less during rush hours. The network copies the city street pattern, with a series of radial lines linked by a single ring subway. Although the lines extend to most parts of the city, the stations are spaced far apart so that it is usually necessary to use them in conjunction with bus, trolley, and streetcar lines.

Subway system

The inflexibility of fixed-line forms of transport poses a potential problem as traffic gradually increases. Many streetcar lines, consequently, have been replaced by bus routes. On the positive side, fares on all forms of transport are very low regardless of distance.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. In the period after the 1917 Revolution, Moscow was divided into 11 administrative districts, or wards. With the expansion of the municipal limits in 1960 the number of administrative units was increased to 17 *rayony* (districts; singular *rayon*). The subsequent huge building program and redistribution of population from central areas to the suburbs necessitated the creation of new divisions in 1968 and again in 1976, when the number reached 30. Further annexations caused an increase by the mid-1980s to 32 *rayony*, a figure that would rise as the city continued to grow. The *rayony* vary in population, the inner *rayony* usually being somewhat smaller in area and

population than the outer. The *rayony* elect delegates to a city council, which has its headquarters on Gorky Street. The council handles the city's annual budget, which is derived chiefly from central government funds. The city council is responsible to the government of Russia rather than to a smaller administrative unit.

Although the centre of national government is the Kremlin, the buildings of various ministries and government departments are scattered fairly widely over the inner city. The Ministry of Foreign Affairs is in a skyscraper of the Stalin period on the Garden Ring. Several ministries are housed in the new tower buildings on Prospekt Kalinina, and a number of foreign embassies have been transferred to the southwestern suburbs on the Lenin Hills, although many are still located in the city centre. Moscow also serves as headquarters of most national bodies and organizations.

Education. Even considering its size and political importance, Moscow has an exceptionally large concentration of educational establishments. At the pre-university level, schools serving the city's own population include those for handicapped children, special foreign language schools, and boarding schools. For children below school age (six years old in Russia) there are nurseries and kindergartens; many are attached to individual places of employment, which permits parents more freedom to work. Moscow's higher educational institutions draw students from throughout the nation. A large percentage of the students are registered for correspondence courses. Although the students are predominantly Russians, they include representatives of several ethnic groups together with a number of overseas students.

Moscow M.V. Lomonosov State University

Higher education. The leading institution of higher learning is the Moscow M.V. Lomonosov State University, which was founded in 1755. Some of the humanities departments are still housed in the old university buildings facing Manezhnaya Square, near the Kremlin. Science departments are located in the complex of buildings on the Lenin Hills, which date from the early 1950s and are dominated by a 34-story skyscraper in the Stalin-period style; this building houses the central administration, the Museum of Earth Science, and accommodations for thousands of students. In 1970–78 two other humanities buildings were constructed on the Lenin Hills site. Moscow's second university, the Patrice Lumumba People's Friendship University, was founded in 1960 to serve students from the world's developing nations.

Among the specialist higher educational foundations are the Moscow Timiryazev Academy of Agriculture in the north of Moscow and the Moscow P.I. Tchaikovsky State Conservatory, where some of the world's finest musicians have received their training. Also important are the Moscow D.I. Mendeleyev Institute of Chemical Technology, the Moscow N.E. Bauman Higher Technical School, and the A.V. Lunacharsky State Institute of Dramatic Art. Many institutes, among them the Moscow Institute of Aviation Technology and an institute for railway engineers, produce specialists for particular industries.

Research. In addition to the large volume of research undertaken in the university and in other teaching establishments, there is a formidable array of scientific research institutions. Between them they constitute the second largest employer in Moscow after industry. A large proportion of those Russian citizens holding the doctor of science degree are employed in Moscow. The main focus of research is the Academy of Sciences of Russia, the Presidium of which is located in a building on Leninsky Prospekt south of Gorky Park. There are also national academies of arts and medical, pedagogical, and agricultural sciences.

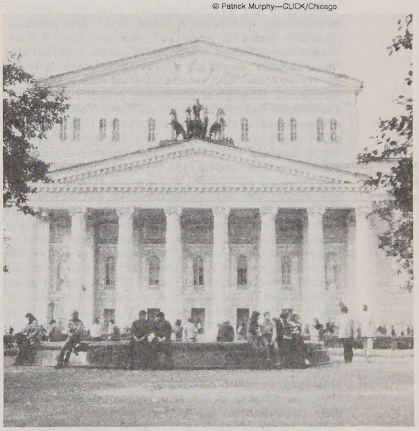
Many scientific institutes, such as the Experimental Research Institute of Metal-Cutting Machine Tools, are concerned with highly specialized industrial research. These are often connected closely with Moscow's own industries, as in the case of the Central Research Institute of Automobile Engineering. Linked to the research bodies are many design bureaus, including an institute that designs hydroelectric power projects and an institute for the planning of metallurgical plants.

Lenin Library

Foremost among Moscow's libraries is the V.I. Lenin State Library, one of the world's largest. There are also a number of specialty libraries in the arts and sciences and in other fields.

Health. The health of the Muscovites is attended to at the neighbourhood level by hundreds of clinics, giving medical, dental, and maternity services. Perhaps the most prominent of the city's numerous hospitals is the Botkinskaya, founded in 1911. Among specialist institutions are maternity, mental, and tuberculosis hospitals, supported by a number of specialist medical research institutions.

CULTURAL LIFE



Moscow has numerous theatres, headed by the renowned State Academic Bolshoi (Great) Theatre, which was founded in 1825, though its present splendid building facing Theatre (formerly Sverdlov) Square dates from 1856. Also on Theatre Square is the Maly (Little) Theatre. The city's principal drama theatre, the Moscow Art Theatre, was founded in 1898 by the actor, director, and producer Konstantin Stanislavsky and the playwright-producer Vladimir Nemirovich-Danchenko; in its early days it was especially noted for its performances of the plays of Anton Chekhov. Also of worldwide fame are the State Central Puppet Theatre and the Moscow State Circus, which in 1971 acquired new quarters on the Lenin Hills. The repertory companies of these theatrical groups tour frequently both in Russia and abroad. There are several concert halls, notably the Tchaikovsky Concert Hall and the two halls of the Conservatory. The national orchestra has won international repute, as have a number of Moscow-based folk dance and choral ensembles.

Motion pictures are a popular form of entertainment in Moscow, and the city's many cinemas are augmented by facilities for showing films in numerous clubs and cultural institutions. The October and Rossiya cinemas are the largest in Russia. Several studios in the city produce motion pictures, notable among which is Mosfilm. The television and radio broadcasting networks also have headquarters in Moscow; programs produced there are received throughout the country.

Museums and galleries

The museums and art galleries in the capital include several of international rank. Foremost among these are the State Pushkin Museum of Fine Arts, with a fine international collection, and the State Tretyakov Gallery. The latter, which began in 1856 as the private collection of a connoisseur, Pavel Tretyakov, is noteworthy for its superb collection of icons, including several by Andrey Rublyov.

© Patrick Murphy—CLICK/Chicago

The State Academic Bolshoi (Great) Theatre.

Other notable museums are the Armoury Museum in the Kremlin, the State Historical Museum on Red Square, and the nearby Central Lenin Museum on Revolution Square.

Although many places of worship were closed, converted into museums, or destroyed after the Revolution, Moscow retained a number of functioning Russian Orthodox churches in addition to a few other Christian churches and Jewish and Muslim places of worship. Beginning in the late 1980s with the Soviet policy of *glasnost* and continuing with the Russian successor government in the early 1990s, religious repression gave way to policies endorsing religious freedom, and houses of worship in Moscow underwent renovation and returned to use. The Russian Orthodox patriarch has a residence in Moscow.

The Luzhniki Park complex is the leading Moscow facility for sports and was one of the main arenas for the 1980 Olympic Games. The Central Lenin Stadium, accommodating 103,000, is flanked by a smaller arena, swimming pool, and the indoor Sports Palace. There are many stadiums and swimming pools in the area, including a large, heated, open-air pool that is in use all year round. In addition there are a large number of soccer fields, gymnasiums, and volleyball and basketball courts; most of these are attached to individual places of work or to sports clubs.

Parks

Outside the Garden Ring, Moscow is well provided with parks and open spaces. Gorky Central Park of Culture along the right bank of the Moskva is the closest to the centre and, with its amusement park, is very popular. A large green area, covering nearly 3,000 acres (1,200 hectares), is Izmaylovsky Park on the east side. To the northeast is the more formal Sokolniki Park, which leads to an extensive tract of forest called Moose Island. North of the city centre are the Botanical Gardens of the Academy of Sciences, one of several such gardens in the city, and the grounds of the Moscow Timiryazev Academy of Agriculture. Bittsevsky Park, also of considerable size, has been established adjacent to the Ring Road south of the city centre. The Moscow Zoo, one of the world's leading zoos, is a popular attraction west of the city centre. The Khimki Reservoir is used for boating and aquatic sports, but even more popular are the other reservoirs to the north, just outside Greater Moscow. The surrounding forest-park zone provides extensive space for recreation.

History

THE EARLY PERIOD

Foundation and medieval growth. The first documentary reference to Moscow is found in the early monastic chronicles under the year 1147, when on April 4 Yury Vladimirovich Dolgoruky, prince of Suzdal, was host at a "great banquet" for his ally the Prince of Novgorod-Seversky "in Moscow." This is the traditional date of Moscow's foundation, although archaeological evidence shows that a settlement had existed on the site since Neolithic times. Archaeological work has also revealed the remains of corduroy roads and evidence of iron and leather working dating from the 11th century. The disturbed times made defense essential, and in 1156 Prince Dolgoruky built the first fortifications—ditches and earthen ramparts topped by a wooden wall with blockhouses. This was the Kremlin. The origin of the word *kremlin* is disputed; some authorities suggest Greek words for "citadel" or "steepness," others the early Russian word *krem,* meaning a conifer providing timber suitable for building. The Kremlin was sited on the relatively high spit of land between the Moskva River and a small tributary, the Neglinnaya. The triangular piece of land between the rivers was protected on the eastern side by a moat joining them. The Neglinnaya now flows through an underground conduit, but part of its course is traced by a street of the same name.

First fortifications

Moscow soon developed as one of the more important towns of the principality of Vladimir-Suzdal. A trading settlement, or *posad,* grew up to the east of the Kremlin, along the Moskva in the area known as Zaradye. Like most other Russian towns, Moscow was captured and burned by the Mongols in their great invasion of 1236–40, and its princes had to accept Mongol suzerainty. It soon recovered, though the Mongols sacked it once again in 1293. Three years later the Kremlin was strengthened with a new earthen wall and oak palisade. Thereafter Moscow grew in importance, in trading and artisan activity, and in size, overtaking the older and previously more important centres of Suzdal and Vladimir. The town was fairly centrally placed in the system of rivers and portages that formed the trade routes across European Russia. The area east of Moscow between the Oka and Volga rivers moreover had rather better soils than most of northern Russia and formed a region of more developed agriculture and prosperous towns. Moscow's authority was greatly enhanced when in 1326 the metropolitan of the Russian Orthodox Church transferred his seat from Vladimir to Moscow. Thereafter the town was to remain the centre of Russian Orthodoxy, and after the fall of Constantinople to the Turks (1453) it claimed the title of the Third Rome. Under Ivan I Kalita the principality of Vladimir was incorporated into that of Moscow. Gradually the princes of Moscow extended their rule over the other surrounding Russian princedoms, and the town became the leader in the long struggle against Mongol hegemony.

Seat of the metropolitan

The struggle at first fluctuated. In 1378 a Muscovite army repulsed a Mongol attack on the Vozha River south of the town, and in 1380 Prince Dmitry of Moscow inflicted a crushing defeat on the Mongols under the great khan Mamai at Kulikovo on the Don River, for which victory he was thereafter known as Dmitry Donskoy ("of the Don"). The Kremlin had been enlarged and given walls and towers of white limestone in 1367, but the new fortifications were unable to withstand a renewed Mongol attack in 1382, when, despite a heroic defense, the khan Tokhtamysh captured and plundered Moscow. Yet another attack in 1408 under Khan Yedigei, however, was beaten off. Moscow grew steadily in size and importance as it continued to absorb the surrounding princedoms. Within the Kremlin the first stone cathedral, the Assumption, was built in 1326. Palaces for the prince and leading boyars, monasteries, and churches were erected. Outside the Kremlin walls, the trading and artisan quarter to the east grew in size and became known as the Kitay-gorod; this name, which originated in the 16th century, probably derives from the word *kita,* a binding of poles used in the fortifications before stone walls were built, and does not mean "Chinese City" as it is sometimes translated.

The rise of Moscow as capital. By the second half of the 15th century, especially after the annexation of Novgorod in 1478, Moscow had become the undisputed centre of a unified Russian state. During the reign of the grand prince of Moscow Ivan III the Great, the Kremlin was again enlarged and given brick walls more than a mile in length and in places up to 60 feet high. From this period also date the rebuilt Cathedral of the Assumption and the equally beautiful Annunciation and (also rebuilt) Archangel cathedrals, the Palace of Facets, and the bell tower of Ivan III. In 1534–38 the Kitay-gorod, previously protected only by earth banks and palisades, was also surrounded by a brick wall, with 12 towers. The town continued to grow and spread outside the walls to form what became known as the Bely Gorod ("White City") in a semicircle around the Kremlin and Kitay-gorod.

Despite its new fortifications, Moscow remained subject to disaster and attack. In 1547 two fires destroyed much of the town. In the mid-16th century Ivan IV the Terrible conquered the Tatar (Mongol) khanates of Kazan (1552) and Astrakhan (1556), but in 1571 the Crimean Tatars captured Moscow, burning everything but the Kremlin. The annals record that only 30,000 of 200,000 inhabitants survived. A further attack was launched by the Crimean Tatars in 1591, but they failed to overcome Moscow's stubborn resistance. The defense was helped by the new walls, built between 1584 and 1591 to protect the Bely Gorod, made of stone and some five miles long. The walls' lines are marked today by the strip of parkland and tree-lined streets of the Boulevard Ring. In 1592 an outer earth rampart with 50 towers was thrown up around the city, including an area on the right bank of the Moskva. This encompassed a further extension of Moscow that had grown up beyond the Bely Gorod; known at first as Sko-

Zemlyanoy Gorod

rodom, this outer sector came to be called the Zemlyanoy Gorod, or Earthen City. The Garden Ring traces the line of its fortifications. As an outermost line of defense, a chain of strongly fortified monasteries was established beyond the ramparts to the south and east, principally the Novodevichy Convent and Donskoy (Don), Danilovsky, Simonov, Novospassky, and Andronikov monasteries, most of which now house museums.

With much improved security, trade and craft manufacture flourished. Distinct quarters were occupied by particular trades; for example, the suburbs of Bronnaya by armour makers, Kuznetskaya by blacksmiths, and Kotelniki by kettle makers. Across the Moskva was the weavers' suburb. These artisan sectors are commonly commemorated today by street or quarter names. State workshops cast cannon and made weapons and gunpowder. The tsar's court and its attendant nobility provided patronage for luxury crafts. Increasingly the boyars took over the Kitay-gorod, with artisans and traders moving to the outer parts; the Kremlin became solely the seat of temporal and ecclesiastical authority. The centre of commercial activity was the market in Red Square between the Kremlin and the Kitay-gorod, where there were rows of stalls, each handling a specific variety of goods; the Russian word for "red" (*krasnaya*) also means "beautiful," which was the original name for the square. Trade with western Europe (especially England and Holland), as well as with Central Asia, Transcaucasia, Persia, and the Black Sea coast, was brisk, furs forming a major staple in this international commerce. Foreign merchants lived in the Nemetskaya Sloboda ("German suburb"), and a flourishing cultural life was marked by the growth of the book trade and the founding in 1553 of the first printing house.

At the turn of the 17th century Moscow, like the rest of Russia, suffered severely during the Time of Troubles. In the reign of Boris Godunov there were severe famines from 1601 to 1603. After Boris' death in 1605, the first False Dmitry seized Moscow with Polish help, and, though he was killed in 1606 and the Poles were driven out, they reoccupied Moscow with a second False Dmitry in 1608–10. In May 1611 the Muscovites attacked the Poles, and the invaders retreated into the Kremlin. Under the energetic leadership of a boyar, Prince Dmitry Mikhaylovich Pozharsky, and a merchant, Kuzma Minin, the Russians forced the Poles to surrender in October 1612.

With the establishment in 1613 of the Romanov dynasty under Michael, relative peace returned to Moscow and with it further economic advance. Nevertheless the conditions of the poor of the town often led to riots and uprisings; similar events had occurred also in 1382, 1445, and 1547. In 1648, as a result of an increase in the salt tax, and again in 1662 (the so-called Copper Riots) there were disturbances by artisans, labourers, and tradesmen. The great revolt of Stenka Razin in southern Russia (1667–71) was echoed by unrest in the capital, and in 1671 Razin was executed in Moscow as a warning to its inhabitants. The revolts were put down by the hereditary militia, the *streltsy,* who in 1698, early in the reign of Peter I the Great, themselves revolted and were suppressed only with great slaughter. Despite the frequent upheavals, however, culture flourished. Russia's first higher educational institution, the Slavonic-Greek-Latin Academy attached to the Zaikonospassky Monastery in the Kitay-gorod, dates from 1687. In 1701 Peter founded a School of Mathematics and Navigation. The first newspaper in Russia began publication in Moscow in 1703.

Riots and uprisings

EVOLUTION OF THE MODERN CITY

The 18th and 19th centuries. In 1703 Peter I began constructing St. Petersburg on the Gulf of Finland, and in 1712 he transferred the capital to his new, "westernized," and outward-looking city. Members of the nobility were compelled to move to St. Petersburg; many merchants and artisans also moved. Both population growth and new building in Moscow languished for a time, but even during Peter's reign the city began to recover from the loss of capital status. Peter himself stimulated economic growth by establishing new industries, and private entrepreneurs followed suit. By 1725 there were some 32 new factories employing 5,500 workers; more than 20 of the factories were textile mills, including a crown enterprise making sailcloth. At the same period there were about 8,500 craft workers.

During the 18th century Moscow retained its major role in the cultural life of Russia. In 1755, on the initiative of the great man of letters and science Mikhail Vasilyevich Lomonosov, Moscow University (now Moscow M.V. Lomonosov State University) was founded, the first university in Russia; a medical and surgical college was opened in 1786. Although serious fires did much damage in 1737, 1748, and 1752, many splendid new buildings appeared, designed by such architects as Giacomo Quarenghi, Vasily Bazhenov, Matvey Kazakov, and Vasily Stasov. In 1741 Moscow was surrounded by a barricade 25 miles long, the Kamer-Kollezhsky barrier, at whose 16 gates customs tolls were collected; its line is traced today by a number of streets called *val* ("rampart") and by place-names such as Kaluga Zastava (Customs Gate). Industry flourished, and by the end of the 18th century there were about 300 factories in Moscow, more than half of them textile mills. The population had grown to 275,000 by 1811.

Moscow University

In 1812 Napoleon invaded Russia; after a bitter 15-hour battle on September 7 at Borodino on the approaches to Moscow, the Russian commander in chief, Gen. M.I. Kutuzov, evacuated troops and civilians from the city, which was occupied by the French a week later. A fire broke out and spread rapidly, eventually destroying more than two-thirds of all the buildings. Looting was rife. The lack of supplies and shelter and continual harassment by Russian skirmishing forces made it impossible for Napoleon to winter in Moscow, however, and on October 19 the French troops began their catastrophic retreat.

In 1813 a Commission for the Construction of the City of Moscow was established. It launched a great program of rebuilding, which included a partial replanning of the city centre. Among many buildings constructed or reconstructed at this time were the Kremlin Great and Armoury palaces, the university, the Manezh (Riding School), and the Bolshoi Theatre. Industry also recovered rapidly and continued to develop through the 19th century. In 1837 the Moscow stock exchange was established. The emancipation of the serfs in 1861 and the beginning of the railway era with the opening of the line to St. Petersburg in 1851 greatly increased labour mobility, and large numbers of peasants from the villages began moving into Moscow. The population, which had reached 336,000 in 1835, had almost doubled, to 602,000, in 1871 and by 1897 had reached 978,000. Moscow became the hub of Russia's railways, with trunk lines to all parts of European Russia. A ring of main line termini was built, mostly on or near the Kamer-Kollezhsky barrier at the limits of the built-up area. Outside the barrier many new factories, particularly those concerned with textiles, began operation. In the 1890s heavy engineering and metalworking industries also developed. Between 1897 and 1915 Moscow yet again doubled in size, to a population of 1,983,700.

The later 19th century was a period of ostentatious building by public bodies and wealthy private persons, in various imitative "Old Russian" styles and the so-called modern style. From this period date the old Town Hall (meeting place of the Gorodskaya Duma, now the Central Lenin Museum), the State Historical Museum, and the Upper Trading Rows (now GUM).

The growth of an industrial proletariat in Moscow, together with the generally low living standards of the workers, brought growing unrest and strikes. Various revolutionary groups were active. In the Revolution of 1905 a small-scale insurrection took place in Moscow, and an attempt was made to seize the Nikolayev (now St. Petersburg) station; the revolt was ruthlessly crushed. In 1917, although a Council of Workers' and Soldiers' Deputies was set up in Moscow, the city remained relatively quiet until after the Bolshevik seizure of power in Petrograd (St. Petersburg) on October 25 (November 7, New Style), which was immediately followed by fighting in Moscow. Military cadets held out for a time in the Kremlin, but by November 3 (16, N.S.) they were overcome and Bolshevik power was firmly established.

The Bolshevik Revolution

Moscow in the Soviet period. In March 1918 Lenin and the Soviet government moved to Moscow, which thereby resumed its former status as capital. This status was formally ratified on Dec. 30, 1922, when the first All-Union Congress of Soviets met in the Bolshoi Theatre and passed the legislation setting up the Union of Soviet Socialist Republics. In the civil war period Moscow, like other Soviet cities, suffered greatly, with grave food shortages, loss of population (falling to 1,027,300 in 1920), and reduction of industry. In the years following the final establishment of Soviet power and peace, recovery was swift, and the beginning of the series of five-year plans in 1928 brought great industrial progress. The city's existing plant and labour force formed one of the main springboards for industrialization elsewhere in the U.S.S.R. Between the censuses of 1926 and 1939, Moscow once more doubled its population, from 2,029,425 to 4,182,916 (within the 1959 boundaries). Priority in investment went to industry, and housing construction was very limited; as a consequence, exceptional overcrowding of existing housing developed, with extremely high population densities.

During World War II, the Germans in late 1941 reached the outskirts of Moscow, less than 25 miles from the Kremlin. Many factories were evacuated, together with much of the government. From October 20 the city was declared to be in a state of siege. Its remaining inhabitants built and manned antitank defenses, while the city was bombarded from the air. A desperate counterattack on December 6 threw the German forces back from the outskirts and saved Moscow. Recovery was quick after the war, with further growth of the city's economy. Two major events have marked the city's progress: in 1947, two years after the war's end, Moscow celebrated its 800th anniversary, and in 1980 it hosted the Summer Olympic Games.

In the postwar period, immigration to Moscow caused a housing shortage that reached grave proportions in the 1950s; the population density within the Garden Ring surpassed 132,000 persons per square mile (51,000 per square kilometre) by 1959. Under Khrushchev a major construction program was initiated. Much of the old housing, often single storied and made of wood, was cleared, and extensive new tracts of large apartment buildings sprang up around the historic core of the city. Considerable urban renewal took place in the central areas, and high-rise buildings now dominate the skyline.

In 1935 a far-reaching development plan for Moscow was formulated; but the plan devised in 1960, in which adjacent satellite towns were incorporated into the city, was even more ambitious than the earlier plan. Under this plan urban growth was to be contained within the Moscow Ring Road, and residential and industrial zones and greenbelts were carefully designated. Implementation of this plan was instrumental in alleviating housing shortages, reducing traffic congestion, and improving air quality in the city centre. By the late 1970s, however, urban growth had outstripped original predictions, and in the 1980s planned urban expansion was initiated beyond the Ring Road.

In August 1991 Moscow was the scene of a coup attempt by hard-line Communists against a reform-minded president, Mikhail Gorbachev. The coup failed but was followed within months by the dissolution of the U.S.S.R.

Post-Soviet Moscow. As the capital of post-Soviet Russia, Moscow was at the centre of the nation's historic transformation. As in other parts of Russia, industrial output dropped sharply, unemployment and underemployment increased, and living standards fell for many. Moscow remained Russia's chief financial and research centre, and its service sector expanded rapidly, but not enough to compensate for the industrial decline. Meanwhile, the criminal activity, including organized crime, increased.

In October 1993 violence broke out in the city when members of the Russian parliament launched an armed revolt against the government of President Boris Yeltsin. Many lives were lost when the rebels attempted to occupy the television tower and studios at Ostankino. The Russian military bombarded the parliament building and eventually put down the revolt. In 1999 bombings in Moscow and other cities killed dozens of people. The government attributed the bombings to Chechen separatists.

Meanwhile, a financial crisis in 1998 caused bank failures in Moscow and a devaluation of the Russian currency. Economic hardship continued into the 21st century for many, and the city faced the continuing challenges of improving living standards for a majority of its residents and fighting organized crime. BIBLIOGRAPHY. A comprehensive single-volume reference source is ALEKSEĬ L. NAROCHNITSKIĬ (ed.), *Moskva—entsiklopediia* (1980), an encyclopaedia containing several topical articles with bibliographies and approximately 5,000 shorter entries, of which more than 1,000 are biographical. LEO GRULIOW, *Moscow* (1977); HENRI CARTIER-BRESSON, *The People of Moscow* (1955); JAN LUCAS, *Moscow: A Book of Photographs* (1964); and KAREL NEUBERT, *Portrait of Moscow* (1964), are interesting pictorial works. The following differ in the depth of coverage, but most include at least one informative map: EVAN MAWDSLEY and MARGARET MAWDSLEY (eds.), *Moscow and Leningrad* (1980), with a street atlas; *Moscow and Leningrad* (1985), from the Berlitz series; IURIĬ FEDOSIUK, *Moskva v kol'tse Sadovykh* (1983); and *Baedeker's Moscow,* text by BERNHARD POLLMAN, trans. from German (1987), the last two providing detailed descriptions of the central parts of the city.

Studies of the city's geography and economy include LESLIE SYMONS *et al.*, *The Soviet Union: A Systematic Geography* (1983), a work with useful bibliographies; IULIAN G. SAUSHKIN and V.G. GLUSHKOVA, *Moskva sredi gorodov mira* (1983), an analysis of economic geography, comparing Moscow to other major cities of the socialist world; YURI SAUSHKIN, *Moscow* (1966; originally published in Russian, 1964), a geographical-historical survey of the city; and ANATOLIĬ P. TSARENKO and EVGENIĬ A. FEDOROV, *Moskovskiĭ metropoliten imeni V.I. Lenina* (1984), a reference work devoted entirely to the Moscow subway.

Moscow's architecture is treated by KATHLEEN BERTON, *Moscow: An Architectural History* (1977), an illustrated survey; and ANDREĬ V. IKONNIKOV, *Kamennaia letopis' Moskvy* (1978), a detailed architectural guide, with maps. M.A. IL'IN, *Moscow: Monuments of Architecture of the 14th–17th Centuries* (1973), and *Moscow: Monuments of Architecture 18th–the First Third of the 19th Century,* 2 vol. (1975); and E. KIRICHENKO, *Moscow: Architectural Monuments of the 1830–1910s* (1977), contain photographs with explanatory texts in both English and Russian. ALBERT J. SCHMIDT, *The Architecture and Planning of Classical Moscow: A Cultural History* (1989), treats the period before and after the major fire of 1812 in the context of the classicism of other Russian and European cities. O.A. SHVIDKOVSKY (ed.), *Building in the USSR, 1917–1932* (1971), focuses on constructionist design. V. KIRILLOV, *Arkhitektura russkogo moderna* (1979); and ANDREĬ V. IKONNIKOV, *Arkhitektura Moskvy, XX vek* (1984), analyze 20th-century architecture. M.V. POSOKHIN (ed.), *Pamiatniki arkhitektury Moskvy: Kreml', Kitaĭ-gorod, tsentral'nye ploshchadi,* 2nd rev. ed. (1983), describes major historical architectural complexes, including the Kremlin.

A historical study of Moscow's culture may be found in ARTHUR VOYCE, *Moscow and the Roots of Russian Culture* (1964, reissued 1972). Cultural treasures in the museums of the Moscow area are described in VLADIMIR CHERNOV and MARCEL GIRARD, *Splendours of Moscow and Its Surroundings,* trans. from French (1967); N.N. VORONIN (ed.), *Palaces and Churches of the Kremlin* (1966); ARTHUR VOYCE, *The Moscow Kremlin: Its History, Architecture, and Art Treasures* (1954, reprinted 1971); BORIS A. RYBAKOV, *Treasures in the Kremlin* (1962); and DAVID DOUGLAS DUNCAN, *Great Treasures of the Kremlin,* rev. ed. (1968, reissued 1979).

INSTITUT ISTORII (AKADEMIIA NAUK SSSR), *Istoriia Moskvy,* 6 vol. in 7 (1952–59), is a comprehensive work on Moscow's historic development, including detailed analyses of the economy, culture, architecture, public health, and other aspects. Also informative is S.S. KHROMOV *et al.* (eds.), *History of Moscow: An Outline,* trans. from Russian (1981). The following are special studies: ROBERT EUGENE JOHNSON, *Peasant and Proletariat: The Working Class of Moscow in the Late Nineteenth Century* (1979); LAURA ENGELSTEIN, *Moscow, 1905: Working-Class Organization and Political Conflict* (1982); DIANE KOENKER, *Moscow Workers and the 1917 Revolution* (1981); and CATHERINE MERRIDALE, *Moscow Politics and the Rise of Stalin: The Communist Party in the Capital, 1925–32* (1990), a political history of the city during an important period. P.P. ANDREEV *et al.*, *Moskva za 50 let Sovetskoĭ vlasti, 1917–1967* (1968), is a survey of the first 50 years of Soviet power. (K.B.M./Ed.)

Moses

Moses (Hebrew: Moshe) was the gifted Hebrew leader who, in the 13th century BCE (before the Common Era, or BC), delivered his people from Egyptian slavery. In the Covenant ceremony at Mt. Sinai, where the Ten Commandments were promulgated, he founded the religious community known as Israel. As the interpreter of these Covenant stipulations, he was the organizer of the community's religious and civil traditions. In the Judaic tradition, he is revered as the greatest prophet and teacher, and Judaism has sometimes loosely been called Mosaism, or the Mosaic faith, in Western Christendom. His influence continues to be felt in the religious life, moral concerns, and social ethics of Western civilization, and therein lies his undying significance.

THE HISTORICAL PROBLEM

Historical views of Moses. Few historical figures have engendered such disparate interpretations as has Moses. Early Jewish and Christian traditions considered him the author of the Torah ("Law," or "Teaching"), also called the Pentateuch ("Five Books"), comprising the first five books of the Bible, and some conservative groups still believe in Mosaic authorship.

Opposing this is the theory of the German scholar Martin Noth, who, while granting that Moses may have had something to do with the preparations for the conquest of Canaan, was very skeptical of the roles attributed to him by tradition. Although recognizing a historical core beneath the Exodus and Sinai traditions, Noth believed that two different groups experienced these events and transmitted the stories independently of each other. He contended that the biblical story tracing the Hebrews from Egypt to Canaan resulted from an editor's weaving separate themes and traditions around a main character Moses, actually an obscure person from Moab.

View of Martin Noth

This article, following the lead of the biblical archaeologist and historian W.F. Albright, presents a point of view that falls somewhere between these two extremes. While the essence of the biblical story (narrated between Exodus 1:8 and Deuteronomy 34:12) is accepted, it is recognized that, during the centuries of oral and written transmission, the account acquired layers of accretions. The reconstruction of the documentary sources of the Pentateuch by literary critics is considered valid, but the sources are viewed as varying versions of one series of events (see BIBLICAL LITERATURE AND ITS CRITICAL INTERPRETATION). Other critical methods (studying the biblical text from the standpoint of literary form, oral tradition, style, redaction, and archaeology) are equally valid. The most accurate answer to a critical problem is therefore likely to come from the convergence of various lines of evidence. The aid of critical scholarship notwithstanding, the sources are so sketchy that the man Moses can be portrayed only in broad outline.

The date of Moses. According to the biblical account, Moses' parents were from the tribe of Levi, one of the groups in Egypt called Hebrews. Originally the term Hebrew had nothing to do with race or ethnic origin. It derived from Habiru, a variant spelling of Ḫapiru (Apiru), a designation of a class of people who made their living by hiring themselves out for various services. The biblical Hebrews had been in Egypt for generations, but apparently they became a threat, so one of the pharaohs enslaved them. Unfortunately, the personal name of the king is not given, and scholars have disagreed as to his identity and, hence, as to the date of the events of the narrative of Moses. One theory takes literally the statement in I Kings 6:1 that the Exodus from Egypt occurred 480 years before Solomon began building the Temple in Jerusalem. This occurred in the fourth year of his reign, about 960 BCE; therefore, the Exodus would date about 1440 BCE.

This conclusion, however, is at variance with most of the biblical and archaeological evidence. The storage cities Pithom and Rameses, built for the pharaoh by the Hebrews, were located in the northeastern part of the Egyptian delta, not far from Goshen, the district in which the Hebrews lived. It is implicit in the whole story that the pharaoh's palace and capital were in the area, but Thutmose III (the pharaoh in 1440) had his capital at Thebes, far to the south, and never conducted major building operations in the delta region. Moreover, Edom and Moab, petty kingdoms in Transjordan that forced Moses to circle east of them, were not yet settled and organized. Finally, as excavations have shown, the destruction of the cities the Hebrews claimed to have captured occurred about 1250, not 1400.

Inasmuch as tradition figured about 12 generations from Moses to Solomon, the reference to 480 years is most likely an editorial comment allowing 40 years for each generation. Since an actual generation was nearer 25 years, the most probable date for the Exodus is about 1290 BCE. If this is true, then the oppressive pharaoh noted in Exodus (1:2–2:23) was Seti I (reigned 1318–04), and the pharaoh during the Exodus was Ramses II (*c.* 1304–*c.* 1237). In short, Moses was probably born in the late 14th century BCE.

YEARS AND DEEDS

The formative years. One of the measures taken by the Egyptians to restrict the growth of the Hebrews was to order the death of all newborn Hebrew males. According to tradition, Moses' parents, Amram and Jochebed (whose other children were Aaron and Miriam), hid him for three months and then set him afloat on the Nile in a reed basket daubed with pitch. The child, found by the pharaoh's daughter while bathing, was reared in the Egyptian court. While many doubt the authenticity of this tradi-

tion, the name Moses (Hebrew Moshe) is derived from Egyptian *mose* ("is born") and is found in such names as Thutmose ([The God] Thoth Is Born). Originally, it is inferred, Moses' name was longer, but the deity's name was dropped. This could have happened when Moses returned to his people or possibly even earlier, because the shortened form Mose was very popular at that time.

The young prince or courtier

Moses' years in the court are passed over in silence, but it is evident from his accomplishments later that he had instruction in religious, civil, and military matters. Since Egypt controlled Canaan (Palestine) and part of Syria and had contacts with other nations of the Fertile Crescent, Moses undoubtedly had general knowledge of life in the ancient Near East. During his education he learned somehow that he was a Hebrew, and his sense of concern and curiosity impelled him to visit his people. According to the biblical narrative, Moses lived 120 years and was 80 when he confronted Pharaoh, but there is no indication how old he was when he went to see the Hebrews. Later Jewish and Christian tradition assumed 40-year periods for his stay in the Egyptian court, his sojourn in Midian, and his wilderness wanderings.

Most likely Moses was about 25 when he took the inspection tour among his people. There he saw the oppressive measures under which they laboured. When he found an Egyptian taskmaster beating a Hebrew, probably to death, he could control his sense of justice no longer. After checking to make sure that no one was in sight, he killed the tough Egyptian overlord. As a prince in the court, Moses was probably in excellent physical condition, and apparently he knew the latest methods of combat.

The flush of victory pulled Moses back the next day. He had removed one threat to his people and was determined to assist them again. This time, however, he found two Hebrews fighting. After parting them, he questioned the offender in an attempt to mediate the disagreement. Two questions jolted him: "Who made you a prince and a judge over us? Do you intend to kill me as you killed the Egyptian?" The confidence of the self-appointed deliverer turned into fear. One of his own knew his "secret" and soon Pharaoh would, too. Realizing that he would have to flee, he went to Midian (mainly in northwest Arabia).

Moses in Midian. In noting the flight to Midian the narrative says nothing of the difficulties involved. Like Sinuhe, the Egyptian court official whose flight in about 1960 BCE was narrated in a famous story, Moses undoubtedly had to filter through the "Wall of the Ruler," a series of forts at the eastern border, approximately where the Suez Canal is now located. From there he made his way southeast through very desolate country. Unfortunately, the Bible does not specify the part of Midian in which Moses resided. Midian proper was east of the Gulf of Aqaba, in the northern section of Hejaz in Arabia, but there is evidence that some of the Midianite clans crossed over the Arabah (the great valley south of the Dead Sea) and settled in the eastern and southern sections of the Sinai Peninsula.

While Moses was resting at a well, according to the biblical account, seven daughters of the Midianite priest Jethro came to water their father's flocks. Other shepherds arrived and drove the girls away in order to water their own flocks. Again Moses showed his courage and prowess as a warrior because he took on the shepherds (perhaps with the girls' help) and routed them. Moses stayed on with Jethro and eventually married Zipporah, one of the daughters. In assuming the responsibility for Jethro's flocks, Moses roamed the wilderness looking for pasture.

The burning bush

One day at the base of a mountain, his attention was attracted by a flaming bush, but, oddly, it was not consumed. He had seen bushes brilliant with flamelike blossoms, but this phenomenon was different, and so he turned aside to investigate it. Before he could do so, he was warned to come no closer. Then he was ordered to remove his sandals because he was standing on holy ground.

Regardless of how one interprets the burning bush, the important fact is that Moses was conscious of an encounter with Deity. This God, who claimed to be the God of Abraham, Isaac, and Jacob, was calling him to deliver the Hebrews from Egypt. Although on his own he had previously been zealous to help his own people, now that he was being commissioned to deliver them he expressed doubt concerning his qualifications. The underlying reason was probably fear—he had fled from Seti I, and he did not relish confrontation with Ramses II. God reassured Moses that in the future he and the Hebrews would worship at this mountain. Then Moses asked to know the name of the Deity commissioning him. The God of the fathers had been known mostly as El 'Elyon (God Most High) or El Shaddai (God of the Mountain or Almighty God), but he identified himself to Moses as Yahweh and gave instructions that he was to be called by his new name from then on. As the causative form of the verb "to be," Yahweh means He Who Creates (Brings Into Being). This revelation enabled Moses to understand the God of the Hebrews as the sovereign Lord over nature and the nations of the world.

Even after further assurances, Moses was still reluctant to accept Yahweh's call; therefore, he pleaded for release because he was a stammerer. Yahweh acknowledged the defect but promised to help him express himself. Awed by his assignment, Moses made a final desperate plea, "Oh, my Lord, send, I pray, some other person." Although angry at Moses, Yahweh would not yield. Moses would still be Yahweh's representative, but his golden-tongued brother Aaron would be the spokesman. Apparently Moses was ready to play the role of God to Pharaoh providing Aaron would serve as his prophet. He returned to Jethro and requested permission to visit his people in Egypt, but he did not disclose that he had been commissioned by Yahweh.

Moses and Pharaoh. Ramses II became king as a teenager and reigned for 67 years. He aspired to defeat the Hittites and control all of Syria, but in the fifth year of his reign Ramses walked into a Hittite trap laid for him at Kadesh, on the Orontes River in Syria. By sheer determination he fought his way out, but in the light of his purpose the battle was an utter failure. Yet Ramses, like all the pharaohs, claimed to be divine; therefore, the defeat had to be interpreted as a marvellous victory in which he alone subdued the Hittites. His wounded ego expressed itself in massive building operations throughout Egypt, and before his reign ended the boast of his success literally filled acres of wall space.

Confrontation with Ramses

It was probably only a few years after the Kadesh incident that Moses and Aaron confronted Ramses with their demand, "Thus says the Lord, the God of Israel, 'Let my people go.' " As a god in human form Ramses was not accustomed to taking orders from lesser gods, let alone an unknown like Yahweh. "Who is the Lord," he inquired, "that I should heed his voice and let Israel go? I do not know the Lord, and moreover I will not let Israel go." Thus the stage was set for a long struggle between a distrustful ruler with an outsize ego and a prophet with a new understanding of Yahweh and his power.

Ramses increased the oppression of the Hebrews by the fiendish plan of requiring them to gather the straw binder for the bricks and still produce the same quota each day. Some of the Hebrews rebuffed Moses, and in frustration he asked Yahweh, "Why didst thou ever send me?" Moses' doubt was allayed by Yahweh's promise to take action against Pharaoh. Scholars differ widely concerning the narrative about the plagues. Some claim that three sources have been combined, but more recent scholarship finds only the two traditions. While granting that some of the plagues had a core of historicity, older critics tended to discount the present accounts as fantastic stories with pious decorations. A recent school of research suggests that, notwithstanding some later additions, all the plagues probably had a historical core.

The basic cause, according to one interpretation, was an unusually high flooding of the Nile. The White Nile originates in the lake region of east central Africa, known today as Uganda. The flow is fairly even throughout the year because of consistent equatorial rains. The Blue Nile, on the other hand, originates in the headwaters of the Ethiopian highlands, and it varies from a small stream to a raging torrent. At the time Moses was bargaining with Ramses, excessively heavy summer rains in Ethiopia

washed powdery, carmine-red soil from the slopes of the hills. Around the Lake Tana region the blood-red torrent picked up bright red algae (known as flagellates) and their bacteria. Since there were no dams at that time, the Nile flowed blood-red all the way to the Mediterranean. It probably reached the delta region in August. Thus, this rare natural event, it is held, set in motion a series of conditions that continued until the following March.

During these months Moses used the plagues of the frogs, gnats, mosquitoes, cattle murrain, boils, hail, locusts, and thick darkness to increase the pressure on Ramses. At first the King was adamant. The Hebrews were not the only disgruntled slaves, and, if he agreed to let them go, then other groups would want the same privilege. To protect his building program, he had to suppress the slave rebellion at its outset. Yet he could not discount the effect of the plagues, and grudgingly he began to acknowledge Yahweh's power. As an expedient attempt to restore order, he offered to let the Hebrews sacrifice in Goshen. When this failed, he suggested that they make offerings to Yahweh at the edge of the Egyptian border. Moses, however, insisted on a three-day journey into the wilderness. Pharaoh countered by allowing the Hebrew men to make the journey, but this, too, was rejected. As his final offer Pharaoh agreed to let the people go. He would keep the livestock, however, as the guarantee of their return. Moses spurned the condition, and in anger Pharaoh drove him out. After nine rounds with Pharaoh it appeared that the deliverance of the Hebrews was no nearer, but, in contrast to his earlier periods of doubt and frustration, Moses showed no despair. Apparently he had an inner assurance that Pharaoh would not have the last word.

From Goshen to Sinai. Chapters 11–14 of Exodus comprise an exceedingly complex section, and at times the traditions have contradictory statements. The drama is more blurred than usual, and scholars vary tremendously in their interpretation of the material. One tradition notes that Pharaoh was shaken when death took his son and that he ordered the Hebrews to leave. Another source indicates that Moses used the period of mourning for the first-born son as the occasion for fleeing secretly from the country. In either case, it is clear that Pharaoh finally had his forces pursue the Hebrews. Although tradition interpreted the Hebrew text to claim that about 2,000,000 people left Egypt, interpretation by critical methods reduces the number to 15,000 or so.

Yahweh's victory at the Reed Sea

The Egyptian army cornered them at the Sea of Reeds (papyrus), which barred their exit to the east. Later Jewish tradition understood the body of water to be the Red Sea, and this erroneous interpretation persists today, even in some of the most recent English translations of the Bible. Scholars disagree as to the precise location of the Reed Sea, but, since papyrus grows only in freshwater, it was most probably a shallow lake in the far northeastern corner of Egypt.

Hemmed in by the Egyptians, the people vented their complaints on Moses. According to one tradition, Moses shared their uneasiness, and he called to Yahweh for help. Another account claims that Moses confidently challenged them to be calm and watch for Yahweh's deliverance. A strong east wind blew all night, creating a dry corridor through the lake and permitting the Hebrews to cross. The pursuing Egyptians were destroyed when the waters returned. The timing of this natural event gave the final answer to Pharaoh's arrogant question, "Who is Yahweh?" Safely on the other side, Moses and his sister Miriam led the people in a victory song of praise to Yahweh (Ex. 15:1–21). The style of the poetry is similar to that of 14th-century Canaanite literature, and there is every reason to believe that the poem virtually preserves the original form of the song, with its refrain, "Sing to the Lord, for he has triumphed gloriously; the horse and his rider he has thrown into the sea."

The route of the Hebrews is contested by scholars, but the most likely possibility is the southern route to Jabal Mūsā, the traditional location of Mt. Sinai (Horeb), in the granite range at the southern tip of the Sinai Peninsula. The journey there traversed some very desolate country, and Moses had to contend with bitter complaints about the lack of water and food. Finally, however, he brought the people to "the mountain of God," where Yahweh had appeared to him in the burning bush.

The Covenant at Sinai. During the 14th century BCE the Hittites of Asia Minor made a number of treaties with neighbouring rulers who came under their control. The agreement was not between equals, but between the Hittite king (the suzerain) and a subordinate ruler (the vassal). In the prologue the Hittite ruler described himself as "the great king," the one granting the treaty. Then followed a historical survey of relationships between the Hittite suzerain and his vassal. Special attention to the kindnesses shown the underling by the overlord was intended to remind the vassal of his obligation to abide by the treaty stipulations. The basic requirement was an oath of loyalty. Since Egypt was involved with the Hittites in the international politics of the time, Moses probably learned about the Hittite treaty form during his years in the Egyptian court.

The revelation at Sinai: the Ten Commandments

The appearance of Yahweh in a terrific storm at Mt. Sinai, narrated in chapters 19 and 20 of Exodus, was a revelatory experience for Moses, just as the burning bush had been. Somehow he realized that the Hittite treaty was an accurate analogy of the relationship between Yahweh and the Hebrews. Yahweh had a claim upon them because he had delivered them. The only proper response to his love and care would be a pledge of obedience to his will. Scholars have tended to date the Ten Commandments, or Decalogue (contained in the revelation at Sinai), after the conquest of Canaan, but there is absolutely nothing in these guidelines to indicate their origin in an agricultural context. More likely they were the stipulations in the covenant ceremony at Mt. Sinai.

Because Yahweh was proclaimed the only true God, one of the first commands was appropriately a ban against all other gods. Authorities have debated whether or not this understanding was interpreted as monotheism. Most certainly it was not the philosophical monotheism of later periods, but it was a practical monotheism in that any gods recognized by other nations were under Yahweh's control. Inasmuch as he had brought them into being and authorized their presence in his council, he was Lord over all gods and nations.

Another early command has been taken to mean a ban on making images of other gods, but originally the prohibition applied to representations of Yahweh himself. Worship in the ancient world was unthinkable without some idol or image; therefore, the uniqueness of Moses' restriction is all the more evident. Yahweh is the unimageable Deity who cannot be represented in material forms. Since Yahweh had revealed the meaning of his name to Moses, it was fitting that the Decalogue should also prohibit any magical or unethical use of his name. Undoubtedly the ideas underlying the other commands came from the religious culture of his day, but they were raised to a significantly higher level because of the holy, righteous character of Yahweh. Moses realized that, if the Covenant people were to have a stable, just society, they would have to emulate their God. Concern for his creatures would mean respect for them as persons. Murder, adultery, theft, lying, and covetousness would never be legitimate because they lead to chaos and breakdown of the community. Moreover, inasmuch as Yahweh had been concerned to protect the powerless Hebrews in Egypt, they in turn would have to guarantee justice for the orphans, widows, resident aliens, and any other disadvantaged persons under their jurisdiction.

Interpretations and elaborations

On confirmation of the Covenant, Moses and the people faced the task of living by the stipulations. This called for interpretations of the commands, and so Moses began issuing ordinances for specific situations. Many of these he drew from the case law of his day, but insight as to their selection and application probably came in the "tent of meeting" (a simple sanctuary tent pitched outside the camp), where Yahweh spoke to Moses "face to face, as a man speaks to his friend." Breaches of the Covenant necessitated means of atonement, which in turn meant provision of a priesthood to function at sacrifices and in worship. In short, the rudiments of the whole Hebrew

cult, according to tradition, originated at Sinai. At Jethro's suggestion Moses instituted a system of judges and hearings to regulate the civil aspects of the community. It was at Sinai, perhaps, where the people were organized into 12 tribes.

One of Moses' most remarkable characteristics was his concern for the Hebrews, in spite of their stubborn, rebellious ways. When they reverted to worshipping a golden calf, Yahweh was ready to disown them and begin anew with Moses and his descendants. Moses rejected the offer, however, and later, when pleading for the forgiveness of the people, he even asked to have his own name blotted out of Yahweh's book of remembrance if the Lord would not forgive them.

From Sinai to Transjordan. After leaving Mt. Sinai, Moses faced increasing resistance and frustration, according to the narrative in the book of Numbers. Apparently his virility did not diminish during these years because he took a Cushite woman as his second wife. But Miriam, with the support of Aaron, opposed the marriage. At Kadesh-barnea the pessimistic majority report of the spies who had been sent out to reconnoitre thwarted Moses' desire to march north and conquer the land of Canaan. When he urged the people to reconsider their action they almost stoned him. But here again, according to tradition, Moses interceded for the people with Yahweh, who threatened to destroy them and raise up another and greater nation. In one instance, however, tradition recalled that Moses' anger overrode his compassion. At Meribah, probably in the area of Kadesh-barnea, Moses addressed the complaining people as rebels and struck a rock twice in anger, whereupon water flowed forth for the thirsty people. He had been angry before in defense of Yahweh's name, honour, and cause, but this time his anger stemmed from utter frustration with his contentious people. Although tradition interpreted this lapse as the reason why Yahweh would not permit Moses to enter Canaan, the remarkable fact is that Moses was able to bear up under such continuous pressure.

In Transjordan the new states of Edom and Moab, vassals of the Midianites, rejected Moses' request for passage. He wisely circled east of them and moved north to conquer Sihon, king of the Amorites, and Og, king of Bashan. Moses permitted some of the tribes to settle in Transjordan, a decision that evoked opposition from the Moabites and their Midianite overlords. They hired the Syrian diviner Balaam to put a curse on the Hebrews, but instead he pronounced a blessing. Some scholars interpret this as proof that Balaam was a convert to Yahwism. If this was indeed the case, he must have reverted later on, because the biblical tradition implies that Balaam incited his former employers to weaken the Hebrews by religious seduction. Moses responded to the enmity of the Midianites with a successful holy war against them not long before his death.

Final conflict against the Midianites

As his last official act Moses renewed the Sinai Covenant with those who had survived the wilderness wanderings. From his camp in the Jordan Valley, Moses climbed to a vantage point on Mt. Pisgah. There he viewed the land of promise. The Hebrews never saw him again, and the circumstances of his death and burial remain shrouded in mystery. Tradition claimed that Yahweh buried him in the valley opposite Beth-peor, the shrine of the people's apostasy.

MOSES THE MAN

Although time undoubtedly enhanced the portrait of Moses, a basic picture emerges from the sources. Five times the narratives claim that Moses kept written records (Ex. 17:14; 24:4; 34:27–28; Num. 33:2; and Deut. 31:9, 24–26). Even with a generous interpretation of the extent of these writings, they do not amount to more than a fifth of the total Pentateuch; therefore, the traditional claim of Mosaic authorship of the whole Pentateuch is untenable. Moses formulated the Decalogue, mediated the Covenant, and began the process of rendering and codifying supplemental interpretations of the Covenant stipulations. Undoubtedly he kept some records, and they served as the core of the growing corpus of law and tradition. In a general sense, therefore, the first five books of the Hebrew Bible can be described as Mosaic. Without him there would have been no Israel and no collection known as Torah.

Moses was a gifted, well-trained person, but his true greatness was probably due to his personal experience of and relationship with Yahweh. This former stammering murderer understood his preservation and destiny as coming from the grace of a merciful Lord who had given him another chance. Moses had an understanding spirit and a forgiving heart because he knew how much Yahweh had forgiven him. He was truly humble because he recognized that his gifts and strength came from Yahweh.

The multiple roles of Moses

Because of the uniqueness of his situation, Moses had to function in a number of roles. As Yahweh's agent in the deliverance of the Hebrews, he was their prophet and leader. As mediator of the Covenant, he was the founder of the community. As interpreter of the Covenant, he was an organizer and legislator. As intercessor for the people, he was their priest. Moses had a special combination of gifts and graces that made it impossible to replace him. Although his successor, Joshua, and the priest Eleazar, the son of Aaron, tried to do so, together they did not measure up to him. Later prophets were great men who spoke out of the spirit that Moses had, but they were not called to function in so many roles. As tradition claimed, he was indeed the greatest of the prophets, and, as history shows, few of mankind's great personalities outrank him in influence.

Moss Animals: Phylum Bryozoa

Bryozoa, also called Polyzoa or Ectoprocta, comprises a phylum in which there are probably more than 4,000 extant species. The bryozoans are a widely distributed, aquatic, invertebrate group of animals whose members form colonies composed of numerous units called zooids (hence the term Polyzoa, which means "many animals"). Until the mid-18th century, bryozoans, like corals, were regarded as plants; hence their name, which means "moss animals." Seventy-five years later, the bryozoans were distinguished from the cnidarians, and the characteristic structure of the zooid was first described.

Bryozoans are separated into three classes: Phylactolaemata (freshwater dwelling); Stenolaemata (marine); and Gymnolaemata (mostly marine). The order Cheilostomata (class Gymnolaemata), containing 600 genera, is the most successful bryozoan group.

GENERAL FEATURES

Distribution and abundance. Bryozoan colonies are found in both fresh and salt waters, most commonly as growths or crusts on other objects. Freshwater bryozoans live among vegetation in clear, quiet, or slowly flowing water. Marine species range from the shore to the ocean depths but are most plentiful in the shallow waters of the continental shelf. They cover seaweeds, form crusts on stones and shells, hang from boulders, or rise from the seabed. Bryozoans readily colonize submerged surfaces, including the hulls of ships and the insides of water pipes. A few types of bryozoans form nonattached populations on sandy seabeds.

The zooid walls, which constitute the most permanent portion of the colony, generally are calcareous (*i.e.*, impregnated with calcium carbonate), giving bryozoans a fossil record that dates from the Ordovician onward (*i.e.*, from about 500,000,000 years ago).

Size range and diversity of structure. Bryozoan colonies vary in size. In the gymnolaemate genus *Monobryozoon*, which lives between marine sand particles, a colony consists of little more than a single feeding zooid less than one millimetre (0.04 inch) in height. Colonies of the coralline genus of European seas *Pentapora*, however, can reach one metre (3.3 feet) or more in circumference; a warm-water gymnolaemate genus, *Zoobotryon*, which hangs from harbour pilings, and the freshwater phylactolaemate *Pectinatella* each produce masses that may be one-half metre across. Colonies that form crusts generally cover only a few square centimetres; erect colonies may rise only two to five centimetres (0.8–2 inches).

The texture of the colonies is variable. Some colonies, especially those in fresh water and on seashores, are gelatinous or membranous; others are tufted, with flat fronds (leaflike structures) or whorls of slender branches, whose horny texture results from light deposits of lime in zooid walls. Still other colonies are hard and have calcified skeletons. Such colonies may form rough-surfaced patches or may rise in slender branching twigs (such as those that form a network in the beautiful lace corals; *e.g.*, *Sertella*).

Colonies

The colonies, diverse and complex in structure, are composed of individual modules, or zooids, and each zooid effectively is a complete animal. A bryozoan colony usually has many zooids, which may be of one type or of types that differ both functionally and structurally. Neighbouring zooids are united and may communicate by tiny pores present in the zooids' walls. Zooids capable of feeding have a ring of slender tentacles at one end on which are found cilia (hairlike projections) that propel tiny particles of food toward the zooid mouth. The mouth opens into a digestive tract that is divided into several regions and terminates at an anus, which is outside (but near) the tentacles (hence the name Ectoprocta, meaning "outside anus"). If zooids are disturbed, they withdraw their tentacles inside the body cavity. Only if the zooids have transparent walls, such as in the gymnolaemates *Bowerbankia* and *Membranipora*, is the digestive tract visible. The internal living parts of each zooid—*i.e.*, the nervous and muscular systems, the tentacles, and the digestive tract—are called the polypide.

NATURAL HISTORY

Reproduction and life cycle. Many animals, bryozoans included, have a life cycle that incorporates phases of asexual and sexual reproduction (Figure 1). Asexual reproduction, in which gametes (sex cells) do not participate, produces genetically identical progeny (clones), which separate in larger animals (*e.g.*, sea anemones). In bryozoans, the progeny, called zooids, are produced by an asexual process called budding and almost invariably remain in intimate contact as a colony. As the colony continues to grow by budding, the zooids become sexually mature, producing eggs and spermatozoa. Sexual reproduction, by the production and subsequent fusion of gametes, generates the genetic variability necessary for a species to survive in a habitat that varies from place to place and from time to time. Fertilized eggs develop into larvae.

Some bryozoans also propagate colonies asexually. The cheilostome *Discoporella* has small, nonattached, saucer-like colonies. Groups of zooids at the colony rim detach

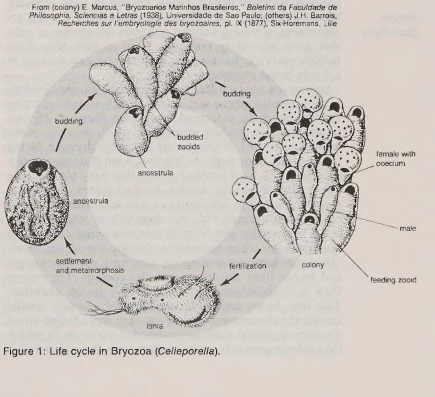

Figure 1: Life cycle in Bryozoa (*Celleporella*).

at special fracture zones and grow into new colonies. The statoblasts (dormant buds) of freshwater bryozoans are another asexual means of reproduction. Asexual reproduction, whether leading to a clone, a colony, or a clone of colonies, is a means of perpetuating and spreading a successful genetic constitution (genotype).

Primary zooid

Budding. The colony formed by asexual budding originates from either a primary zooid (or ancestrula) or a statoblast. The ancestrula is formed by the metamorphosis of a sexually produced larva (Figure 1). New zooids bud from the ancestrula to produce colonies of definite shape and growth habit. In the phylactolaemates, the primitive zooids are cylindrical in form, and the budding pattern results in a branched colony. In more highly evolved phylactolaemates, colonies are compact, and discrete zooids can be recognized only with difficulty. New polypides, which originate by ingrowth of the superficial cell layer, or epithelium, remain suspended within a common colonial coelom, or body cavity.

Among living members of the primitive (and mainly fossil) marine stenolaemates, the long and slender zooids have calcified tubular skeletons. A larva metamorphoses into a hemispherical primary disk (or proancestrula). A cylindrical extension grows from the proancestrula, and the matrix of the colony then is built up by repeated divisions of the zooidal walls. Internal walls of the colony are called septa. The growth and budding zones of the colony are found at its outer edges. Cells from the surface epithelium push inward to produce the polypide, and the septa create a chamber around it. The walled portion of a zooid is called the cystid.

In the gymnolaemates, in which the zooids frequently are flattened, budding occurs as transverse septa form and cut off parts of the primary zooid (or any other parent zooid). As each bud enlarges to become a zooid, a polypide forms inside. In the order Cheilostomata, budding usually produces rows of identical zooids that radiate from the primary zooid. The rows divide periodically to keep pace with the increasing circumference of the colony. Successive zooids in a row are separated by transverse septa, but adjoining rows are separated by double walls. Interzooidal pores are present both in the walls and in the septa.

Reproduction. Mature gymnolaemate and phylactolaemate zooids are generally hermaphroditic (*i.e.,* both male and female reproductive organs in the same zooid); small gonads are attached in clusters to the membrane that lines the body wall or the polypide. In a few species the individual zooids are of one sex only. In these circumstances, female zooids are usually larger (*e.g.,* the cheilostome *Reptadeonella*), male zooids may be simpler (*e.g.,* the cheilostome *Hippoporidra*), or female and male reproductive zooids each may be distinguishable from ordinary feeding zooids (*e.g.,* the cheilostome *Celleporella*). Among living stenolaemates most zooids contain only testes (male gonads). The few female zooids enlarge to form spacious brood chambers, which are called gonozooids. During development, a young embryo squeezes off groups of cells that form secondary embryos; these in turn may form tertiary embryos. In this way, many larvae can develop in a single brood chamber.

Brood chambers

Among the phylactolaemates, the fertilized egg develops in an internal embryo sac; a larva, which already contains the first polypide, is formed there, then liberated. Phylactolaemates also produce statoblasts, which develop on the funiculus, a cord of tissue that links the stomach to the lining of the body wall. As it grows, each statoblast is surrounded by a hard protective case that may also include an air-filled float and slender, hooked spines. Statoblasts usually develop in late summer and are liberated as the colony disintegrates with the approach of winter. Statoblasts survive dry and freezing conditions and can initiate a new colony when favourable climatic conditions recur.

In gymnolaemates one oocyte at a time usually enlarges and bursts from the ovary into the coelom. The oocyte then is fertilized and transferred to a brood chamber. This may be an undifferentiated part of a zooid; usually among the cheilostomes, however, each reproducing zooid develops a special globular or hooded ooecium in which the embryo grows. In most cheilostomes the egg at transfer has sufficient yolk to nourish its developing embryo, but in the cheilostomes *Bugula* and *Celleporella* the egg, which is small at transfer, establishes a pseudoplacenta with tissues of the mother zooid and receives nourishment as the embryo develops. The ciliated larvae, spherical and often about ¼ millimetre in diameter, are liberated when fully developed and may swim first toward the light and thus away from the parent colony; later, however, the larvae avoid light as they seek a place in which to settle. Metamorphosis of larvae to adults occurs within a few hours after larvae are liberated.

In certain genera (*e.g., Membranipora*) of the class Gymnolaemata, each zooid produces many tiny eggs, which are fertilized by sperm from another zooid as they are shed directly into the sea. The fertilized eggs develop into triangular, bivalved larvae, known as cyphonautes, which for several weeks live among, and feed on, plankton. Larvae from brood chambers and cyphonautes settle in a similar way; *i.e.,* both locate a suitable surface and explore it with sensory cilia. Attachment is achieved by flattening a sticky holdfast, which pulls the larva down on top of it. As metamorphosis proceeds, larval organization degenerates, and the first polypide develops inside a primary zooid.

Ecology. *Freshwater bryozoans.* Freshwater bryozoans live mainly on leaves, stems, and tree roots in shallow water. Before drinking water was filtered, they regularly polluted water supply pipes. Though not uncommon, freshwater bryozoans are inconspicuous in pools, lakes, or gently flowing rivers, especially in slightly alkaline water.

Bryozoans along shores

Marine bryozoans. The most familiar marine bryozoans are those that inhabit shores, though they occur in greater numbers below tidemarks. Dredge hauls of stones and shells yield colonies in abundance. Colonies also occur on the ocean bed, even at great depths, but the frequently muddy bottom of the oceanic abyss is an unfavourable habitat. A few species tolerate hypersaline or brackish waters. The predominantly marine Gymnolaemata have a few freshwater representatives; *e.g., Paludicella.*

Shallow, sheltered channels that have currents but are protected from severe waves are typical bryozoan habitats. Open coastlines support fewer species, but noncalcareous species occur abundantly on intertidal algae in temperate waters. A familiar genus is the lacy gymnolaemate *Membranipora*, which is found throughout the world and is well adapted to living on kelp weeds at, and just below, the low-water mark. Although the zooid walls of *Membranipora* colonies are calcified, they contain flexible joints, which allow the colony to bend as the alga sways in the waves. *Membranipora,* which may cover large areas with a million or more zooids, always grows predominantly toward the youngest part of an algal frond. Overhangs, which form when soft rock erodes along a shoreline, as well as the shaded pilings of jetties and piers are other favoured bryozoan habitats. Since they do not require light and can grow in dark places, bryozoans can avoid competition from algae that could smother them. Sea slugs and sea spiders appear to be the principal predators of bryozoans.

Food and feeding. Bryozoans feed on minute planktonic particles that are captured by the tentacles (from eight to about 30), which, in marine species, spread as a funnel with the mouth at its vertex (Figure 2). The beating of long lateral cilia draws water into the top of the funnel and propels it out between the tentacles. Particles are projected toward the mouth, and those that would leave the funnel between the tentacles appear to be flicked back into it by a reversal of the ciliary beat. Shorter cilia on the inner face of the tentacles carry food particles toward the mouth without the involvement of mucus; from there they are sucked into the pharynx. Diatom shell valves are separated or broken in the gizzard, when present. Digestion and absorption occur in the stomach, and indigestible remains are compacted by rotation and expelled as fecal pellets. Freshwater bryozoans have more tentacles, which are disposed in a crescent shape, the ends of which project behind the mouth.

FORM AND FUNCTION

Zooids. Although zooid appearance and structure vary considerably from class to class, all conform to a basic

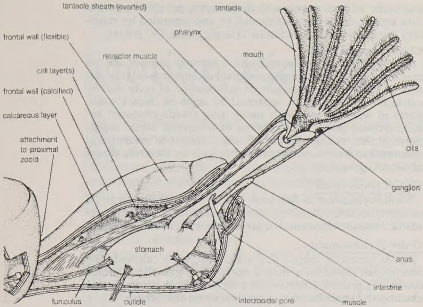

Figure 2: Characteristics of the bryozoan zooid with the lophophore protruded.

From *Treatise on Invertebrate Paleontology*, part G, Bryozoa revised, vol. 1, fig. 4, p. 8; courtesy of The Geological Society of America and University of Kansas

plan (Figure 2). Zooids are rarely longer than one millimetre; the most primitive are cylindrical, suggesting that the bryozoan ancestor was probably wormlike. The skeleton is external, ranging from a thin, cuticular cover to a thick, calcified layer. The tentacles, collectively termed the lophophore, are raised above the zooid on a slender extension of the body wall (the tentacle sheath, or introvert). When not spread for feeding, the tentacles are withdrawn into the coelom in a movement that involves the inrolling of the tentacle sheath as the mouth and tentacles are pulled down within by the action of paired retractor muscles. Eversion of the tentacle sheath and tentacles is effected by raising the hydrostatic pressure of the body fluid. Phylactolaemates have a muscular and contractile body wall for this purpose; in gymnolaemates the wall is nonmuscular but in whole or in part flexible, so that it can be pulled inward by the body musculature associated with it (parietal muscles). In most extant bryozoans the zooids are not cylindrical but flat, with rigid side walls. The upward-facing or frontal wall either remains flexible or has concealed below its calcified surface a membranous cavity, the ascus (sac), which can be inflated with seawater, thereby compressing the body fluid. At the free end of a cylindrical zooid or near the distal end of a flat zooid is an opening known as the orifice, through which the tentacle sheath and tentacles emerge; in cheilostome gymnolaemates the orifice has a closable lid, the operculum. Stenolaemate zooids are different, and the walls have the form of a slender calcareous tube, no part of which can be inflected to evert the tentacles; instead, body fluid is forced from one part of the zooid to another by muscles.

Digestive system

The digestive canal forms a deep loop; the pharynx descends to the stomach, the anterior part of which forms a gizzard in some genera, such as the gymnolaemate *Bowerbankia;* the rectum rises from the stomach, and the anus is situated just outside the lophophore. Respiratory, circulatory, and excretory systems are absent in bryozoans. The reproductive organs (ovary, testes) are sited on the lining of the body wall or on the funiculus, a cord of tissue that links the stomach to the lining of the body wall and distributes nutrients throughout the colony. The polypide degenerates periodically during the lifetime of a zooid, and a compact mass, called a brown body, frequently remains in its place. A new polypide soon differentiates from living cells of the cystid.

Zooid polymorphism exists among the cheilostome colonies, and the operculum seems to have been significant in the evolution of the specialized zooids of this order. The avicularium type of zooid has a small body and a rudimentary polypide; the operculum, however, is proportionally larger, has strong adductor (closing) muscles, and has become, in effect, a jaw. Avicularia are found among normal zooids but usually are smaller and attached to normal zooids, as in the gymnolaemate *Schizoporella.* In the gymnolaemate *Bugula* the avicularia are movable on short stalks and closely resemble miniature birds' heads—hence the name avicularium. Another specialized form of zooid is the vibraculum, in which the operculum has become a whiplike seta (*i.e.,* hairlike projection). The functions of avicularia and vibracula are not clearly known, but both types of zooids may help to keep the colony free from particles and epizoites (*i.e.,* organisms that attach to the surface of the colony but do not parasitize it).

Colonies. Despite their ill-defined shape, colonies, at least in extant bryozoans, are not just aggregations of zooids but whole organisms having an integrated physiology and behaviour that appear to be coordinated to some extent. The agency for integration is the system of interzooidal pores (Figure 2) and the cells that traverse them. Most conspicuous are those of the funiculus, which in gymnolaemates becomes a colonial network capable of distributing nutrients to nonfeeding areas, such as the growing edge. The nervous system of bryozoans consists of a small ganglion (brain) positioned between the mouth and the anus that supplies nerves to the zooidal organs. In some bryozoans there is also a colonial network that unites the zooids through the interzooidal pores. A stimulus that causes the lophophore to withdraw in a zooid of the gymnolaemate *Membranipora* almost instantaneously evokes the same response nearby, and nerve impulses can at that time be recorded. Nevertheless, to a large extent the colony is not individualistic; for example, it usually has no definite shape, can grow in any direction, and can be partially destroyed without harm to the rest. It may live a few months or a couple of years, or it may be theoretically immortal, its life of continual budding terminated only by some catastrophe.

EVOLUTION AND PALEONTOLOGY

The Bryozoa have a long history. From the Lower Ordovician (500,000,000 to 430,000,000 years ago) onward, most limestone formations, especially those with shale alternations, are rich in bryozoan fossils. The skeletons of calcified bryozoans are easily preserved. Stenolaemates are abundant fossils; after their appearance in the Upper Jurassic (140,000,000 years ago), cheilostome fossils also are abundant. The soft-bodied phylactolaemates, on the other hand, have left no fossil record, and fossilized ctenostomes are rare but long antedate the cheilostomes.

Oldest bryozoan fossil

The most ancient bryozoans are stenolaemates from the Lower Ordovician of the United States and Russia (Arenig series, about 488,000,000 years old); both cystoporate and trepostome stenolaemates have been found. The ceramoporoids, a group belonging to the order Cystoporata, flourished during the Ordovician and evidently were the progenitors of a more advanced group, the fistuliporoids, which were successful until the end of the Permian (280,000,000 to 225,000,000 years ago).

Dominant among the early Paleozoic (570,000,000 to 225,000,000 years ago) stenolaemates, however, was the order Trepostomata, which evolved rapidly during the Ordovician and attained its peak during the upper part of the same system. The long, slender zooids of trepostomes grew together to form large, solid colonies. As a zooid grew longer and longer, diaphragms (or transverse partitions) were deposited. The trepostomes declined in importance after the Ordovician, perhaps as a result of competition from the cryptostomes, and were extinct by the close of the Permian (225,000,000 years ago).

Cryptostomes evolved rapidly during the Ordovician. They were similar to the trepostomes but evolved freely erect, leaflike, branching or lacy colonies in the ptilodictyoids, or branching in rhabdomesoids, and were the dominant bryozoans from the start of the Devonian until the Permian (395,000,000 to 225,000,000 years ago). For reasons not yet clear, the cryptostomes dwindled and became extinct soon after the end of the Paleozoic Era (225,000,000 years ago).

The Cyclostomata arose in the Paleozoic, flourished during the Jurassic (190,000,000 to 136,000,000 years ago) and Lower Cretaceous, and still survive.

The ctenostomes (class Gymnolaemata) have left a sparse fossil record. During the Late Jurassic Period they appar-

ently gave rise to the complex and successful cheilostomes. The early cheilostomes had encrusting flat zooids similar to some of their contemporary ctenostomes, but with side walls that were calcified. This type of organization, termed anascan (meaning without an ascus), permitted inflexion of the front wall to evert the lophophore but seemed to offer little protection. The Ascophora (ascus bearers) evolved in the Late Cretaceous by calcifying the membranous front but preserving its hydrostatic function by a flexible infolding (ascus) below the wall. The parietal muscles attach to the ascus and pull its lower surface into the coelom to evert the lophophore, while the ascus itself fills with seawater.

CLASSIFICATION

Distinguishing taxonomic features. Although both colony type and zooid morphology are used to classify bryozoans, zooidal characters are more reliable. The cylindrical zooids are of rather uniform appearance in the stenolaemates, making classification difficult. Wall structure and the morphology of the embryo chambers are important taxonomic characters. In cheilostomes the skeletal features of the zooids, particularly the presence, extent, and structure of the frontal wall—together with shape of the orifice, type of ooecia, and zooid polymorphism—provide the most important distinguishing taxonomic criteria. Among ctenostomes and phylactolaemates, whose zooids lack skeletal features, colony form is more important. Statoblasts are of taxonomic value. Internal characters have been used less, but the presence or absence of a gizzard, number of tentacles, and colour of developing embryos are of taxonomic significance.

Annotated classification.

PHYLUM BRYOZOA

Sedentary, aquatic invertebrates; form colonies of zooids by budding; each zooid with circular or crescentic lophophore surrounding a mouth from which slender, ciliated tentacles arise; anterior part of body forms an introvert within which the lophophore can be withdrawn; alimentary canal deeply looped; anus opens near mouth but outside lophophore; excretory organs and a blood vascular system absent; each zooid secretes a rigid or gelatinous wall to support colony; over 4,000 extant species.

Class Phylactolaemata

Zooids basically cylindrical, with a crescentic lophophore and an epistome (hollow flap overhanging mouth); body wall noncalcareous, muscular, used for everting the lophophore; coelom continuous between zooids; new zooids arise by replication of polypides; special dormant buds (statoblasts) are produced; zooids monomorphic; exclusively freshwater; cosmopolitan; apparently primitive, but with no certain fossil record; about 12 genera.

Class Stenolaemata

Fossil except for some Cyclostomata; zooids cylindrical; body wall calcified, without muscle fibres; not used for everting the lophophore; zooids separated by septa; new zooids produced by division of septa; limited polymorphism; marine; Ordovician to present; about 550 genera.

Order Cyclostomata

Orifice of zooid circular; lophophore circular; no epistome; zooids interconnected by open pores; sexual reproduction involves polyembryony, usually in special reproductive zooids; all seas; Ordovician to present; about 250 genera.

Order Cystoporata

Zooid skeletons long and tubular, interconnected by pores and containing diaphragms (transverse partitions); cystopores (not pores but supporting structures between the zooid skeletons) present; Ordovician to Permian; about 80 genera.

Order Trepostomata

Colonies generally massive, composed of long tubular zooid skeletons with lamellate calcification; without interzooidal pores; orifices polygonal; sometimes with numerous diaphragms, zooid walls thin proximally, thicker distally; Ordovician to Permian; about 100 genera.

Order Cryptostomata

Colonies mostly with foliaceous or reticulate fronds or with branching stems; zooid skeletons tubular, shorter than in trepostomes; without pores; with diaphragms; proximal portions thin walled, distal portions funnellike and separated by extensive calcification; Ordovician to Triassic; about 130 genera.

Class Gymnolaemata

Zooids cylindrical or squat, with a circular lophophore; no epistome; body wall sometimes calcified; nonmuscular; eversion of lophophore dependent on deformation of body wall by extrinsic muscles; zooids separated by septa or duplex walls; pores in walls plugged with tissue; new zooids produced behind growing points by formation of transverse septa; zooids polymorphic; mainly marine; all seas; Jurassic to present, but presumed to have been established at least by the Ordovician; about 650 genera.

Order Ctenostomata

Zooids cylindrical to flat; walls not calcified; orifice terminal or nearly so, often closed by a pleated collar; no ooecia or avicularia; Jurassic to present, but presumed older; about 40 genera.

Order Cheilostomata

Zooids generally shaped like a flat box, walls calcified; orifice frontal, closed by a hinged operculum; specialized zooids commonly present; embryos often developing in ooecia (brood chambers); Upper Jurassic to present; about 600 genera.

Critical appraisal. Classification of bryozoans began in 1837 when the freshwater and marine Bryozoa were separated into the classes now known as Phylactolaemata and Gymnolaemata. Later a third class, the Stenolaemata, was separated from the Gymnolaemata. The cyclostomes and the fossil trepostomes were placed in the new class, which was acceptable to many paleontologists. In recent years, the cryptostomes have also been placed in the Stenolaemata. The most satisfactory system, therefore, separates the bryozoans into three classes, distinct since the beginning of the fossil record.

Most of the bryozoan orders were named many years ago. Cheilostomata, Ctenostomata, and Cyclostomata were named in 1852; Trepostomata was named in 1882; and Cryptostomata was named in 1883. In 1964 a Soviet bryozoologist introduced a new order, Cystoporata, which includes the Paleozoic ceramoporoids and fistuliporoids. Some authorities regard the phylum Entoprocta to be related to Bryozoa (it is sometimes classified as a subphylum of Bryozoa), but the evidence is conflicting and opinion divided.

BIBLIOGRAPHY. J.S. RYLAND, *Bryozoans* (1970), is a general survey of fossil and living bryozoans for the nonspecialist. Advanced accounts include LIBBIE HENRIETTA HYMAN, "The Lophophorate Coelomates—Phylum Ectoprocta," ch. 20 in the author's *Invertebrates,* vol. 5, "Smaller Coelomate Groups" (1959); ROBERT M. WOOLLACOTT and RUSSELL L. ZIMMER (eds.), *Biology of Bryozoans* (1977); and J.S. RYLAND, "Physiology and Ecology of Marine Bryozoans," a review in *Advances in Marine Biology,* vol. 14, pp. 285–443 (1976). Proceedings of the seventh international conference of the International Bryozoology Association, held in 1986, resulted in the collection of current research in JUNE R.P. ROSS (ed.), *Bryozoa: Present and Past* (1987). Other contributions to the subject are found in RICHARD S. BOARDMAN, ALAN H. CHEETHAM, and WILLIAM A. OLIVER, JR. (eds.), *Animal Colonies: Development and Function Through Time* (1973); G. LARWOOD and B.R. ROSEN (eds.), *Biology and Systematics of Colonial Organisms* (1979); JEREMY B.C. JACKSON, LEO W. BUSS, and ROBERT E. COOK (eds.), *Population Biology and Evolution of Clonal Organisms* (1985); and J.L. HARPER, B.R. ROSEN, and J. WHITE (eds.), *The Growth and Form of Modular Organisms* (1986). Well-illustrated surveys of the bryozoans may be found on pp. 667–677 of ch. 26, "Lophophorates," in VICKI PEARSE *et al., Living Invertebrates* (1987), and on pp. 238–242 of ch. 14, "Lesser Lights," in RALPH BUCHSBAUM *et al., Animals Without Backbones,* 3rd ed. (1987). Extensive introductions are offered in the four works belonging to the "Synopses of the British Fauna" series: J.S. RYLAND and P.J. HAYWARD, *British Anascan Bryozoans: Cheilostomata, Anasca: Keys and Notes for the Identification of the Species* (1977); P.J. HAYWARD and J.S. RYLAND, *British Ascophoran Bryozoans* (1979); P.J. HAYWARD, *Ctenostome Bryozoans* (1985); and P.J. HAYWARD and J.S. RYLAND, *Cyclostome Bryozoans* (1985). A classification of extant Bryozoa is provided by J.S. RYLAND, "Bryozoa," pp. 743–769, vol. 2, in SYBIL P. PARKER (ed.), *Synopsis and Classification of Living Organisms,* 2 vol. (1982).

Motion Pictures

A remarkably effective medium in conveying drama and especially in the evocation of emotion, motion pictures consist of the projection of luminous moving images onto a screen. The art of motion pictures is exceedingly complex, requiring contributions from nearly all of the other arts as well as countless technical skills. Nonetheless, probably no other art has proliferated as much in the 20th century nor can any other equal it in popularity or influence.

The motion picture is the newest of the generally recognized "fine arts." It is the product of photographic and technological developments that culminated by 1900 in practical devices for the recording of a moving image and its projection onto a flat surface. During its early development, the motion picture was discounted by many critics for its supposed subservience to commercial interests, for the immediacy of its appeal to the uninstructed, for its seemingly mechanical technique, and for its apparent lack of an identifiable artist as its primary creator. After the middle of the 20th century, however, increasing attention was devoted to it as a form of artistic endeavour that is as legitimate as the theatre, literature, dance, music, or the visual arts. (R.St.)

This article traces the historical development of the motion picture, the art of film, and film technology. Other articles in which specialized aspects of the subject are treated include SOUND; PHOTOGRAPHY; and OPTICS, PRINCIPLES OF.

History

EARLY YEARS: 1830–1910

Persistence of vision and the phi phenomenon

Origins. The illusion of motion pictures is based on the optical phenomena known as persistence of vision and the phi phenomenon. The first of these causes the brain to retain images cast upon the retina of the eye for a fraction of a second beyond their disappearance from the field of sight, while the latter creates apparent movement between images when they succeed one another rapidly. Together, these phenomena permit the succession of still frames on a motion-picture film strip to represent continuous movement when projected at the proper speed (traditionally 16 frames per second for silent films and 24 frames per second for sound films). Before the invention of photography, a variety of optical toys exploited this effect by mounting successive phase drawings of things in motion on the face of a twirling disk (the phenakistoscope, *c.* 1832) or inside of a rotating drum (the zoetrope, *c.* 1834). Then, in 1839, Louis-Jacques-Mandé Daguerre, a French painter, perfected the positive photographic process known as daguerreotypy, and that same year the English scientist William Henry Fox Talbot successfully demonstrated a negative photographic process that theoretically allowed unlimited positive prints to be produced from each negative. As photography was innovated and refined over the next few decades, it became possible to replace the phase drawings in the early optical toys and devices with individually posed phase photographs, a practice that was widely and popularly carried out.

There would be no true motion pictures, however, until live action could be photographed spontaneously and simultaneously as it occurred. This required not only a reduction in exposure time from the hour or so necessary for the pioneer photographic processes to the one-hundredth (and, ultimately, one-thousandth) of a second achieved in 1870 but also the development of the technology of series photography by the British-American photographer Eadweard Muybridge between 1872 and 1877. During that time, Muybridge was employed by Governor Leland Stanford of California, a zealous racehorse breeder, to prove that at some point in its gallop a running horse lifts all four hooves off the ground at once. Conventions of 19th-century illustration suggested otherwise, and the

Series photography

movement itself occurred too rapidly for perception by the naked eye; so Muybridge experimented with multiple cameras to take successive photographs of horses in motion. Finally, in 1877, he set up a battery of 12 cameras along a Sacramento racecourse with wires stretched across the track to operate their shutters. As a horse strode down the track, its hooves tripped each shutter individually to expose a successive photograph of the gallop, confirming Stanford's belief. When Muybridge later mounted these images on a rotating disk and projected them on a screen through a magic lantern, they produced a "moving picture" of the horse at full gallop as it had actually occurred in life.

The French physiologist Étienne-Jules Marey took the first series photographs with a single instrument in 1882; once again, the impetus was the analysis of motion too rapid for perception by the human eye. Marey invented the chronophotographic gun, a camera shaped like a rifle that recorded 12 successive photographs per second, in order to study the movement of birds in flight. These images were imprinted on a rotating glass plate (later, paper roll film), and Marey subsequently attempted to project them. Like Muybridge, however, Marey was interested in deconstructing movement rather than synthesizing it, and he did not carry his experiments much beyond the realm of high-speed, or instantaneous, series photography. Muybridge and Marey, in fact, conducted their work in the spirit of scientific inquiry; they both extended and elaborated existing technologies in order to probe and analyze events that occurred beyond the threshold of human perception. Those who came after would return their discoveries to the realm of normal human vision and exploit them for profit.

In 1887 in Newark, N.J., an Episcopalian minister named Hannibal Goodwin first used celluloid roll film as a base for photographic emulsions, and within the year his idea had been appropriated by the industrialist George Eastman, who in 1888 began to mass-produce celluloid roll film for still photography at his plant in Rochester, N.Y. This event was crucial to the development of cinematography: series photography such as Marey's chronophotography could employ glass plates or paper strip film because it recorded events of short duration in a relatively small number of images, but cinematography would inevitably find its subjects in longer, more complicated events, requiring thousands of images and therefore just the kind of flexible but durable recording medium represented by celluloid. It remained for someone to combine the principles embodied in the apparatuses of Muybridge and Marey with celluloid strip film to arrive at a viable motion-picture camera—an innovation achieved by William Kennedy Laurie Dickson in the West Orange, N.J., laboratories of the Edison Company in 1888.

Edison and the Lumière brothers. Thomas Alva Edison invented the phonograph in 1877, and it had quickly become the most popular home entertainment device of the century. It was to provide a visual accompaniment to the phonograph that Edison commissioned Dickson, a young laboratory assistant, to invent a motion-picture camera in 1887. Dickson built upon the work of Muybridge and Marey, a fact that he readily acknowledged, but he was the first to combine the two final essentials of motion-picture camera and projection technology. These were a device, adapted from the escapement mechanism of a clock, to ensure the intermittent but regular motion of the film strip through the camera and a regularly perforated celluloid film strip to ensure precise synchronization between the film strip and the shutter. Dickson's camera was patented as the Kinetograph in 1893, and it initially imprinted up to 50 feet of celluloid film at the rate of about 40 frames per second.

The Kinetograph

Dickson was not the only person who had been tackling the problem of recording and reproducing moving images. Inventors throughout the world had been trying for years to devise working motion-picture machines. In fact, several European inventors, including the Frenchborn Louis Le Prince and the Englishman William Friese-Greene, applied for patents on various cameras, projectors, and camera-projector combinations contemporaneously or even before Edison and his associates did. These machines were unsuccessful for a number of reasons, however, and little evidence survives of their actual practicality or workability.

Because Edison had originally conceived of motion pictures as an adjunct to his phonograph, he did not commission the invention of a projector to accompany the Kinetograph. Rather, he had Dickson design a type of peep-show viewing device called the Kinetoscope in which a continuous 47-foot film loop ran on spools between an incandescent lamp and a shutter for individual viewing. Starting in 1894, Kinetoscopes were marketed commercially through the firm of Raff and Gammon for $250 to $300 apiece, and the Edison Company established its own Kinetograph studio (a single-room building called the "Black Maria" that rotated on tracks to follow the sun) in West Orange, N.J., to supply films for the Kinetoscopes that Raff and Gammon were installing in penny arcades, hotel lobbies, amusement parks, and other such semipublic places. In April of that year the first Kinetoscope parlour was opened in a converted storefront in New York City. The parlour charged 25 cents for admission to a bank of five machines.

The syndicate of Maguire and Baucus acquired the foreign rights to the Kinetoscope in 1894 and began to market the machines. Edison had declined to file for international patents on either his camera or his viewing device, and as a result the machines were widely and legally copied throughout Europe, where they were modified and improved far beyond the American originals. In fact, it was a Kinetoscope exhibition in Paris that inspired the Lumière brothers, Auguste and Louis, to invent the first commercially viable projector. Their *cinématographe*, which functioned as a camera and printer as well as a projector, ran at the economical speed of 16 frames per second. It was given its first commercial demonstration on Dec. 28, 1895.

Unlike the Kinetograph, which was battery-driven and weighed more than 1,000 pounds, the *cinématographe* was hand-cranked, lightweight (less than 20 pounds), and relatively portable. This naturally affected the kinds of films that were made with each machine: Edison films initially featured material such as circus or vaudeville acts that could be brought into a small studio and played out before an inert camera, while early Lumière films were mainly documentary views, or "actualities," shot outdoors on location. In both cases, however, the films themselves were composed of a single, unedited shot emphasizing lifelike movement; they contained little or no narrative content. (After a few years design changes in the machines made it possible for Edison and the Lumières to shoot the same

The *cinématographe*

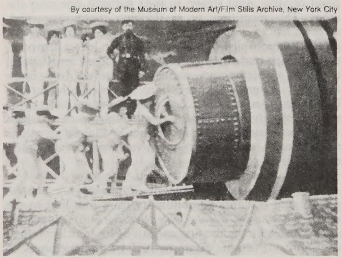
An early series of photographs by Eadweard Muybridge (1887).

kinds of subjects.) In general, Lumière technology became the European standard during the early primitive era, and because the Lumières sent their cameramen all over the world in search of exotic subjects, the *cinématographe* became the founding instrument of such far-flung cinemas as the Russian, the Australian, and the Japanese. (It also, of course, is the source for the word cinema.)

In the United States, the Kinetoscope installation business had reached saturation point by the summer of 1895, although it was still quite profitable for Edison as a supplier of films. Raff and Gammon persuaded Edison to buy the rights to a state-of-the-art projector, developed by Thomas Armat of Washington, D.C., which incorporated a superior intermittent movement mechanism and a loop-forming device (known as the Latham loop, after its earliest promoters, Grey and Otway Latham) to reduce film breakage, and in early 1896 Edison began to manufacture and market this machine as his own invention. Given its first public demonstration on April 23, 1896, at Koster and Bial's Music Hall in New York City, the Edison Vitascope brought projection to the United States and established the format for American film exhibition for the next several years. It also encouraged the activities of such successful Edison rivals as the American Mutoscope and Biograph Company, which was formed in 1896 to exploit the Mutoscope peep-show device and the American Biograph camera and projector patented by W.K.L. Dickson in 1896. During this time, which has been characterized as the "novelty period," emphasis fell on the projection device itself, and films achieved their main popularity as self-contained vaudeville attractions. Vaudeville houses, among which there was intense competition at the turn of the century, headlined the name of the machines rather than the films (The Vitascope—Edison's Latest Marvel, The Amazing Cinématographe). The projectors came supplied from the producer, or manufacturer, with an operator and a program of shorts. These films, whether they were Edison-style theatrical variety shorts or Lumière-style actualities, were perceived by their original audiences not as motion pictures in the modern sense of the term but as "animated photographs" or "living pictures," emphasizing their continuity with more familiar media of the time.

The novelty period

During the novelty period, the film industry was autonomous and unitary, with production companies leasing a complete film service of projector, operator, and shorts to the vaudeville market as a single, self-contained act. Starting around 1897, however, manufacturers began to sell both projectors and films to itinerant exhibitors who traveled with their programs from one temporary location (vaudeville theatres, fairgrounds, circus tents, lyceums) to another as the novelty of their films wore off at a given site. This new mode of screening by circuit marked the first separation of exhibition from production and gave the exhibitors a large measure of control over early film form, since they were responsible for arranging the one-shot films purchased from the producers into audience-pleasing programs. The putting together of these programs—which often involved narration, sound effects, and music—was in effect a primitive form of editing, so that it is possible to regard the itinerant projectionists working between 1896 and 1904 as the earliest directors of motion pictures. Several of them, notably Edwin S. Porter, were, in fact, hired as directors by production companies after the industry had stabilized in the first decade of the 20th century.



By encouraging the practice of peripatetic exhibition, the U.S. producers' policy of outright sales inhibited the development of permanent film theatres in the United States until nearly a decade after their appearance in Europe, where England and France had taken an early lead in both production and exhibition. Britain's first projector, the theatrograph (later, the animatograph), had been demonstrated in 1896 by the scientific instrument maker Robert W. Paul. In 1899 Paul formed his own production company for the manufacture of actualities and trick films, and until 1905 Paul's Animatograph Works, Ltd., was England's largest producer, turning out an average of 50 films per year. Between 1896 and 1898, two Brighton photographers, George Albert Smith and James Williamson, constructed their own motion-picture cameras and began producing trick films featuring superimpositions (*The Corsican Brothers,* 1897) and interpolated close-ups (*Grandma's Reading Glass,* 1900; *The Big Swallow,* 1901). Smith subsequently developed the first commercially successful photographic colour process (Kinemacolor, *c.* 1906–08, with Charles Urban), while Williamson experimented with parallel editing as early as 1900 (*Attack on a Chinese Mission Station*) and became a pioneer of the chase film (*Stop Thief!,* 1901; *Fire!,* 1901). Both Smith and Williamson had built studios at Brighton by 1902 and, with their associates, came to be known as members of the "Brighton school," although they did not represent a coherent movement. Another important early British filmmaker was Cecil Hepworth, whose *Rescued by Rover* (1905) is regarded by many historians as the most skillfully edited narrative produced before the Biograph shorts of D.W. Griffith.

Méliès and Porter. The shift in consciousness away from films as animated photographs to films as stories, or narratives, began to take place around the turn of the century and is most evident in the work of the French filmmaker Georges Méliès. Méliès was a professional magician who had become interested in the illusionist possibilities of the *cinématographe:* when the Lumières refused to sell him one, he bought an animatograph projector from Paul in 1896 and reversed its mechanical principles to design his own camera. The following year he organized the Star Film company and constructed a small glass-enclosed studio on the grounds of his house at Montreuil, where he produced, directed, photographed, and acted in more than 500 films between 1896 and 1913.

Méliès' "trick" films

Initially, Méliès used stop-motion photography (the camera and action are stopped while something is added to or removed from the scene, then filming and action are continued) to make one-shot "trick" films in which objects disappeared and reappeared, or transformed themselves into other objects entirely. These films were widely imitated by producers in England and the United States. Soon, however, Méliès began to experiment with brief multi-scene films, such as *L'Affaire Dreyfus* (*The Dreyfus Affair,* his first, 1899), which followed the logic of linear temporality to establish causal sequences and tell simple stories. By 1902 he had produced the influential 30-scene narrative *Le Voyage dans la lune (A Trip to the Moon).* Adapted from a novel by Jules Verne, it was nearly one reel in length (about 825 feet, or 14 minutes).

Le Voyage dans la lune (1902), directed by Georges Méliès.

The first film to achieve international distribution (mainly through piracy), *Le Voyage dans la lune* was an enormous popular success. It helped to make Star Film one of the world's largest producers (an American branch was opened in 1903) and to establish the fiction film as the cinema's mainstream product. In both respects Méliès dethroned the Lumières' cinema of actuality. Despite his innovations, Méliès' productions remained essentially filmed stage plays. He conceived them quite literally as successions of living pictures or, as he termed them, "artificially arranged scenes." From his earliest trick films through his last successful fantasy, *La Conquête du pole* ("The Conquest of the Pole," 1912), Méliès treated the frame of

the film as the proscenium arch of a theatre stage, never once moving his camera or changing its position within a scene. He ultimately lost his audience in the late 1910s to filmmakers with more sophisticated narrative techniques.

The origination of many such techniques is closely associated with the work of Edwin S. Porter, a free-lance projectionist and engineer who joined the Edison Company in 1900 as production head of its new skylight studio on East 21st Street in New York City. For the next few years, he served as director-cameraman for much of Edison's output, starting with simple one-shot films (*Kansas Saloon Smashers,* 1901) but progressing rapidly to trick films (*The Finish of Bridget McKeen,* 1901) and short multi-scene narratives based on political cartoons and contemporary events (*Sampson-Schley Controversy,* 1901; *Execution of Czolgosz, with Panorama of Auburn Prison,* 1901). Porter also filmed the extraordinary *Pan-American Exposition by Night* (1901), which used time-lapse photography to produce a circular panorama of the exposition's electrical illumination, and the 10-scene *Jack and the Beanstalk* (1902), a narrative that simulates the sequencing of lantern slides to achieve a logical, if elliptical, spatial continuity.

Continuity editing

It was probably Porter's experience as a projectionist at the Eden Musee theatre in 1898 that ultimately led him in the early 1900s to the practice of continuity editing. The process of selecting one-shot films and arranging them into a 15-minute program for screen presentation was very much like that of constructing a single film out of a series of separate shots. Porter, by his own admission, was also influenced by other filmmakers—especially Méliès, whose *Le Voyage dans la lune* he came to know well in the process of duplicating it for illegal distribution by Edison in October 1902. Years later, Porter claimed that the Méliès film had given him the notion of "telling a story in continuity form," which resulted in *The Life of an American Fireman* (about 400 feet, or six minutes, produced in late 1902 and released in January 1903). This film, which was also influenced by James Williamson's *Fire!,* combined archival footage with staged scenes to create a nine-shot narrative of a dramatic rescue from a burning building. It was for years the subject of controversy because in a later version the last two scenes were intercut, or crosscut, into a 14-shot parallel sequence. It is now generally believed that in the earliest version of the film these scenes, which repeat the same rescue operation from an interior and exterior point of view, were shown in their entirety, one after the other. This repetition, or overlapping continuity, which owes much to magic lantern shows, clearly defines the spatial relationships between scenes but leaves temporal relationships underdeveloped and, to modern sensibilities, confused. Contemporary audiences, however, were conditioned by lantern slide projections and even comic strips; they understood a sequence of motion-picture shots to be a series of individual moving photographs, each of which was self-contained within its frame. Spatial relationships were clear in such earlier narrative forms because their only medium was space.

Motion pictures, however, exist in time as well as space, and the major problem for early filmmakers was the establishment of temporal continuity from one shot to the next. Porter's *The Great Train Robbery* (1903) is widely acknowledged to be the first narrative film to achieve such continuity of action. Comprised of 14 separate shots of noncontinuous, nonoverlapping action, the film contains an early example of parallel editing, two credible back, or rear, projections (the projection from the rear of previously filmed action or scenery onto a translucent screen to provide the background for new action filmed in front of the screen), two camera pans, and several shots composed diagonally and staged in depth—a major departure from the frontally composed, theatrical staging of Méliès.

The Great Train Robbery

The industry's first spectacular box-office success, *The Great Train Robbery* is credited with establishing the realistic narrative, as opposed to Méliès-style fantasy, as the commercial cinema's dominant form. The film's popularity encouraged investors and led to the establishment of the first permanent film theatres, or nickelodeons, across the country. Running about 12 minutes, it also helped to

The Great Train Robbery (1903), directed by Edwin S. Porter.

boost standard film length toward one reel, or 1,000 feet (about 16 minutes at the average silent speed). Despite the film's success, Porter continued to practice overlapping action in such conventional narratives as *Uncle Tom's Cabin* (1903) and the social-justice dramas *The Ex-Convict* (1904) and *The Kleptomaniac* (1905). He experimented with model animation in *Dream of a Rarebit Fiend* (1906) and *The Teddy Bears* (1907) but lost interest in the creative aspects of filmmaking as the process became increasingly industrialized. He left Edison in 1909 to pursue a career as a producer and equipment manufacturer. Porter, like Méliès, could not adapt to the linear narrative modes and assembly-line production systems that were developing.

Industrialization of European cinema

Early growth of the film industry. Méliès' decline was assisted by the industrialization of the French and, for a time, the entire European cinema by the Pathé Frères company, founded in 1896 by the former phonograph importer Charles Pathé. Financed by some of France's largest corporations, Pathé acquired the Lumière patents in 1902 and commissioned the design of an improved studio camera that soon dominated the market on both sides of the Atlantic (it has been estimated that, before 1918, 60 percent of all films were shot with a Pathé). Pathé also manufactured his own film stock and in 1902 established a vast production facility at Vincennes where films were turned out on an assembly-line basis under the managing direction of Ferdinand Zecca. The following year, Pathé began to open foreign sales agencies, which would soon become full-blown production companies—Hispano Film (1906), Pathé-Rouss, Moscow (1907), Film d'Arte Italiano (1909), Pathé-Britannia, London (1909), and Pathé-America (1910). He acquired permanent exhibition sites, building the world's first luxury cinema (the Omnia-Pathé) in Paris in 1906. In 1911 Pathé became Méliès' distributor and helped to drive Star Film out of business.

Pathé's only serious rival on the Continent at this time was Gaumont Pictures, founded by the engineer-inventor Léon Gaumont in 1895. Though never more than a quarter the size of Pathé, Gaumont followed the same pattern of expansion, manufacturing its own equipment and mass-producing films under a supervising director (through 1906, Alice Guy, the cinema's first woman director; afterward, Louis Feuillade). Like Pathé, Gaumont opened foreign offices and acquired theatre chains. From 1905 to 1914 its studios at La Villette, Fr., were the largest in the world. Pathé and Gaumont dominated pre-World War I motion-picture production, exhibition, and sales in Europe, and they effectively brought to an end the artisanal mode of filmmaking practiced by Méliès and his British contemporaries.

The formation of film exchanges

In the United States a similar pattern was emerging through the formation of film exchanges and the consolidation of an industry-wide monopoly based on the pooling of patent rights. Around 1897 producers had adopted the practice of selling prints outright, which had the effect of promoting itinerant exhibition and discriminating against the owners of permanent sites. In 1903, in response to the needs of theatre owners, Harry J. and Herbert Miles

opened a film exchange in San Francisco. The exchange functioned as a broker between producers and exhibitors, buying prints from the former and leasing them to the latter for 25 percent of the purchase price (in subsequent practice, rental fees were calculated on individual production costs and box-office receipts). The exchange system of distribution quickly caught on because it profited nearly everyone: the new middlemen made fortunes by collecting multiple revenues on the same prints; exhibitors were able to reduce their overheads and vary their programs without financial risk; and, ultimately, producers experienced a tremendous surge in demand for their product as exhibition and distribution boomed nationwide. (Between November 1906 and March 1907, for example, producers increased their weekly output from 10,000 to 28,000 feet and still could not meet demand.)

The most immediate effect of the rapid rise of the distribution sector was the nickelodeon boom, the exponential growth of permanent film theatres in the United States from a mere handful in 1904 to between 8,000 and 10,000 by 1908. Named for the Nickelodeon (ersatz Greek for "nickel theatre"), which opened in Pittsburgh in 1905, these theatres were makeshift facilities lodged in converted storefronts. They showed approximately an hour's worth of films for an admission price of five to 10 cents. Originally identified with working-class audiences, nickelodeons appealed increasingly to the middle class as the decade wore on, and they became associated with the rising popularity of the story film. Their spread also forced the standardization of film length at one reel, or 1,000 feet, to facilitate high-efficiency production and the trading of products within the industry.

By 1908 there were about 20 motion-picture production companies operating in the United States. They were constantly at war with one another over business practices and patent rights, and they had begun to fear that their fragmentation would cause them to lose control of the industry to the two new sectors of distribution and exhibition. The most powerful among them—Edison, Biograph, Vitagraph, Essanay, Kalem, Selig Polyscope, Lubin, the American branches of the French Star Film and Pathé Frères, and Kleine Optical, the largest domestic distributor of foreign films—therefore entered into a collusive trade agreement to ensure their continued dominance. On Sept. 9, 1908, these companies formed the Motion Picture Patents Company (MPPC), pooling the 16 most significant U.S. patents for motion-picture technology and entering into an exclusive contract with the Eastman Kodak Company for the supply of raw film stock.

The Motion Picture Patents Company

The MPPC, also known as the "Trust," sought to control every segment of the industry and therefore set up a system to issue licenses and assess royalties therefrom. The use of its patents was granted only to licensed equipment manufacturers; film stock could be sold only to licensed producers; licensed producers and importers were required to fix rental prices at a minimum level and to set quotas for foreign footage to reduce competition; Patents Company films could be sold only to licensed distributors, who could lease them only to licensed exhibitors; and only licensed exhibitors had the right to use Patents Company projectors and rent company films. To further ensure their control, in 1910—the same year in which motion-picture attendance in the United States rose to 26,000,000 persons a week—the MPPC formed the General Film Company, which integrated the licensed distributors into a single corporate entity. Although it was clearly monopolistic in practice and intent, the MPPC helped to stabilize the American film industry during a period of unprecedented growth and change by standardizing exhibition practice, increasing the efficiency of distribution, and regularizing pricing in all three sectors. Its collusive nature, however, provoked a reaction that ultimately destroyed it.

In a sense, the MPPC's iron-clad efforts to eliminate competition merely fostered it. Almost from the outset there was widespread resistance to the Patents Company on the part of independent distributors (numbering 10 or more in early 1909) and exhibitors (estimated at 2,000 to 2,500); and in January 1909 they formed their own trade association, the Independent Film Protective Association—reorganized that fall as the National Independent Moving Picture Alliance—to provide financial and legal support against the Trust. A more effective and powerful anti-Trust organization was the Motion Picture Distributing and Sales Company, which began operation in May 1910 (three weeks after the inception of General Film) and which eventually came to serve 47 exchanges in 27 cities. For nearly two years, independents were able to present a united front through the Sales Company, which finally split into two rival camps in the spring of 1912 (the Mutual Film Corporation and the Universal Film Manufacturing Company).

By imitating Patents Company practices of joining forces and licensing, the early independents were able to compete effectively against the Trust in its first three years of operation, netting about 40 percent of all American film business. In fact, their product, the one-reel short, and their mode of operation were initially fundamentally the same as the MPPC's. The independents later revolutionized the industry, however, by adopting the multiple-reel film as their basic product, a move that caused the MPPC to embrace the one-reeler with a vengeance, hastening its own demise.

THE SILENT FEATURE: 1910–27

Introduction of the feature film

Pre-World War I U.S. cinema. Multiple-reel films had appeared in the United States as early as 1907, when Adolph Zukor distributed Pathé's three-reel *Passion Play;* but when Vitagraph produced the five-reel *The Life of Moses* in 1909, the Patents Company forced it to be released in serial fashion at the rate of one reel a week. The multiple-reel film—which came to be called a "feature," in the vaudevillian sense of a headline attraction—achieved general acceptance with the smashing success of Louis Mercanton's three-and-one-half-reel *Les Amours de la Reine Elizabeth* (*Queen Elizabeth,* 1912), which starred Sarah Bernhardt and was imported by Adolph Zukor (who founded the independent Famous Players production company with its profits). In 1912 Enrico Guazzoni's nine-reel Italian super-spectacle *Quo Vadis?* was road-shown in legitimate theatres across the nation at a top admission price of one dollar, and the feature craze was on.

At first, there were difficulties in distributing features, because the exchanges associated with both the Patents Company and the independents were geared toward cheaply made one-reel shorts. Owing to their more elaborate production values, features had relatively higher negative costs. This was a disadvantage to distributors, who charged a uniform price per foot. By 1914, however, several national feature-distribution alliances that correlated pricing with a film's negative cost and box-office receipts were organized. These new exchanges demonstrated the economic advantage of multiple-reel films over shorts. Exhibitors quickly learned that features could command higher admission prices and longer runs; single title packages were also cheaper and easier to advertise than programs of multiple titles. As for manufacturing, producers found that the higher expenditure for features was readily amortized by high volume sales to distributors, who in turn were eager to share in the higher admission returns from the theatres. The whole industry soon reorganized itself around the economics of the multiple-reel film, and the effects of this restructuring did much to give motion pictures their characteristic modern form.

Feature films, for example, made motion pictures respectable for the middle class by providing a format that was analogous to that of the legitimate theatre and was suitable for the adaptation of middle-class novels and plays. This new audience had more demanding standards than the older lower-class one, and producers readily increased their budgets to provide high technical quality and elaborate productions. The new viewers also had a more refined sense of comfort, which exhibitors quickly accommodated by replacing their storefronts with large, elegantly appointed new theatres in the major urban centres (one of the first was Mitchell L. Marks's 3,300-seat Strand, which opened in the Broadway district of Manhattan in 1914). Known as "dream palaces" because of the fantastic luxuriance of their interiors, these houses had to show features

End of the nickelodeon era

rather than a program of shorts to attract large audiences at premium prices. By 1916 there were more than 21,000 movie palaces in the United States. Their advent marked the end of the nickelodeon era and foretold the rise of the Hollywood studio system, which dominated urban exhibition from the 1920s to the 1950s. Before the new studio-based monopoly could be established, however, the patents-based monopoly of the MPPC had to expire, and this it did as a result of its own basic assumptions in about 1914.

As conceived by Edison, the basic operating principle of the Trust was to control the industry through patents pooling and licensing, an idea logical enough in theory but difficult to practice in the context of a dynamically changing marketplace. Specifically, the Trust's failure to anticipate the independents' widespread and aggressive resistance to its policies cost it a fortune in patent-infringement litigation. Furthermore, the Trust badly underestimated the importance of the feature film, permitting the independents to claim this popular new product as entirely their own. Another issue that the MPPC misjudged was the power of the marketing strategy known as the "star system." Borrowed from the theatre industry, this system involves the creation and management of publicity about key performers, or stars, to stimulate demand for their films. Trust company producers used this kind of publicity after 1910, when Carl Laemmle of Independent Motion Pictures (IMP) promoted Florence Lawrence into national stardom through a series of media stunts in St. Louis, Mo., but they never exploited the technique as forcefully or as imaginatively as the independents. Finally, and most decisively, in August 1912 the U.S. Justice Department brought suit against the MPPC for "restraint of trade" in violation of the Sherman Antitrust Act. Delayed by countersuits and by World War I, the government's case was finally won and the MPPC formally dissolved in 1918, although it had been functionally inoperative since 1914.

The rise and fall of the Patents Company was concurrent with the industry's move to southern California. As a result of the nickelodeon boom, exhibitors had begun to require as many as 20 to 30 new films per week, and it became necessary to put production on a systematic year-round schedule. Because most films were still shot outdoors in available light, such schedules could not be maintained in the vicinity of New York City or Chicago, where the industry had originally located itself in order to take advantage of trained theatrical labour pools. As early as 1907, production companies, such as Selig Polyscope, began to dispatch production units to warmer climates during winter. It was soon clear that what producers required was a new industrial centre—one with warm weather, a temperate climate, a variety of scenery, and other qualities (such as access to acting talent) essential to their highly unconventional form of manufacturing.

Hollywood

Various companies experimented with location shooting in Jacksonville, Fla., in San Antonio, Texas, in Santa Fe, N.M., and even in Cuba, but the ultimate site of the American film industry was a Los Angeles suburb (originally a small industrial town) called Hollywood. It is generally thought that Hollywood's distance from the MPPC's headquarters in New York City made it attractive to the independents, but Patents Company members such as Selig, Kalem, Biograph, and Essanay had also established facilities there by 1911 in response to a number of the region's attractions. These included the temperate climate required for year-round production (the U.S. Weather Bureau estimated that an average of 320 days per year were sunny and/or clear); a wide range of topography within a 50-mile radius of Hollywood, including mountains, valleys, forests, lakes, islands, seacoast, and desert; the status of Los Angeles as a professional theatrical centre; the existence of a low tax base; and the presence of cheap and plentiful labour and land. This latter factor enabled the newly arrived production companies to buy up tens of thousands of acres of prime real estate on which to locate their studios, standing sets, and backlots.

By 1915 approximately 15,000 workers were employed by the motion-picture industry in Hollywood, and more than 60 percent of American production was centred there. In that same year, the trade journal *Variety* reported that capital investment in American motion pictures—the business of artisanal craftsmen and fairground operators only a decade before—had exceeded $500,000,000. The most powerful companies in the new film capital were the independents, who were flush with cash from their conversion to feature production. These included the Famous Players-Lasky Corporation (later Paramount Pictures, *c.* 1927), which was formed by a merger of Adolph Zukor's Famous Players Company, Jesse L. Lasky's Feature Play Company, and the Paramount distribution exchange in 1916; Universal Pictures, founded by Carl Laemmle in 1912 by merging IMP with Powers, Rex, Nestor, Champion, and Bison; Goldwyn Picture Corporation, founded in 1916 by Samuel Goldfish (later Goldwyn) and Edgar Selwyn; Metro Picture Corporation and Louis B. Mayer Pictures, founded by Louis B. Mayer in 1915 and 1917, respectively; and the Fox Film Corporation (later 20th Century-Fox, 1935), founded by William Fox in 1915. After World War I, these companies were joined by Loew's, Inc. (parent corporation of MGM, by merger of Metro, Goldwyn, and Mayer companies cited above, 1924), a national exhibition chain organized by Marcus Loew and Nicholas Schenck in 1919; First National Pictures, Inc., a circuit of independent exhibitors who established their own production facilities at Burbank, Calif., in 1922; Warner Bros. Pictures, Inc., founded by Harry, Albert, Samuel, and Jack Warner in 1923; and Columbia Pictures, Inc., incorporated in 1924 by Harry and Jack Cohn.

These organizations became the backbone of the Hollywood studio system, and the men who controlled them shared several important traits. They were all independent exhibitors and distributors who had outwitted the Trust and earned their success by manipulating finances in the post-nickelodeon feature boom, merging production companies, organizing national distribution networks, and ultimately acquiring vast theatre chains. They saw their business as basically a retailing operation modeled on the practice of chain stores such as Woolworth's and Sears. Not incidentally, these men were all first- or second-generation Jewish immigrants from eastern Europe, most of them with little formal education, while the audience they served was 90 percent Protestant and Catholic. This circumstance would become an issue during the 1920s, when the movies became a mass medium that was part of the life of every American citizen and when Hollywood became the chief purveyor of American culture to the world.

Pre-World War I European cinema. Before World War I European cinema was dominated by France and Italy. At Pathé Frères, director-general Ferdinand Zecca perfected the *course comique*, a uniquely Gallic version of the chase film, which inspired Mack Sennett's Keystone Kops, while the immensely popular Max Linder created a comic persona that would deeply influence the work of Charlie Chaplin. The episodic crime film was pioneered by Victorin Jasset in the "Nick Carter" series, produced for the small Éclair Company, but it remained for Gaumont's Louis Feuillade to bring the genre to aesthetic perfection in the extremely successful serials *Fantômas* (1913–14), *Les Vampires* (1915–16), and *Judex* (1916).

French *film d'art* movement

Another influential phenomenon to appear from prewar France was the *film d'art* movement. It began with *L'Assassinat du duc de Guise* (1908), directed by Charles Le Bargy and André Calmettes of the Comédie Française for the Société Film d'Art, which was formed for the express purpose of transferring prestigious stage plays starring famous performers to the screen. *L'Assassinat's* success inspired other companies to make similar films, which came to be known as *films d'art*. These films were long on intellectual pedigree and short on narrative sophistication. The directors simply filmed theatrical productions in toto, without adaptation. Their brief popularity nevertheless created a context for the lengthy treatment of serious material in motion pictures and was directly instrumental in the rise of the feature.

Italian super-spectacles

No country, however, was more responsible for the popularity of the feature than Italy. The Italian cinema's lavishly produced costume spectacles brought it international prominence in the years before the war. The prototypes of

the genre, by virtue of their epic material and lengths, were the Cines company's six-reel *Gli ultimi giorni di Pompei* (*The Last Days of Pompei*), directed by Luigi Maggi in 1908, and its 10-reel remake, directed by Ernesto Pasquali in 1913; but it was Cines' nine-reel *Quo vadis?* (1912), with its huge three-dimensional sets of ancient Rome and 5,000 extras, that established the standard for the superspectacle and briefly conquered the world market for Italian motion pictures. Its successor, the Italia company's 12-reel *Cabiria* (1914), was even more extravagant in its historical reconstruction of the Second Punic War, from the burning of the Roman fleet at Syracuse to Hannibal crossing the Alps and the sack of Carthage. The Italian superspectacle stimulated public demand for features and influenced such important directors as Cecil B. deMille, Ernst Lubitsch, and especially D.W. Griffith.

Griffith. There has been a tendency in modern film scholarship to view motion-picture narrative form as being governed by the operations of an overall production system. Although narrative film was and continues to be strongly influenced by a combination of economic, technological, and social factors, it also owes a great deal to the individual artists who viewed film as a medium of personal expression. Chief among these innovators was D.W. (David Wark) Griffith. It is true that Griffith's self-cultivated reputation as a Romantic artist—"the father of film technique," "the man who invented Hollywood," "the Shakespeare of the screen," and the like—is somewhat overblown. It is also true that by 1908 film narrative had already been systematically organized to accommodate the material conditions of production. Griffith's work nevertheless transformed that system from its primitive to its classical mode. He was the first filmmaker to realize that the motion-picture medium, properly vested with technical vitality and seriousness of theme, could exercise enormous persuasive power over an audience, or even a nation, without recourse to print or human speech.

Griffith began his film career in late 1907 as an actor. He was cast as the lead in the Edison Company's *Rescued from an Eagle's Nest* (1907) and also appeared in many Biograph films. He had already attempted to make a living as a stage actor and a playwright without much success, and his real goal in approaching the film companies seems to have been to sell them scripts. In June 1908 Biograph gave him an opportunity to replace its ailing director, George "Old Man" McCutcheon, on the chase film *The Adventures of Dollie.* With the advice of the company's two cameramen, G.W. "Billy" Bitzer (who would become Griffith's personal cinematographer for much of his career) and Arthur Marvin (who actually shot the film), Griffith turned in a fresh and exciting film. His work earned him a full-time director's contract at Biograph, where, over the next five years, he directed more than 450 one- and two-reel films.

In the Biograph films, Griffith experimented with all of the narrative techniques he would later use in the epics *The Birth of a Nation* (1915) and *Intolerance* (1916)—techniques that helped to formulate and stabilize Hollywood's classical narrative style. A few of these techniques were already in use when Griffith started; he simply refined them. Others were innovations Griffith devised to solve practical problems in the course of production. Still others resulted from his conscious analogy between film and literary narrative, chiefly Victorian novels and plays. In all cases, however, Griffith brought to the practice of filmmaking a seriousness of purpose and an intensity of vision, which, combined with his intuitive mastery of film technique, made him the first great artist of the cinema.

Griffith's innovations in editing

Griffith's first experiments were in the field of editing and involved varying the standard distance between the audience and the screen. In *Greaser's Gauntlet,* made one month after *Dollie,* he first used a "cut-in" from a long shot to a full shot to heighten the emotional intensity of a scene. In an elaboration of this practice, he was soon taking shots from multiple camera set-ups—long shots, full shots, medium shots, close shots, and, ultimately, close-ups—and combining their separate perspectives into single dramatic scenes. By October 1908, Griffith was practicing parallel editing between the dual narratives of *After Many Years,* and the following year he extended the technique to the representation of three simultaneous actions in *Lonely Villa,* cutting rapidly back and forth from a band of robbers breaking into a suburban villa, to a woman and her children barricaded within, to the husband rushing from town to the rescue. This type of crosscutting or intercutting came to be known as the "Griffith last-minute rescue" and was employed as a basic structural principle in both *The Birth of a Nation* and *Intolerance.* It not only employed the rapid alternation of shots but also called for the shots themselves to be held for shorter and shorter durations as the parallel lines of action converged; in its ability to create the illusion of simultaneous actions, the intercut chase sequence prefigured Soviet theories of montage by at least a decade, and it remains a basic component of narrative film form to this day.

Griffith's use of camera movement and placement

Another area of experiment for Griffith involved camera movement and placement, most of which had been purely functional before him. When Biograph started sending his production unit to southern California in 1910, Griffith began to practice panoramic panning shots not only to provide visual information but also to engage his audience in the total environment of his films. Later, he would prominently employ the tracking, or traveling, shot, in which the camera—and therefore the audience—participates in the dramatic action by moving with it. In California, Griffith discovered that camera angle could be used to comment upon the content of a shot or to heighten its dramatic emphasis in a way that the conventionally mandated head-on medium shot could not; and, at a time when convention dictated the flat and uniform illumination of every element in a scene, he pioneered the use of expressive lighting to create mood and atmosphere. Like so many of the other devices he brought into general use, these had all been employed by earlier directors, but Griffith was the first to practice them with the care of an artist and to rationalize them within the overall structure of his films.

Griffith's one-reelers grew increasingly complex between 1911 and 1912, and he began to realize that only a longer and more expansive format could contain his vision. At first he made such two-reel films as *Enoch Arden* (1911), *Man's Genesis* (1912), *The Massacre* (1912), and *The Mothering Heart* (1913), but these went virtually unnoticed by a public enthralled with such recent features from Europe as *Queen Elizabeth* and *Quo Vadis?.* Finally, Griffith determined to make an epic himself, based on the story of Judith and Holofernes from the Apocrypha. The result was the four-reel *Judith of Bethulia* (1913), filmed secretly on a 12-square-mile set in Chatsworth Park, Calif. In addition to its structurally complicated narrative, *Judith* contained massive sets and battle scenes unlike anything yet attempted in American film. It cost twice the amount Biograph had allocated for its budget. Company officials, stunned at Griffith's audacity and extravagance, tried to relieve the director of his creative responsibilities by promoting him to studio production chief. Griffith quit instead, publishing a full-page advertisement in *The New York Dramatic Mirror* (Dec. 3, 1913), in which he took credit for all of the Biograph films he had made from *The Adventures of Dollie* through *Judith,* as well as for the narrative innovations they contained. He then accepted an offer from Harry E. Aitken, the president of the recently formed Mutual Film Corporation, to head the feature production company Reliance-Majestic; he took Bitzer and most of his Biograph stock company with him.

Griffith's departure from Biograph

As part of his new contract, Griffith was allowed to make two independent features per year, and for his first project he chose to adapt *The Clansman,* a novel about the Civil War and Reconstruction by the Southern clergyman Thomas Dixon, Jr. (As a Kentuckian whose father had served as a Confederate officer, Griffith was deeply sympathetic to the material, which was highly sensational in its depiction of Reconstruction as a period in which mulatto carpetbaggers and their black henchmen had destroyed the social fabric of the South and given birth to a heroic Ku Klux Klan.) Shooting on the film began in secrecy in late 1914. Although a script existed, Griffith kept most of the continuity in his head—a remarkable feat considering

that the completed film contained 1,544 separate shots at a time when the most elaborate of foreign spectacles boasted fewer than 100. When the film opened in March 1915, retitled *The Birth of a Nation,* it was immediately pronounced "epoch-making" and recognized as a remarkable artistic achievement. The complexity of its narrative and the epic sweep of its subject were unprecedented, but so too were its controversial manipulations of audience response, especially its blatant appeals to racism. Despite its brilliantly conceived battle sequences, its tender domestic scenes, and its dignified historical reconstructions, the film also contained shocking images of miscegenation and racial violence that provoked fear and disgust. As the film's popularity swept the nation, denunciations followed, and many who had originally praised it, such as President Woodrow Wilson, were forced to recant. Ultimately, after screenings of *The Birth of a Nation* had caused riots in several cities, it was banned in eight northern and midwestern states. (First Amendment protection was not extended to motion pictures in the United States until the late 1950s.) Such measures, however, did not prevent *The Birth of a Nation* from becoming the single most popular film in history to date; it achieved national distribution in the year of its release and was seen by nearly 3,000,000 people.

The Birth of a Nation

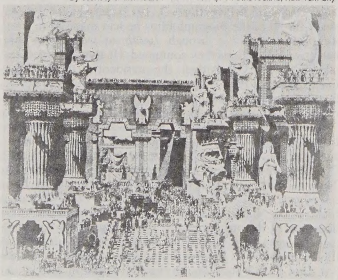
Although it is difficult to believe that the film's racism was unconscious, as some have claimed, it is easy to imagine that Griffith had not anticipated the power of his own images. He seems to have been genuinely stunned by the hostile public reaction to his masterpiece, and he fought back by publishing a pamphlet entitled *The Rise and Fall of Free Speech in America* (1915), which vilified the practice of censorship and especially intolerance. At the height of his notoriety and fame, Griffith decided to produce a spectacular cinematic polemic against this flaw in human character as it had endangered civilization throughout history. The result was the massive epic *Intolerance* (1916), which interweaves stories of martyrdom from four separate historical periods. The film was conceived on a scale so monumental as to dwarf all predecessors. Crosscutting freely between a contemporary tale of courtroom injustice, the fall of ancient Babylon to Cyrus the Great in 539 BC, the St. Bartholomew's Day Massacre in 16th-century France, and the Crucifixion of Christ, Griffith created an editing structure so abstract that contemporary audiences could not understand it. Even the extravagant sets and exciting battle sequences could not save *Intolerance* at the box-office. To reduce his losses, Griffith withdrew the film from distribution after 22 weeks; he subsequently cut into the negative and released the modern and the Babylonian stories as two separate features, *The Mother and the Law* and *The Fall of Babylon,* in 1919. (Although ignored by Americans, *Intolerance* was both popular and vastly influential in the Soviet Union, where filmmakers minutely analyzed Griffith's editing style and techniques.)

Intolerance

It would be fair to say that Griffith's career as an innovator of film form ended with *Intolerance,* but his career as a film artist certainly did not. He went on to direct another 26 features between 1916 and 1931, chief among them the World War I anti-German propaganda epic (financed, in part, by the British government) *Hearts of the World* (1918), the subtle and lyrical *Broken Blossoms* (1919), and the rousing melodrama *Way Down East* (1920). The financial success of the latter made it possible for Griffith to establish his own studio at Mamaroneck, N.Y., where he produced the epics *Orphans of the Storm* (1921) and *America* (1924), which focused on the French and American revolutions, respectively; both lost money. Griffith's next feature was the independent semidocumentary *Isn't Life Wonderful?* (1925), which was shot on location in Germany and is thought to have influenced both the "street" films of the German director G.W. Pabst and the post-World War II Italian Neorealist movement.

Griffith's last films, with the exception of *The Struggle* (1931), were all made for other producers. Not one could be called a success, although his first sound film, *Abraham Lincoln* (1930), was recognized as an effective essay in the new medium. The critical and financial failure of *The Struggle,* however, a version of Zola's *L'Assommoir* (*The Drunkard*), forced Griffith to retire.

It might be said of Griffith that, like Méliès and Porter, he outlived his genius, but that is not true. Griffith was fundamentally a 19th-century man who became one of the 20th-century's greatest artists. Transcending personal defects of vision, judgment, and taste, he developed the narrative language of film. He lost touch with his contemporaries because his subjects came to seem old-fashioned, but he remains peculiarly, uniquely in touch with the present because the techniques and structure he contributed to the motion-picture medium are still in use.



Post-World War I European cinema. Prior to World War I, the American cinema had lagged behind the film industries of Europe, particularly those of France and Italy, in such matters as feature production and the establishment of permanent theatres. During the war, however, European film production virtually ceased, in part because the same chemicals used in the production of celluloid were necessary for the manufacture of gun powder. The American cinema, meanwhile, experienced a period of unprecedented prosperity and growth. By the end of the war it exercised nearly total control of the international market: when the Treaty of Versailles was signed in 1919, 90 percent of all films screened in Europe, Africa, and Asia were American, and the figure for South America was (and remained through the 1950s) close to 100 percent. The main exception was Germany, which had been cut off from American films from 1914 until the end of the war.

Germany. Before World War I, the German motion-picture audience was largely uneducated and unemployed or from the working class. Most of the films exhibited were imported from other countries, particularly Denmark. The few German films produced were usually cheaply and crudely made. This impoverished state of the domestic industry became a matter of concern among military leaders during the war, when a flood of effective anti-German propaganda films began to pour into Germany from the Allied countries. Therefore, on Dec. 18, 1917, the German general Erich Ludendorff ordered the merger of the main German production, distribution, and exhibition companies into the government-subsidized conglomerate Universum Film Aktiengesellschaft. UFA's mission was to upgrade the quality of German films. The organization proved to be highly effective, and when the war ended in Germany's defeat in November 1918, the German film industry was prepared for the first time to compete in the international marketplace. Transferred to private control, UFA became the single largest studio in Europe and produced most of the films associated with the "golden age" of German cinema during the Weimar Republic (1919–33).

UFA

UFA's first peacetime productions were elaborate costume dramas (*Kostümfilme*) in the vein of the prewar Italian superspectacles, and the master of this form was Ernst Lubitsch, who directed such lavish and successful historical pageants as *Madame Dubarry* (released in the United

States as *Passion,* 1919), *Anna Boleyn* (*Deception,* 1920), and *Das Weib des Pharao* (*The Loves of Pharaoh,* 1921) before emigrating to the United States in 1922. These films earned the German cinema a foothold in the world market, but it was an Expressionist work, *Das Kabinett des Dr. Caligari* (*The Cabinet of Dr. Caligari,* 1919), that brought the industry its first great artistic acclaim. Based on a scenario by the Czech poet Hans Janowitz and the Austrian writer Carl Mayer, the film recounts a series of brutal murders that are committed in the north German town of Holstenwall by a somnambulist at the bidding of a demented mountebank, who believes himself to be the incarnation of a homicidal 18th-century hypnotist named Dr. Caligari. Erich Pommer, *Caligari*'s producer at Decla-Bioskop (an independent production company that was to merge with UFA in 1921), added a scene to the original scenario so that the story appears to be narrated by a madman confined to an asylum of which the mountebank is director and head psychiatrist. To represent the narrator's tortured mental state, the director, Robert Wiene, hired three prominent Expressionist artists—Hermann Warm, Walter Röhrig, and Walter Reimann—to design sets that depicted exaggerated dimensions and deformed spatial relationships. To heighten this architectural stylization (and also to economize on electric power, which was rationed in postwar Germany), bizarre patterns of light and shadow were painted directly onto the scenery and even onto the characters' makeup.

German Expressionism

Werner Krauss in *The Cabinet of Dr. Caligari,* directed by Robert Wiene (1919).

In its effort to embody disturbed psychological states through decor, *Caligari* influenced enormously the UFA films that followed it and gave rise to the movement known as German Expressionism. The films of this movement were completely studio-made and often used distorted sets and lighting effects to create a highly subjective mood. They were primarily films of fantasy and terror that employed horrific plots to express the theme of the soul in search of itself. Most were photographed by one of the two great cinematographers of the Weimar period, Karl Freund and Fritz Arno Wagner. Representative works include F.W. Murnau's *Der Januskopf* (*Janus-Faced,* 1920), adapted from Robert Louis Stevenson's *Dr. Jekyll and Mr. Hyde;* Paul Wegener and Carl Boese's *Der Golem* (*The Golem,* 1920), adapted from a Jewish legend in which a gigantic clay statue becomes a raging monster; Arthur Robison's *Schatten* (*Warning Shadows,* 1922); Wiene's *Raskolnikow* (1923), based on Dostoyevsky's *Crime and Punishment;* Paul Leni's *Das Wachsfigurenkabinett* (*Waxworks,* 1924); and Henrik Galeen's *Der Student von Prag* (*The Student of Prague,* 1926), which combines the Faust legend with a doppelgänger, or double, motif. In addition to winning international prestige for German films, Expressionism produced two directors who would become major figures in world cinema, Fritz Lang and F.W. (Friedrich Wilhelm) Murnau.

Lang had already directed several successful serials, including *Die Spinnen* (*The Spiders,* 1919–20), when he collaborated with his future wife, the scriptwriter Thea von Harbou, to produce *Der müde Tod* ("The Weary Death"; English title: *Destiny,* 1921) for Decla-Bioscop. This episodic Romantic allegory of doomed lovers, set in several different historical periods, earned Lang acclaim for his dynamic compositions of architectural line and space. Lang's use of striking, stylized images is also demonstrated in the other films of his Expressionist period, notably the crime melodrama *Dr. Mabuse, der Spieler* (*Dr. Mabuse, the Gambler,* 1922), the Wagnerian diptych *Siegfried* (1922–24) and *Kriemhilds Rache* (*Kriemhild's Revenge,* 1922–23), and the stunningly futuristic *Metropolis* (1926), perhaps the greatest science-fiction film ever made. After directing the early sound masterpiece *M* (1931), based on child murders in Dusseldorf, Lang became increasingly estranged from German political life. He emigrated in 1933 to escape the Nazis and began a second career in the Hollywood studios the following year.

Murnau made several minor Expressionist films before directing one of the movement's classics, an (unauthorized) adaptation of Bram Stoker's novel *Dracula* entitled *Nosferatu—eine Symphonie des Grauens* ("Nosferatu, a Symphony of Horror," 1922), but it was *Der letzte Mann* ("The Last Man"; English title: *The Last Laugh,* 1924), a film in the genre of *Kammerspiel* ("intimate theatre"), that made him world famous. Scripted by Carl Mayer and produced by Erich Pommer for UFA, *Der letzte Mann* told the story of a hotel doorman who is humiliated by the loss of his job and—more important, apparently, in postwar German society—of his splendid paramilitary uniform. Murnau and Freund, his cameraman, gave this simple tale a complex narrative structure through their innovative use of camera movement and subjective point-of-view shots. In one famous example, Freund strapped a lightweight camera to his chest and stumbled drunkenly around the set of a bedroom to record the inebriated porter's point of view. In the absence of modern cranes and dollies, at various points in the filming Murnau and Freund placed the camera on moving bicycles, fire engine ladders, and overhead cables in order to achieve smooth, sustained movement. The total effect was a tapestry of subjectively involving movement and intense identification with the narrative.

Use of subjective camera movement in *The Last Laugh*

Der letzte Mann was universally hailed as a masterpiece and probably had more influence on Hollywood style than any other single foreign film in history. Its "unchained camera" technique (Mayer's phrase) spawned many imitations in Germany and elsewhere, the most significant being E.A. (Ewald André) Dupont's circus-tent melodrama *Variété* (1925). The film also brought Murnau a long-term Hollywood contract, which he began to fulfill in 1927 after completing two last super-productions, *Tartüff* (1925) and *Faust* (1926), for UFA.

In 1924 the German mark was stabilized by the so-called Dawes Plan, which financed the long-term payment of Germany's war reparations debt and curtailed all exports. This created an artificial prosperity in the economy at large, which lasted only until the stock market crash of 1929, but it was devastating to the film industry, the bulk of whose revenues came from foreign markets. Hollywood then seized the opportunity to cripple its only serious European rival, saturating Germany with American films and buying its independent theatre chains. As a result of these forays and its own internal mismanagement, UFA stood on the brink of bankruptcy by the end of 1925. It was saved by a $4,000,000 loan offered by two major American studios, Famous Players-Lasky (later Paramount) and Metro-Goldwyn-Mayer, in exchange for collaborative rights to UFA studios, theatres, and creative personnel. This arrangement resulted in the founding of the Parufamet (Paramount-UFA-Metro) Distribution Company in early 1926 and the almost immediate emigration of UFA film artists and technicians to Hollywood, where they worked for a variety of studios. This first Germanic migration was temporary. Many of the filmmakers returned to UFA disgusted at the assembly-line character of the American studio system, but many—such as Lubitsch, Freund, Murnau, and Kertész—stayed on to launch full-fledged Hollywood careers, and many more would come back during the 1930s to escape Adolf Hitler.

In the meantime, the new sensibility that had entered German intellectual life turned away from the morbid psychological themes of Expressionism toward an acceptance of "life as it is lived." Called *die neue Sachlichkeit* ("the new objectivity"), this spirit stemmed from the economic dislocations that beset German society in the wake of the war, particularly the impoverishment of the middle classes through raging inflation. In cinema, *die neue Sachlichkeit* translated into the grim social realism of the "street" films of the late 1920s, including G.W. Pabst's *Die freudlose Gasse* (*The Joyless Street,* 1925), Bruno Rhan's *Dirnentragödie* (*Tragedy of the Streets,* 1927), Joe May's *Asphalt* (1929), and Piel Jutzi's *Berlin-Alexanderplatz* (1931). Named for their prototype, Karl Grune's *Die Strasse* (*The Street,* 1923), these films focused on the disillusionment, cynicism, and ultimate resignation of ordinary German people whose lives were crippled during the postwar inflation.

The master of the form was G.W. (Georg Wilhelm) Pabst, whose work established conventions of continuity editing that would become essential to the sound film. In such important realist films as *Die freudlose Gasse*, *Die Liebe der Jeanne Ney* (*The Love of Jeanne Ney,* 1927), *Die Büchse der Pandora* (*Pandora's Box,* 1929), and *Tagebuch einer Verlorenen* (*Diary of a Lost One,* 1929), Pabst created complex continuity sequences using techniques that became key features of the Hollywood "invisible" editing style, such as cutting on action, cutting from a shot of a character's glance to one of what the character sees (motivated point-of-view shots), and cutting to a reverse angle shot (one in which the camera angle has changed 180 degrees; *e.g.,* in a scene in which a man and a woman face one another in conversation, the man is seen from the woman's point of view, then the woman is shown from the man's point of view). Pabst later became an important figure of the early sound period, contributing in his pacifist films *Westfront 1918* (1930) and *Kameradschaft* ("Comradeship," 1931) two significant works. A few years later, however, Pabst found himself making films for the Nazis, a condition that afflicted the entire German film industry after 1933.

Pabst's editing techniques

By March 1927, UFA was once again facing financial collapse, and it turned this time to the Prussian financier Alfred Hugenberg, a director of both the powerful Krupp industrial empire and the right-wing German National Party, who was sympathetic to the Nazis. Hugenberg bought out the American interests in UFA, acquiring a majority of the company's stock and directing the remainder into the hands of his political allies. As chairman of the UFA board, he quietly instituted a nationalistic production policy that gave increasing prominence to the Nazis and their cause and that enabled the Nazis to subvert the German film industry when Hitler came to power in 1933. German cinema then fell under the authority of Joseph Goebbels and his Ministry of Public Enlightenment and Propaganda. For the next 12 years every film made in the Third Reich had to be personally approved for release by Goebbels. Jews were officially banned from the industry, causing a vast wave of German film artists to emigrate to Hollywood. Los Angeles became known as "the new Weimar," and the German cinema was emptied of the talent and brilliance that had created its golden age.

German cinema under the Third Reich

The Soviet Union. Before the Bolshevik Revolution of October 1917, Russia for all practical purposes had no native film industry. In the industrialized nations of the West, motion pictures had first been accepted as a form of cheap recreation and leisure for the working class. From that base, they had reached out successfully to the middle class and gained wide popularity among all classes by about 1914. In prerevolutionary Russia, however, the working class was composed largely of serfs too poor to support a native industry, and the small movie business that did develop was dominated by foreign interests and foreign films—mainly French, German, and Danish.

The first native Russian company was not founded until 1908, and by the time of the Revolution, there were perhaps 20 more; but even these were small, importing all of their technical equipment and film stock from Germany and France. When Russia entered World War I in August 1914, foreign films could no longer be imported, and the tsarist government established the Skobelev Committee to stimulate domestic production and produce propaganda in support of the regime. The committee had little immediate effect, but when the Tsar fell in March 1917 the provisional Kerensky government reorganized it to produce antitsarist propaganda. When the Bolsheviks inherited the group eight months later, they transformed it into the Cinema Committee of the People's Commissariat of Education.

A minority party with approximately 200,000 members, the Bolsheviks had assumed the leadership of 160,000,000 people who were scattered across the largest continuous landmass in the world, spoke more than 100 separate languages, and were mostly illiterate. Vladimir Ilich Lenin and other Bolshevik leaders looked on the motion-picture medium as a means of unifying the huge, disparate nation. Lenin was the first political leader of the 20th century to recognize both the importance of film as propaganda and its power to communicate quickly and effectively. He understood that audiences did not require literacy to comprehend a film's meaning and that more people could be reached through mass-distributed motion pictures than through any other medium of the time. Lenin declared: "The cinema is for us the most important of the arts," and his government gave top priority to the rapid development of the Soviet film industry, which was nationalized in August 1919 and put under the direct authority of Lenin's wife, Nadezhda Krupskaya.

There was, however, little to build upon. Most of the prerevolutionary producers had fled to Europe, taking their equipment and film stock with them, wrecking their studios as they left. A foreign blockade prevented the importation of new equipment or stock (there were no domestic facilities for manufacturing them), and massive power shortages restricted the use of what limited resources remained. The Cinema Committee was not deterred however; its first act was to found a professional film school in Moscow to train directors, technicians, and actors for the cinema.

The Vsesoyuznyi Gosudarstvenyi Institut Kinematografii (VGIK; "All-Union State Institute of Cinematography") was the first such school in the world and is still among the most respected. Initially, it trained people in the production of *agitki,* existing newsreels reedited for the purpose of agitation and propaganda (agitprop). The *agitki* were transported on specially equipped agit-trains and agit-steamers to the provinces, where they were exhibited to generate support for the Revolution. (The state-controlled Cuban cinema used the same tactic after the revolution of 1959.) In fact, during the abysmal years of the Civil War (1918–20), nearly all Soviet films were *agitki* of some sort. Most of the great directors of the Soviet silent cinema were trained in that form, although, having very little technical equipment and no negative film stock, they were often required to make "films without celluloid."

Soviet *agitki*

Students at the VGIK were instructed to write, direct, and act out scenarios as if they were before cameras. Then—on paper—they assembled various "shots" into completed "films." The great teacher Lev Kuleshov obtained a print of Griffith's *Intolerance* and screened it for students in his "Kuleshov workshop" until they had memorized its shot structures and could rearrange its multilayered editing sequences on paper in hundreds of different combinations.

Kuleshov further experimented with editing by intercutting the same shot of a famous actor's expressionless face with several different shots of highly expressive content—a steaming bowl of soup, a dead woman in a coffin, and a little girl playing with a teddy bear. The invariable response of film school audiences when shown these sequences was that the actor's face assumed the emotion appropriate to the intercut object—hunger for the soup, sorrow for the dead woman, paternal affection for the little girl. Kuleshov reasoned from this phenomenon, known today as the "Kuleshov effect," that the shot in film always has two values: that which it carries in itself as a photographic image of reality, and that which it acquires when placed into juxtaposition with another shot. He reasoned further that the second value is more important to cinematic

The Kuleshov effect

signification than the first and that, therefore, time and space in the cinema must be subordinate to the process of editing, or montage (coined by the Soviets from the French verb *monter*, "to assemble"). Kuleshov ultimately conceived of montage as an expressive process whereby dissimilar images could be linked together to create nonliteral or symbolic meaning.

Although Kuleshov made several important films, including *By the Law* (1926), it was as a teacher and theorist that he most deeply influenced an entire generation of Soviet directors. Two of his most brilliant students were Sergey Eisenstein and Vsevolod Illarionovich Pudovkin.

Sergey Eisenstein

Eisenstein was, with Griffith, one of the great pioneering geniuses of the modern cinema, and like his predecessor he produced a handful of enduring masterworks. Griffith, however, had elaborated the structure of narrative editing intuitively, whereas Eisenstein was an intellectual who formulated a modernist theory of editing based on the psychology of perception and Marxist dialectic. Trained as a civil engineer, in 1920 he joined the Moscow Proletkult Theatre, where he fell under the influence of the stage director Vsevolod Meyerhold and directed a number of plays in the revolutionary style of Futurism. In the winter of 1922–23 Eisenstein studied under Kuleshov and was inspired to write his first theoretical manifesto, "The Montage of Attractions." Published in the radical journal *Lef*, the article advocated assaulting an audience with calculated emotional shocks for the purpose of agitation.

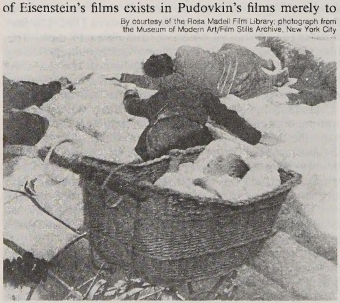
Eisenstein was invited to direct the Proletkult-sponsored film *Strike* in 1924, but, like Griffith, he knew little of the practical aspects of production. He therefore enlisted the aid of Eduard Tisse, a brilliant cinematographer at the state-owned Goskino studios, beginning a lifelong artistic collaboration. *Strike* is a semidocumentary representation of the brutal suppression of a strike by tsarist factory owners and police. In addition to being Eisenstein's first film, it was also the first revolutionary mass-film of the new Soviet state. Conceived as an extended montage of shock stimuli, the film concludes with the now famous sequence in which the massacre of the strikers and their families is intercut with shots of cattle being slaughtered in an abattoir.

Strike was an immediate success, and Eisenstein was next commissioned to direct a film celebrating the 20th anniversary of the failed 1905 revolution against tsarism. Originally intended to provide a panorama of the entire event, the project eventually came to focus on a single representative episode—the mutiny of the battleship *Potemkin* and the massacre of the citizens of the port of Odessa by tsarist troops. *Battleship Potemkin* (1925) emerged as one of the most important and influential films ever made, especially in Eisenstein's use of montage, which had improved far beyond the formulaic, if effective, juxtapositions of *Strike*.

Although agitational to the core, *Potemkin* is a work of extraordinary pictorial beauty and great elegance of form. It is symmetrically broken into five movements or acts, according to the structure of Greek tragedy. In the first of these, "Men and Maggots," the flagrant mistreatment of the sailors at the hands of their officers is demonstrated, while the second, "Drama on the Quarterdeck," presents the actual mutiny and the ship's arrival in Odessa. "Appeal from the Dead" establishes the solidarity of the citizens of Odessa with the mutineers, but it is the fourth sequence, "The Odessa Steps," which depicts the massacre of the citizens, that thrust Eisenstein and his film into the historical eminence that both occupy today. Its power is such that the film's conclusion, "Meeting the Squadron," in which the *Potemkin* in a show of brotherhood is allowed to pass through the squadron unharmed, is anticlimactic.

Eisenstein's theory of montage

Unquestionably the most famous sequence of its kind in film history, "The Odessa Steps" incarnates the theory of dialectical montage that Eisenstein later expounded in his collected writings, *The Film Sense* (1942) and *Film Form* (1949). Eisenstein believed that meaning in motion pictures is generated by the collision of opposing shots. Building on Kuleshov's ideas, Eisenstein reasoned that montage operates according to the Marxist view of history as a perpetual conflict in which a force (thesis) and a counterforce (antithesis) collide to produce a totally new and greater phenomenon (synthesis). He compared this dialectical process in film editing to "the series of explosions of an internal combustion engine, driving forward its automobile or tractor." The force of the Odessa steps sequence arises when the viewer's mind combines individual, independent shots and forms a new, distinct conceptual impression that far outweighs the shots' narrative significance. Through Eisenstein's accelerated manipulations of filmic time and space, the slaughter on the stone steps—where hundreds of citizens find themselves trapped between descending tsarist militia above and Cossacks below—acquires a powerful symbolic meaning. With the addition of a stirring revolutionary score by the German Marxist composer Edmund Meisel, the agitational appeal of *Potemkin* became nearly irresistible, and, when exported in early 1926, it made Eisenstein world famous.



Eisenstein's next project, *October* (1928), was commissioned by the Central Committee to commemorate the 10th anniversary of the Bolshevik Revolution. Accordingly, vast resources, including the Soviet Army and Navy, were placed at the director's disposal. Eisenstein based the shooting script on voluminous documentary material from the era and on John Reed's book *Ten Days That Shook the World*. When the film was completed in November 1927, it was just under four hours long. While Eisenstein was making *October*, however, Joseph Stalin had taken control of the Politburo from Leon Trotsky, and the director was forced to cut the print by one-third to eliminate references to the exiled Trotsky.

Eisenstein had consciously used *October* as a laboratory for experimenting with "intellectual" or "ideological" montage, an abstract type of editing in which the relationships established between shots are conceptual rather than visual or emotional. When the film was finally released, however, Stalinist critics attacked this alleged "formalist excess" (aestheticism or elitism). The same charge was leveled even more bitterly against Eisenstein's next film, *Old and New* (1929), which Stalinist bureaucrats completely disavowed. Stalin hated Eisenstein because he was an intellectual and a Jew, but the director's international stature was such that he could not be publicly purged. Instead, Stalin used the Soviet state-subsidy apparatus to foil Eisenstein's projects and attack his principles at every turn, a situation that resulted in the director's failure to complete another film until *Alexander Nevsky* was commissioned in 1938.

Eisenstein's nearest rival in the Soviet silent cinema was his fellow student Pudovkin. Like Eisenstein, Pudovkin developed a new theory of montage but one based on cognitive linkage rather than dialectical collision. He maintained that "the film is not shot, but built, built up from the separate strips of celluloid that are its raw material." Pudovkin, like Griffith, most often used montage for narrative rather than symbolic purpose. His films are more personal than Eisenstein's; the epic drama that is the focus of Eisenstein's films exists in Pudovkin's films merely to

Pudovkin's use of montage

The descent of the baby carriage during the "Odessa Steps" sequence from *Battleship Potemkin*, Sergey Eisenstein (1925).

provide a backdrop for the interplay of human emotions.

Pudovkin's major work is *Mother* (1926), a tale of strike-breaking and terrorism in which a woman loses first her husband and then her son to the opposing sides of the 1905 Revolution. The film was internationally acclaimed for the revolutionary intensity of its montage, as well as for its emotion and lyricism. Pudovkin's later films include *The End of St. Petersburg* (1927), which, like Eisenstein's *October,* was commissioned to celebrate the 10th anniversary of the Bolshevik Revolution, and *The Heir to Genghis Khan* (1928; English title: *Storm over Asia*), which is set in Central Asia during the 1920 Civil War. Both mingle human drama with the epic and the symbolic as they tell a story of a politically naive person who is galvanized into action by tsarist tyranny. Although Pudovkin was never persecuted as severely by the Stalinists as Eisenstein, he too was publicly charged with formalism for his experimental sound film *A Simple Case* (1932) and was forced to release the film without its sound track. Pudovkin made several more sound films but remains best known for his silent work.

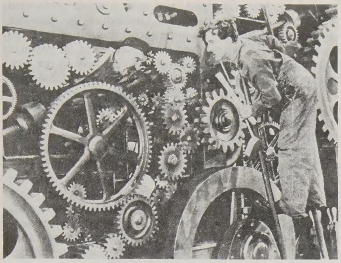
Two other seminal figures of the Soviet silent era were Aleksandr Dovzhenko and Dziga Vertov (original name Denis Kaufman). Dovzhenko, the son of Ukrainian peasants, had been a political cartoonist and painter before becoming a director at the state-controlled Odessa studios in 1926. After several minor works, he made *Zvenigora* (1928), a collection of boldly stylized tales about a hunt for an ancient Scythian treasure set during four different stages of Ukrainian history; *Arsenal* (1929), an epic film poem about the effects of revolution and civil war upon the Ukraine; and *Earth* (1930), which is considered to be his masterpiece. *Earth* tells the story of the conflict between a family of wealthy land-owning peasants (kulaks) and the young peasants of a collective farm in a small Ukrainian village, but the film is less a narrative than a lyric hymn to the cyclic recurrence of birth, life, love, and death in nature and in humankind. Although the film is acclaimed today, when it was released Stalinist critics denounced it as counterrevolutionary. Soon after, Dovzhenko entered a period of political eclipse, during which, however, he continued to make films.

Dziga Vertov's theory of the *kino-glaz*

Dziga Vertov (a pseudonym meaning "spinning top") was an artist of quite different talents. He began his career as an *agitki* photographer and newsreel editor and is now acknowledged as the father of *cinéma-vérité* (a self-consciously realistic documentary movement of the 1960s and '70s) for his development and practice of the theory of the *kino-glaz* ("cinema-eye"). Vertov articulated this doctrine in the early 1920s in a number of radical manifestos in which he denounced conventional narrative cinema as impotent and demanded that it be replaced with a cinema of actuality based on the "organization of camera-recorded documentary material." Between 1922 and 1925, he put his idea into practice in a series of 23 carefully crafted newsreel-documentaries entitled *Kino-Pravda* ("film truth") and *Goskinokalender.* Vertov's most famous film is *Man with a Movie Camera* (1929), a feature-length portrait of Moscow from dawn to dusk. The film plays upon the "city symphony" genre inaugurated by Walter Ruttman's *Berlin, the Symphony of a Great City* (1927), but Vertov repeatedly draws attention to the filmmaking process to create an autocritique of cinema itself.

Unlike most of his contemporaries, Vertov welcomed the coming of sound, envisioning it as a "radio-ear" to accompany the "cinema-eye." His first sound film, *Symphony of the Donbas* (1931), was an extraordinary contribution to the new medium, as was *Three Songs About Lenin* (1934), yet Vertov could not escape the charge of formalist error any more than his peers. Although he did make the feature film *Lullaby* in 1937, for the most part the Stalinist establishment reduced him to the status of a newsreel photographer after 1934.

Many other Soviet filmmakers played important roles in the great decade of experiment that followed the Revolution, among them Grigory Kozintsev and Leonid Trauberg (*The Overcoat,* 1926; *The New Babylon,* 1929), Boris Barnet (*The House on Trubnaya Square,* 1928), Yakov Protazanov (*Aelita,* 1924), Olga Preobrazhenskaya (*Women of Ryazan,* 1927), Abram Room (*Bed and Sofa,* 1927), and the documentarian Esther Shub (*The Fall of the Romanov Dynasty,* 1927). The period came to an abrupt end in 1929, when Stalin removed the state film trust (then called Sovkino) from the jurisdiction of the Commissariat of Education and placed it under the direct authority of the Supreme Council of the National Economy. Reorganized as Soyuzkino, the trust was turned over to the reactionary bureaucrat Boris Shumyatsky, a proponent of the narrowly ideological doctrine known as socialist realism. This policy, which came to dominate the Soviet arts, dictated that individual creativity be subordinated to the political aims of the party and the state. In practice, it militated against the symbolic, the experimental, and the avant-garde in favour of a literal-minded "people's art" that glorified representative Soviet heroes and idealized Soviet experience. The restraints imposed made it impossible for the great filmmakers of the postrevolutionary era to produce creative or innovative work, and the Soviet cinema went into decline.



Soviet socialist realism

Post-World War I U.S. cinema. During the 1920s in the United States, motion-picture production, distribution, and exhibition became a major national industry and movies perhaps the major national obsession. The salaries of stars reached monumental proportions, filmmaking practices and narrative formulas were standardized to accommodate mass production, and Wall Street began to invest heavily in every branch of the business. The growing industry was organized according to the studio system that, in many respects, the producer Thomas Harper Ince had developed at Inceville, his studio in the Santa Ynez Canyon near Hollywood, between 1914 and 1918. Ince functioned as the central authority over multiple production units, each headed by a director who was required to shoot an assigned film according to a detailed continuity script. Every project was carefully budgeted and tightly scheduled, and Ince himself supervised the final cut. This central producer system was the prototype for the studio system of the 1920s, and, with some modification, it prevailed as the dominant mode of Hollywood production for the next 40 years.

Virtually all of the major film genres evolved and were codified during the 1920s, but none was more characteristic of the period than the slapstick comedy. This form was originated by Mack Sennett, who, at his Keystone Studios, produced countless one- and two-reel shorts and features (*Tillie's Punctured Romance,* 1914; *The Surf Girl,* 1916; *Teddy at the Throttle,* 1917) whose narrative logic was subordinated to fantastic, purely visual humour. An anarchic mixture of circus, vaudeville, burlesque, pantomime, and the chase, Sennett's Keystone comedies created a world of inspired madness and mayhem, and they employed the talents of such future stars as Charlie Chaplin, Harry Langdon, Roscoe "Fatty" Arbuckle, Mabel Normand, and Harold Lloyd. When these performers achieved fame, many of them left Keystone, often to form their own production companies, a practice still (if briefly) possible in the early 1920s.

Charlie Chaplin

Chaplin, for example, who had developed the persona of the "little tramp" at Keystone, went on to direct and star in a series of shorts produced by Essanay in 1915 (*The Tramp, A Night in the Show*) and Mutual between 1916 and 1917 (*One A.M., The Rink, Easy Street*). In 1917 he was offered an eight-film contract with First National that enabled him to establish his own studio. He directed his first feature there, the semiautobiographical *The Kid* (1921), but most of his First National films were two-reelers. In 1919 Chaplin, Griffith, Mary Pickford, and Douglas Fairbanks, the four most popular and powerful film artists of the time, jointly formed the United Artists Corporation in order to produce and distribute—and thereby retain artistic and financial control over—their own films. Chaplin directed three silent features for United Artists: *A Woman of Paris* (1923), his great comic epic *The Gold Rush* (1925), and *The Circus* (1928), which was released after the introduction of sound into motion pictures. He later made several sound films, but the two most successful—his first two, *City Lights* (1931) and *Modern Times* (1936)—were essentially silent films with musical scores.

Buster Keaton

Buster Keaton possessed a very different kind of comic talent than Chaplin; but both men were wonderfully subtle actors with a keen sense of the tragic often contained within the comic, and both were major directors of their period. Keaton, like Chaplin, was born into a theatrical family and began performing in vaudeville skits at a young age. Intrigued by the new film medium, he left the stage and worked for two years as a supporting comedian for Arbuckle's production company. In 1919 Keaton formed his own production company, where, over the next four years, he made 20 shorts (*One Week,* 1920; *The Boat,* 1921; *Cops,* 1922; *The Balloonatic,* 1923) that represent, with Chaplin's Mutual films, the acme of American slapstick comedy. A Keaton trademark was the "trajectory gag," in which perfect timing of acting, directing, and editing propels his film character through a geometric progression of complicated sight gags that seem impossibly dangerous but are still dramatically logical. Such routines inform all of Keaton's major features—*Our Hospitality* (1923), *Sherlock Jr.* (1924), *The Navigator* (1924), *Seven Chances* (1925), and his masterpieces *The General* (1927) and *Steamboat Bill, Jr.* (1928). Keaton's greatest films, all made before his company was absorbed by MGM, have a reflexive quality that indicates his fascination with film as a medium. Although some of his MGM films were financially successful, the factory-like studio system stifled Keaton's creativity, and he was reduced to playing bit parts after the early 1930s.

Important but lesser silent comics were Lloyd, the team of Stan Laurel and Oliver Hardy, Langdon, and Arbuckle. Working at the Hal Roach Studios, Lloyd cultivated the persona of an earnest, sweet-tempered boy-next-door. He specialized in a variant of Keystone mayhem known as the "comedy of thrills," in which—as in Lloyd's most famous features, *Safety Last* (1923) and *The Freshman* (1925)—an innocent protagonist finds himself placed in physical danger. Laurel and Hardy also worked for Roach. They made 27 silent two-reelers, including *Putting Pants on Philip* (1927) and *Liberty* (1929), and became even more popular in the 1930s in such sound films as *Another Fine Mess* (1930) and *Sons of the Desert* (1933). Their comic characters were basically grown-up children whose relationship was sometimes disturbingly sadomasochistic. Langdon also traded on a childlike, even babylike, image in such popular features as *The Strong Man* (1926) and *Long Pants* (1927), both directed by Frank Capra. Arbuckle, however, in his few years of stardom, unfortunately created the character of a leering, sensual adult. Arbuckle's talent was limited, but his persona affected the course of American film history in a quite unexpected way.

By the early 1920s some 40,000,000 Americans—half of them minors—were attending the movies each week. The rapid spread of the medium and its easy accessibility had already caused mild public concern, especially since films had begun to feature increasingly risqué plots and situations. Concern increased as Hollywood became identified in the popular mind with the materialism, cynicism, and sexual license of the Jazz Age. Then, in September 1921 the popular Arbuckle was charged with the rape and manslaughter of a young starlet, and the concern turned into anger and rage. Arbuckle was eventually exonerated, but other Hollywood scandals surfaced—the murder of director William Desmond Taylor, the death from drug addiction of matinee idol Wallace Reid—and the tabloid press screamed for blood.

The Hays Office

In an attempt to stave off probable mass boycotts and government censorship, in March 1922 the studio heads formed a self-regulatory trade organization, the Motion Picture Producers and Distributors of America (MPPDA), and hired the U.S. postmaster general, Will H. Hays, to head it. In practice, the Hays Office, as the MPPDA was known, functioned as an advisory body and engaged in little actual censorship. It promulgated an unenforceable "Purity Code," which was facetiously called the "Don'ts and Be Carefuls," and it endorsed a policy of "compensating values," whereby all manner of screen vileness could be depicted so long as it was shown to be punished by the film's end. Throughout the 1920s, the Hays Office primarily (and successfully) served to mollify pressure groups and to manage public relations.

The leading practitioner of the compensating values formula was the flamboyant director Cecil B. deMille. He first became famous after World War I for a series of sophisticated comedies of manners that were aimed at Hollywood's new middle-class audience (*Old Wives for New,* 1918; *Forbidden Fruit,* 1921). When the Hays Office was established deMille turned to the sex- and violence-drenched religious spectacles that made him an international figure, notably *The Ten Commandments* (1923; remade 1956). DeMille's chief rival in the production of stylish sex comedies was the German émigré Ernst Lubitsch. An early master of the UFA *Kostümfilm,* Lubitsch excelled at sexual innuendo and understatement in such urbane essays as *The Marriage Circle* (1924). Also popular during the 1920s were the swashbuckling exploits of Douglas Fairbanks, whose lavish adventure spectacles, including *Robin Hood* (1922) and *The Thief of Bagdad* (1924), thrilled a generation, and the narrative documentaries of Robert Flaherty, whose *Nanook of the North* (1922) and *Moana* (1926) were unexpectedly successful with the public and with critics.

The most enigmatic and unconventional figure working in Hollywood at the time, however, was without a doubt the remarkable Viennese émigré Erich von Stroheim. Stroheim, who also acted, learned directing as an assistant to Griffith on *Intolerance* and *Hearts of the World.* His first three films—*Blind Husbands* (1918), *The Devil's Passkey* (1919), and *Foolish Wives* (1922)—constitute an obsessive trilogy of adultery; each features a sexual triangle in which an American wife is seduced by a Prussian army officer. Even though all three films were enormously popular, the great sums Stroheim was spending on the extravagant production design and costuming of his next project brought him into conflict with his Universal producers, and he was replaced.

Stroheim then signed a contract with Goldwyn Pictures and began work on a long-cherished project—an adaptation of Frank Norris' grim, naturalistic novel *McTeague.* Shot entirely on location in the streets and rooming houses of San Francisco, in Death Valley, and in the California hills, the film was conceived as a sentence-by-sentence translation of its source. Stroheim's original version ran approximately 10 hours. Realizing that the film was too long to be exhibited, he cut almost half of the footage. The film was still deemed too long, so Stroheim, with the help of director Rex Ingram, edited it down into a four-hour version that could be shown in two parts. By that time, however, Goldwyn Pictures had merged with Metro Pictures and Louis B. Mayer Pictures to become MGM. MGM took the negative from Stroheim and cut out another two hours, destroying the excised footage in the process. Released as *Greed* (1924), the film had enormous gaps in continuity, but it was still recognized as a work of genius in its rich psychological characterization and in its creation of a naturalistic analogue for the novel.

Stroheim made one more film for MGM, a darkly satiric

adaptation of the Franz Lehár operetta *The Merry Widow* (1925). He then went to Celebrity Pictures, where he directed *The Wedding March* (1928), a two-part spectacle of imperial Vienna, but his work was taken from him and recut into a single film when Celebrity was absorbed by Paramount. Stroheim's last directorial duties were on the botched *Queen Kelly* (1929) and *Walking Down Broadway* (1932), although he was removed from both films for various reasons. He made his living thereafter by writing screenplays and acting.

Decline of independent filmmaking

Although many of Stroheim's troubles with Hollywood were personal, he was also a casualty of the American film industry's transformation during the 1920s from a speculative entrepreneurial enterprise into a vertically and horizontally integrated oligopoly that had no tolerance for creative difference. His situation was not unique; many singular artists, including Griffith, Sennett, Chaplin, and Keaton, found it difficult to survive as filmmakers under the rigidly standardized studio system that had been established by the end of the decade. The industry's conversion to sound at that time reinforced its big-business tendencies and further discouraged independent filmmakers. The studios, which had borrowed huge sums of money on the very brink of the Great Depression in order to finance the conversion, were determined to reduce production costs and increase efficiency. They therefore became less and less willing to tolerate artistic innovation or eccentricity.

THE PRE-WORLD WAR II SOUND ERA

Introduction of sound. The idea of combining motion pictures and sound had been around since the invention of the cinema itself: Edison had commissioned the Kinetograph to provide visual images for his phonograph, and Dickson had actually synchronized the two machines in a device briefly marketed in the 1890s as the "Kinetophone." Léon Gaumont's Chronophone in France and Cecil Hepworth's Vivaphone system in England employed a similar technology, and each was used to produce hundreds of synchronized shorts between 1902 and 1912. In Germany, producer-director Oskar Messter began to release all of his films with recorded musical scores as early as 1908. By the time the feature had become the dominant film form in the West, producers regularly commissioned orchestral scores to accompany prestigious productions, and virtually all films were accompanied by cue sheets suggesting appropriate musical selections for performance during exhibition.

Actual recorded sound required amplification for sustained periods of use, however, which became possible only after Lee De Forest's perfection in 1907 of the Audion tube, a three-element, or triode, vacuum tube that magnified sound and drove it through speakers so that it could be heard by a large audience. In 1919 De Forest developed an optical sound-on-film process patented as Phonofilm, and between 1923 and 1927 he made more than 1,000 synchronized sound shorts for release to specially wired theatres. The public was widely interested in these films, but the major Hollywood producers, to whom De Forest vainly tried to sell his system, were not: they viewed "talking pictures" as an expensive novelty with little potential return.

By that time, Western Electric, the manufacturing subsidiary of American Telephone & Telegraph Company, had perfected a sophisticated sound-on-disc system called Vitaphone, which their representatives attempted to market to Hollywood in 1925. Like De Forest, they were rebuffed by the major studios, but Warner Bros., then a minor studio in the midst of aggressive expansion, bought both the system and the right to sublease it to other producers. Warner Bros. had no more faith in talking pictures than did the major studios but thought that the novelty could be exploited for short-term profits. The studio planned to use Vitaphone to provide synchronized orchestral accompaniment for all Warner films, thereby enhancing their marketability to second- and third-run exhibitors who could not afford to hire live orchestral accompaniment. After mounting a $3,000,000 promotion, Warners gave the system its debut on Aug. 6, 1926, in *Don Juan,* a lavish costume drama starring John Barrymore, directed by Alan Crosland, and with a score performed by the New York Philharmonic Orchestra. The response was enthusiastic; Warners announced that all of its films for 1927 would be released with synchronized musical accompaniment and then turned immediately to the production of its second Vitaphone feature. *The Jazz Singer* (1927), also directed by Crosland, included popular songs and incidental dialogue in addition to the orchestral score; its phenomenal success virtually ensured the industry's conversion to sound.

Success of Warners' first sound films

Sensing that Warners' gamble on sound might pay off, MGM, First National, Paramount, and others had asked the MPPDA to investigate competing sound systems in early 1927. There were several sound-on-film systems that were technologically superior to Vitaphone, but the rights to most of them were owned by William Fox, president of Fox Film Corporation. Fox, like the Warners, had seen sound as a way of cornering the market among smaller exhibitors. In the summer of 1926 he therefore acquired the rights to the Case-Sponable sound-on-film system (the similarity of which to De Forest's Phonofilm was the subject of subsequent patent litigation) and formed the Fox-Case Corporation to make shorts under the trade name Fox Movietone. Six months later he secretly bought the American rights to the German Tri-Ergon process, whose flywheel mechanism was essential to the continuous reproduction of optical sound. To cover himself completely Fox negotiated a reciprocal pact between Fox-Case and Vitaphone in which each licensed the other to use its sound systems, equipment, and personnel. The sound-on-film system eventually prevailed over sound-on-disc because it enabled image and sound to be recorded simultaneously in the same (photographic) medium, ensuring their precise and automatic synchronization.

Despite Warners' obvious success with its sound films, film industry leaders were not eager to lease sound equipment from a direct competitor. They banded together, and Warner Bros. was forced to give up its rights to the Vitaphone system in exchange for a share in any new royalties earned. The major film companies then wasted no time. By May 1928 virtually every studio in Hollywood, major and minor, was licensed by Western Electric's newly created marketing subsidiary, Electrical Research Products, Incorporated (ERPI), to use Western Electric equipment with the Movietone sound-on-film recording system. ERPI's monopoly did not please the Radio Corporation of America (RCA), which had tried to market a sound-on-film system that had been developed in the laboratories of its parent company, General Electric, and had been patented in 1925 as RCA Photophone. In October 1928, RCA therefore acquired the Keith-Albee-Orpheum vaudeville circuit and merged it with Joseph P. Kennedy's Film Booking Offices of America (FBO) to form RKO Radio Pictures for the express purpose of producing sound films using the Photophone system (which ultimately became the industry standard).

The wholesale conversion to sound of all three sectors of the American film industry took place in less than 15 months between late 1927 and 1929, and the profits of the major companies increased during that period by as much as 600 percent. Although the transition was fast, orderly, and profitable, it was also enormously expensive. The industrial system as it had evolved for the previous three decades needed to be completely overhauled; studios and theatres had to be totally reequipped and creative personnel retrained or fired. In order to fund the conversion, the film companies were forced to borrow in excess of $350,000,000, which placed them under the indirect control of the two major New York-based financial groups, the Morgan group and the Rockefeller group.

Furthermore, although cooperation among the film companies through such agencies as the the MPPDA, the Academy of Motion Picture Arts and Sciences, and the Society of Motion Picture Engineers (SMPE) ensured a smooth transition in corporate terms, inside the newly wired theatres and studio sound stages there was confusion and disruption. The three competing systems—Vitaphone, Movietone, and Photophone—were all initially incompatible, and their technologies were under such constant

modification that equipment was sometimes obsolete before it was uncrated. Whatever system producers chose, exhibitors during the early transitional period were forced to maintain both sound-on-disc and sound-on-film reproduction equipment. Even as late as 1931, studios were still releasing films in both formats to accommodate theatres owned by sound-on-disc interests.

Production problems caused by conversion to sound

It was in the area of production, however, that the greatest problems arose. The statement that "the movies ceased to move when they began to talk" accurately described the films made during the earliest years of the transition, largely because of technical limitations. Early microphones, for example, had a very limited range. In addition, they were large, clumsy, and difficult to move, so that they were usually concealed in a single, stationary location on the set. The actors, who had to speak directly into the microphones to register on the sound track, were therefore forced to remain practically motionless while speaking dialogue. The microphones caused further problems because they were omnidirectional within their range and picked up every sound made near them on the set, especially the noisy whir of running cameras (which were motorized in 1929 to run at an even speed of 24 frames per second to ensure undistorted sound synchronization; silent cameras had been mainly hand-cranked at rates averaging 16 to 18 frames per second). To prevent the recording of camera noise, cameras and their operators were initially enclosed in soundproof glass-paneled booths that were only six feet long per side. The booths, which were facetiously called "ice-boxes" because they were uncomfortably hot and stuffy, literally imprisoned the camera. The filmmakers' inability to tilt or dolly the camera (although they could pan it by as much as 30 degrees on its tripod), combined with the actors' immobility, helps to account for the static nature of so many early sound films.

The impact of sound recording on editing was even more regressive because sound and image had to be recorded simultaneously to be synchronous. In sound-on-disc films, scenes were initially made to play for 10 minutes at a time in order to record dialogue continuously on 16-inch discs; such scenes were impossible to edit until the technology of rerecording was perfected in the early 1930s. Sound-on-film systems also militated against editing at first because optical sound tracks run approximately 20 frames in advance of their corresponding image tracks, making it extremely difficult to cut a composite print without eliminating portions of the relevant sound. As a result, no matter which system of sound recording was used, most of the editing in early sound films was purely functional. In general, cuts could only be made—and the camera moved—when no sound was being recorded on the set.

Most of these technical problems were resolved by 1933, although equilibrium was not fully restored to the production process until after the mid-1930s. Sound-on-disc filming, for example, was abandoned in 1930, and by 1931 all the studios had removed their cameras from the ice-boxes and converted to the use of lightweight, soundproof camera housings known as "blimps." Within several years, smaller, quieter, self-insulating cameras were produced, eliminating the need for external soundproofing altogether. It even became possible to move the camera again by using a wide range of boom cranes, camera supports, and steerable dollies. Microphones, too, became increasingly mobile as a variety of booms were developed for them from 1930 onward. These long radial arms suspended the microphone above the set, allowing it to follow the movements of actors and rendering the stationary microphones of the early years obsolete. Microphones also became more directional throughout the decade, and track noise suppression techniques came into use as early as 1931.

Postsynchronization

The technological development that most liberated the sound film, however, was the practice known variously as postsynchronization, rerecording, or dubbing, in which image and sound are printed on separate pieces of film so that they can be manipulated independently. Postsynchronization enabled filmmakers to edit images freely again. Because the overwhelming emphasis of the period from 1928 to 1931 had been on obtaining high-quality sound in production, however, the idea that the sound track could be modified after it was recorded took a while to catch on. Many motion-picture artists and technicians felt that sound should be reproduced in films exactly as it had originally been produced on the set; they believed that anything less than an absolute pairing of sound and image would confuse audiences.

For several years, both practice and ideology dictated that sound and image be recorded simultaneously, so that everything heard on the sound track would be seen on the screen, and vice versa. A vocal minority of film artists nevertheless viewed this practice of synchronous, "naturalistic," sound-recording as a threat to the cinema. In their 1928 manifesto "Sound and Image," the Soviet directors Eisenstein, Pudovkin, and Grigory Aleksandrov denounced synchronous sound in favour of asynchronous, contrapuntal sound—sound that would counterpoint the images it accompanied to become another dynamic element in the montage process. Like the practical editing problem, the theoretical debate over the appropriate use of sound was eventually resolved by the practice of postsynchronization.

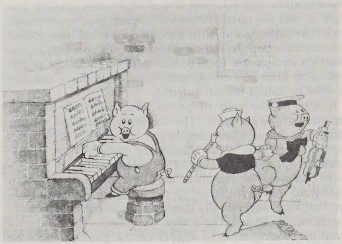
Postsynchronization seems to have first been used by the American director King Vidor in the all-black musical *Hallelujah* (1929) for a sequence in which the hero is chased through Arkansas swamplands. Vidor shot the action on location without sound, using a freely moving camera. Later, in the studio, he added to the film a separately recorded sound track containing both naturalistic and impressionistic effects. In the following year Lewis Milestone's *All Quiet on the Western Front* and Pabst's *Westfront 1918* both used postsynchronization for their battle scenes. Lubitsch used dubbing in his first American sound films, the dynamic musicals *The Love Parade* (1929) and *Monte Carlo* (1930), as did the French director René Clair in *Sous les toits de Paris* (1930). In all of these early instances, sound was recorded and rerecorded on a single track, although some American directors, including Milestone and the Russian-born Armenian Rouben Mamoulian (*Applause,* 1929; *City Streets,* 1931), had experimented with multiple microphone setups and overlapping dialogue as early as 1929. Generally, through 1932, either dialogue or music dominated the sound track unless they had been simultaneously recorded on the set. In 1933, however, technology was introduced that allowed filmmakers to mix separately recorded tracks for background music, sound effects, and synchronized dialogue at the dubbing stage. By the late 1930s, postsynchronization and multiple-channel mixing had become standard industry procedure.

Other changes wrought by sound were more purely human. Directors, for example, could no longer literally direct their performers while the cameras were rolling and sound was being recorded. Actors and actresses were suddenly required to have pleasant voices and to act without the assistance of mood music or the director's shouted instructions through long dialogue takes. Many found that they could not learn lines; others tried and were defeated by heavy foreign accents (*e.g.,* Emil Jannings, Pola Negri, Vilma Banky, and Lya de Putti) or voices that did not match their screen image (*e.g.,* Colleen Moore, Corinne Griffith, Norma Talmadge, and John Gilbert). Numerous silent stars were supplanted during the transitional period by stage actors or film actors with stage experience. "Canned theatre," or literal transcriptions of stage hits, became a dominant Hollywood form between 1929 and 1931, which brought many Broadway players and directors into the film industry on a more or less permanent basis. In addition, to fulfill the unprecedented need for dialogue scripts, the studios imported hundreds of editors, critics, playwrights, and novelists, many of whom would make lasting contributions to the verbal sophistication of the American sound film.

Sound's effect on film genres

As sound demanded new filmmaking techniques and talents, it also created new genres and renovated old ones. The realism it permitted inspired the emergence of tough, socially pertinent films with urban settings. Crime epics such as Mervyn LeRoy's *Little Caesar* (1930), William Wellman's *Public Enemy* (1931), and Howard Hawks's *Scarface* (1932) used sound to exploit urban slang and the

audible pyrotechnics of the recently invented Thompson submachine gun. Subgenres of the gangster film appeared in the prison film (*The Big House,* 1930; Hawks's *The Criminal Code,* 1931; LeRoy's *I Am a Fugitive from a Chain Gang,* 1932) and the newspaper picture (Milestone's *The Front Page;* LeRoy's *Five Star Final,* 1931; John Cromwell's *Scandal Sheet,* 1931; Frank Capra's *Platinum Blonde,* 1931), both of which relied on authentic-sounding vernacular speech.



The public's fascination with speech also accounted for the new popularity of historical biographies, or "biopics." These films were modeled on the UFA's silent *Kostümfilm,* but dialogue enhanced their verisimilitude. Several actors with impressive speaking voices were often associated with the genre, notably George Arliss (*Disraeli,* 1929; *The House of Rothschild,* 1934) and Paul Muni (*The Life of Emile Zola,* 1937; *Juarez,* 1939) in the United States and Charles Laughton (Alexander Korda's *The Private Life of Henry VIII,* 1933, and *Rembrandt,* 1936) in England.

In the realm of comedy, pure slapstick could not and did not survive, predicated as it was on purely visual humour. It was replaced by equally vital—but ultimately less surreal and abstract—sound comedies: the anarchic dialogue comedies of the Marx Brothers (*The Cocoanuts,* 1929; *Animal Crackers,* 1930; *Monkey Business,* 1931; *Horse Feathers,* 1932; *Duck Soup,* 1933) and W.C. Fields (*The Golf Specialist,* 1930; *The Dentist,* 1932; *Million Dollar Legs,* 1932) and the fast-paced wisecracking "screwball" comedies of directors like Frank Capra (*Lady for a Day,* 1933; *It Happened One Night,* 1934; *Mr. Deeds Goes to Town,* 1936), Howard Hawks (*Twentieth Century,* 1934; *Bringing Up Baby,* 1938), Gregory La Cava (*My Man Godfrey,* 1936), Mitchell Leisen (*Easy Living,* 1937), and Leo McCarey (*The Awful Truth,* 1937).

The horror-fantasy genre, traditionally rooted in German Expressionism, was greatly enhanced by sound, which not only permitted the addition of eerie sound effects but also restored the dimension of literary dialogue present in so many of the original sources. Appropriately, Universal Pictures' three great horror classics—Tod Browning's *Dracula* (1931), James Whale's *Frankenstein* (1931), and Karl Freund's *The Mummy* (1932)—were all early sound films.

One significant genre whose emergence was obviously contingent upon sound was the musical. Versions of Broadway musicals were among the first sound films made (including, of course, the catalyst for the conversion, Warner Bros.' *The Jazz Singer*), and by the early 1930s the movie musical had developed in formal sophistication to become perhaps the major American genre of the decade. Among the formidable artists who helped to achieve this sophistication were Lubitsch at Paramount (*The Love Parade,* 1929; *Monte Carlo,* 1930; *The Smiling Lieutenant,* 1931), dance director Busby Berkeley at Warners (*42nd Street,* 1933: *Gold Diggers of 1933,* 1933; *Footlight Parade,* 1933; *Dames,* 1934), and dancer-star Fred Astaire, who choreographed and directed his own integrated dance sequences at RKO (*The Gay Divorcee,* 1934; *Roberta,* 1935; *Top Hat,* 1935; *Swing Time,* 1936).

Walt Disney pioneered a genre that might be called the animated musical with *The Skeleton Dance* (1929), the first entry in his "Silly Symphony" series. Unburdened by the awkward logistics of live-action shooting, Disney was free to combine sound and image asynchronously or with perfect frame-by-frame synchronization in such classic cartoons as *Steamboat Willie* (1928—Mickey Mouse's debut) and *The Three Little Pigs* (1933). To enhance their fantasy-like appeal, both the musical and the animated film made early use of the photographic colour systems introduced by the Technicolor Corporation during the conversion to sound (two-colour imbibition, 1928; three-colour, three-strip imbibition, 1932), and the two genres quickly became associated with colour in the public mind.

Walt Disney pioneered the use of sound and colour in motion pictures with such cartoon shorts as *The Three Little Pigs* (1933).

Early colour effects

Introduction of colour. Photographic colour entered the cinema at approximately the same time as sound, although, as with sound, various colour effects had been used in films since the invention of the medium. Méliès, for example, employed 21 women at his Montreuil studio to hand-colour his films frame by frame, but hand-colouring was not cost-effective unless films were very short. In the mid-1900s, as films began to approach one reel in length and more prints of each film were sold, mechanized stenciling processes were introduced. In Pathé's Pathécolor system, for example, a stencil was cut for each colour desired (up to six) and aligned with the print; colour was then applied through the stencil frame by frame at high speeds. With the advent of the feature and the conversion of the industry to mass production during the 1910s, frame-by-frame stenciling was replaced by mechanized tinting and toning. Tinting coloured all the light areas of a picture and was achieved by immersing a black-and-white print in dye or by using coloured film base for printing. The toning process involved chemically treating film emulsion to colour the dark areas of the print. Each process produced monochrome images, the colour of which was usually chosen to correspond to the mood or setting of the scene. Occasionally, the two processes were combined to produce elaborate two-colour effects. By the early 1920s, nearly all American features included at least one coloured sequence; but after 1927, when it was discovered that tinting or toning film stock interfered with the transmission of optical sound, both practices were temporarily abandoned, leaving the market open to new systems of colour photography.

Photographic colour can be produced in motion pictures using either an additive process or a subtractive one (see below *Technology: Introduction of colour*). The first systems to be developed and used were all additive ones, such as Charles Urban's Kinemacolor (*c.* 1906) and Gaumont's Chronochrome (*c.* 1912). They achieved varying degrees of popularity, but none was entirely successful, largely because all additive systems involve the use of both special cameras and projectors, which ultimately makes them too complicated and costly for widespread industrial use.

One of the first successful subtractive processes was a two-colour one introduced by Herbert Kalmus' Technicolor Corporation in 1922. It used a special camera and a complex procedure to produce two separate positive prints that were then cemented together into a single print. The final print needed careful handling but could be projected using ordinary equipment. This "cemented positive" process was used successfully in such features as *Toll of the Sea* (1922) and Douglas Fairbanks' *The Black Pirate* (1926). In 1928 Technicolor introduced an improved process in which two gelatin positives were used as relief matrices to "print" colour onto a single strip of film. This printing process, known as imbibition or dye-transfer, made it possible to mass-produce sturdy, high-quality prints. Its introduction resulted in a significant rise in Technicolor production between 1929 and 1932. Colour reproduction in the two-colour Technicolor process was good, but because only two of the three primary colours were used, it was still not completely lifelike. Its popularity began to decline sharply in 1932, and Technicolor replaced it with a three-colour system that employed the same basic principles but included all three primary colours.

Drawbacks of Technicolor's three-colour system

For the next 25 years almost every colour film made was produced using Technicolor's three-colour system. Although the quality of the system was excellent, there were drawbacks. The bulk of the camera made location shooting difficult. Furthermore, Technicolor's virtual monopoly gave it indirect control of the production companies, which were required to rent—at high rates—equipment, crew, consultants, and laboratory services from Technicolor every time they used the system. In the midst of the Depression, therefore, conversion to colour was slow and never really complete. After three-colour Technicolor was used successfully in Disney's cartoon short *The Three Little Pigs* (1933), the live-action short *La Cucaracha* (1934), and Rouben Mamoulian's live-action feature *Becky Sharp* (1935), however, it gradually worked its way into mainstream feature production (*The Garden of Allah,* 1936; *Snow White and the Seven Dwarfs,* 1937; *The Adventures of Robin Hood,* 1938; *The Wizard of Oz,* 1939; *Gone with the Wind,* 1939), although it remained strongly associated with fantasy and spectacle.

The Hollywood studio system. If the coming of sound changed the aesthetic dynamics of the filmmaking process, it altered the economic structure of the industry even more, precipitating some of the largest mergers in motion-picture history. Throughout the 1920s, Paramount, MGM, First National, and other studios had conducted ambitious campaigns of vertical integration by ruthlessly acquiring first-run theatre chains. It was primarily in response to these aggressive maneuvers that Warners and Fox sought to dominate smaller exhibitors by providing prerecorded musical accompaniment to their films. The unexpected success of their strategy forced the industry-wide conversion to sound and transformed Warners and Fox into major corporations. By 1929, Warners had acquired the Stanley theatre circuit, which controlled nearly all of the first-run houses in the mid-Atlantic states, and the production and distribution facilities of its former rival First National to become one of the largest studios in Hollywood. Fox went even further, building the multimillion-dollar Movietone City in Westwood, Calif., in 1928 and acquiring controlling shares of both Loew's, Inc., the parent corporation of MGM, and Gaumont British, England's largest producer-distributor-exhibitor. Its holdings were surpassed only by those of Paramount, which controlled an international distribution network and the vast Publix theatre chain. In an effort to become even more powerful, Paramount in 1929 acquired one-half of the newly formed Columbia Broadcasting System and proposed a merger with Warner Bros. It was then that the U.S. Department of Justice intervened, forbidding Paramount's merger with Warners and divorcing Fox from Loew's.

Without government interference, "Paramount-Vitaphone" and "Fox-Loew's" might have divided the entertainment industries of the entire English-speaking world between them. As it was, by 1930, 95 percent of all American production was concentrated in the hands of only eight studios—five vertically integrated major companies, which controlled production, distribution, and exhibition, and three horizontally integrated minor ones that controlled production and distribution. Distribution was conducted at both a national and an international level: since about 1925, foreign rentals had accounted for half of all American feature revenues, and they would continue to do so for the next two decades. Exhibition was controlled through the major studios' ownership of 2,600 first-run theatres, which represented 16 percent of the national total but generated three-fourths of the revenue. Film production throughout the 1930s and '40s consumed only 5 percent of total corporate assets, while distribution accounted for another 1 percent. The remaining 94 percent of the studios' investment went to the exhibition sector. In short, as film historian Douglas Gomery pointed out, the five major studios of the time can best be characterized as "diversified theater chains, producing features, shorts, cartoons, and newsreels to fill their houses."

The major studios

Each studio produced a distinctive style of entertainment, depending on its corporate economy and the personnel it had under contract. Metro-Goldwyn-Mayer, the largest and most powerful of the major studios, was also the most "American" and was given to the celebration of middle-class values in a visual style characterized by bright, even, high-key lighting and opulent production design. Paramount, with its legions of UFA-trained directors, art directors, and cameramen, was thought to be the most "European" of the studios. It produced the most sophisticated and visually baroque films of the era. Conditioned by its recent experience as a struggling minor studio, Warner Bros. was the most cost-conscious of the major companies. Its directors worked on a quota system, and a flat, low-key lighting style was decreed by the studio to conceal the cheapness of its sets. Warners' films were often targeted for working-class audiences. 20th Century-Fox was formed in 1935 by the merger of Fox Film Corporation and Joseph M. Schenck's 20th Century Pictures after William Fox was bankrupted through his financial manipulations. The studio acquired a reputation for its tight budget and production control, but its films were noted for their glossy attractiveness and state-of-the-art special effects. RKO Radio was the smallest of the major companies and never achieved complete financial stability during the studio era; it became prominent, however, as the producer of *King Kong* (1933), the Astaire-Rogers dance cycle, and Orson Welles's *Citizen Kane* (1941) and also as the distributor of Disney's features.

The minor studios were Carl Laemmle's Universal Pictures, which became justly famous for its horror films; Harry Cohn's Columbia Pictures, whose main assets were director Frank Capra and screenwriter Robert Riskin; and United Artists, which functioned as a distributor for independent American features and for Alexander Korda's London Film Productions. In terms of total assets, the five major studios were about four times as big as the three minor ones, with MGM, Paramount, Warners, and 20th Century-Fox all about the same size and RKO approximately 25 percent smaller than its peers. At the very bottom of the film industry hierarchy were a score of poorly capitalized studios, such as Republic, Monogram, and Grand National, that produced cheap, formulaic, hour-long "B-films" for the second half of double bills. The double feature, an attraction introduced in the early 1930s to counter the Depression-era box-office slump, was the standard form of exhibition for about 15 years. The larger studios were, for the most part, not interested in producing B-films for double bills because unlike the main feature, whose earnings were based on box-office receipts, the second feature rented at a flat rate, which meant that the profit it returned, though guaranteed, was fixed at a small amount. At their peak, the B-film studios produced 40–50 films per year and provided a training ground for such stars as John Wayne. The films were made as quickly as possible, and directors functioned as their own producers, with complete authority over their projects' minuscule budgets.

B-films

The Production Code

An important aspect of the studio system was the Production Code, which was implemented in 1934 in response to pressure from the Legion of Decency and public protest against the graphic violence and sexual suggestiveness of some sound films (the urban gangster films, for example, and the films of Mae West). The Legion had been established in 1933 by the American bishops of the Roman Catholic Church (armed with a mandate from the Vatican) to fight for better and more "moral" motion pictures. In April 1934, with the support of both Protestant and Jewish organizations, the Legion called for a nationwide boycott of movies it considered indecent. The studios, having lost millions of dollars in 1933 as the delayed effects of the Depression caught up with the box office, rushed to appease the protesters by authorizing the MPPDA to create the Production Code Administration. A prominent Catholic layman, Joseph I. Breen, was appointed to head the administration, and under Breen's auspices, Father Daniel A. Lord, a Jesuit priest, and Martin Quigley, a Catholic publisher, coauthored the code whose provisions would dictate the content of American motion pictures, without exception, for the next 20 years.

In a swing away from the excesses of the "new morality" of the Jazz Era, the Production Code was monumentally repressive, forbidding the depiction on screen of almost

everything germane to the experience of normal human adults. It prohibited showing "scenes of passion," and adultery, illicit sex, seduction, and rape could not even be alluded to unless they were absolutely essential to the plot and severely punished by the film's end. The code demanded that the sanctity of marriage be upheld at all times, although sexual relations were not to be suggested between spouses. It forbade the use of profanity, vulgarity, and racial epithets; prostitution, miscegenation, sexual deviance, or drug addiction; nudity, sexually suggestive dancing or costumes, and "lustful kissing"; and excessive drinking, cruelty to animals or children, and the representation of surgical operations, especially childbirth, "in fact or silhouette." In the realm of violence, it was forbidden to display or to discuss contemporary weapons, to show the details of a crime, to show law enforcement officers dying at the hands of criminals, to suggest excessive brutality or slaughter, or to use murder or suicide except when crucial to the plot. Finally, the code required that all criminal activity be shown to be punished; under no circumstances could any crime be represented as justified. Studios were required to submit their scripts to Breen's office for approval before beginning filming, and completed films had to be screened for the office, and altered if necessary, in order to receive a Production Code Seal, without which no film could be distributed in the United States. Noncompliance with the code's restrictions brought a fine of $25,000, but the studios were so anxious to please that the fine was never levied in the 22-year lifetime of the code.

Studio acceptance of the code

The studio heads were willing not merely to accept but also to institutionalize this system of de facto censorship and prior restraint because they believed it was necessary for the continued success of their business. The economic threat of a national boycott during the worst years of the Depression was real, and the film industry, which depends on pleasing a mass audience, could not afford to ignore public opinion. Producers found, moreover, that they could use the code to increase the efficiency of production. By rigidly prescribing and proscribing the kinds of behaviour that could be shown or described on the screen, the code could be used as a scriptwriter's blueprint. A love story, for example, could only move in one direction (toward marriage), adultery and crime could have only one conclusion (disease or horrible death), dialogue in all situations had well-defined parameters, and so forth. The code, in other words, provided a framework for the construction of screenplays and enabled studios to streamline what had always been (and still is) one of the most difficult and yet most essential tasks in the production process—the creation of filmable continuity scripts. Finally, the Depression was a time of open political anti-Semitism in the United States and the men who controlled the American motion-picture industry were all Jewish; it was not a propitious moment for them to antagonize their predominantly non-Jewish audience.

Between 1930 and 1945, the studio system produced more than 7,500 features, every stage of which, from conception through exhibition, was carefully controlled. Among these assembly-line productions are some of the most important American films ever made, the work of gifted directors who managed to transcend the mechanistic nature of the system to produce work of unique personal vision. These directors include Josef von Sternberg, whose exotically stylized films starring Marlene Dietrich (*Shanghai Express*, 1932; *The Scarlet Empress*, 1934) constitute a kind of painting with light; John Ford, whose vision of history as moral truth produced such mythic works as *Stagecoach* (1939), *Young Mr. Lincoln* (1939), *The Grapes of Wrath* (1940), *My Darling Clementine* (1946), and *She Wore a Yellow Ribbon* (1949); Howard Hawks, a master of genres and the architect of a tough, functional "American" style of narrative exemplified in his films *Scarface* (1932), *Twentieth Century*, *Only Angels Have Wings* (1939), and *The Big Sleep* (1946); British émigré Alfred Hitchcock, whose films appealed to the popular audience as suspense melodramas but were in fact abstract visual psychodramas of guilt and spiritual terror (*Rebecca*, 1940; *Suspicion*, 1941; *Shadow of a Doubt*, 1943; *Notorious*, 1946); and Frank Capra, whose cheerful screwball comedies (*It Happened One Night*) and populist fantasies of good will (*Mr. Smith Goes to Washington*, 1939) sometimes gave way to darker warnings against losing faith and integrity (*It's a Wonderful Life*, 1946). Other significant directors with less consistent thematic or visual styles were William Wyler (*Wuthering Heights*, 1939; *The Little Foxes*, 1941), George Cukor (*Camille*, 1936; *The Philadelphia Story*, 1940), Leo McCarey (*The Awful Truth*, 1937; *Going My Way*, 1944), Preston Sturges (*Sullivan's Travels*, 1941; *The Miracle of Morgan's Creek*, 1944), and George Stevens (*Gunga Din*, 1939; *Woman of the Year*, 1942).

Lauren Bacall and Humphrey Bogart in Howard Hawks's *The Big Sleep* (1946), based on the Raymond Chandler novel and adapted for the screen by William Faulkner.

Welles's innovations in *Citizen Kane*

The most extraordinary film to emerge from the studio system, however, was Orson Welles's *Citizen Kane* (1941), whose controversial theme and experimental technique combined to make it a classic. The first of six films Welles had contracted to produce for RKO with his Mercury Theater radio ensemble company, *Citizen Kane* made radically innovative use of sound and deep-focus photography as it examined the life of Charles Foster Kane, a character based on the press baron William Randolph Hearst. The film employs a complicated flashback structure in which Kane's friends and associates give their accounts of the man after his death, paradoxically revealing not greatness or might but pathetic insecurity and emptiness. In creating this portrait of a powerful American who could bend international politics to his will but never fathom human love, Welles stretched the technology of image and sound recording beyond its contemporary limits. Using a newly available Eastman film stock with increased sensitivity to light, plastic-coated wide-angle lenses opened to smaller than normal apertures, and high-intensity arc lamps, cinematographer Gregg Toland achieved a photographic depth of field that approximated the perceptual range of the human eye and enabled Welles to place the film's characters in several different planes of depth within a single scene. These deep-focus sequence shots are complemented throughout the film by the techniques of ambient and directional sound that Welles had learned from radio. Most important of all, the resonance of the film's narrative matches the technical brilliance of its presentation, functioning on several levels at once, the historical, the psychological, and the mythic. Although recognized by many critics as a work of genius, *Citizen Kane* was a financial failure on its release, and Welles directed only three other films under his RKO contract. *Citizen Kane* remains, nevertheless, one of the most influential films ever made and is widely considered to be one of the greatest.

European conversion to sound

International cinema. Having created large new markets for their sound recording technologies in the United States, Western Electric and RCA were anxious to do the same abroad. Their objective coincided with the desire of the major American film studios to extend their control of the international motion-picture industry. Accordingly, the studios began to export sound films in late 1928, and ERPI and RCA began installing their equipment in European theatres at the same time. Exhibitors in the

United Kingdom converted the most rapidly, with 22 percent wired for sound in 1929 and 63 percent by the end of 1932. Continental exhibitors converted more slowly, largely because of a bitter patents war between the German cartel Tobis-Klangfilm, which controlled the European rights to sound-on-film technology, and Western Electric. The dispute was finally resolved at the 1930 German-American Film Conference in Paris, where Tobis, ERPI, and RCA agreed to pool their patents and divide the world market among themselves. The language problem also delayed the conversion to sound on the Continent. Because dubbing was all but impossible in the earliest years of the transition, films had to be shot in several different languages (sometimes featuring a different cast for each version) at the time of production in order to receive wide international distribution. Paramount therefore built a huge studio in the Paris suburb of Joinville in 1930 to mass-produce multilingual films. The other major American studios quickly followed suit, making the region a factory for the round-the-clock production of movies in as many as 15 separate languages. By the end of 1931, however, the technique of dubbing had been sufficiently perfected to replace multilingual production, and Joinville was converted into a dubbing centre for all of Europe.

Great Britain. Because of the lack of a language barrier, the United Kingdom became Hollywood's first major foreign market for sound films. The British motion-picture industry was protected from complete American domination, however, by the Cinematograph Films Act passed by Parliament in 1927. The act required that a certain minimum proportion of the films exhibited in British theatres be of domestic origin. Although most of the films made to fulfill this condition were low-budget, low-standard productions known as "quota quickies," the British cinema produced many important film artists (most of whom were soon lured to Hollywood). One of the first major British talents to emerge after the introduction of sound was Hitchcock, who directed a series of stylish thrillers for British International Pictures and Gaumont British, before he moved to Hollywood in 1939. His first sound film, *Blackmail* (1929), marked the effective beginning of sound production in England. The film was already in production as a silent when the director was ordered to make it as a "part-talkie." It was especially noted for the expressive use of both naturalistic and nonnaturalistic sound, which became a distinguishing feature of Hitchcock's later British triumphs (*The Man Who Knew Too Much,* 1934; *The Thirty-Nine Steps,* 1935; *Sabotage,* 1936), as well as of the films of his American career. Among the significant British filmmakers who remained based in London were the Hungarian-born brothers Alexander, Zoltán, and Vincent Korda, who founded London Films in 1932 and collaborated on some of England's most spectacular pre-World War II productions (*e.g., The Private Life of Henry VIII; Rembrandt; Elephant Boy,* 1937; *The Four Feathers,* 1939), and John Grierson, who produced such outstanding documentaries as Robert Flaherty's *Industrial Britain* (1933) and Basil Wright's *Song of Ceylon* (1935) for the Empire Marketing Board Film Unit and its successor, the General Post Office (GPO) Film Unit.

"Quota quickies"

France. In France during the 1920s, as a result of the post-World War I decline of the Pathé and Gaumont film companies, a large number of small studios had leased their facilities to independent companies, which were often formed to produce a single film. This method of film production had lent itself readily to experimentation, encouraging the development of the avant-garde film movement known as Impressionism (led by Germaine Dulac, Jean Epstein, Marcel L'Herbier, and Fernand Léger) and the innovative films of Abel Gance (*La Roue,* 1923; *Napoléon vu par Abel Gance,* 1927) and Dmitri Kirsanoff (*Ménilmontant,* 1926). Because the French film industry had evolved no marketable technology for sound recording, however, the coming of sound left producers and exhibitors alike vulnerable to the American production companies at Joinville and to the German Tobis-Klangfilm, which had been purchasing large studios in the Paris suburb of Epinay since 1929. In the face of this threat, the French industry attempted to regroup itself around what was left of the Pathé and Gaumont empires, forming two consortia—Pathé-Natan and Gaumont-Franco-Film-Aubert—for the production and distribution of sound films. Although neither group was financially successful, they seem to have created an unprecedented demand for French-language films about French subjects, reinvigorating the country's cinema. Between 1928 and 1938, French film production doubled from 66 to 122 features, and in terms of box-office receipts, the French audience was considered to be second only to the American one. By 1937–38 French cinema had become the most critically acclaimed in the world, leading export markets in every industrial nation in the West.

The rise of French cinema

Many filmmakers contributed to the prominence of French cinema during the 1930s, but the three most important were René Clair, Jean Vigo, and Jean Renoir. Clair was a former avant-gardist whose contributions to the aesthetics of sound, although not so crucial as Hitchcock's, were nevertheless significant. His *Sous les toits de Paris* (1930), frequently hailed as the first artistic triumph of the sound film, was a lively musical comedy that mixed asynchronous sound with a bare minimum of dialogue. Clair used the same technique in *Le Million* (1931), which employed a wide range of dynamic contrapuntal effects. *À nous la liberté* (*Liberty Is Ours,* 1931) was loosely based on the life of Charles Pathé and dealt with more serious themes of industrial alienation, although it still used the musical-comedy form. The film's intelligence, visual stylization, and brilliant use of asynchronous sound made it a classic of the transitional period.

Vigo completed only two features before his early death: *Zéro de conduite* (*Zero for Conduct,* 1933) and *L'Atalante* (1934). Both are lyrical films about individuals in revolt against social reality. Their intensely personal nature is thought to have influenced the style of poetic realism that characterized French cinema from 1934 to 1940 and that is exemplified by Jacques Feyder's *Penston mimosas* (1935), Julien Duvivier's *Pépé le Moko* (1937), and Marcel Carné's *Quai des brumes* (*Port of Shadows,* 1938) and *Le Jour se lève* (*Daybreak,* 1939). Darkly poetic, these films were characterized by a brooding pessimism that reflected the French public's despair over the failure of the Popular Front movement of 1935–37 and the seeming inevitability of war.

Jean Renoir, the son of the Impressionist painter Pierre-Auguste Renoir, made nine films before he directed the grimly realistic *La Chienne* (*The Bitch,* 1931) and *La Nuit du carrefour* (*Night at the Crossroads,* 1932), his first important essays in sound. Renoir subsequently demonstrated a spirit of increasing social concern in such films as *Boudu sauvé des eaux* (*Boudu Saved from Drowning,* 1932), a comic assault on bourgeois values; *Toni* (1934), a realistic story of Italian immigrant workers; *Le Crime de Monsieur Lange* (*The Crime of Monsieur Lange,* 1935), a political parable about the need for collective action against capitalist corruption; and *La Vie est à nous* (*Life Is Ours,* 1936), a propaganda film for the French Communist Party that contains both fictional and documentary footage. The strength of his commitment is most clearly expressed, however, by the eloquent appeal he makes for human understanding in his two pre-World War II masterworks. *La Grande Illusion* (*Grand Illusion,* 1937), set in a World War I prison camp, portrays a civilization on the brink of collapse due to national and class antagonisms; in its assertion of the primacy of human relationships and the utter futility of war (the "grand illusion"), the film stands as one of the greatest antiwar statements ever made. In *La Règle du jeu* (*Rules of the Game,* 1939), set in contemporary France, the breakdown of civilization has already occurred. European society is shown to be an elegant but brittle fabrication in which feeling and substance have been replaced by "manners," a world in which "the terrible thing," to quote the protagonist Octave (played by Renoir), "is that everyone has his reasons." In both films Renoir continued his earlier experiments with directional sound and deep-focus composition. His technical mastery came to influence the American cinema when he emigrated to the United States to escape the Nazis in 1940.

Renoir's social concern

Germany. Because of its ownership of the Tobis-Klang-

Early German sound films

film patents, the German film industry found itself in a position of relative strength in the early years of sound, and it produced several important films during that period, including Sternberg's *Der blaue Engel* (*The Blue Angel,* 1930), Pabst's two antiwar films, *Westfront 1918* (1930) and *Kameradschaft* (1931), and his adaptation of Bertolt Brecht's *Die Dreigroschenoper* (*The Threepenny Opera,* 1931). The most influential of the early German sound films, however, was Lang's *M* (1931), which utilized a dimension of aural imagery to counterpoint its visuals in the manner of Hitchcock's *Blackmail. M* has no musical score but makes expressive use of nonnaturalistic sound, as when the child murderer (played by Peter Lorre) is heard to whistle a recurring theme from Grieg's *Peer Gynt* before committing his crimes offscreen.

German cinema became moribund after Hitler took power in 1933, primarily because Goebbels encouraged filmmakers to produce trivial and escapist entertainment rather than more meaningful or thought-provoking fare. One director who did create films of undeniable artistic quality under Goebbels' regime was Leni Riefenstahl. She made striking use of asynchronous sound and montage in two propaganda epics commissioned by Hitler, *Triumph des Willens* (*Triumph of the Will,* 1935) and *Olympische Spiele 1936* (1938). A similar situation existed in Mussolini's Italy, where Fascist censorship mandated the production of *telefono bianco,* or "white telephone" films (lightweight romantic comedies with glamorous studio sets), and occasional nationalist propaganda, although Mussolini did establish a national film school (the Centro Sperimentale di Cinematografia, 1935) and a huge new studio complex (Cinecittà, 1937) in Rome.

Soviet Union. Although the Soviet engineers P.G. Tager and A.F. Shorin had designed optical sound systems as early as 1927, neither was workable until 1929. Sound was slow in coming to the Soviet Union: most Soviet transitional films were technically inferior to those of the West, and Soviet filmmakers continued to make silent films until the mid-30s. As in Germany and Italy, however, sound reemphasized film's propaganda value, and through the authoritarian government's policy of socialist realism the Soviet cinema became an instrument of mass indoctrination as never before. The filmmakers most affected by the new policy were the great montage artists of the 1920s. Each of them made admirable attempts to experiment with sound—Kuleshov's *The Great Consoler* (1933), Vertov's *Symphony of the Donbas* (1931) and *Three Songs About Lenin* (1934), Eisenstein's *Bezhin Meadow* (1935; terminated by Shumyatsky in mid-production), Pudovkin's *A Simple Case* (1932) and *Deserter* (1933), and Dovzhenko's *Ivan* (1932)—but their work was ultimately suppressed or defamed by the party bureaucracy. Only Eisenstein was powerful enough to reassert his genius: in the nationalistic epic *Alexander Nevsky* (1938), whose contrapuntal sound track is a classic of its kind, and in the operatically stylized *Ivan the Terrible, Parts I and II* (1944–46), a veiled critique of Stalin's autocracy. Most of the films produced at the time were propaganda glorifying national heroes (Sergey and Georgy Vasiliev's *Chapayev,* 1934; Vladimir Petrov's *Peter the First, Parts I and II,* 1937–39), literary adaptations (Mark Donskoy's Gorky trilogy: *The Childhood of Maxim Gorky,* 1938; *My Apprenticeship,* 1939; and *My Universities,* 1940), or escapist, Hollywood-style musicals (Grigory Aleksandrov's *Jazz Comedy,* 1934).

Japanese conversion to sound

Japan. In Japan, as in the Soviet Union, the conversion to sound was a slow process: in 1932 only 45 of 400 features were made with sound, and silent films continued to be produced in large numbers until 1937. The main reason for the slow conversion was that Japanese motion pictures had "talked" since their inception through the mediation of a *benshi,* a commentator who stood to the side of the screen and narrated the action for the audience in the manner of Kabuki theatre. The arrival of recorded sound liberated the Japanese cinema from its dependence on live narrators and was resisted by the *benshi,* many of whom were stars in their own right and possessed considerable box-office appeal. In the end, however, Japan's conversion to sound was complete.

As in the United States, the introduction of sound enabled the major Japanese film companies (Nikkatsu, founded 1912; Shochiku, 1920; and Toho, *c.* 1935) to acquire smaller companies and form vertical monopolies controlling production, distribution, and exhibition. Production procedures were standardized and structured for the mass production of motion pictures, and the studios increased their efficiency by specializing in either *jidaigeki,* period films set before 1868 (the year marking the beginning of the Meiji Restoration, 1868–1912, and the abolition of the feudal shogunate), or *gendai-geki,* films of contemporary life, set any time thereafter. Although, as a matter of geopolitical circumstance, there was hardly any export market for Japanese films prior to World War II, the domestic popularity of sound films enabled the Japanese motion-picture industry to become one of the most prolific in the world, releasing 400 films annually to the nation's 2,500 theatres. Most of these films had no purpose other than entertainment, but in the late 1930s, as the government became increasingly expansionist and militaristic, Japan's major directors turned to works of social criticism called "tendency" films, such as Ozu Yasujirō's *The Only Son* and Mizoguchi Kenji's *Osaka Elegy* and *Sisters of the Gion* (all 1936). In response the government imposed a strict code of censorship that was retained throughout the war.

India. In India, sound created a major industrial boom by reviving a popular 19th-century theatrical form: the folk-music drama based on centuries-old religious myths. Despite the fact that films had to be produced in as many as 10 regional languages, the popularity of these "all-talking, all-singing, all-dancing" mythologicals or historicals played an enormous role in winning acceptance for sound throughout the subcontinent and in encouraging the growth of the Indian film industry. An average of 230 features were released per year throughout the 1930s, almost all for domestic consumption.

THE WAR YEARS AND POST-WORLD WAR II TRENDS

Decline of the Hollywood studios. During the U.S. involvement in World War II, the Hollywood film industry cooperated closely with the government to support its war-aims information campaign. Following the declaration of war on Japan, the government created a Bureau of Motion Picture Affairs to coordinate the production of entertainment features with patriotic, morale-boosting themes and messages about the "American way of life," the nature of the enemy and the allies, civilian responsibility on the home front, and the fighting forces themselves. Initially unsophisticated vehicles for xenophobia and jingoism with titles like *The Devil with Hitler* and *Blondie for Victory* (both 1942), Hollywood's wartime films became increasingly serious as the war dragged on (Lang's *Hangmen Also Die,* Renoir's *This Land Is Mine,* Tay Garnett's *Bataan,* all 1943; Delmer Daves's *Destination Tokyo,* 1944; Hitchcock's *Lifeboat,* 1944; Milestone's *The Purple Heart,* 1944; *A Walk in the Sun,* 1946). In addition to commercial features, several Hollywood directors produced documentaries for government and military agencies. Among the best-known of these films, which were designed to explain the war to both servicemen and civilians, are Frank Capra's seven-part series *Why We Fight* (1942–44), William Wyler's *The Memphis Belle* (1944), John Ford's *The Battle of Midway* (1942), and John Huston's *The Battle of San Pietro* (1944). The last three were shot on location and were made especially effective by their immediacy.

When World War II ended, the American film industry seemed to be in an ideal position. Full-scale mobilization had ended the Depression domestically, and victory had opened vast, unchallenged markets in the war-torn economies of western Europe and Japan. Furthermore, from 1942 through 1945, Hollywood had experienced the most stable and lucrative three years in its history, and in 1946, when two-thirds of the American population went to the movies at least once a week, the studios earned record-breaking profits. The euphoria ended quickly, however, as inflation and labour unrest boosted domestic production costs and as important foreign markets, including Britain and Italy, were temporarily lost to protectionist quotas.

The Paramount decrees

The industry was more severely weakened in 1948, when a federal antitrust suit against the five major and three minor studios ended in the "Paramount decrees," which forced the studios to divest themselves of their theatre chains and mandated competition in the exhibition sector for the first time in 30 years. Finally, the advent of network television broadcasting in the 1940s provided Hollywood with its first real competition for American leisure time by offering consumers "movies in the home."

The American film industry's various problems and the nation's general postwar disillusionment generated several new film types in the late 1940s. Although the studios continued to produce traditional genre films, such as westerns and musicals, their financial difficulties encouraged them to make realistic, small-scale dramas rather than fantastic, lavish epics. Instead of depending on spectacle and special effects to create excitement, the new lower-budget films tried to develop thought-provoking or perverse stories reflecting the psychological and social problems besetting returning war veterans and and others adapting to postwar life. Some of the American cinema's grimmest and most naturalistic films were produced during this period, including those of the so-called social consciousness cycle, which attempted to deal realistically with such endemic problems as racism (Elia Kazan's *Gentleman's Agreement,* 1947; Alfred Werker's *Lost Boundaries,* 1949), alcoholism (Stuart Heisler's *Smash-Up,* 1947), and mental illness (Anatole Litvak's *The Snake Pit,* 1948); the semidocumentary melodrama, which reconstructed true criminal cases and were often shot on location (Kazan's *Boomerang,* 1947; Henry Hathaway's *Kiss of Death,* 1947); and the *film noir,* whose dark, fatalistic interpretations of contemporary American reality are unique in the industry's history (Tay Garnett's *The Postman Always Rings Twice,* 1946; Welles's *The Lady from Shanghai,* 1948; Jacques Tourneur's *Out of the Past,* 1947; Abraham Polonsky's *Force of Evil,* 1948).

Hollywood blacklisting

Film content was next influenced strongly by the fear of Communism that pervaded the United States during the late 1940s and early '50s. Anti-Communist "witch-hunts" began in Hollywood in 1947 when the House Un-American Activities Committee (HUAC) decided to investigate Communist influence in motion pictures. More than 100 witnesses, including many of Hollywood's most talented and popular artists, were called before the committee to answer questions about their own and their associates' alleged Communist affiliations. On Nov. 24, 1947, a group of eight screenwriters and two directors, later known as the Hollywood Ten, were sentenced to serve up to a year in prison for refusing to testify. That evening the members of the Association of Motion Picture Producers, which included the leading studio heads, published what became known as the Waldorf Declaration, in which they fired the members of the Hollywood Ten and expressed their support of HUAC. The studios, afraid to antagonize already shrinking audiences, then initiated an unofficial policy of blacklisting, refusing to employ any person even suspected of having Communist associations. Hundreds of people were fired from the industry, and many creative artists were never able to work in Hollywood again. Throughout the blacklisting era, filmmakers refrained from making any but the most conservative motion pictures; controversial topics or new ideas were carefully avoided. The resulting creative stagnation, combined with financial difficulties, contributed significantly to the demise of the studio system, although, paradoxically, the actions that the studios took between 1952 and 1965, including the practice of blacklisting, can be viewed as an attempt to halt the industry's decline.

The film industry's reaction to television

The film industry believed that the greatest threat to its continued success was posed by the television industry, especially in light of the Paramount decrees. The studios seemed to be losing their control of the nation's theatres at the same time that exhibitors were losing their audiences to television. The studios therefore attempted to diminish television's appeal by exploiting the two obvious advantages that film enjoyed over the new medium—the size of its images and, at a time when all television broadcasting was in black and white, the ability to produce photographic colour. (In the 1952–53 season, the ability to produce multiple-track stereophonic sound joined this list.) In the late 1940s, less than 12 percent of Hollywood features were produced in colour, primarily because of the expense of three-strip Technicolor filming. In 1950, however, a federal consent decree dissolved the Technicolor Corporation's de facto monopoly on the process, and Kodak simultaneously introduced a new multilayered film stock in which emulsions sensitive to the red, green, and blue parts of the spectrum were bonded together on a single roll. Patented as Eastmancolor, this "integral tripack" process offered excellent colour resolution at a low cost because it could be used with conventional cameras. Its availability hastened the industry's conversion to full colour production. By 1954 more than 50 percent of American features were made in colour, and the figure reached 94 percent by 1970.

The aspect ratio (the ratio of width to height) of the projected motion-picture image had been standardized at 1.33 to 1 since 1932, but as television eroded the film industry's domestic audience, the studios increased screen size as a way of attracting audiences back into theatres. For both optical and architectural reasons this change in size usually meant increased width, not increased height. Early experiments with multiple-camera wide-screen (Cinerama, 1952) and stereoscopic 3-D (Natural Vision, 1952) provoked audience interest, but it was an anamorphic process called CinemaScope that prompted the wide-screen revolution. Introduced by 20th Century-Fox in the biblical epic *The Robe* (1953), CinemaScope used an anamorphic lens to squeeze a wide-angle image onto conventional 35-millimetre film stock and a similar lens to restore the image's original width in projection. CinemaScope's aspect ratio was 2.55 to 1, and the system had the great advantage of requiring no special cameras, film stock, or projectors. By the end of 1954, every Hollywood studio but Paramount had leased a version of the process from Fox (Paramount adopted a nonanamorphic process called VistaVision that exposed double-frame images by running film through special cameras and projectors horizontally rather than vertically), and many studios were experimenting with wide-gauge film systems (*e.g.,* Todd-AO, 1955; Panavision-70, 1960) that required special equipment but eliminated the distortion inherent in the anamorphic process.

Like the coming of sound, the conversion to wide-screen formats produced an initial regression as filmmakers learned how to compose and edit their images for the new elongated frame. Sound had promoted the rise of aurally intensive genres such as the musical and the gangster film, and the wide-screen format similarly created a bias in favour of visually spectacular subjects and epic scale. The emergence of the three-to-four hour wide-screen "blockbuster" in such films as *War and Peace, Around the World in Eighty Days,* and *The Ten Commandments* in 1956 coincided with the era's affinity for safe and sanitized material. Given the political paranoia of the times, few subjects could be treated seriously, and the studios concentrated on presenting traditional genre fare—westerns, musicals, comedies, and blockbusters—suitable for wide-screen treatment. Only a director like Hitchcock, whose style was oblique and imagist, could prosper in such a climate. He produced his greatest work during the period, much of it in VistaVision (*Rear Window,* 1954; *The Man Who Knew Too Much,* 1956; *Vertigo,* 1958; *North by Northwest,* 1959; *Psycho,* 1960; *The Birds,* 1963).

In spite of the major film companies' elaborate strategies of defense, they continued to decline throughout the 1950s and '60s. Because they could no longer dominate the exhibition sector, they faced serious competition for the first time from independent and foreign filmmakers. "Runaway" productions (films made away from the studios, frequently abroad, to take advantage of lower costs) became common, and the Production Code was dissolved as a series of federal court decisions between 1952 and 1958 extended First Amendment protection to motion pictures. As their incomes shrank, the major companies' vast studios and backlots became liabilities that ultimately crippled them. The minor companies, however, owned

modest studio facilities and had lost nothing by the Paramount decrees because they controlled no theatres. They were thus able to prosper during this era, eventually becoming major companies themselves in the 1970s.

Italian Neorealist movement

International cinema. *Italy.* World War II physically and economically devastated the film industries of the Soviet Union, Japan, and most of the European nations. Italy's early surrender, however, left its facilities relatively intact, enabling the Italian cinema to lead the post-World War II film renaissance with its development of the Neorealist movement. Although it had roots in both Soviet expressive realism and French poetic realism, Neorealism was decidedly national in focus, taking as its subject the day-to-day reality of a country traumatized by political upheaval and war.

Most of the major figures in the Neorealist movement had studied at Mussolini's Centro Sperimentale, but they vigorously rejected the stagy, artificial style associated with the *telefono bianco* films in favour of a Marxist aesthetic of everyday life. The first identifiable Neorealist film was Luchino Visconti's *Ossessione* (*Obsession,* 1942), a bleak contemporary melodrama shot on location in the countryside around Ferrara. It was suppressed by the Fascist censors, however, so that international audiences were first introduced to the movement through Roberto Rossellini's *Roma, città aperta* (*Open City,* 1945), which was shot on location in the streets of Rome only two months after Italy's surrender. The film featured both professional and nonprofessional actors and focused on ordinary people caught up in contemporary events. Its documentary texture, postrecorded sound track, and improvisational quality became the hallmark of the Neorealist movement. Rossellini followed it with *Paisà* (*Paisan,* 1946) and *Germania, anno zero* (*Germany, Year Zero,* 1947) to complete his "war trilogy." Visconti's second contribution to Neorealism was *La terra trema* (*The Earth Trembles,* 1948), an epic of peasant life that was shot on location in a Sicilian fishing village. In many respects it is more exemplary of the movement than *Ossessione* and is widely regarded as a masterpiece. Neorealism's third major director was Vittorio De Sica, who worked in close collaboration with scriptwriter Cesare Zavattini, the movement's major theorist and spokesman. De Sica's films sometimes tend toward sentimentality but in *Sciuscià* (*Shoeshine,* 1946), *Ladri di biciclette* (*The Bicycle Thief,* 1948), and *Umberto D.* (1952), he produced works central to the movement.

Lamberto Maggiorani and Enzo Staiola as the father and son in Vittorio De Sica's *The Bicycle Thief* (1948).

Influence of Neorealism

Neorealism was the first postwar cinema to reject Hollywood's narrative conventions and studio production techniques, and, as such, it had enormous influence on future movements like British "social realism," Brazilian *Cinema Nôvo,* and the French and Czech New Wave. It also heralded the practices of shooting on location using natural lighting and postsynchronizing sound that later became standard in the film industry. Despite its influence, in the 1950s Neorealism disappeared as a distinct national movement, together with the socioeconomic context that had produced it, as the Marshall Plan began to work its "economic miracle" in Europe. Italian cinema remained prominent nevertheless through the films of several gifted directors who began their careers as Neorealists and went on to produce their major work during the 1960s and '70s.

Federico Fellini had worked as a scriptwriter for Rossellini before directing in the 1950s an impressive series of films whose form was Neorealist but whose content was allegorical (*I vitelloni* [*The Loafers*], 1953; *La strada* [*The Road*], 1954; *Le notti di Cabiria* [*Nights of Cabiria*], 1956). During the 1960s Fellini's work became increasingly surrealistic (*La dolce vita* [*The Sweet Life*], 1960; *Otto e mezzo* [*8½*], 1963; *Giulietta degli spiriti* [*Juliet of the Spirits*], 1965; *Fellini Satyricon,* 1969), and by the 1970s he was perceived to be a flamboyant ironic fantasist—a reputation that sustained him through such serious and successful films as *Fellini Roma* (1972), *Amarcord* (1974), and *E la nave va* (*And the Ship Sails On,* 1983).

Michelangelo Antonioni had also collaborated with Rossellini. Accordingly, his first films were Neorealist documentary shorts (*Gente del Po* [*People of the Po*], 1947), but during the 1950s he turned increasingly to an examination of the Italian bourgeoisie in such films as *Cronaca di un amore* (*Story of a Love Affair,* 1950), *La signora senza camelie* (*Camille Without Camellias,* 1953), and *Le amiche* (*The Girlfriends,* 1955), and in the early 1960s Antonioni produced a trilogy on the malaise of the middle class that made him internationally famous. In *L'avventura* (*The Adventure,* 1959), *La notte* (*The Night,* 1960), and *L'eclisse* (*The Eclipse,* 1962), he used long-take sequence shots equating film time with real time to create a vision of the reverberating emptiness of modern urban life. Antonioni then began to use colour expressionistically in *Deserto rosso* (*Red Desert,* 1964) and *Blow-Up* (1966) to convey alienation and abstraction from human feeling, and all of his later works in some way concerned the breakdown of personal relationships (*Zabriskie Point,* 1970; *Identificazione di una donna* [*Identification of a Woman*], 1982) and of identity itself (*The Passenger,* 1975).

While Fellini and Antonioni were putting Italy in the vanguard of modernist cinema, the country's second post-World War II generation of directors emerged. Ermanno Olmi (*Il posto* [*The Job*], 1961; *Un certo giorno* [*One Fine Day*], 1968; *L'albero degli zoccoli* [*The Tree of Wooden Clogs*], 1979) continued the Neorealist tradition in tales of ordinary people caught up in systems beyond their comprehension. Pier Paolo Pasolini, who had worked as a scriptwriter for Fellini, achieved international recognition for *Il vangelo secondo Matteo* (*The Gospel According to St. Matthew,* 1964), a brilliant semidocumentary reconstruction of the life of Christ with Marxist overtones. Before his murder in 1975, Pasolini went on to direct a series of astonishing, often outrageous films that set forth a Marxist interpretation of history and myth—*Edipo re* (*Oedipus Rex,* 1967), *Teorema* (*Theorem,* 1968), *Porcile* (*Pigsty,* 1969), *Medea* (1969), and *Salò* (1975). Like Pasolini, Bernardo Bertolucci is a Marxist intellectual whose films attempt to correlate sexuality, ideology, and history; his most successful films have been *Il conformista* (*The Conformist,* 1970), a striking dissection of the psychopathology of fascism, *Ultimo tango a Parigi* (*Last Tango in Paris,* 1972), a meditation on sex and death, and *Novecento* (*1900,* 1976), a six-hour epic covering 50 years of Italian class conflict.

Since the 1970s, the declining European economy has compelled many Italian directors to make co-productions with American, French, German, and Swedish companies. In order to maximize profits, several such films featured international stars in leading roles. This dependence on world markets—as well as the increased popularity of television throughout Italy—often led to the loss of national identity in Italian films, although such filmmakers as Roberto Benigni, Carlo Verdone, and Maurizio Nichetti were able to use the new situation to good advantage. Perhaps the most individual voice in recent Italian cinema has been Nanni Moretti, whose humorous, satiric works, such as *Caro diario* (*Dear Diary,* 1994), critique the social values of the late 20th century.

France. French cinema of the Occupation and postwar era produced many fine films (Marcel Carné's *Les Enfants du paradis* [*The Children of Paradise*], 1945; Jean

Cocteau's *La Belle et la bête* [*Beauty and the Beast*], 1946; René Clément's *Jeux interdits* [*Forbidden Games*], 1952; Jacques Becker's *Casque d'or* [*Golden Helmet*], 1952; Henri-Georges Clouzot's *Le Salaire de la peur* [*The Wages of Fear*], 1953), but their mode of presentation relied heavily on script and was predominantly literary. There were exceptions in the austere classicism of Robert Bresson (*Le Journal d'un curé de campagne* [*The Diary of a Country Priest*], 1950; *Un Condamné à mort s'est échappé* [*A Man Escaped*], 1956), the absurdist comedy of Jacques Tati (*Les Vacances de M. Hulot* [*Mr. Hulot's Holiday*], 1953; *Mon oncle* [*My Uncle*], 1958), and the lush, magnificently stylized masterworks of the German émigré Max Ophüls, whose *La Ronde* (1950), *Le Plaisir* (1952), *Madame de . . .* (1953), and *Lola Montès* (1955) represent significant contributions to world cinema. An independent documentary movement, which produced such landmark nonfiction films as Georges Rouquier's *Farrebique* (1948), Georges Franju's *Le Sang des bêtes* (*The Blood of the Beasts,* 1949), and Alain Resnais's *Nuit et brouillard* (*Night and Fog,* 1956), also emerged at this time. It provided a training ground for young directors outside the traditional industry system and influenced the independent production style of the movement that culminated the French postwar period of renewal—the *nouvelle vague,* or New Wave movement.

French New Wave movement

The most important source of the New Wave lay in the theoretical writings of Alexandre Astruc and, more prominently, of André Bazin, whose thought molded an entire generation of filmmakers, critics, and scholars. In 1948 Astruc formulated the concept of the *caméra-stylo* ("camera-pen"), in which film was regarded as a form of audiovisual language and the filmmaker, therefore, as a kind of writer in light. Bazin's influential journal *Cahiers du Cinéma,* founded in 1951, elaborated this notion and became the headquarters of a group of young *cinéphiles* ("film-lovers")—the critics François Truffaut, Jean-Luc Godard, Claude Chabrol, Jacques Rivette, and Eric Rohmer—who were to become the major directors of the New Wave. Bazin's basic principle was a rejection of montage aesthetics—both radical Eisensteinian cutting and Hollywood-style continuity, or invisible, editing—in favour of the long take and composition in depth, or what he called mise-en-scène. Borrowed from the theatre, this term literally means "the placing in the scene," but Bazin used it to designate such elements of filmic structure as camera placement and movement, the lighting of shots, and blocking of action—that is, everything that precedes the editing process.

The *Cahiers* critics embraced mise-en-scène aesthetics and borrowed the idea of authorship from Astruc. In proposing *la politique des auteurs* ("the policy of authors"), christened the auteur theory by the American critic Andrew Sarris, they maintained that film should be a medium of personal artistic expression and that the best films are those imprinted with their makers' individual signature. As a logical consequence of this premise, the *Cahiers* critics rejected mainstream French cinema and its "tradition of quality" in favour of the classical mise-en-scène tradition (exemplified in the films of Feuillade Murnau, Stroheim, Renoir, Welles, Ophüls), Hollywood studio directors who had transcended the constraints of the system to make personal films (Hawks, Sternberg, Hitchcock, Ford), and the low-budget American B-film in which the director usually had total control over production.

The first films of the New Wave were independently produced dramatic shorts shot in 16-millimetre by the *Cahiers* critics in 1956–57, but 1959 was the year that brought the movement to international prominence, when each of its three major figures made their first features. Truffaut's *Les Quatre cents coups* (*The 400 Blows*), Alain Resnais's *Hiroshima, mon amour,* and Godard's *À bout de souffle* (*Breathless*) were all in their different ways paradigms of a fresh new style based on elliptical editing and location shooting with hand-held cameras. This style was both radically destructive of classical Hollywood continuity and pragmatically suited to the New Wave's need to make its films quickly and cheaply. Its ultimate effect was to deconstruct the narrative language that had evolved over the previous 60 years and to create a reflexive cinema, or meta-cinema, whose techniques provided a continuous comment on its own making.

Truffaut, Resnais, and Godard

The critical and commercial success of the first New Wave features produced an unprecedented creative explosion within the French industry. Between 1960 and 1964, literally hundreds of low-budget experimental films were made by *cinéphiles* with little or no experience. Many of these ended in failure, and the New Wave as a collective phenomenon was over by 1965. But the three figures who had initiated the movement and a small group of sophisticated but less spectacular talents—Claude Chabrol, Louis Malle, Eric Rohmer, Agnès Varda, Jacques Demy, and Jacques Rivette—continued to dominate French cinema until well into the 1970s.

Jean-Pierre Léaud as Antoine Doinel (centre) in *The 400 Blows* (1959), directed by François Truffaut.

Truffaut was the most commercially successful of the original New Wave group, and through such films as *Jules et Jim* (1961) and the autobiographical "Antoine Doinel" series, which began with *Les Quatre Cents Coups,* he acquired a reputation as a romantic ironist. Truffaut's range also extended to parodies of Hollywood genres (*Tirez sur le pianiste* [*Shoot the Piano Player*], 1960), homages to Hitchcock (*La Mariée etait en noir* [*The Bride Wore Black*], 1967), historical reconstructions (*L'Enfant sauvage* [*The Wild Child*], 1970), reflexive narratives (*La Nuit américaine* [*Day for Night*], 1973), and literary adaptations (*L'Histoire d'Adèle H.* [*The Story of Adele H.*], 1975; *Le Dernier Métro* [*The Last Metro*], 1980).

Godard was the most stylistically and politically radical of the early New Wave directors. Some of his early films were parodies of Hollywood genres (*Une Femme est une femme* [*A Woman Is a Woman*], 1961; *Alphaville,* 1965; *Pierrot le fou,* 1965), but the majority treated political and social themes from a Marxist, and finally Maoist, perspective (*Le Petit Soldat* [*The Little Soldier*], 1960; *Vivre sa vie* [*My Life to Live*], 1962; *Les Carabiniers* [*The Riflemen*], 1963; *Bande à part* [*Band of Outsiders*], 1964); *Une Femme mariée* [*A Married Woman*], 1964). With *Masculin-féminin* (1966), Godard turned away from narrative toward the form of the *cinéma vérité*-style essay, and his later films became increasingly ideological and structurally random (*Made in U.S.A.,* 1966; *Deux ou trois choses que je sais d'elle* [*Two or Three Things I Know About Her*], 1967; *La Chinoise,* 1967; *Week-end,* 1967; *One Plus One,* 1968). During the 1970s, Godard made films for the radical Dziga Vertov production collective (*Pravda,* 1969; *Le Vent d'est* [*Wind from the East*], 1969; *Letter to Jane,* 1972) and experimented with combinations of film and videotape (*Numero deux* [*Number Two*], 1975; *La Communication,* 1976). In the 1980s Godard returned to theatrical filmmaking, purified of ideology but no less controversial for it, with such provocative features as *Sauve qui peut/La Vie* (*Every Man for Himself,* 1980), *Passion* (1982), and *Je vous salue, Mary* (*Hail Mary,* 1986).

Resnais was slightly older than the *Cahiers* group, but he identified with the New Wave through style and theme. His most famous film is the postmodern mystery *L'Année dernière à Marienbad* (*Last Year at Marienbad,* 1961), which questions the processes of thought and memory—

central concerns in Resnais's work. *Muriel* (1963), *La Guerre est finie* (*The War Is Over,* 1966), *Stavisky* (1974), *Providence* (1977), and *Mon oncle d'Amérique* (*My Uncle in America,* 1978) are all in various ways concerned with the effects of time on human memory from both a historical and a personal perspective.

Other important New Wave figures who remain influential are Claude Chabrol, whose entire career can be seen as an extended homage to Hitchcock (*La Femme infidèle* [*Unfaithful Wife*], 1968; *Que la bête meure* [*This Man Must Die*], 1969; *Le Boucher* [*The Butcher*], 1970; *Violette Nozière,* 1978); Louis Malle, a master of film types who relocated in the United States (*Le Feu follet* [*The Fire Within*], 1963; *Le Souffle au coeur* [*Murmur of the Heart*], 1971; *Lacombe, Lucien,* 1973; *Pretty Baby,* 1978; *Atlantic City,* 1980); Eric Rohmer, whose "moral tales," including *Ma Nuit chez Maud* (*My Night at Maud's,* 1968) and *Le Genou de Claire* (*Claire's Knee,* 1970), established the ironic perspective on human passion that he maintained in such later films as *Pauline à la plage* (*Pauline at the Beach,* 1983); *Le Bonheur* [*Happiness*], 1965); Jacques Demy, whose best films are homages to the Hollywood musical (*Les Parapluies de Cherbourg* [*The Umbrellas of Cherbourg*], 1964; *Les Demoiselles de Rochefort* [*The Young Girls of Rochefort*], 1967); and Jacques Rivette, the most austerely abstract and experimental of the *Cahiers* group (*La Religieuse* [*The Nun*], 1965; *L'Amour fou,* 1968; *Céline et Julie vont en bateau* [*Celine and Julie Go Boating*], 1974; *Duelle,* 1977).

Influence of the New Wave

Few national movements have influenced international cinema as strongly as the French New Wave. By promoting the concept of personal authorship, its directors demonstrated that film is an audiovisual language that can be crafted into "novels" and "essays"; and by deconstructing classical Hollywood conventions, they added dimensions to this language that made it capable of expressing a new range of internal and external states. In the process, the New Wave helped to reinvigorate such stylistically moribund cinemas as the British, West German, and American, and it created a current of "second waves" and "third waves" in the already flourishing Italian, Polish, Czech, Hungarian, and Japanese cinemas.

The New Wave made France the leading centre of Modernist and postmodern film and film theory, a position it continued to hold for many years. By the 1990s, France followed the lead of other European countries in assimilating itself into the world market. The influences of the New Wave were still evident, but increased demands for commercial fare resulted in several crime thrillers and period costume dramas, genres that were often specialties of young directors.

Unique among European filmmakers, however, many French directors remain unfettered by commercial demands. At the turn of the 21st century, Claude Chabrol was still a dominant force, with such films as *La Cérémonie* (*Judgment in Stone,* 1995) demonstrating his continued mastery of the psychological thriller. Prominent young directors included Manuel Poirier, who specialized in affectionate, offbeat romances and "buddy pictures," such as *Western* (1997); Claire Simon, who, after several years of directing documentaries, adapted her characteristic ironic humour to such fictional films as *Sinon, oui* (*A Foreign Body,* 1997) and *Ca c'est vraiment toi* (*That's Just Like You,* 2000); and Robert Guédiguian, a writer-producer-director known for works such as *Marius et Jeannette* (1997) and *À la place du coeur* (1998), which effectively blend affectionate character studies with biting social satire.

Great Britain. In Great Britain the post-World War II cinema was even more literary than in France, relying heavily on the adaptation of classics in the work of such directors as Laurence Olivier (*Henry V,* 1944; *Hamlet,* 1948; *Richard III,* 1955), David Lean (*Great Expectations,* 1946; *Oliver Twist,* 1948), and Anthony Asquith (*The Importance of Being Earnest,* 1952). Even less conventional films had literary sources (Carol Reed's *Outcast of the Islands,* 1951; Michael Powell's and Emeric Pressberger's *The Red Shoes,* 1948, and *The Tales of Hoffman,* 1951). There were exceptions to this trend in a series of witty irreverent comedies made for Michael Balcon's Ealing Studios (*The Lavender Hill Mob,* 1951; *The Man in the White Suit,* 1951; *Kind Hearts and Coronets,* 1949), most of them starring Alec Guinness, but on the whole British postwar cinema was elitist and culturally conservative.

Jean Simmons as Estella, Martita Hunt as Miss Havisham, and Anthony Wager as young Pip in David Lean's *Great Expectations* (1946).

In reaction, a younger generation of filmmakers led by Lindsay Anderson, Czechoslovak-born Karel Reisz, and Tony Richardson organized the Free Cinema movement in the mid-50s. Its purpose was to produce short, low-budget documentaries illuminating problems of contemporary life (Anderson's *O Dreamland,* 1953; Richardson's *Momma Don't Allow,* 1955). Grounded in the ideology and practice of Neorealism, Free Cinema emerged simultaneously with a larger social movement assailing the British class structure and calling for the replacement of bourgeois elitism with liberal working-class values. In the cinema this antiestablishment agitation resulted in the New Cinema or social realist movement signaled by Reisz's *Saturday Night and Sunday Morning* (1960), the first British postwar feature with a working class protagonist and proletarian themes. Stylistically influenced by the New Wave, with which it was concurrent, the social realist film was generally shot in black and white on location in the industrial Midlands and cast with unknown young actors and actresses. Like the New Wave films, social realist films were independently produced on low budgets (many of them for Woodfall Film Productions, the company founded in 1958 by Richardson and playwright John Osborne to adapt the latter's *Look Back in Anger*), but their freshness of both content and form attracted an international audience. Some of the most famous were Richardson's *A Taste of Honey* (1961) and *The Loneliness of the Long Distance Runner* (1962), John Schlesinger's *A Kind of Loving* (1962) and *Billy Liar* (1963), and Anderson's *This Sporting Life* (1963), and Reisz's *Morgan: A Suitable Case for Treatment* (1966).

British social realist movement

These films brought such prestige to the British film industry that London briefly became the production capital of the Western world, delivering such international hits as Richardson's *Tom Jones* (1963), Schlesinger's *Darling* (1965), Richard Lester's two Beatles films, *A Hard Day's Night* (1964) and *Help!* (1965), Schlesinger's *Far from the Madding Crowd* (1967), and Anderson's *If . . .* (1968), as well as such foreign importations as Roman Polanski's *Repulsion* (1965) and *Cul-de-sac* (1966), Truffaut's *Farenheit 451* (1966), Antonioni's *Blow-Up* (1966), and Stanley Kubrick's *2001: A Space Odyssey* (1968) and *A Clockwork Orange* (1971). This activity inspired a new, more visually oriented generation of British filmmakers—Peter Yates, John Boorman, Ken Russell, Nicolas Roeg, and Ridley Scott—who would make their mark in the 1970s; but as England's economy began its precipitous decline during that decade, so too did its film industry. Many British directors and performers defected to Hollywood, while the English-language film market simultaneously experienced a vigorous and unprecedented challenge from Australia. In the 1980s, amid widespread speculation about the collapse

of the industry, British annual production reached an all-time low.

Britain's film industry, however, has a long history of rebounding from periods of crisis. A major factor in the revival of British cinema during the late 20th century was the founding in 1982 of Channel 4, a television network devoted to commissioning—rather than merely producing—original films. Their success led to the establishment of a subsidiary, FilmFour Ltd., in 1998. Internationally acclaimed films produced or coproduced under either the Channel 4 or FilmFour banner include *A Room with a View* (1986), *The Crying Game* (1992), *Four Weddings and a Funeral* (1994), *Trainspotting* (1996), *The Full Monty* (1997), and *Elizabeth* (1998). Also contributing to the resurgence of British film is the National Lottery, established in 1994, which annually contributes millions of pounds to the film industry.

Germany. Germany's catastrophic defeat in World War II and the subsequent partitioning of the country virtually destroyed its film industry, which had already been corrupted by the Nazis. Rebuilt during the 1950s, the West German industry became the fifth largest producer in the world, but the majority of its output consisted of low-quality *Heimatfilme* ("homeland films") for the domestic market. When this market collapsed in the 1960s because of changing demographic patterns and the diffusion of television, the industry was forced to turn to the federal government for subsidies. In recognition of the crisis, 26 writers and filmmakers at the Oberhausen Film Festival in 1962 drafted a manifesto proclaiming the death of German cinema and demanding the establishment of a *junger deutscher Film,* a "young German cinema." The members of this Oberhausen group became the founders of *das neue Kino,* or New German Cinema, which was brought into being over the next decade through the establishment of the Kuratorium Junger Deutscher Film (1965; Young German Film Board, a grant agency drawing on the cultural budgets of the federal states), the Filmförderungsanstalt, or FFA (Film Subsidies Board, which makes production funds available by levying a federal tax on theatre tickets), and the independent distributing company Filmverlag der Autoren (1971; Authors' Film-Publishing Group), with additional funding from the two West German television networks.

New German Cinema

These institutions made it possible for a new generation of filmmakers to produce their first features and establish a vital new cinema for West Germany that attempted to examine the nation's *unbewältige Vergangenheit,* or "unassimilated past." The first such films, which were influenced by the New Wave, included Volker Schlöndorff's *Der junge Törless* (*Young Torless,* 1966) and Alexander Kluge's *Die Artisten in der Zirkuskuppel: ratlos* (*The Artists Under the Big Top: Disoriented,* 1968). In the 1970s, however, three major figures emerged as leaders of the movement—Rainer Werner Fassbinder, Werner Herzog, and Wim Wenders. Fassbinder was the most prolific, having made more than 40 features before he died in 1982. His films are also the most flamboyant. Nearly all of them take the form of extreme melodrama, ending in murder or suicide—*Warum läuft Herr R. amok?* (*Why Does Herr R. Run Amok?,* 1969), *Die bitteren Tränen der Petra von Kant* (*The Bitter Tears of Petra von Kant,* 1972), *Angst essen Seele auf* (*Fear Eats the Soul/Ali,* 1973)—and several are consciously focused on German wartime and postwar society (*Die Ehe der Maria Braun* [*The Marriage of Maria Braun*], 1979; *Lola,* 1981; *Veronika Voss,* 1982).

Herzog's films tended more toward the mystical and the spiritual than the social, although there is nearly always some contemporary referent in his work—the image of idealism turned to barbarism in *Aguirre, der Zorn Gottes* (*Aguirre, the Wrath of God,* 1972); the inability of science to address the human condition in *Jeder für sich und Gott gegen alle* (*Every Man for Himself and God Against All/Kaspar Hauser,* 1974); the destructive nature of technology in *Herz aus Glas* (*Heart of Glass,* 1977); the incomprehensible nature of pestilence in his remake of Murnau's *Nosferatu* (1979). Wenders, on the other hand, is profoundly postmodern in his contemplation of alienation through spatial metaphor. In such existential works as *Die Angst des Tormanns beim Elfmeter* (*The Goalie's Anxiety at the Penalty Kick,* 1971) and *Im Lauf der Zeit* (*In the Course of Time/Kings of the Road,* 1976), he addressed the universal phenomena of dislocation and rootlessness that afflict society.

The state subsidy system has enabled hundreds of filmmakers, many of whom are women (*e.g.,* Margarethe von Trotta) or members of minorities, to participate in the New German Cinema. With the exception of the work of Fassbinder, Herzog, and Wenders, however, the New German Cinema did not find a large audience outside of West Germany. Yet in terms of exploring and extending the audio-language system of film, it was to the 1970s and '80s very much what the New Wave was to the '60s, and its influence was widely felt.

Since the reunification of Germany in 1990, a national identity has yet to be forged in any of the various arts. Several outstanding German directors and production artists have emerged, however, most of them achieving their greatest success in Hollywood. Roland Emerich (*Independence Day,* 1996; *The Patriot,* 2000) has proven a skillful practitioner of the action-adventure genre; and Wolfgang Petersen, who received international acclaim for *Das Boot* (1982), has earned a reputation for tense thrillers (*In the Line of Fire,* 1993) and unrelenting visual spectacles (*The Perfect Storm,* 2000). German cinematographers (Michael Ballhaus, Karl Walter Lindenlaub) and composers (Hans Zimmer, Christopher Franke) have also been among the more notable artisans in Hollywood films at the turn of the 21st century.

Africa. The development of an indigenous film culture in Africa occurred at different moments in the history of the continent. The various time lines are related to the political, social, and economic situations in each country and to the varying effects of colonialism on the continent. Only Egypt had a truly active film industry for the first half of the 20th century; the development of cinema elsewhere on the continent was largely the result of individual efforts. One such example is that of Paul Soumanou Vieyra, the first African graduate of the French film school Institut des Hautes Études Ciné, who joined with friends to produce the short film *Afrique sur Seine* (1955), considered the first fiction film by black Africans.

Some countries, such as Morocco, have never developed a strong national cinema; others, such as Algeria and Tunisia, have nationalized all or parts of their film industries. Several African nations are members of the Fédération Pan-Africaine des Cinéastes (FEPACI; "Federation of African Filmmakers"), formed in 1969 to oversee the political and financial problems of the film industries throughout the continent.

At the end of the 20th century, many filmmakers and scholars began to examine the questions of, first, what constitutes an "African film" and, second, how film can best deal with the diaspora of the African people. On one hand, African filmmakers to some extent acknowledge and learn from the conventions of Western film. On the other, they often use film to highlight and preserve aspects of the African culture that has been threatened by Western colonialism. As part of this search to define the goals of African cinema, African filmmakers often use the medium as a means to explore the social issues plaguing postcolonial Africa. Directors such as Adama Drabo (*Ta Dona* [*Fire*], 1991) and Moufida Tlatli (*Les silences du palais* [*The Silences of the Palace*], 1994) explored such matters as education, the environment, and women's rights and suggested that traditional approaches to such issues must be adapted to the realities of contemporary Africa. Aspects of these realities were examined by such directors as Tsitsi Dangarembga (*Everyone's Child,* 1996) and Salem Mekuria (*Ye Wonz Maibel* [*Deluge*], 1995), who dealt with the AIDS crisis and political violence, respectively. Colonization itself was examined by such directors as Bassek ba Kobhio, whose satiric study of Albert Schweitzer, *Le Grand Blanc de Lambaréné* (*The Great White Man of Lambaréné,* 1995), shows how colonialism damages both colonizer and the colonized.

Japan. Although more than half of Japan's theatres were destroyed during World War II, most of its studio facilities

were left intact. Japan, therefore, continued to produce films in quantity during the Allied occupation (1945–52). Many traditional Japanese subjects were forbidden by the Allied Command as promoting feudalism, however, including all films classified as *jidai-geki.* Nevertheless, the film that first brought Japanese cinema to international attention belonged to that category: Kurosawa Akira's *Rashomon* (1950), which won the Golden Lion at the 1951 Venice Film Festival. The film, a meditation on the nature of truth set in the medieval past, marked the beginning of the Japanese cinema's unprecedented postwar renaissance. During this period, new export markets opened in the West, and Japanese filmmakers produced some of their finest work. Kurosawa, already well known in his homeland, became the most famous Japanese director in the West on the strength of his masterful samurai epics—*Seven Samurai* (1954), *The Throne of Blood* (1957), *The Hidden Fortress* (1958), and *Yojimbo* (1961)—which raised the *chambara,* or "sword-fight," film to the status of art. He made films in other genres, including literary adaptations (*The Idiot,* 1951; *The Lower Depths,* 1957), *gendai-geki* (*Ikiru* [*To Live/Living*], 1952; *Dodesukaden,* 1970), gangster films (*Stray Dog,* 1949; *The Bad Sleep Well,* 1960; *High and Low,* 1963), and period films that cannot be categorized at all (*Red Beard,* 1965; *Dersu Uzala,* 1975); but Kurosawa always returned to the samurai form for his most profound statements about life and art (*Kagemusha* [*The Shadow Warrior*], 1980; *Ran,* 1985).

Japanese cinema's postwar renaissance

Rashomon (1950), directed by Kurosawa Akira.

Two other established directors of the postwar period were Mizoguchi Kenji and Ozu Yasujirō. Both began their careers in the silent era and were more traditionally Japanese in style and content than Kurosawa. Mizoguchi's films, whether period (*Sansho the Bailiff,* 1954; *Crucified Lovers,* 1954) or contemporary (*Women of the Night,* 1948; *Gion Festival Music,* 1953), were frequently critiques of feudalism that focused on the condition of women within the social order. His greatest postwar films are *The Life of Oharu* (1952), the biography of a 17th-century courtesan, and *Ugetsu* (1953), the story of two men who abandon their wives for fame and glory during the 16th-century civil wars. Both are masterworks that clearly demonstrate Mizoguchi's expressive use of luminous decor, extended long takes, and deep-focus composition. As one of the great mise-en-scène directors, Mizoguchi can be compared to Murnau, Ophüls, and Welles, but his transcendental visual style makes him unique in the history of cinema.

Japanese social critique

Ozu, too, was a stylist, but the majority of his 54 films are *shomin-geki,* a variety of *gendai* film dealing with the lives of lower-middle-class families (*The Only Son,* 1936; *There Was a Father,* 1942; *Late Spring,* 1949; *Early Summer,* 1951; *Tokyo Story,* 1953; *Early Spring,* 1956; *Tokyo Twilight,* 1957; *Equinox Flower,* 1958; *Floating Weeds,* 1959; *An Autumn Afternoon,* 1962). They are all very much alike and, in a sense, are all part of a single large film, whose subject is the ordinary lives of ordinary people and the sacred beauty therein. Ozu's minimalist style—originating in both Zen Buddhist aesthetics and the fact that most of his films were shot within the confines of a typical Japanese house—is based on his use of low-angle long takes in which the camera is positioned about three feet off the floor at the eye-level of a person seated on a tatami mat. This practice led Ozu to an especially imaginative use of offscreen space and "empty scenes."

The second postwar generation of Japanese filmmakers was mainly composed of Kobayashi Masaki, Ichikawa Kon, and Shindo Kaneto. Kobayashi is best known for *The Human Condition* (1959–61), his three-part antiwar epic set during Japan's brutal occupation of Manchuria, the two graphic *jidai-geki Harakiri* (1962) and *Rebellion* (1967), and the beautiful ghost film *Kwaidan* (1964). Ichikawa's major works are the pacifist films *The Burmese Harp* (1956) and *Fires on the Plain* (1959) and his beautifully composed wide-screen films, *Conflagration* (1958), *The Key* (1959), and *Tokyo Olympiad* (1965). Shindo is best known for his poetic semidocumentary *The Island* (1960) and the bizarre, folkloristic *Onibaba* (1964).

The third generation of postwar directors was most active during the 1960s and '70s. They were deeply influenced by the French New Wave and included Teshigahara Hiroshi (*Woman in the Dunes,* 1964), Masumura Yasuzo (*The Red Angel,* 1965), Imamura Shohei (*The Pornographer,* 1966), Hani Susumu (*The Inferno of First Love,* 1968), Shinoda Masahiro (*Double Suicide,* 1969), Yoshida Yoshishige (*Eros plus Massacre,* 1970), and, quintessentially, Oshima Nagisa (*The Man Who Left His Will on Film,* 1970; *In the Realm of the Senses,* 1976). In the mid-1960s, however, competition from television and American distributors forced Japan's film industry into economic decline. A decade later, two major studios were bankrupt, and film production was dominated by two domestic exploitation genres, the *yakuza-eiga,* or urban gangster film, and the semipornographic "eroduction" film, which mixed sex and sadism. During the 1980s and '90s, Japan continued to produce the highest annual volume of films of any nation in the world, but the studios remained in decline and most serious productions, such as Kurosawa's *Kagemusha,* were funded by foreign interests. At the turn of the 21st century, funding for films remained low, although the market for films was greater than ever. This situation led to the mass production of low-budget films, as well as to the increased popularity of amateur and experimental films.

Decline of the Japanese film industry

China, Taiwan, and Korea. Other Asian nations have had spotty cinematic histories, although most developed strong traditions during the late 20th century. The film industries of China, Taiwan, and Korea were marked by government restrictions for most of the 20th century, and the majority of their output consisted of propaganda films. The loosening of many restrictions in the 1980s and '90s resulted in a new wave of Asian directors who have attained worldwide prominence. China's "Fifth Generation Cinema" is known for such outstanding young directors as Zhang Yimou, who specializes in tales of political oppression and sexual repression. Korea's cinematic history is difficult to assess, as virtually no films made prior to World War II exist today, but works produced during the 1950s and '60s—the "golden age" of Korean cinema—have gained a strong international reputation. The most successful Asian director of the late 20th century was Taiwan's Ang Lee, who has directed films ranging from American morality tales (*The Ice Storm,* 1997; *Ride with the Devil,* 1999) to the lavish and widely popular martial-arts fantasy *Crouching Tiger, Hidden Dragon* (2000).

India. Serious postwar Indian cinema was for years associated with the work of Satyajit Ray, a director of singular talent who produced the great Apu trilogy (*Pather panchali* [*The Song of the Road*], 1955; *Aparajito* [*The Unvanquished*], 1956; *Apur sansar* [*The World of Apu*], 1959) under the influence of both Jean Renoir and Italian Neorealism. Ray continued to dominate the Indian cinema

through the 1960s and '70s with such artful Bengali films as *Devi* (*The Goddess,* 1960), *Charulata* (*The Lonely Wife,* 1964), *Aranyer din ratri* (*Days and Nights in the Forest,* 1970), and *Ashanti sanket* (*Distant Thunder,* 1973).

In 1961 the Indian government established the Film Institute of India to train aspiring directors. It also formed the Film Finance Commission (FFC) to fund independent and experimental films. The National Film Archive was founded in 1964. These organizations encouraged the production of such important first features as Mrinal Sen's *Bhuvan Shome* (*Mr. Shome,* 1969), Basu Chatterji's *Sara akaash* (*The Whole Sky,* 1979), Mani Kaul's *Uski roti* (*Daily Bread,* 1969), Kumar Shahani's *Maya darpan* (*Mirror of Illusion,* 1972), Avtar Kaul's *27 Down* (1973), and M.S. Sathyu's *Garam hawa* (*Scorching Wind,* 1973) and promoted the development of a nonstar "parallel cinema" centred in Bombay. During the 1970s the regional industries of the southwestern states—especially those of Kerala and Karnātaka—began to subsidize independent production, resulting in a "southern new wave" in the films of such diverse figures as G. Aravindan (*Kanchana sita* [*Golden Sita*], 1977), Adoor Gopalakrishnan (*Elipathayam* [*Rat-Trap*], 1981), and Girish Karnad (*Kaadu* [*The Forest*], 1973). Despite the international recognition these films have earned, the Indian government's efforts to raise the artistic level of the nation's cinema have been largely unsuccessful. India remains a land of some one billion people, most of them illiterate and poor, whose exclusive access to audiovisual entertainment is film; television is the medium of the rich and powerful middle class. The Indian film industry therefore continues to be the world's largest producer of low-quality films for domestic consumption, releasing 1,000 features per year in 16 languages. (For coverage of recent trends in Indian cinema, see the *Micropædia* article BOLLYWOOD.)

Development of Australian cinema

Australia. Australia was a country virtually without a film industry until the late 1960s and early '70s, when the federal government established the Australian Film Development Corporation (after 1975, the Australian Film Commission) to subsidize the growth of an authentic national cinema, founded a national film school (the Australian Film and Television School, or AFTS) to train directors and other creative personnel, and initiated a system of lucrative tax incentives to attract foreign investment capital to the new industry. The result was a creative explosion unprecedented in the English-language cinema. Australia produced nearly 400 films between 1970 and 1985—more than had been made in all of its prior history.

With financing from the Film Commission and such semiofficial bodies as the New South Wales Film Corporation (by the end of the decade each of the federal states had its own funding agency), the first films began to appear in the early 1970s, and within the next few years several talented directors began to receive recognition, including Peter Weir (*Picnic at Hanging Rock,* 1975), Bruce Beresford (*The Getting of Wisdom,* 1977), Fred Schepisi (*The Chant of Jimmy Blacksmith,* 1978), George Miller (*Mad Max,* 1979), and the first AFTS graduates, Phillip Noyce (*Newsfront,* 1978) and Gillian Armstrong (*My Brilliant Career,* 1979). Unlike the productions financed with foreign capital by the Canadian Film Development Corporation during the same period, these new Australian films had indigenous casts and crews and treated distinctly national themes. By the end of the 1970s, Australian motion pictures were being prominently featured at the Cannes International Film Festival and competing strongly at the box office in Europe. In 1981 Australia penetrated the American market with two critical hits, Beresford's *Breaker Morant* (1980) and Weir's *Gallipoli* (1981), and the following year achieved a smashing commercial success with Miller's *Mad Max II* (1981; retitled *The Road Warrior,* 1982). In the 1980s and '90s many Australian directors came to work for the American film industry, with varying degrees of success. Despite this temporary talent drain and a decline in government tax concessions, the Australian cinema remains one of the most influential and creatively vital in the world. Prominent younger directors who have helped maintain Australia's world status include Baz Luhrmann, noted for his flamboyant visual style on such films as *William Shakespeare's Romeo + Juliet* (1996) and *Moulin Rouge* (2001).

Russia, eastern Europe, and the former Soviet bloc countries. After World War II the Soviet Union's film industry experienced greater stagnation than that of any other nation except Germany. The socialist realism doctrine imposed during Stalin's dictatorship caused film production to fall from 19 features in 1945 to five in 1952. Although Stalin died the following year, the situation did not improve until the late 1950s when such films as Mikhail Kalatozov's *The Cranes Are Flying* (1957) and Grigory Chukhrai's *Ballad of a Soldier* (1959) emerged to take prizes at international film festivals. Some impressive literary adaptations were produced during the 1960s, but the most important phenomenon of the decade was the graduation of a whole new generation of Soviet directors from the VGIK, many of them from the non-Russian republics. By far the most brilliant of the new directors were Sergey Paradzhanov and Andrey Tarkovsky, who both were later persecuted for the unconventionality of their work. Paradzhanov's greatest film is *Shadows of Forgotten Ancestors* (1964), a hallucinatory retelling of a Ukrainian folk legend of ravishing formal beauty. Tarkovsky created a body of work whose seriousness and symbolic resonance had a major impact on world cinema (*Ivan's Childhood,* 1962; *Andrey Rublev,* 1966; *Solaris,* 1971; *Mirror,* 1974; *Stalker,* 1979; *Nostalgia,* 1983; *The Sacrifice,* 1986), even though it was frequently tampered with by Soviet censors.

During the 1970s, the policy of socialist realism (euphemized as "pedagogic realism") was again put into practice, so that only two types of films could safely be made—literary adaptations (Andrey Mikhalkov-Konchalovsky's *Uncle Vanya,* 1970; Nikita Mikhalkov's *Oblomov,* 1980) and *bytovye,* or films of everyday life (Georgy Danelia's *Autumn Marathon,* 1979; Vladimir Menshov's *Moscow Does Not Believe in Tears,* 1980). The Soviet cinema then experienced a far-reaching liberalization under the regime of Party Secretary Mikhail Gorbachev, whose policy of *glasnost* ("openness") took control of the industry away from bureaucratic censors and placed it in the hands of the filmmakers themselves. The Soviet cinema began to be revitalized as formerly suppressed films, such as Elem Klimov's *Agoniya* (1975), were distributed for the first time, and films that dealt confrontationally with Stalinism, such as Tengiz Abuladze's *Repentance* (1987) were made without government interference.

Liberalization of Soviet cinema

Of the eastern European nations that fell under Soviet control after World War II, all except East Germany and Albania produced distinguished cinemas. Following the pattern set by the Soviets, these countries nationalized their film industries and established state film schools. They experienced a similar period of repressive government-imposed restrictions between 1945 and 1953, with a "thaw" during the late 1950s under premier Nikita Khrushchev. In Poland the loosening of ideological criteria gave rise to the so-called Polish School led by Jerzy Kawalerowicz (*Mother Joan of the Angels,* 1961), Andrzej Munk (*Eroica,* 1957; *Passenger,* 1963), and, preeminently, Andrzej Wajda (*A Generation,* 1954; *Canal,* 1956; *Ashes and Diamonds,* 1958). Wajda's reputation grew throughout the 1960s and '70s, when he was joined by a second generation of Polish filmmakers that included Roman Polanski (*Knife in the Water,* 1962), Jerzy Skolimowski (*Barrier,* 1966), and Krzysztof Zanussi (*Structure of Crystals,* 1969; *Illumination,* 1972). The Polish cinema expressed its support of the Solidarity trade union in the late 1970s through films by Wajda (*Man of Marble,* 1977; *Without Anesthesia,* 1978; *Man of Iron,* 1981), Zanussi (*Camouflage,* 1977; *The Constant Factor,* 1980), and such younger directors as Krysztof Kieslowski, Agnieszka Holland, and Feliks Falk.

The example of the Polish School encouraged the development of the Czech New Wave (1962–68), which became similarly entangled in politics. The Czechoslovak films that reached international audiences during this period were widely acclaimed for their freshness and formal experimentation, but they faced official disapproval at home and many were suppressed for being politically subversive. Among the directors who were most critical of President

Czech New Wave

Antonín Novotný's hard-line regime were Věra Chytilová (*Daisies,* 1966), Jaromil Jireš (*The Joke,* 1968), Ján Kadár (*The Shop on Main Street,* 1965), Miloš Forman (*Firemen's Ball,* 1967), Jiří Menzel (*Closely Watched Trains,* 1966), Evald Schorm (*Everyday Courage,* 1964), and Jan Němec (*The Party and the Guests,* 1966). When Alexander Dubček became president in January 1968, the Czechoslovak cinema eagerly participated in his brief attempt to give Socialism "a human face." After the Soviet invasion of August 1968, many New Wave films were banned, the Czechoslovak film industry was reorganized, and several prominent figures, including Forman and Němec, were forced into exile.

In Hungary, the abortive revolution of 1956 forestalled a postwar revival until the late 1960s, when the complex work of Miklos Jancsó (*The Round-Up,* 1965; *The Red and the White,* 1967; *Red Psalm,* 1972) began to be internationally recognized. The rigorous training given students at the Budapest Film Academy ensured that the younger generation of Hungarian filmmakers would rise to prominence, as has been the case for István Szábo (*Mephisto,* 1981), István Gaál (*Falcons,* 1970), Márta Mészáros (*Adoption,* 1975), and Pál Gábor (*Angi Vera,* 1978), many of whose films—as do Jancsó's—involve ideological interpretations of the national past.

Yugoslavia, Romania, and Bulgaria, unlike their more sophisticated Warsaw Pact allies, did not begin to develop film industries until after World War II. Yugoslavia was the most immediately successful and produced the countries' first internationally known director: the political avant-gardist Dušan Makavejev (*The Tragedy of the Switchboard Operator,* 1967; *W.R.—Mysteries of the Organism,* 1971). Makavejev belonged to the late-1960s movement known as *novi film* ("new film"), which also included such directors as Puriša Djordjević, Aleksandar Petrović, and Živojin Pavlović, all of whom were temporarily purged from the film industry during a reactionary period in the early 1970s. This dark period came to an end in 1976 when the filmmakers of the Prague school made their debuts. Goran Marković, Rajko Grlić, Srdjan Karanović, Lordan Zafranović, and Emir Kusturica were all graduates of the FAMU film school in Prague who had begun their careers working for Yugoslav television. Their offbeat, visually flamboyant social comedies brought a new breath of life into Yugoslav cinema and won a number of international prizes. Like Czechoslovakia, whose Jiří Trnka brought puppet animation to a state of perfection in the 1950s, Yugoslavia also became world famous for its animation, especially that of the "Zagreb School" founded by Vatroslav Mimica and Dušan Vukotić.

For decades, state money was readily available for filmmaking throughout the bloc countries, providing the films were ideologically acceptable. This of course changed with the collapse of the Soviet Union in January 1992, whereupon funding became the chief obstacle to filmmaking in the region. By the late 1990s, fewer than two dozen films per year were produced in Russia. Adding to the decline were such factors as theatres that were closed or converted into businesses such as car dealerships, a home-video industry that was barely in its inceptive stages, and the popularity of American and Asian films. Although such directors as Sergei Bodrov and Vladimir Khotinenko have received a degree of international acclaim, the financial situation of the film industries throughout Russia and eastern Europe suggests that it will be many years before these nations establish a degree of prominence in world cinema.

Spain and Mexico. Of the smaller film industries of the West, Spain's should be noted because it produced one of the world's greatest satirists in Luis Buñuel, and Mexico's should be commended because it allowed Buñuel to work after he was forced out of Spain by the Fascists. (Buñuel also worked frequently in France.) In a career that spanned most of film history, Buñuel directed scores of brilliantly sardonic films that assaulted the institutions of bourgeois Christian culture and Western civilization. Buñuel deeply influenced Carlos Saura, another Spanish filmmaker whose work tends toward the grotesque and darkly comic (*La caza* [*The Hunt*], 1966; *La prima Angélica* [*Cousin Angelica*], 1974; *Bodas de sangre* [*Blood Wedding*], 1981), as well as an entire generation of younger directors who began to work after Spanish dictator Francisco Franco's death in 1975 (*e.g.,* Victor Erice, Manuel Gutiérrez Aragón, Jaime Chavarri, and Pilar Miró). Hailed as Spain's most innovative director since Buñuel is Pedro Almodóvar, whose provocative, postmodernist works include *Mujeres al borde de un ataque de nervios* (*Women on the Verge of a Nervous Breakdown,* 1988) and *Todo sobre mi madre* (*All About My Mother,* 1999).

Buñuel's controversial satires

Sweden. The Scandinavian film industries are small, state-subsidized, and (since the introduction of sound) oriented largely toward the domestic market; however, the post-World War II Swedish cinema, like the Spanish, is noted for producing a single exceptional talent: Ingmar Bergman. Bergman first won international acclaim in the 1950s for his masterworks *The Seventh Seal* (1956), *Wild Strawberries* (1957), and *The Virgin Spring* (1960). His trilogies of the 1960s—*Through a Glass Darkly* (1961), *Winter Light* (1963), and *The Silence* (1963); *Persona* (1966), *Hour of the Wolf* (1968), and *Shame* (1968)—were marked by a deep spiritual and intellectual probing, and later films, such as *Cries and Whispers* (1972) and *Fanny and Alexander* (1984), confirmed that he is essentially a religious artist.

RECENT TRENDS IN U.S. CINEMA

In the United States, as elsewhere, the last half of the 1960s was a time of intense conflict between generations and of rapid social change. Deeply involved with its own financial crisis, Hollywood was slow to respond to this new environment, and the studios made increasingly desperate attempts to attract a demographically homogeneous audience that no longer existed. The stupendous failure of 20th Century-Fox's blockbuster *Cleopatra* (1963) was briefly offset by the unexpected success of its *The Sound of Music* (1965), but over the next few years one box-office disaster after another threatened the studios' independence until most were absorbed by conglomerates. The impact of such mergers was pronounced because they reduced filmmaking in the United States to a subordinate role; in the profit-making machinery of multinational corporations, film production was often less important than the production of such items as refined sugar, ball bearings, field ammunition, rubber tires, and soft drinks.

Corporate acquisition of Hollywood studios

Before conglomeration restructured the industry, however, there was an exciting period of experiment as Hollywood tried various things to attract new audiences. In an effort to lure members of the first "television generation" into theatres, the studios even recruited directors from the rival medium, such as Irvin Kershner (*A Fine Madness,* 1966), John Frankenheimer (*Seconds,* 1966), Sidney Lumet (*The Pawnbroker,* 1965), Robert Altman (*Countdown,* 1968), Arthur Penn (*Mickey One,* 1965), and Sam Peckinpah (*Major Dundee,* 1965). These directors collaborated with film-school-trained cinematographers (including Conrad Hall, Haskell Wexler, and William Fraker), as well as with the Hungarian-born cinematographers Laszlo Kovacs and Vilmos Zsigmond, to bring the heightened cinematic consciousness of the French New Wave to the American screen. Their films frequently exhibited unprecedented political and social consciousness as well.

The years 1967–69 marked a turning point in American film history as Penn's *Bonnie and Clyde* (1967), Stanley Kubrick's *2001: A Space Odyssey* (1968), Peckinpah's *The Wild Bunch* (1969), Wexler's *Medium Cool* (1969), and Dennis Hopper's *Easy Rider* (1969) attracted the youth market to theatres in record numbers. (Altman's *M*A*S*H* [1970] provided a novel comedic coda to the quintet.) The films were unequal aesthetically (the first three being major revisions of their genres, the latter two canny exploitations of the prevailing mood), but all shared a cynicism toward established values and a fascination with apocalyptic violence. There was a sense, however briefly, that such films might provide the catalyst for a cultural revolution. Artistically, the films domesticated New Wave camera and editing techniques, enabling once-radical practices to enter the mainstream narrative cinema. Financially, they were so successful that producers quickly

saturated the market with low-budget youth-culture movies, only a few of which achieved even limited distinction.

Concurrent with the youth-cult boom was the new permissiveness toward sex made possible by the institution of the MPAA ratings system in 1968 (and modified slightly throughout the years). Unlike the Production Code, this system of self-regulation did not proscribe the content of films but merely categorized them according to their appropriateness for young viewers. (G designates general audiences; PG recommends parental guidance for children under 17; PG-13 suggests parental guidance for children under 13; R indicates that the film is restricted for persons under 17, unless they are accompanied by a parent or guardian; and X or NC-17 signifies that no one under 17 may be admitted to the film. In practice, the X rating is usually given to unabashed pornography and the G rating to children's films, which had the effect of concentrating sexually explicit but serious films in the R and NC-17 categories.) The introduction of the ratings system led immediately to the production of serious, nonexploitative adult films, such as John Schlesinger's *Midnight Cowboy* (1969) and Mike Nichols' *Carnal Knowledge* (1971), in which sexuality was treated with a maturity and realism unprecedented on the American screen.

MPAA ratings system

Despite increasing costs, the unprecedented popularity of a few films (Francis Ford Coppola's *The Godfather,* 1972; Steven Spielberg's *Jaws,* 1975; George Lucas' *Star Wars,* 1977) produced enormous financial profits and stimulated a wildcat mentality within the industry. In this environment, it was not uncommon for the major companies to invest their working capital in the production of only five or six films a year, hoping that one or two would be extremely successful. At one point, Columbia reputedly had all of its assets invested in Spielberg's *Close Encounters of the Third Kind* (1977), a gamble that paid off handsomely; United Artists' similar investment in Michael Cimino's financially disastrous *Heaven's Gate* (1980), however, caused the sale of the company and its virtual destruction as a corporate entity.

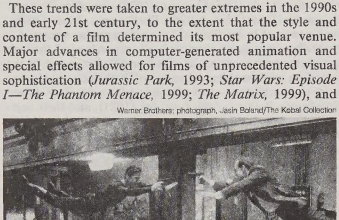
The new generation of directors that came to prominence at this time included many who had been trained in university film schools—Francis Ford Coppola and Paul Schrader at the University of California at Los Angeles, George Lucas and John Milius at the University of Southern California, Martin Scorsese and Brian De Palma at New York University, Steven Spielberg at California State College. These filmmakers brought to their work a technical sophistication and a sense of film history eminently suited to the new Hollywood, whose quest for enormously profitable films demanded slick professionalism and a thorough understanding of popular genres. The directors achieved success as highly skilled technicians in the production of cinematic thrills, although many were serious artists as well.

The graphic representation of violence and sex, which had been pioneered with risk by *Bonnie and Clyde, The Wild Bunch,* and *Midnight Cowboy* in the late 1960s, was exploited for its sensational effect during the '70s in such well-produced R-rated features as Coppola's *The Godfather,* Friedkin's *The Exorcist* (1973), Spielberg's *Jaws,* Scorsese's *Taxi Driver* (1976), De Palma's *Carrie* (1976), and scores of lesser films. The newly popular science-fiction/adventure genre was similarly supercharged through computer-enhanced special effects and Dolby sound, as the brooding philosophical musings of Kubrick's *2001* gave way to the cartoon-strip violence of Lucas' *Star Wars,* Spielberg's *Raiders of the Lost Ark* (1981), and their myriad sequels and copies. There was, however, originality in the continuing work of veterans Robert Altman (*McCabe and Mrs. Miller,* 1971; *Nashville,* 1975; *Three Women,* 1977), Stanley Kubrick (*A Clockwork Orange,* 1971; *The Shining,* 1980), and American Film Institute graduate Terrence Malick (*Badlands,* 1973; *Days of Heaven,* 1978). In addition, Coppola (*The Godfather, The Godfather, Part II,* 1974; *Apocalypse Now,* 1979) and Scorsese (*Mean Streets,* 1973; *Raging Bull,* 1980) created films of unassailable importance. Some of the strongest films of the era came from émigré directors working within the American industry—John Boorman's *Deliverance* (1972), Roman Polanski's *Chinatown* (1974), Miloš Forman's *One Flew over the Cuckoo's Nest* (1975), and Ridley Scott's *Alien* (1979). In general, however, Hollywood's new corporate managers lacked the judgment of industry veterans and tended to rely on the recently tried and true (producing an unprecedented number of high-budget sequels) and the viscerally sensational.

To this latter category belong the spate of "psycho-slasher" films that glutted the market in the wake of John Carpenter's highly successful, low-budget chiller, *Halloween* (1978). The formula for producing films of this type begins with the serial murder of teenagers by a ruthless psychotic and adds gratuitous sex and violence, with realistic gore provided by state-of-the-art makeup and special-effects artists. Its success was confirmed by the record-breaking receipts of the clumsily made *Friday the Thirteenth* (1980). There were precedents for psycho-killer violence in Hitchcock's *Psycho* (1960) and Tobe Hooper's *The Texas Chainsaw Massacre* (1974), but for decades the exploitation of gore had existed only at the periphery of the industry (in the "splatter" movies of Herschell Gordon Lewis, for example). The slasher films took the gore and violence into the mainstream of Hollywood films.

Growth of exploitation films

During the 1980s, the fortunes of the American film industry were increasingly shaped by new technologies of video delivery and imaging. Cable networks, direct-broadcast satellites, and half-inch videocassettes provided new means of motion-picture distribution, and computer-generated graphics provided new means of production, especially of special effects, forecasting the prospect of a fully automated "electronic cinema." Many studios, including Universal and Columbia, devoted the majority of their schedules to the production of telefilms for the commercial television networks, and nearly all of the studios began the practice of preselling their theatrical features for cable and videocassette distribution. In fact, Tri-Star, one of Hollywood's major producer/distributors, was a joint venture of CBS Inc., Columbia Pictures, and Time-Life's premium cable service Home Box Office (HBO). HBO and Showtime both function as producer/distributors in their own right by directly financing films and entertainment specials for cable television. In the '80s, for the first time since the 1910s, independent film producers released more motion pictures than the major studios, largely to satisfy the demands of the cable and home-video markets.



Influence of video technology

The strength of the cable and video industries led producers to seek properties with video or "televisual" features that would play well on the small television screen (*Flashdance,* 1983; *Footloose,* 1984), or to attempt to draw audiences into the theatres with the promise of spectacular 70-millimetre photography and multitrack Dolby sound (*Amadeus,* 1984; *Aliens,* 1986). Ironically, the long-standing 35-millimetre theatrical feature survived in such unexpected places as "kidpix" (a form originally created to

exploit the PG-13 rating when it was instituted in 1984—*The Breakfast Club,* 1985; *Stand by Me,* 1986) and, more dramatically, the Vietnam combat film (Oliver Stone's *Platoon,* 1986; Coppola's *Gardens of Stone,* 1987; Kubrick's *Full Metal Jacket,* 1987).

These trends were taken to greater extremes in the 1990s and early 21st century, to the extent that the style and content of a film determined its most popular venue. Major advances in computer-generated animation and special effects allowed for films of unprecedented visual sophistication (*Jurassic Park,* 1993; *Star Wars: Episode I—The Phantom Menace,* 1999; *The Matrix,* 1999), and

audiences preferred the experience of seeing such films on large theatre screens. Computer animation was also put to good use in films that play equally well on theatre or television screens, such as *Toy Story* (1995), *Antz* (1998), and *Chicken Run* (2000). Independent producers, especially those who specialized in low-budget films of intimate subject matter, regained strength under the new regime of home video and created some of the most unconventional and interesting work the American cinema had seen in some time; they included Joel and Ethan Coen (*Blood Simple,* 1984; *Fargo,* 1996; *O Brother, Where Art Thou?,* 2000), Spike Jonze (*Being John Malkovich,* 1999), and Quentin Tarantino (*Pulp Fiction,* 1994; *Jackie Brown,* 1997). It was also an era in which low-cost marketing via the Internet could turn a $50,000 independent film into a $100,000,000 blockbuster (*The Blair Witch Project,* 1999). These "indie" films were too original to have been made in the studio era and too eccentric for the mass-market economies of the late 20th century. They hark back to the vitality and integrity of the pre-studio age—to the work of Griffith, Keaton, Stroheim, and Chaplin—when anything was possible because everything was new. (D.A.C.)

Rise of independent production

The art of film

ESSENTIAL CHARACTERISTICS OF MOTION PICTURES

In its short history, the art of motion pictures has frequently undergone changes that seemed fundamental, such as that resulting from the introduction of sound. It exists today in styles that differ significantly from country to country and in forms as diverse as the documentary created by one person with a hand-held camera and the multimillion-dollar "epic," involving hundreds of performers and technicians. Despite its diversity, however, an essential unchanging nature can be discerned in most of its manifestations.

A number of factors come to mind in connection with the motion-picture experience. For one thing, there is something mildly hypnotic about the illusion of movement that holds the attention and may even lower critical resistance. The accuracy of the film image is compelling because it is made by a nonhuman, scientific process. In addition, the motion picture gives what has been called a strong sense of being present; the film always appears to be in the present tense. There is also the concrete nature of film; it appears to show actual people and things.

No less important are the conditions under which the movie ideally is seen, where everything helps to dominate the spectators. They are taken from their everyday environment, partially isolated from others, and seated in a dark auditorium. The darkness concentrates their attention and prevents comparison of the image on the screen with surrounding objects or people. For a while, spectators live in the world the motion picture unfolds before them.

Still, the escape into the world of the film is not complete. Only rarely does the audience react as if the events on the screen were real; for instance, by ducking before an onrushing locomotive in a special three-dimensional effect. Moreover, such effects are considered to be a relatively low form of the art of motion pictures. Much more often, viewers expect a film to be truer to certain unwritten conventions than to the real world. Although spectators may sometimes expect exact realism in details of dress or locale, just as often they expect the film to escape from the real world and make them exercise their imaginations, a demand made by great works of art in all forms.

The unwritten conventions

The sense of reality most films strive for results from a set of codes, or rules, that are implicitly accepted by viewers and confirmed through habitual filmgoing. The use of brownish lighting, filters, and props, for example, has come to signify the past in films about American life in the early 20th century (*The Godfather,* 1972; *Days of Heaven,* 1978). The brownish tinge that is associated with such films is a visual code (one that may have some basis in reality; brown was a leading decorative element in clothing and furniture of the time). Storytelling codes are even more conspicuous in their manipulation of actual reality to achieve an effect of reality. Audiences are prepared to skip over huge expanses of time in order to reach the dramatic moments of a story. *La battaglia di Algeri* (*The Battle of Algiers,* 1966), for example, begins in a torture chamber where a captured Algerian rebel has just given away the location of his cohorts. In a matter of seconds that location is attacked, and the drive of the search-and-destroy mission pushes the audience to believe in the fantastic speed and precision of the operation. Furthermore, the audience readily accepts shots from impossible points of view if other aspects of the film signal the shot as real. For example, the rebels in *The Battle of Algiers* are shown inside a walled-up hiding place, yet this unrealistic view seems authentic because the film's grainy photography plays on the spectator's unconscious association of poor black-and-white images with newsreels.

Fidelity in the reproduction of details is much less important than the appeal made by the story to an emotional response, an appeal based on innate characteristics of the motion-picture medium. These essential characteristics can be divided into those that pertain primarily to the motion-picture image, those that pertain to motion pictures as a unique medium for works of art, and those that derive from the experience of viewing motion pictures.

Qualities of the film image. The primary unit of expression in film is the image, or the single shot. The attribution of magical properties to images has a long history; this association is well documented among many primitive peoples, and it is even reflected in the term magic lantern as a synonym for the film projector. Any image taken out of the everyday world and projected onto a screen to some extent appears to become magically transmuted. This magical quality helps to explain the enthusiastic reception accorded such early films as *La Sortie des ouvriers de l'usine Lumière* ("Workers Leaving the Lumière Factory"), which were merely photographic records of commonplace scenes in France in the 1890s by the French film pioneers, the Lumière brothers.

Intensity, intimacy, ubiquity. The qualities of intensity, intimacy, and ubiquity have been singled out as the salient characteristics of the motion-picture image. Its intensity derives from its power to hold the complete attention of the spectator on whatever bit of reality is being shown. Outside the theatre, a person's attention is usually dispersed in the endless reality around him, except for sporadic moments of concentration on what he selects for closer scrutiny. In the cinema he is compelled to look at something that not he but the filmmaker has selected, for reasons that are not always immediately apparent. This quality of intensity becomes most noticeable when the camera remains fixed on something for a longer time than seems warranted,

Focusing the viewer's attention

and the spectator gradually becomes acutely conscious of his loss of volition over his own attention. This technique is not often used but is very effective when used well.

The intimacy of the film image is related to the camera's ability to see things in greater detail than the eye can. This ability is demonstrated in long-distance shots through a telephoto lens as well as in close-ups. At the beginning of the Japanese film *Woman in the Dunes* (1964), for example, a pervading theme of the film is indicated by shots of grains of sand many times enlarged.

The impression of ubiquity—being everywhere at once—is achieved in part by the camera's apparent freedom to move from place to place or to approach or withdraw instantaneously. No less important to this illusion of ubiquity is the effect achieved by editing, which allows countless images representing a long, elaborate action to be presented in a comparatively short film or sequence, such as that exemplified by the opening of *The Battle of Algiers*. The geographic and temporal authority of the image even permits credibility to be given to sequences representing the past, the future, and dreams.

Particularity. Other equally important characteristics of the film image may be singled out. One of these is its particularity. The language of words lends itself to generalization and abstraction. In themselves, words such as man or house do not suggest a particular man or a particular house but men and houses in general; and more abstract terms such as love or dishonesty have even less precise associations with specific things. Motion pictures, on the other hand, only show particular things—a particular man or a particular house. In this way a film image may be less ambiguous than the language of words but also less evocative, less likely to be enriched by imagination, association, or recollection. Despite its particularity, however, the motion-picture image may also be ambiguous in that it shows but does not explain. It does not in itself tell what it means, and people instinctively search for meanings in images. This is why commentary is thought to be essential in tying down precise meaning in educational films. On the other hand, many evocative documentaries, from Robert Flaherty's *Nanook of the North* (1922) to Frederick Wiseman's *High School* (1968), abjure commentary, thus forcing the spectator to take in the remarkable and untranslatable specific sights and sounds they collect. The particular insistence of given photographed objects also explains why the juxtapositions of montage are so effective—the spectator compulsively searches for the reason behind a particular sequence of images.

The mind and the eye

Neutrality. Another characteristic of the film image is its neutrality. The world people see around them is strongly influenced by their emotions and their interests. A plumber fixing pipes in a museum may not see the masterpieces around him, while an angry man may hear an insult where none was intended. The camera and the microphone, however, are thought to reproduce images and sounds without feeling. Although focus, directionality, and other technological factors limit what can be seen and heard, audiences are prepared to believe that the motion picture itself is nonhuman or even superhuman in its passive reception of information. Courts of law, for example, are more likely to accept film as evidence of an occurrence such as a bank robbery than they are to accept an artist's sketch or a journalist's report of the same incident. When a film appears to be charged with emotion, it is usually because the director has carefully manipulated the images to give this illusion. In everyday life, the eyes follow the mind; in the cinema, the mind follows the eyes.

Characteristics of the medium. Four characteristics may be stressed as factors that differentiate the motion-picture medium, either in degree or in kind, from other mediums for works of art: luminosity, movement, realism, and montage.

Luminosity. The intense brightness of the picture projected by powerful light onto a coated screen in itself transforms the most mundane element of reality. The appeal of a luminous picture is attested by efforts of advertisers to achieve luminous effects in posters and displays and in the popularity of viewing still photographs as transparencies rather than as ordinary prints. The luminosity of the motion-picture image also results in a considerable range of tone, between the brightest highlight and the deepest black. Both in black-and-white and in colour films, the most delicate gradations in the image are therefore possible.

Movement. As a feature of the motion picture, movement is so obvious that its central importance is sometimes forgotten. The motion picture has much in common with the graphic arts, but the added dimension of movement transforms it, allowing a narrative or a drama to unfold in time, in a way no other graphic art can. Both in filmmaking and in film appreciation, movement must constantly be borne in mind: composition in the motion picture is kinetic rather than static. It is not a single colour but the cumulative effect that matters, not a single situation but a developing plot. The composition within any frame, or exposure, of a motion picture is less important than the relationship of that frame to those that precede and follow it.

Realism. Another essential element of the motion-picture image is that it gives an impression of reality. Whether in a drama enacted expressly for the camera or in a documentary film of an event at which the camera just happened to be present, this feeling of realism deriving from motion-picture photography accounts for much of the force of motion pictures. Animated films, which lack this element of photographic realism, tend to be taken as fantasies.

The attempt of the motion picture to reproduce three-dimensional reality on a flat screen presents the same problems and opportunities that are encountered in still photography and in painting. The standard camera lens, in fact, is constructed to produce visual effects precisely similar to those achieved by painters using the principles of perspective that were developed during the Renaissance.

Cinematic realism is most fully heightened when the images are accompanied by synchronous sound, whereby a second sense, hearing, ratifies what the eyes see. Although reproduced sound can be manipulated with regard to distance, timbre, clarity, and duration, in combination with photographed moving images, it forcefully brings alive its subject as present in a way unavailable to the other arts of representation.

Montage. Perhaps the most essential characteristic of the motion picture is montage, from the French *monter*, "to assemble." Montage refers to the editing of the film, the cutting and piecing together of exposed film in a manner that best conveys the intent of the work. Montage is what distinguishes motion pictures from the performing arts, which exist only within a performance. The motion picture, by contrast, uses the performances as the raw material, which is built up as a novel or an essay or a painting, studiously put together piece by piece, with an allowance for trial and error, second thoughts, and, if necessary, reshooting. The order in which the segments of film are presented can have drastically different dramatic effects.

Several major contributions to the theory of montage were made by Soviet directors. After the Russian Revolution of 1917, Soviet films were encouraged for their propaganda value, but film stocks were scarce. Soviet directors carefully studied the films of D.W. Griffith and other masters to make the most effective use of their own meagre resources. One of these early Russian directors, Lev Kuleshov, conducted an experiment involving identical shots of an actor's expressionless face. He inserted it in a film before a shot of a bowl of soup, again before a shot of a child playing, and still again before one of a dead old woman. An unsuspecting audience, which was asked to evaluate the actor's performance, praised his ability to express, respectively, hunger, tenderness, and grief.

Kuleshov's experiment

Sergey Eisenstein, who excelled both as a director and as a teacher, based much of his theory of film on montage, which he compared to the compounding of characters in Japanese writing. The character for "dog" added to the character for "mouth," he noted, results not merely in "dog's mouth" but in the new concept of "bark"; similarly, film montage results in more than the sum of its parts. Still another great Russian director, Vsevolod I. Pu-

dovkin, also stressed the importance of the carry-over in the spectator's mind. Only if an object is presented as part of a synthesis, he said, is it endowed with filmic life.

Three types of montage may be distinguished—narrative, graphic, and ideational. In narrative montage the multifarious images and scenes involve a single subject followed from point to point. In a fiction film, a character or location is explored from multiple angles while the audience builds a comprehensive image of the situation being explored or explained. Graphic montage occurs when shots are juxtaposed not on the basis of their subject matter but because of their physical appearance. Some avant-garde works depend on the spectator's ability to match the graphic relations of assorted images, such as the people, objects, and the shapes of numerical and alphabetical figures in Fernand Léger's *Le Ballet mécanique* (1924) or the torpedoes, swimming seals, and blimps in Bruce Conner's *A Movie* (1958). In graphic montage cutting usually occurs during shots of movement rather than ones of static action. This cutting on motion facilitates the smooth replacement of one image by the next. In ideational montage, two separate images are related to a third thing, an idea that they help to produce and by which they are governed. In *Strike* (1924), for example, the director Eisenstein, to whom the theory of ideational montage is credited, effectively conveys the idea of slaughter by intercutting a shot of cattle being butchered with shots of workers being cut down by cavalry.

These three types of montage seldom appear in their pure form. Most ideational montage proceeds on the basis of the graphic similarity of its components, as does narrative montage when relying on graphic cutting to cover its movement. Similarly, the graphic matches between torpedoes, seals, and blimps in *A Movie* ultimately construct an idea of movement toward explosion and destruction. Besides the complications brought about by the intermixing of these types, the addition of the sound track multiplies the possibilities and effects of montage. Eisenstein and Pudovkin referred to such possibilities as "vertical" montage, opposing it to the "horizontal" unrolling of shot after shot. Because sound permits the establishment of relations between what is seen and heard at each moment, the film image can no longer be said to be a self-contained unit; it interacts with the sound that accompanies it. Sound relations (including dialogue, music, and ambient noise or effects) may be built in constant rapport with the image track or may create a parallel organization and design that subtends what is seen. In all, montage appears to be the most extraordinary factor differentiating the motion picture from the other arts, and it is the one often singled out as the basis of the medium. Nevertheless, many films, including those of Mizoguchi Kenji of Japan, Roberto Rossellini of Italy, and Miklós Jancsó of Hungary, rely not on montage but on the medium's unique qualities of luminosity, movement, and realism to convey their power and beauty.

The motion-picture experience. Other distinguishing characteristics of the motion picture are more closely related to the conditions under which they are normally seen.

The Kinetoscope, a peep-show motion picture that could be seen by only one person at a time, became obsolete soon after it was introduced by Thomas A. Edison in 1894, because it could not compete with projected films, which could accommodate audiences. Since that time, an atmosphere of group entertainment has been associated with films. Even for films being seen on broadcast or cable television, this aspect of community viewing remains significant; although the audience before any particular set may be as small as a single individual, each spectator brings to it past associations of films seen in the theatre and the realization that millions of other people are watching the same broadcast.

Collective versus private film viewing

Since 1980, however, this tradition has been reversed and the peep show has returned in the guise of the videocassette. The proliferation of videocassette recorders (VCRs) and portable television sets demonstrates that films serve multiple functions in culture. The function usually deemed primary might be termed "concentrated entertainment." The private viewing conditions provided by the VCR can enhance this function and may be preferred by some viewers in the same way that a stereo recording of a Beethoven symphony is preferred by some to the concert hall experience. The less socially acceptable function of pornography, which has been represented in motion pictures since their inception, is also well served by the anonymity and privacy characteristic of VCR viewing. Other, more public, functions of motion pictures contribute to sociability. Although the movie theatre remains a key site for such activity, television serves a significant population that prefers to stay at home either because of convenience or because the more casual viewing conditions permit them to participate in additional activities. This latter quality is also found in older phenomena, such as the drive-in theatre, where families or small groups maintained their own cohesiveness while viewing a motion picture. Such epiphenomena as talking and eating, which were encouraged by the drive-in venue, are replicated in living rooms where movies are watched on cassettes. In sum, the motion picture raises questions of the privacy and sociability of artistic representations more insistently

The concluding montage from *Strike!* (1924), directed by Sergey Eisenstein. (Top and bottom) Shots of the massacre of the strikers and their families are intercut with (centre) images of cattle being slaughtered.

than any other medium, but few generalizations about its "pure" state stand up. Different eras and different cultures use motion pictures in different ways. Its connection to both personal and collective vision is always relevant and is always affected by the site of its exhibition.

Although the motion-picture experience is most often a group experience, it is exceptional for its impersonal nature. In this respect the cinema is quite different from live theatre, for example, in which the audience feels the presence of the actors and the equally compelling presence of the audience. Whether at home in front of a television set or in a movie theatre, the film viewer feels less inhibited. People come and go as they please, generally unnoticed, in an easy, relaxing atmosphere. Especially in the heyday of the large movie palaces there was little feeling of association with the other members of the cinema audience, whereas at a ballet, opera, or play, members of the audience sense a collective ritual that is reinforced by intermissions during which they mingle with one another. The impersonality of the motion-picture experience enhances its private function, although the informality of the cinema has probably contributed to the tendency to regard it less seriously than other performing arts.

Another basic feature of motion pictures is their accessibility to an audience of vast size. A drama presented in a theatre can be attended by no more than a few hundred persons at a time. In a film, however, the same drama and the same performers may be seen throughout the world by millions of people almost simultaneously. Accessibility has been a determining characteristic of films. From the start, they were a sidewalk attraction, and with the advent of television in addition to cinemas, motion pictures are available almost anywhere at almost any time.

Effect of the mass audience

This mass audience allowed the motion-picture industry to develop vast production and distribution organizations, but it also limited the artistic development of films, since it was commercially safer to present the simplest and least demanding entertainment that would appeal to the widest audience. After television took over much of this mass audience in the 1950s, many motion pictures were taken more seriously by a more discriminating audience. Since the days of the *film d'art* movement in France (*c.* 1910), many films have claimed the status of art, but the "art films" that are shown in specialized art theatres are a product of this competition with television. After 1980 cable distribution as well as the videocassette market decentralized distribution, providing potential outlets targeting limited audiences. Despite these developments, the motion picture, and critical or artistic attitudes toward it, has been greatly shaped by its seemingly universal appeal.

EXPRESSIVE ELEMENTS OF MOTION PICTURES

Many observers have seen in films a means of expression comparable to a language. The French poet and filmmaker Jean Cocteau (1889–1963), for example, called the cinema "picture writing." The language of motion pictures, however, is not the language of words, even though spoken dialogue has been an integral part of motion pictures since the late 1920s and written captions were usually required to explain the action before that. It is primarily in the qualities of its images and sounds that the expressivity of the cinema must be sought. Certain basic traits of motion pictures may operate with the logic of natural language, but few theorists have held that cinematic expression follows rules like those of natural language. As Christian Metz, one of the foremost modern theorists, argued, it is not linguistics so much as poetics that should serve as a model for those interested in understanding or explaining how a film works; making and watching a film is far closer to writing or appreciating a novel or symphony than a sentence or discourse.

Various codes of expression have, nevertheless, been shown to operate naturally or to have been inculcated, and their effects can be calculated. Such codes and effects occur in all aspects of the medium and can most readily be categorized into those affecting cinematography, editing, sound, the script, acting, and design.

Cinematographic expression. The filmmaker has a number of ways of modifying the camera's neutrality and thereby the "reality" that is conveyed to the audience. It is largely by means of these devices that the motion picture becomes such an expressive medium. Several of these expressive techniques should be emphasized. First, there is framing; that is, carefully selecting what will be included within each frame of the film and what will be excluded. Second, there is scale, the size and placement of a particular object or a part of a scene in relation to the rest, a relationship that is determined by the placement of the camera. Third is camera movement, or the lack of it, during shooting. Fourth, there are the peculiar advantages of either colour or black-and-white photography that can be exploited. Finally, through the cinematographer's skill and knowledge of laboratory processes, other highly expressive techniques can be achieved. Each of these means of expression will be discussed below.

Framing. The process of framing is intended to eliminate what is unessential in the motion picture, to direct the spectator's attention to what is important, and to give it special meaning and force. Each frame of film, which corresponds in shape to the image projected on the screen, forms the basis for a graphic composition in the same way as the frame of a painting encloses the area in which the painting must be organized. Several different ratios of frame width to frame height (called "aspect ratios") have been used in motion pictures. The most common, known as the Academy ratio, is 1.33 to 1, or 4 to 3, a ratio corresponding to the dimensions of the frame of 35-millimetre film. By using 70-millimetre film or a special CinemaScope lens, an image with wider horizontal and shorter vertical dimensions is achieved—a proportion of about 5 to 2, or between 2.2 to 1 and 2.65 to 1. A similar effect, called wide screen, was sometimes achieved without the expensive equipment required for CinemaScope by using 35-millimetre film and masking the top or bottom, or both, giving a ratio of 1.75 to 1, or 7 to 4. Although some theatres in the 1970s were enlarged and widened to accommodate 70-millimetre images, a trend toward smaller theatres fixed the image ratio close to 1.85 to 1 in the United States and 1.66 to 1 in Europe.

The aspect ratio

The moderate elongation provided by the Academy ratio has proved most versatile for achieving standard compositional effects. For example, an expansive feeling is easily rendered when small-scale figures in the foreground are shot against a towering sky, as in *Days of Heaven.* In the wide CinemaScope dimension, the tension established between the outward movement of the composition and the rectangle of the screen can readily be lost; nevertheless, early fears about wide screen's insensitivity to intimate love scenes proved to be unfounded, at least in the hands of careful cinematographers. A number of foreign directors, notably Kurosawa Akira (Japan), François Truffaut (France), and Miklós Jancsó (Hungary) achieved stunning effects in CinemaScope by overcoming the fear of moving the camera, as seen in, respectively, the battle scenes of *Seven Samurai* (1954), the bicycle ride in *Jules et Jim* (1961), and the nonstop camera dance of *Red Psalm* (1972). Wide screen calls for an altered aesthetic, because the spectator's eye is invited to roam the visual field, making connections that in the standard ratio are more tightly determined.

Regardless of its ratio, the frame may be divided to show two or more scenes at the same time. This technique is generally reserved for credit sequences, musical interludes, or moments when the presentation on a single screen of two or more simultaneous occurrences results in comic interrelationships.

An effective use of framing consists of temporarily or permanently excluding a vital part of the action. Offscreen space may be said to function more actively in cinema than in painting or the theatre. For example, the camera may remain fixed on the hero while the villain is perceived only by a voice saying "Hands up!"; or in a science-fiction film, the camera may linger on the horror expressed by the victim before revealing the monster that is causing it.

Use of offscreen space

Finally, very strong dramatic effects may be obtained by oblique framing; that is, by turning the camera sideways so that the image on the screen appears askew. This was done in the early Russian film *The Ghost That Never*

Returns (1929), in which a prison riot shown by oblique framing gives the impression that the building is being pushed over. Some directors, such as Britain's Carol Reed, have made this a trademark (*The Third Man,* 1949).

Scale. Since scale in the cinema constantly changes from shot to shot, the spectator can easily be deceived about the size of objects. When appearing next to enormous tables and chairs, for instance, the actors can be made to look like midgets or children, as in the Stan Laurel and Oliver Hardy comedy *Brats* (1930). By contrast, in *King Kong* (1933) a small-scale model of New York City was used to give the illusion of the actual city under attack by a giant gorilla. Scale may have a marked effect on the emotional tone of a scene. In the distance an actor may seem lonely, remote, helpless, pathetic; close up, he may appear powerful, threatening, bestial. The scale of shots for artistic purposes ranges from an extreme long shot (the widest view on the smallest scale), with houses or ships appearing as tiny dots on the horizon, through medium shots, two shots (*i.e.,* a shot of convenient size to include two actors) and others, to the close-up, with part of a face, an eye, or a fist filling the screen (the most restricted view on the largest scale). Telescopic or microscopic shots beyond these extremes are usually of scientific rather than of artistic interest.

Scale of shots

Different scales are occasionally juxtaposed in a single shot to produce an unmistakable dramatic or rhetorical effect. In Orson Welles's *Citizen Kane* (1941) significant characters are repeatedly framed in the right or left foreground while in the background an action takes place which disturbs that character or which that character somehow controls. The gigantic political poster of Kane that rises behind the podium on which he, in the foreground, makes a speech promising to ruin his rival, Gettys, becomes suddenly the size of a postage stamp when the shot changes to one in which Gettys is in the foreground looking down from a balcony on the insignificant speaker. Through this use of different scales, Gettys is shown to have power over the action.

Orson Welles in *Citizen Kane* (1941).

As has been noted, the camera exaggerates perspective, and this exaggeration adds to the dramatic effect. It is most striking in an ordinary still photograph of an enormous hand or a sunbather's giant feet that were close to the camera lens. In cinematography, the director ordinarily minimizes the effect of this distortion, but occasionally he uses it in an extreme form. In *Easy Rider* (1969), for instance, it was used to give an atmosphere of hallucination and nightmare to a drug-taking session, and in *Brazil* (1985) it was used continuously to promote an atmosphere of paranoia and nightmare.

Finally, scale is affected by what precedes and follows. The close-up has its most dramatic impact coming after long or medium shots, and after many close-ups, it is a relief to escape to the middle or far distance.

Shooting angle and point of view. Another element in motion-picture language is shooting angle. In common language, the phrases "to look up to" and "to look down on" have connotations of admiration and condescension in addition to their obvious reference to physical viewpoint. In one sense or another, children, dogs, and beggars are often looked down upon, while the preacher in his pulpit, the judge on the bench, and the policeman on his horse are looked up to. Even a slight upward or downward angle of a camera is enough to express a mood of inferiority or superiority.

Upward or downward shooting angles lead to questions of objectivity and subjectivity. In most motion pictures, both for variety and for breadth of treatment, the camera's viewpoint switches from one character to another and sometimes is associated with none of the characters but merely looks on. The camera may take the viewpoint of the heroine, looking with dismay at the villain as he breaks into her room; in this case, an upward camera angle gives a subjective impression of her fear. Similar subjectivity may be seen in a shot of buildings reeling in the way they might appear to a drunken man, as in the German classic *The Last Laugh* (1924), or in a rapid camera movement from a window to the pavement below to express a thought of suicide, as in the Italian Neorealist film *Umberto D.* (1952). Occasionally, an entire motion picture may be shot from one person's point of view, often with a personal narration accompanying the images. Very rarely does this point of view literally take over the optical view of the character for an extended period. (One noted exception is the 1946 film directed by the actor Robert Montgomery, *Lady in the Lake,* in which the camera actually plays the main character. The entire film is seen from the camera/character's point of view so that the audience sees only what the camera/character sees. The movie is an interesting experiment in the use of subjective camera, but it is considered an artistic failure.) More often voice-over, music, or other elements are combined with shooting angle to render a particular character's feelings throughout a film. Alfred Hitchcock is generally considered the master of point of view, controlling (and even misguiding) viewer sympathy.

The camera's viewpoint

Extreme upward or downward angles are too far removed from ordinary experience to have many applications in motion pictures, but they may express exceptional situations—a sick man on his back, a baby's or a dog's point of view, a man in a pit or in a coffin, a spy covertly looking down on an enemy meeting. As with scale, the shots that precede and follow alter the effect of the shooting angle. Upward angles are stronger following a level or downward-looking camera, and vice versa.

Camera movement. Framing, scale, and shooting angle are all greatly modified by the use of camera movement. Filmmakers began experimenting with camera movement almost immediately after the motion-picture camera was developed. In 1897 photographers employed by Auguste and Louis Lumière floated a *cinématographe,* the combination camera/projector devised by the French brothers, in a gondola through Venice to give viewers all over the world a dynamic view of that much-painted city.

One of the simplest and most common movements is to turn, or pan (from the word panorama), the camera horizontally so that it sweeps around the scene. It can also be tilted up or down in a vertical panning shot, or in a diagonal pan, as when it follows an actor up a stairway. Panning was possible quite early in film history, but methods of physically conveying the camera itself through a scene developed more slowly. Initially, the camera was mounted on a dolly, truck, or other hand-propelled wheeled vehicle to facilitate smooth movement. Later, tracks were laid for the dolly or truck to ride on, providing even smoother, more effortless motion. Trucking, dollying, and tracking can even be combined with panning in a complex movement that may require the adjustment of focus or aperture en route. One such camera movement that is often used imitates the gaze of a traveler who turns in a moving automobile or train to focus on a stationary point of interest.

Panning and tracking

Often commercial vehicles, such as trolleys, automobiles, or airplanes, are used to transport the camera; the relatively jerky ride they supply simulates real movement more accurately than does the steady motion provided

by a specially designed apparatus. Nevertheless, the film industry has long sought equipment that would allow the camera (and the viewer) to weave in and out of action in the most ethereal way. The crane, which facilitates aerial movement, was developed in the late 1920s, replacing the jerry-built movable platforms, the slings, and the sleds that ingenious directors, such as Abel Gance (for *Napoléon,* 1927) and Marcel L'Herbier (for *L'Argent,* 1929), both in France, had devised to achieve vertical or elevated swinging movements. A host of such special camera supports now exists, many of which were originally developed for use on medical and scientific films. The most advanced equipment can be operated from a distance with electronic viewfinders, allowing the camera to follow vigorous, continuous action with unprecedented ease and intimacy, as in the pre-credit sequence of *Raiders of the Lost Ark* (1981). The look and style of film art is constantly changing as technological advances increase the mobility of the camera and consequently the flexibility of the spectator's viewpoint.

Regardless of the state of technical capability, the effect of camera movement depends on the context and on the pace of movement. At a deliberate pace the camera can explore a scene and reveal significant details. If it is raised well above the ground, the movement has a dreamlike power, and, when combined with slow motion, it may give a somnolent impression or express recollection or hallucination. The camera movement may end dramatically on a dagger, on a gun half-hidden in an assailant's hand, or on a suspicious bulge in a pocket. It may link the hero walking in the garden and the heroine watching him with loving eyes from a window. It may bring a dramatic surprise, as in the American western *Stagecoach* (1939), when director John Ford had the camera, mounted high above a rocky defile, move slowly from the stagecoach below to reveal a band of Indians waiting in ambush. On the other hand, the camera may simply turn away from a scene to leave the remainder to the spectator's imagination, as when it withdraws from a torture scene or from a love scene. In filming a conversation, the director may turn the camera from one speaker to the other, thus animating the scene with movement and showing the expression of the speaker, or listener, more closely than would be possible with a static two shot. Camera movement can even be used to change the scene to a distant place, to a different period of time, or to an imaginary world.

Very rapid camera movements may express a sudden surge of emotion or a contemplated action, as in the suicide example from *Umberto D.* In *The Rains Came* (1939), as the heroine realizes with horror that she has drunk from a glass that may be contaminated with typhus, the camera rushes forward to a close-up on the fatal glass, shining in the darkness. These movements are often effected without physically moving the camera, by means of a zoom lens, a lens of variable focal length that

Zooming

simulates the effect of moving toward or away from a subject by increasing or decreasing the size of the subject as the focal length changes. Although a zoom shot is generally smoother than a tracking shot, it always results in pictorial distortion. To zoom in from a distance to a close-up, the focal length of the lens is changed from, for example, 18 millimetres to 125 millimetres. The former length curves the picture anamorphically on the sides, giving great depth to the background, while the latter tends to flatten the background. All objects within view are enlarged at the same rate. Tracking in from a distance to a close-up requires careful adjustment of focus, but depth and dimension appear more realistic.

Camera movement is one of the key indicators of the presence of a narrator. When the camera moves independently of the action, the narrator can be thought of as hovering above the action, poetically reacting to it or commenting on it. When the camera moves instead to keep the action in view, to follow as many elements as possible, the narrator can be thought of as a reporter investigating but not commenting on what is seen. The documentary tradition, particularly since 1959 when lightweight cameras and tape recorders first permitted extended hand-held filming, represents this investigative function of cinema and of camera movement.

Montage versus mise-en-scène

Directorial styles may be cataloged on the basis of an overall predilection for linking elements in a scene via cuts (montage) or camera movement. Eisenstein has already been cited as a master of montage. One of the directors most acclaimed for the expressive use of camera movement is Japan's Mizoguchi Kenji. Although Mizoguchi was not beyond making strongly rhetorical points by juxtaposing shots, the overall impression his films convey derives from the use of a seemingly floating camera to join not only elements within a scene but also the scenes themselves. In *Ugetsu* (1953) the hero, seduced in a hot spring by a beautiful ghost woman, moves screen right to join her, while the camera pans left across the pool and then tracks along the ground. The shot dissolves imperceptibly into one in which the camera pans up to reframe the couple picnicking in an extreme long shot. The magical mixture of spaces and the conflation of time sensuously express the erotic imagination that both the hero and the audience have fallen prey to. Mizoguchi is known as a mise-en-scène director, one who is primarily concerned with the relationships within a shot rather than those between shots. He employs long takes, camera movement, and the expressive use of elements within the film frame to convey mood and emotion. The possibility of movement was so important to Mizoguchi that at the end of his career he invariably directed from a crane, even during static scenes.

Colour and black and white. A practical, accurate commercial system of colour cinematography was not perfected until Technicolor was introduced in Walt Disney's animated short *Flowers and Trees* (1932) and in the feature film *Becky Sharp* (1935). The introduction of colour was less revolutionary than the introduction of sound; the silent film soon disappeared, but even though most feature films made since the 1960s have been in colour, the black-and-white film has continued to be made. In fact, directors such as Woody Allen (*Manhattan,* 1980) and Martin Scorsese (*Raging Bull,* 1979) have chosen to film in black and white to give their movies a calculated tone.

Use of black and white for realism

A black-and-white motion picture is not merely a picture that lacks colour but rather is an artistic creation with positive qualities of its own. An ample range of effects can be obtained—from precise images in which every hair, every grain can be clearly seen, to a smudged charcoal effect. Oddly, black and white often gives a stronger impression of realism than colour does, perhaps because of associations with newsreels and newspaper photographs. Black and white may suggest the hard news of the daily paper, while colour may connote the fantasies of glossy fashion magazines, advertisements, and comic strips. In the cinema, black-and-white composition is often stronger and more dramatic than colour.

Nevertheless, colour introduced a new world into the cinema and steadily grew more effective. It can be used to produce a powerful dramatic impression. The German

director Rainer Werner Fassbinder, for example, used garish colours in films such as *Despair* (1977) to lend a seductive but finally suffocating tone to his melodramas. The Italian director Michelangelo Antonioni claimed to have studied colour for years before venturing to make his first colour film, *The Red Desert* (1964). In that film he used disturbing yellows, pinks, grays, and greens, even going so far as to paint dump heaps and fruit gray for one scene, to express a neurotic woman's sensibility and the oppressiveness of her industrial environment. He changed film stock for a sequence in which the woman tells her child a story about a girl on the beach. The bright postcard colours seen in that sequence contrast dramatically with the sickly grays and greens of the rest of the film. Colour can be employed even more symbolically than this—in Eisenstein's *Ivan the Terrible, Part II* (1946), red turning to a bluish shade represents the fear of a pretender about to be assassinated.

Role of the cinematographer. Cinematographers remain virtually unknown outside the motion-picture industry even though their contribution sometimes matches that of the director in importance. Although the director has ultimate control over the visual image, the cinematographer actually records that image on film, translating the director's ideas and creating the atmosphere and the look of the film. The association between the cinematographers and the processing laboratory is also of highest importance because the cinematographer often spends hours there after shooting, checking the negative. On most feature films a camera team (often consisting of a director of photography, cameraman, and assistant cameraman) shares the responsibilities.

Cinematographers are responsible for exact framing, sometimes for screens of more than one type. They also must decide upon the use of masking, the choice of lens, the camera angle, and the control of camera movement. They must either keep the focus sharp or put all or part of the picture out of focus if this effect is required. Cinematographers also control slow motion or accelerated motion; with early hand-cranked cameras, the camera operator simply slowed down or cranked faster, but later special controls and cameras were developed. Trick photography was once effected by simple manipulation of the camera: magical transformations were made simply by stopping it and changing the scene; and the impression of backward motion was achieved by turning the camera upside down and reversing the film. More elaborate processes now at the cinematographer's command involve laboratory technicians as much as the camera crew. Many effects require the actors to perform against a background of previously prepared film. The cinematographer must be in command of all these processes. The best cinematographers give a motion picture a visual style that is peculiarly their own.

Editing. The process of trimming and piecing together lengths of film in order to make an artistically concise and complete motion picture is certainly the most obvious technique of film language and the one most often discussed. The terms editing, cutting, and montage are often applied interchangeably to the process. In montage the emphasis is on the juxtaposition of ideas resulting from this process, cutting stresses the physical work with the actual strips of film, and editing encompasses both.

Editing, cutting, and montage

A single shot (*i.e.*, the length of film exposed at one time, without interruption, by one camera), makes a visual and aural record of some segment of the physical world; by effective editing, this record can be taken apart, restructured, and shaped into an imaginative world or a discourse about the world. While all viewers presumably notice that a film is made up of a number of scenes, few realize that fiction films contain on the average approximately 600 cuts, one every 10 seconds. Editors strive to hide their work by cutting on action, so that the movement of a character's arm in one location flows into another such movement elsewhere, masking the change of shot. More important is the principle by which an editor anticipates the spectator's line of inquiry. By releasing information just as the spectator needs it, the editor constructs a natural drama whose seams are invisible.

Invisible editing

Probably the most common convention of this sort is the "accordion" sequence wherein, for example, a drawing room conversation between two people is introduced in an establishing shot of the setting and the actors. The editor will cut to a full shot of the actors once they begin their dialogue, because their speech gives them prominence over the setting. To help viewers understand the nuances of the dialogue, the editor will move in for a medium shot, showing both characters from the waist up. While many directors and editors stop here, Hollywood has traditionally gone in even closer, using alternating close-ups of each character (generally from over-the-shoulder shots) to convey innuendos and reactions. In the earlier days of cinema, an editor was likely to back out of the sequence in the reverse order, going from close-up to medium shot, to full shot, and finally to long shot, thus making the structure of the sequence resemble the in-and-out movement of an accordion. Most contemporary, faster-paced films skip some of these "logical" steps, but they nevertheless usually include other strategies that let the viewer glide into and out of the action unconsciously.

Unforgettable moments in films are often made possible through shocking juxtapositions. When an initially smooth progression is disrupted by a quick cut to a close-up, as in the *Halloween* cycle of horror films, the effect can be startling and frightening. In such cases the editor insists upon a strange or important connection in a scene.

Beyond rendering scenes in unobtrusive or striking ways, editing connects scenes into sequences and larger units. It serves as a system of punctuation. In the standard Hollywood film a straight cut between two scenes suggests that the scenes are close in space or time, whereas other more visible forms of transition signal more distant relations. The picture may fade out and fade in, the screen being left dark for a moment. Or it may dissolve, or mix, to a new scene, one image showing on top of the other for a moment. The filmmakers may use other devices, such as a wipe (*i.e.*, a line moving across the screen that wipes out the preceding image while introducing the next), irising (gradually reducing the old image from the edges to a pinpoint size and then expanding the new one in the reverse way), or a turnover (in which the entire screen seems to turn over, with the new image seeming to appear on what was the reverse side).

The director may introduce creative touches in cutting. The German-born director Max Ophüls, for example, connected the separate episodes of *La Ronde* (1950) by means of the musical leitmotiv of a hurdy-gurdy tune. In *Vivre sa vie* (1962), Jean-Luc Godard, one of the outstanding French New Wave directors of the late 1950s, introduced chapter headings marking the heroine's step-by-step involvement in prostitution and, ultimately, her murder, as if it were a didactic 19th-century novel. Alfred Hitchcock, probably the greatest director of suspense films, in his British film *The Thirty-nine Steps* (1935) cut from a woman's scream to the similar sound of a train whistle, an effect so dramatic that it was frequently imitated thereafter.

Editing permits highly dramatic effects that could never be staged in a single shot. In the American western film *Butch Cassidy and the Sundance Kid* (1969), for example, the title characters are seen cornered by lawmen on a high cliff overlooking a river, into which they make an almost suicidal leap to their escape. Actually, the scenes involving the two leading actors on the cliff and those of the dives were shot weeks apart, and they involved different crews and even different rivers, yet the audience readily accepts the illusion created by the editing. *The Stunt Man* (1978) takes such editing as its very theme. The main character is engaged in the rigged dangers and tricks involved in making a movie, while the audience is fooled by the greater tricks of the film that it is watching. Editing opens up a bagful of ingenious tricks of substitution, tricks that allow a marvelous or tragic experience to appear as a natural occurrence in the filmed world.

Illusions created by editing

The common illusionistic experience of motion pictures depends on editing for its force and excitement, but editing can play an even more important role in films that bypass or refuse the illusion of realism. The use of graphic and ideational montage demonstrates that some filmmakers

purposely flaunt the fabrication involved in motion pictures. Many films incorporate extraneous material within their fictions in order to set the illusion of the story they tell against the hard reality of other types of images. In Warren Beatty's *Reds* (1981), for example, interviews with "witnesses" to the events portrayed in the film open, and occasionally interrupt, the story in order to validate the fiction being re-created as history. Editing permits the juxtaposition of very different kinds of material for a variety of rhetorical effects.

The editor's function. Like camera-work, editing is a function that is ordinarily hidden from the audience, but it is vital to the finished picture. It is the editor's job to judge the length of each shot, choosing the exact moment to cut. The length of a shot may depend upon the amount of detail it contains, its scale, its dramatic impact, or its context in relation to the shots that precede and follow it. Though the audience is unconscious of these judgments, the impact of the finished film depends on how well they are made.

The director generally views the day's rushes (*i.e.,* advance prints of the film shot that day) and, in consultation, selects what is to be used. Some directors spend a good deal of time in the cutting room; others spend none at all. Often, the editor is influential in rearranging shots, discarding them, or even ordering reshooting or additional shooting. An important factor in the work of the editor is the cutting ratio—the proportion of film shot to that used in the final film. Some directors shoot as little as three times as much as is required, while others may shoot 10 times as much or even more. In its widest sense, editing includes mixing the sounds and correlating them with the visual film.

Cutting ratio

Cinema time. The motion picture has been defined as a series of images of space that are arranged in time. The time of film language is quite different from that of reality and that conveyed by the other arts, such as drama and literature. Movement on the screen is produced by showing the spectator 24 frames, or still photographs, with dark intervals between them, every second. The movement seems to be at the same rate as that of ordinary life only if the pictures are taken and shown at the same speed. Slow motion may be achieved either by speeding up the camera or slowing down the projector, and accelerated motion is obtained in the opposite way. In common practice, the speed of the projector is constant, and the speed of the camera is varied to achieve these effects. Like extremes of scale, extremes of speed—such as in accelerated-motion films of plant growth or slow-motion films of bullets, explosions, or materials being broken—are of less interest to the art of motion pictures than to science. Moderate slow motion has been used, however, to give a mythic or legendary quality to scenes of destruction and violence, as in Arthur Penn's *Bonnie and Clyde* (1967) and the films of Sam Peckinpah. It can also be used to express dreams or ecstasy, while accelerated motion is often very effective in comedy. The cinema can give the illusion of reversing time by showing events happening backward, or of holding time still by showing the same image again and again.

Time conventions. Despite the possibilities for manipulating it, the time presented in a single shot of film is ordinarily the time of the real world. From shot to shot, however, the time is presented according to certain conventions. In most motion pictures, the story may be assumed to be presented in chronological order and in real time except when certain conventions are invoked, such as ellipsis, repetition for emphasis, flashbacks, or dream sequences.

The narrative may be advanced with immense speed and economy simply by the omission, or ellipsis, of what is not essential. A straight cut may be used between a shot of a girl dressing for a ball and a shot of her at the ball itself. To show a lapse of years, however, it may be necessary to fade one shot slowly from the screen and fade the next in, or to use a dissolve, or mix, which shows both shots superimposed as one supersedes the other.

To emphasize important scenes of short duration, repetition is an effective device. Such a scene may be shown from different angles, from a distance and then close up, and it may occupy much more time on the screen than would the actual event. By emphasizing what is important and eliminating the rest, a motion picture can give the illusion of covering a lifetime in only 90 minutes.

A flashback is an interruption of the actual chronology of a story to relate a significant event of an earlier time. The flash forward, a much less used device, interjects future events in the same way. These devices require special optical effects, such as fades, dissolves, or irising, to stress the break in continuity. The break can also be stressed by the use of a melody associated with the past, or by an unusual camera movement, as well as by the more obvious devices of using noticeably different period styles in the settings or having the actors made up to look much older or younger.

Flashback and flash forward

A thought or dream sequence requires similar emphasis on the departure from chronology of real time. Nearly all of *La Rivière de l'Hibou* (1962), a prize-winning French short film adapted from Ambrose Bierce's 1891 short story, *An Occurrence at Owl Creek Bridge,* consists of the fleeting last thoughts of a man about to be hanged. By not indicating a break between the actual events of the hanging and the fantasy of the condemned man, the film deceives the audience, until the very end, into thinking he is making an escape.

Tempo. The tempo or pace that an audience senses in a film may be influenced in three ways: by the actual speed and rhythm of movement and cuts within the film, by the accompanying music, and by the content of the story. For most people, time seems to pass quickly during moments of happiness, excitement, or exhilaration, and slowly during sadness or boredom. In films, it is possible to reverse this apparent cause-and-effect relationship and to induce a feeling of happiness, excitement, or exhilaration by making the picture seem to move quickly. Means of accomplishing this include lively music, quick cutting, or fast action. Conversely, a sense of sadness or boredom can be induced by solemn music or immobility of the images.

A feeling of suspense is unusual in combining excitement with a sense that time is passing slowly. Much of the suspense depends upon the audience's awareness of a danger unknown to the characters in the film. Conversely, the sense of serenity and wisdom achieved by directors such as India's Satyajit Ray or Japan's Ozu Yasujirō emanates from the deliberateness with which they pace even the most dramatic of actions.

Tempo is not necessarily related to the actual length of a motion picture. A poorly made short film may seem long, for example, while *Intolerance* (1916), D.W. Griffith's 3½-hour masterpiece, can command the full attention of connoisseurs.

Sound. Mechanical reproduction of sound was developed as early as the first motion pictures, but the problems of amplifying sound sufficiently for an audience and synchronizing it with the film image were not solved until the late 1920s. Although sound attracted crowds to the cinema to hear the new miracle, the artistic levels of the best silent pictures were not reached immediately. The new "talkies" were mostly poor imitations of theatrical plays, with dialogue and sound used indiscriminately. Sound equipment was cumbersome and imperfect. The mobile camera of the silent film lost its freedom, and the editing of film tied to a sound track became stodgy and slow.

Sound also resulted in great advantages, however. The cumbersome captions of the silent film could be dropped; certain strained methods of showing sound in pictures, such as shots of factory whistles, guns firing, or rows of clapping hands, became unnecessary. Music could be composed for a film and enjoyed in the humblest as well as the grandest cinema. Just as the visual image in the frame of a motion picture was elevated from the profusion of nature and could be seen fresh, so could sound be isolated for artistic purposes—the screech of automobile tires, the ticking of a watch, the baying of hounds, the whinny of a horse. The dramatic effect of sound could be tremendous. The rushing, crackling sound of a great fire in the last scene of Robert Bresson's *Trial of Joan of Arc* (1962) is as terrifying as any visual effect could be. In Hitchcock's *Torn Curtain* (1966) there is a desperate struggle in the

Dramatic effect of sound

kitchen of a lonely farmhouse; as the doomed man's head is held in an oven, and his hands (the only thing in the picture) convulsively twitch, the sound of hissing gas dominates the scene. The introduction of sound also made it possible to use silence with a dramatic effect that is more telling than either words or music.

Like images, sounds can be used to represent subjective thoughts, indicating not what the character is saying but what is in his mind. For example, in Hitchcock's *Blackmail* (1929), the first English sound film, the words "knife, knife, knife" are repeated in the thoughts of a frightened girl who thinks that she has committed a murder.

In terms of montage, sound, dialogue, and music are used in combination not only with one another but also with the visual image. They can overlap and vary in intensity in a flexible and complex pattern. The finished sound track may involve mixing together tracks of dialogue, background noises, and music recorded at different times; the tracks must be matched to one another and to the visual film. Though the audience may hear it simply as an accompaniment to what they see, the sound may be the most expensive and difficult part of a motion picture.

Music. The live music that accompanied silent films varied from a full orchestra to a honky-tonk piano, according to the size of the cinema. Music was effectively used on the film set to improve an actor's performance. With sound, music became an integral part of the picture on the screen. Early mood music was so expressive that often it now seems overblown. Conscientious filmmakers soon learned the virtue of restraint, using music less frequently but with more effect. Since the 1960s, electronic music, as in *Close Encounters of the Third Kind* (1977), has come to be commonly used.

Music often has an important function in emotional climaxes of motion pictures. It can be used effectively to relieve or sublimate intolerable intensity—of grief, pain, or ecstasy. *The Gospel According to St. Matthew* (1964) by the Italian director Pier Paolo Pasolini reveals how expressive periods of silence can be, and how great music can ennoble scenes like those of Christ's persecution and agony on the cross. Music may also be used symbolically. In *Léon Morin, prêtre* (*Leon Morin, Priest,* 1961), for example, a sequence of harsh chords represents the German occupation forces, and a dancing bugle motif represents the Italian troops. Organ music is used in scenes showing the heroine with the priest in church, and piano music when they are in his flat. Hurdy-gurdy music represents two gossiping spinsters, and in a climactic scene louder and louder electronic music represents the heroine's obsessive sexual feeling for the priest, until she reaches out to take his hand.

Sound engineering. It is the function of the sound engineer to select and modify sound as the cameraman selects visual images. Since the noise of crockery, cutlery, or paper or the chirping of crickets would be intolerable transferred in full volume to the screen, the sound engineer must tone them down. Treble and bass must be balanced. In other cases, in order to get the effect needed, sound has to be built up and orchestrated as if it were music. Again, sound need not correspond exactly with the visual images. Artistic use can be made of asynchronism; that is, contrasting the sound to the visual image. Motion-picture sound is capable of remarkable delicacy, richness, and variety. Sound libraries put most conceivable sounds readily at the disposal of filmmakers. Instruments and voices can be modified, overlapped, echoed, or given a resonance and volume that transform them. Dialogue can be crystal clear, bringing the audience far closer to an actor than in the theatre, or it may deliberately reproduce the careless enunciation of everyday speech.

The script. Although conventions vary from one country to another, the script usually develops over a number of distinct stages, from a synopsis of the original idea, through a "treatment" that contains an outline and considerably more detail, to a shooting script. Although the terms are used ambiguously, script, or screenplay, usually refers to the dialogue and the annotations necessary to understand the action; a script reads much like other printed forms of dramatic literature, while "shooting script" or "scenario" more often includes not only all of the dialogue but also extensive technical details regarding the setting, the camera work, and other factors. Moreover, a shooting script may have the scenes arranged in the order in which they will be shot, a radically different arrangement from that of the film itself since, for economy, all of the scenes involving the same actors and sets are ordinarily shot at the same time. Some scripts are subsequently modified into novels and distributed in book form, such as the U.S. best-seller *Love Story* (1970) by Erich Segal, and, in the instance of Dylan Thomas' *The Doctor and the Devils* (1953), a script became a literary work without ever having been made into a motion picture. Generally, more elaborate productions require more elaborate shooting scripts, while more personal films may be made without any form of written script. The script's importance can vary greatly, however, depending on the director. Griffith and other early directors, for example, often worked virtually without a script, while directors such as Hitchcock planned the script thoroughly and designed pictorial outlines, or storyboards, depicting specific scenes or shots before shooting any film.

Shooting script

Adaptation from other art forms must take into account differences of complexity and scale in film. A film often must omit characters and incidents in the novel from which it is adapted, for example, and the pace usually must be accelerated. Ordinarily, only a fraction of a novel's dialogue can be included. In an adaptation of a play, the curtailment is less severe, but much dialogue still must be cut or expressed visually.

Film adaptations of literary works

Well over half of all fiction films made since 1920 have been adapted from plays or novels, and it is understandable that certain formulas have been tacitly accepted to facilitate the remaking of literature into moving pictures. Adaptation has been thought of as an aesthetically inferior exercise, because most such films merely illustrate the classics or reshape a literary text until it conforms to standard cinematic practice. The particular qualities that made the original interesting are often lost in such a process. Certain films and filmmakers, however, have achieved an aesthetic premium by accepting the literariness of the original and then confronting this with the technology and methods of the cinema. Since the 1970s numerous directors have explored literature in an almost documentary manner. The artifice of the French director Eric Rohmer's *Die Marquise von O.* (1976), for example, aptly expresses the literary sensibility of Heinrich von Kleist's romantic, ironic work. On the other hand, less adventurous, big-budget adaptations continue to reshape the literary works they are based on into conventional "Hollywood" movies, as some critics complained about Sidney Pollack's *Out of Africa* (1985). The delicate and changing sensibility of the main character, evident in the prose of the original, was not reflected in the film's traditional, albeit grand, presentation.

Although many eminent literary authors, including F. Scott Fitzgerald and William Faulkner, have worked on film scripts, the ability to write a good original script, especially under strict studio conditions, frequently belongs to lesser-known scenarists with a strong visual sense. Some writers, particularly in France, have tried to narrow the gap between the written and cinematic modes of expression. Marguerite Duras and Alain Robbe-Grillet became leaders of a new kind of author who is able and willing to "write" directly on film. Both have directed their own films, which they see as equivalent to their novels and plays.

Motion-picture acting. Of all the artists involved in films, the actors and actresses are closest to the audience. The public more often goes to see a motion picture for its stars than for any other single reason. The divergent techniques of stage and film acting are well understood, and there are many leading players who excel in both. But the greatest film stars have a talent peculiar to the screen alone. This talent often seems to be related not to how well they act, but to the sort of person they appear to be.

Being oneself

Film acting requires restraint. "Don't act, think," was the advice of the eminent German director F.W. Murnau. While stage actors may be praised for a performance that is highly wrought, film stars usually must appear to be themselves. Close-ups accentuate the more intimate rela-

tionship the actor can establish with a film audience, an audience that has often followed the actual life of certain actors whom the industry promotes as "stars." The German theorist Walter Benjamin argued that the image of the star compensated the film audience for the loss of direct access to live performance. For this reason film actors from movie to movie are likely to be cast in similar roles, as the case of John Wayne makes clear.

Some actors, however, have deliberately tried to avoid being typecast. Robert De Niro, for example, is well known for the violent, obsessive characters he played in such films as *Taxi Driver* (1976) and *Raging Bull,* but he has been equally effective in more quiet, controlled roles, such as the charismatic hero in *The Deer Hunter* (1977) or the romantic movie producer in *The Last Tycoon* (1976). In his films, De Niro downplayed his own personality to "become" the characters he portrayed, even transforming himself physically by gaining excessive weight for his role in *Raging Bull.* Actors who have been strongly identified with one role have found it harder to change their image. Sean Connery, for example, has appeared in more than 40 films, playing such diverse characters as an eccentric poet in *A Fine Madness* (1966), an Arab chieftain in *The Wind and the Lion* (1975), a medieval monk in *The Name of the Rose* (1986), and a Prohibition-era Chicago policeman in *The Untouchables* (1987), but he remains most recognized for the seven films in which he starred as the sophisticated British secret agent James Bond.

A motion-picture performance can be synthesized bit by bit, by the joint efforts of the actor, the director, the cameraman, and others. The conditions of film production, however, are such that some actors find them trying. They may have to put up with long hours on the set and endless repetition, they must adapt to shooting scenes out of sequence, and in close-ups they often have to respond to the camera rather than to another actor. They require a talent different from, but equal to, that of theatrical performers.

Styles of acting

Throughout the history of the art, acting styles have frequently led to major revolutions in film style. Most of the shifts in acting have been toward what is deemed a more "realistic" approach. Often this realism is the result of the studied application of acting precepts, as when Marlon Brando brought to *On the Waterfront* (1954) the lessons he had digested at the Actors Studio (the professional workshop in New York City). In the 1960s several successful Czechoslovak films featured effective performances by what appeared to be average citizens; but in truth the players' long silences, their bumbling, and the foibles that seemed so natural were the result of lifelong practice and interminable rehearsals. Some films, however, have exploited the documentary power of the medium to reveal the behaviour of untrained but expressive individuals. Many of the masterpieces of the postwar Italian Neorealist movement relied on absolute amateurs, who were frequently picked up off the streets by the casting director.

Side by side with the never-ending quest for naturalness in acting, an opposite impulse has brought to the screen both stylized and histrionic performances of great power. Cinematic expressionism (largely identified with German films from the 1920s but also evident in Eisenstein's *Ivan the Terrible*) depends on contorted bodily and facial gestures, which are amplified by decor and camera angle. Eminent actors, including Laurence Olivier and Orson Welles, have shown that some types of film thrive on expansive theatrical voicing and gesture.

Comedy requires other considerations. The impassive visages of the silent star Buster Keaton and the French comic Jacques Tati helped transform their bodies into expressive machines that interacted with the greater machine of the films they starred in. The Marx Brothers, on the other hand, depended on loose cinematic construction, dialogue, and zany, spontaneous action. In short, there can be no single theory of film acting.

Motion-picture design. Under the heading of design, all of the elements of a picture's setting may be included—art direction, scenic composition, set design, costume, and makeup. At its simplest and most naturalistic, the camera can choose and frame ordinary people in a real location. At its most elaborate, motion-picture production may involve the expenditure of vast sums to put up gigantic sets that require building houses, ships, churches, and monuments, or re-creating lost cities, bygone landscapes, or ancient battles, and dressing thousands of extras in period costumes. Thunderstorms, tornadoes, snowstorms, earthquakes, volcanic eruptions, and tidal waves may be simulated, or monsters, spaceships, and cities of the future created.

Film sets are constructed more solidly than stage scenery, but of the lightest, cheapest materials that will both look authentic and photograph well. Whether for black and white or for colour, their shades, proportions, and shapes are chosen for the camera rather than the eye. The camera can deceive the viewer about scale, however, and the model makers and special effects technicians can reproduce virtually anything in miniature, from the aurora borealis shining on an igloo to a tempest destroying the Spanish Armada. A whole series of film monsters have attracted goggle-eyed audiences since the French pioneer Georges Méliès' formidable man-in-the-moon of 1902. Miracles can be achieved in film, either in the colossal form of the crossing of the Red Sea by the children of Israel in Cecil B. deMille's epic *The Ten Commandments* (1956) or in the comparatively simple treatment of angels and miracles in Frank Capra's *It's a Wonderful Life* (1946) or Warren Beatty's *Heaven Can Wait* (1978). Film publicity makes much of the creations of epics such as *Cleopatra* (1963) or *Apocalypse Now,* but, even on a more

Use of sets to depict the bleak life of the future generation.

modest scale, sets can contribute enormously to a motion picture, as in Ken Adam's sets for *Dr. Strangelove* (1964), *Sleuth* (1972), and the James Bond series.

The Expressionist influence on set design

The strongest single artistic influence in motion-picture set design was the German Expressionist cinema of the 1920s, which combined elements of Max Reinhardt's theatre, a Wagnerian philosophy of doom, and Expressionist painting and graphics. Expressionist films such as *The Cabinet of Dr. Caligari* (1919), *The Golem* (1920), *Nosferatu* (1922), and *Metropolis* (1926) created a world of fantasy and horror peopled with menacing, shadowy figures. In other German Expressionist motion pictures, such as *The Student of Prague* (1926) or *The Nibelungen* (1924), there was a baroque beauty of architectural, woodland, and floral settings. The influence of Expressionism can be seen in later cinema in the work of the directors Orson Welles and Carl Dreyer, and in many gangster movies.

Subject matter and how it is treated is reflected in all the elements of design in a motion picture. In the hectic atmosphere of a horror movie or a thriller, a studio set may pass unnoticed, even though it would seem disconcertingly artificial in another film. In a musical everything may look artificial: a chambermaid's bedroom may be a model of daintiness and taste. Some films, however, depend on realistic sets for dramatic effect. Accordingly, some directors, especially the French master Jean Renoir in his 1930s films, went to great lengths to be authentic, avoiding the use of rear screen projection, or process shots (*i.e.*, a shot in which new action is filmed in front of a screen on which previously filmed background footage is projected). All of the train sequences in Renoir's *La Bête humaine* (1938), for example, were shot on a moving engine, except the final scene, in which the hero, played by Jean Gabin, leaps to his death. Another French director of the same era, Marcel Pagnol, had his cast and crew construct the farmhouse for his masterpiece, *Angèle* (1934), not to save production money but to increase the naturalness of their behaviour on the set during shooting.

In historical epics, such as *A Passage to India* (1984), or science fiction films, such as *Blade Runner* (1982), settings vie with actors and story for the viewer's attention. In carefully constructed, intimate dramas, such as those by Robert Bresson (*L'Argent,* 1983) or Jim Jarmusch (*Stranger Than Paradise,* 1984), the setting can embody the tone of the film. Numerous stylistic options are attached to decor: its richness or sparseness; its naturalness or artificiality; its contemporaneity or period look; its cleverness or simplicity. Because all these factors are related to the full conception of the film, the set designer is one of the first artistic collaborators called in by the director in the quest for a strong, forceful production.

Lighting. In a medium consisting of the projection of impressions on a light-sensitive material, lighting is of special importance. Daylight is the readiest, cheapest, and strongest source of lighting. Hollywood was said to owe its preeminence as a motion-picture production centre to its sunny climate. Even in daylight shooting, however, artificial aids may be necessary to reduce the highlights or to lighten the shadows.

Lighting as a method of composition

Lighting, a part of camera-work, is under the control of the chief cameraman or lighting cameraman. In black-and-white films, lighting is of paramount importance in giving the overall light or dark tone of the scene and in providing for dramatic contrasts or emphasis within the scene. In colour, the lighting works indirectly to bring out or modify the colour. Lighting in the cinema is a method of composition, used to complement and reinforce the dramatic situation. Generally, dark lighting is associated with tragedy and bright light with romance or comedy, but overlighting gives ghastly or unearthly effects, as in the memory sequence at the beginning of the Swedish director Ingmar Bergman's *Sawdust and Tinsel* (1953; also called *Naked Night*). Lighting an actor from above gives his face a spiritual effect; from below, an uncanny or evil appearance. Front lighting blurs faults but takes away character; side lighting gives relief and solidity but may show wrinkles and defects. Lighting from behind tends to idealize a subject and give it an ethereal quality.

Fashions in film lighting have fluctuated through the years. Early films tended to be flat and uniform. Later, especially in German Expressionist films of the 1920s, strong contrasts of light and shade were favoured for their highly dramatic effect. Still later, this tendency was modified toward more balanced lighting. Even in dramatic scenes, the centre of interest now tends to be more discreetly emphasized.

Occasionally, different types of lighting are used for dramatic effect in a single film. For his Shakespearean adaptation *Henry V* (1944), Laurence Olivier employed uniform, bright light for the sequences modeled on medieval book illustrations, but in the contemplative sequences (Falstaff's death and Henry's solitude the night before the battle) he used single-source lighting from the side, which allows extensive gradation of light and shadows, making the images look like paintings by Rembrandt. The elegiac humanity of the latter scenes contrasts with the brittle, eternal quality of the former. More often, directors choose a single look. Stanley Kubrick's decision to film *Barry Lyndon* (1975) in candlelight is a notable example.

Related to lighting is the development of the print in the laboratory, where sections of film shot under different conditions can be modified to avoid a violent contrast where none is desired. Finally, the lighting of the projector that shows the picture and the brilliance of the screen are important. As light sources for the projector, both the traditional carbon arc and the modern Xenon lamp have advocates; what matters most is that the light be powerful, brilliant, and unvarying throughout the projection of the picture.

Settings. A salient feature of the cinema is its ability to reproduce natural scenery. From the earliest years filmmakers have mixed outdoor footage with scenes shot

inside the studio to give audiences the impression that the carefully calculated dramas they are witnessing are faithful records of events that occurred spontaneously in the real world. Just after World War I the Swedish directors Mauritz Stiller and Victor Sjöström stunned audiences with their films featuring simple folktales set in the mountains. The seasons of the year, the weather, and the Swedish streams, lakes, and waterfalls were active participants in these tales. After the success of such documentary features as those by Robert Flaherty (*Nanook of the North*), even Hollywood made room for films in which the natural setting was clearly the main protagonist, with the fictional drama used as a way to convey the audience around the landscape. More often the landscape provides an alternative attraction, allowing viewers to see favourite stars in exotic locations, as in *Out of Africa*. Another trend has been the use of familiar surroundings as the sets for futuristic dramas. Jean-Luc Godard's *Alphaville* (1965) turned Paris into an oppressive metropolis on another planet, and *Blade Runner* made contemporary Los Angeles look like a city of the 21st century.

Location filming

With the invention of lighter, more portable equipment, filming on location—that is, in an actual setting like the one in which the story takes place rather than in a studio set—has become less difficult and expensive and more often used. As a result, many earlier motion pictures now look artificial, since no studio set can equal the authenticity of a real location. Nonetheless, films may have to be shot in a studio when natural settings are unavailable, as in historical films, or are too remote. On the other hand, the effect of certain films can be utterly lost when inauthentic locations are substituted for genuine ones. The 1948 British Technicolor epic *Scott of the Antarctic*, for example, was shot in the Swiss Alps, which facilitated filming but ruined the documentary aspect of the film. In some cases, rear screen projection can be used to provide a background setting against which the actors perform.

Costume. Actors in motion pictures have been dressed in noticeable and often significant ways since the beginning of film history. The Italian epics made before World War I displayed Roman and Egyptian styles that the public had come to expect from popular paintings and stage plays dealing with these ancient subjects. After World War I, Ernst Lubitsch gained fame directing historical dramas, such as *Madame Dubarry* (1919), that were termed "costume dramas" even in their own day. From the 1920s to the 1950s various national cinemas, but particularly those in France and the United States, vied with one another in using the cinema to promote fashion. Christian Dior's rise in the world of haute couture was accelerated by his experiments with, and his advertising of, costumes in motion pictures. In Hollywood a motion picture was often an opportunity for an actress to wear one gorgeous costume after another, and many screen designs initiated popular offscreen fashion trends. After World War II the Italian Neorealist movement proved that audiences could also be drawn by authenticity of dress. Since then, many films attempting to convey a realistic effect have been outfitted not from the costume shop but from second-hand clothing stores.

Costume and the actor's identity

Costume also once played a more important role in an actor's identity. Charlie Chaplin, Buster Keaton, Mae West, and other stars of the 1920s and '30s all created characters in which costume was an integral part of the total identity. Audiences were often able to discern the type of character an actor was portraying—hero, villain, comic foil, romantic rival—by the clothes that he was wearing.

Makeup. Film makeup differs significantly from that of the stage, where heavy lines are required to convey a characteristic expression to the audience. By means of the camera, the motion-picture audience can study the actor's face quite closely. The makeup must be flawless to stand up under such scrutiny, but since it need not be applied nightly for several months running, as in theatre, elaborate preparations are feasible. Many of the greatest filmmakers, such as Carl Dreyer and Robert Bresson, have favoured naturalism in makeup—the unadorned lines of old age or a face caked with dust, running with perspiration. Whatever the style of makeup, its purpose is to make the face a more photogenic object, whether monster or ingenue. The efforts of wig makers, dentists, and plastic surgeons, as well as cosmeticians, are aimed at a heightened reality.

The cosmetics industry grew up in the 1920s alongside motion pictures. Max Factor's fame owes much to the work his company did in modifying makeup to adjust to new types of film and lighting, including the shift to colour cinematography. With changing audience perceptions, caused by television and other factors, more natural makeup styles became just as popular as the "idealized" methods applied to the great studio stars. Sylvester Stallone is one actor whose makeup is exceedingly important in emphasizing his craggy, often sweating features. Ironically, the "natural look" is often the result of extensive makeup tests.

While makeup generally is meant to remain unnoticed or to play servant to the beauty of a face, in science fiction and horror films it may take centre stage. Although it is an art as old as society itself, makeup is, like the other aspects of cinema, subject to technological development. Advances in contact lenses, in prosthetics, and in chemistry have made possible such magnificent and startling displays as *2001: A Space Odyssey* (1968), *Planet of the Apes* (1968), *Time Bandits* (1981), and the never-ending flow of creatures that terrorize horror-film audiences.

Authority of the director

Motion-picture directing. The modern motion-picture director is the person most responsible for the ultimate style, structure, and quality of a film. Cinema is an art of collaboration, and in some instances someone other than the director may come to dominate (for example, a producer with authority over the final cut, or an actor whose box-office popularity gives him the power to direct the director), but in general it is assumed that the person assigned to direct the picture must take the credit or blame for its form and content.

While the function the director serves has always been filled by someone, the priority of that function has not always been recognized. Georges Méliès, for example, thought of himself as a "producer" of films, and indeed from 1896 to 1912 he took care of all aspects of the making of the films bearing his name, including set design, acting, and camera-work. Charles Pathé, in turn-of-the-century France, was one of the first producers to assign an assistant (Ferdinand Zecca) specifically to direct the pictures of his rapidly expanding film empire. At France's Gaumont Pictures, Louis Feuillade and Alice Guy, the first woman to take on a key position in cinema, shared the task of directing, each specializing in separate genres. In the United States as in Europe, many of the first

film directors were cameramen (Edwin S. Porter) or actors (D.W. Griffith) until circumstance compelled them to take on various directorial duties. The movie industry was growing rapidly, however, and by 1910 the number of films required to fill the many newly constructed movie theatres was such that production had to be delegated. The director's role was to work with the actors, designers, technicians, and others involved in the moviemaking process, coordinating and overseeing their efforts in order to rapidly turn out interesting and comprehensible movies within given financial and material strictures.

As early as the 1920s those who wrote seriously about motion pictures had no qualms about attributing successes and failures to the director. Some directors, notably F.W. Murnau and Fritz Lang in Germany and Victor Sjöström in Sweden, were virtually as famous as the stars who acted in their films. In 1926 William Fox paid Murnau $1,000,000 to relocate in Hollywood in the hopes that he would make the greatest movies the world had yet seen. The primary issue of this marriage of art and money, *Sunrise* (1927), remains an anomaly in the history of the film industry, for Murnau was given unusual control and virtually unlimited resources. The film still astounds critics, but it was not a commercial success and it stunted for a time the growing stature of the director. Erich von Stroheim's more dramatic encounters with producers such as Irving Thalberg further encouraged this businesslike attitude, which led to the practice of quickly typing directors as either workmanlike or difficult.

In the great age of the studio system (1927–48), strong directors vied with the factory conditions in which films were made. Those directors with powerful personalities (such as Frank Capra, Howard Hawks, John Ford, and Ernst Lubitsch) were given great freedom, but they still had to work with actors and actresses contracted to the studio, with union personnel following time-honoured routines, with scripts and scriptwriters selected by the studio, and with deadlines that discouraged experimentation.

The auteur theory

The "auteur theory," which was propagated by French film theorists in the 1950s, offered a powerful method for studying and evaluating the films of the studio era. The word "auteur" (literally "author" in French) had been employed in France in the 1930s in legal battles over the rights to artistic property. This legal struggle to determine whether a film "belonged" to its scriptwriter, director, or producer strengthened the belief held by many critics and theorists that it was the director alone who deserved credit for a film, just as an architect could be credited for a building even though it was built and used by other people. While this view made eminent sense when strong directors were concerned, it tended to ignore average filmmakers.

Auteurs are defined as directors with solid technique, a well-defined vision of the world, and a degree of control over their productions. Some directorial situations are easy to evaluate. Griffith and Chaplin had complete financial control over their major efforts; European art directors, such as Ingmar Bergman, enjoyed similar freedom. Indeed their films were often marketed as the expressions of important artistic personalities. The auteur theory, however, was developed to encourage the reevaluation of countless films by directors operating in the middle of suffocating studio situations. Directors such as Leo McCarey, Gregory La Cava, and Anthony Mann stylistically and thematically imbued their films, whatever the genre, with a consistent, personal aesthetic. Their output, even when unsuccessful, is deemed immeasurably more valuable than the undistinguished films of weaker directors who merely translated the words and actions indicated in a script into routine screen images. (Scriptwriters in the studio years worked mainly in teams. A single script often passed through the hands of several different writers so that most films are more recognizable as the product of a particular studio than of an individual writer.)

The tension between director and genre or studio is thought to be productive of films that appeal to the public while expressing the vision of an individual. Thus, through the auteur, the popular art of cinema is able to achieve the traditional goals of poetry and the fine arts, goals of authentic expression and of genius.

The auteur theory was especially influential in the 1960s and arguably was instrumental in creating not only the French New Wave but also similar movements in Britain and the United States. Directors such as Lindsay Anderson, Joseph Losey, Stanley Kubrick, John Cassavetes, Francis Ford Coppola, and Arthur Penn thought of themselves as budding auteurs and earned critical and popular acclaim for their distinctive styles and themes. With the fall of the studio system in the 1950s there was indeed room for a single personality to take control of a film and to market it on the basis of personal vision.

Artisanal format of filmmaking

After 1960 first-rank American motion-picture directors began to make films under conditions that had been in practice in Europe throughout the century. The insignificant studio system of France, for example, had enabled and encouraged individual entrepreneurs to put together film projects on a onetime basis. Such projects generally revolved around an *équipe*, or team of creative personnel, with the director at its head. The director could then truly shape the work of the designer, composer, and (most importantly) the scenarist, so that the film had a consistent and relatively personal style from beginning to end. In this artisanal format, a producer depends on the director to develop a distinctive way of handling scenes. The director may even be required to rewrite the scenario in order to achieve a particular effect. As a result of this personal commitment, the well-publicized arguments that occur during the production of many important films almost always involve the director.

Alfred Hitchcock was one director who disdained arguments. He kept the blueprint of his films in his head and provided detailed instructions for each shot, without any discussion. His producers were not given the opportunity to offer alternative suggestions or to recut the film. The scenes fit together in one way only, Hitchcock's way. While some critics have complained that the acting in a Hitchcock film is often stilted, that the sets are artificial, and that the rear-projection shots are obvious, the Hitchcock style is immediately recognizable. Most people admire the effectiveness of Hitchcock's direction, some even claiming that in his films can be found profound moral and metaphysical insight.

Major directors throughout the world have often enjoyed such respect. Among others, Mizoguchi Kenji and

North by Northwest, © 1959 Loew's Incorporated; photograph from the Museum of Modern Art/Film Stills Archive, New York City

Cary Grant in *North by Northwest* (1959), directed by Alfred Hitchcock.

Kurosawa Akira of Japan, Satyajit Ray of India, Federico Fellini of Italy, Luis Buñuel of Spain, and Carl Dreyer of Germany have been given rare opportunities to make individual artistic statements. Some have been treated as virtual national treasures whose films bring cultural glory to the countries within which they work.

Television versus film directing

Despite these exceptions, most directors labour under great restrictions, particularly in the age of the television industry. A conventional television series rotates directors episode after episode so that the producers, actors, and production crew, who work continuously on the show, have much greater control over the product. Each scene of a television program is typically filmed from three different camera setups. The director strives to get the best performances possible from the actors, confident that the crew is delivering appropriate images, and an editor later chooses the best shots to use to tell the story. In comparison, powerful film directors have often involved themselves deeply in editing and postproduction. The television industry has accentuated the assembly-line features of the studio system, while independent film production today often distinguishes itself by according the director dictatorial power.

Whether granted complete or restricted control, every director must approve the screenplay and then concentrate on the scene being filmed in its relation to the overall design of the film. The management unit (an assistant director and script girl) concerns itself with the details of organization so that the director can interact with the creative personnel on the set (cinematographers, lighting and sound crews, set decorators, and, of course, actors). As for postproduction, all directors look with the editor at daily rushes from the lab, but only some follow through and become involved with the editing, music, and mixing phases. In all cases, the director is the one person to maintain a complete view of the project, drawing the best from all the personnel, from writer through sound mixer, and shaping their efforts so that the film attains a consistent look and meaning.

Successful directing has much to do with intangible social relations, such as keeping harmony (or productive competition) alive on the set, drawing the best possible performances from actors, shaping a script into a form that takes advantage of the talents of the director of photography or of the main actor, or beseeching the producer for the money needed for a special shot. Beyond such routine expectations, the great director is identified for a unique or ingenious approach to the medium. Directors have earned praise for their audacious handling of stories. Refusing to be hemmed in by the standard requirements of a two-hour drama dealing with a few central characters, Francis Ford Coppola, for example, pieced together a truly epic fresco in his two-part masterpiece *The Godfather,* as did Robert Altman in such collage narratives as *Nashville* (1975). Italian directors have experimented with the epic form, as in Ermanno Olmi's *The Tree of Wooden Clogs* (1979) or Bernardo Bertolucci's *1900* (1976), and with narrative structure, as in Rossellini's *Paisà* (1946) and Ettore Scola's *Le Bal* (1983), which abandon traditional plot construction and a single story line in favour of separate short episodes that are thematically or historically linked.

Some directors gain more fame for their visual style than for their narrative acuity. Bertolucci's films, for example, are not always well received, but his fluid, saturated images and their "psychoanalytic" effect have made their mark in films such as *The Conformist* (1970) and *Luna* (1979). The same might be said for Federico Fellini, Andrey Tarkovsky, and Werner Herzog. Some critics feel that Coppola's *One from the Heart* (1982) projects an intense, personal vision, which is much more interesting from the directorial point of view than his more commercially successful efforts, including *The Godfather.* Although many directors credit their cinematographers for achieving such notable visions, most cinematographers claim merely to solve technical problems at the behest of the director.

The same can be said of effects achieved in postproduction. The incredibly dense aural ambience surrounding Coppola's *Apocalypse Now,* for example, resulted from the concatenation of scores of individual sound tracks mixed by a team of talented experts, but Coppola himself had already evinced a powerful understanding of the possibilities of sound in his much smaller film *The Conversation* (1974). Similarly, a good share of Robert Altman's fame must go to the engineers who coordinated the radio miking of as many as a dozen characters in a single scene in *Nashville.* It was, however, Altman who recognized the total effect that two hours of overlapping conversations would have on the spectator. Martin Scorsese's rugged editing in *Taxi Driver* and *Raging Bull* was a function not only of an editor's ingenuity but also of a total conception of script, acting style, camera-work (including harsh black-and-white tones for the latter film), and music.

The director as problem solver

A director might best be thought of as a problem solver. Seldom concerned with technology, the director takes the resources at hand (the technological capabilities and the conventions of filmmaking operating at the moment) and searches for effective solutions to dramatic or visual problems. A style emerges when these solutions, or "techniques," are applied consistently across a series of films. For example, Robert Bresson's penchant for employing off-camera sound to signal important events (a car wreck in *Au Hasard Balthasar,* 1966; a bank robbery in *L'Argent*) defies standard filmmaking conventions and reaches toward a peculiarly valuable way of understanding an interior or spiritual drama. Bresson's sound techniques have become part of his austere and evocative style.

Directors may be characterized by the solutions they regularly arrive at when a story or scene is presented to them. Murnau and Mizoguchi preferred the languorous tracking shot to editing a dramatic situation, so that the drama could be seen to arise in the midst of the shot. Antonioni let the camera continue to shoot well after the characters were out of range, so that the spectator could observe the way a dramatic scene disappeared or sense its smallness in the landscape that remained. Most American directors have employed hard-hitting, swift techniques to give power to the gritty stories that dominated world cinema after 1970. Close-up sound, pounding music, and abrupt editing keep the spectator interested and excited. Within this general American style, however, individual directors have found different methods to achieve similar effects, and they have discovered that using similar techniques does not guarantee similar results. It is generally acknowledged that the best directors are those who consistently contribute not only ingenious techniques but also an effective, coherent, personal style or theme to their films. Brian De Palma's use of point-of-view strategies, for example, gives a particular horror to such films as *Carrie* (1976) and *Body Double* (1984), and his technique has been compared to that of Hitchcock. Most critics agree, however, that Hitchcock is the more significant director because the rigorous point-of-view strategy that Hitchcock employed in such films as *Rear Window* (1954) was far more than a tour de force of moviemaking technique; it was an expression of the director's thoughts on vision and knowledge. (D.A.)

TYPES OF MOTION PICTURES

Film modes

Most connoisseurs of the art of motion pictures feel that the greatest films are the artistic and personal expression of strong directors. The cinema exists, however, for many social functions, and its "art" has served many types of film that do not set out to be artistic. In practical terms these functions divide films into what are usually termed modes, including the documentary, the experimental, and the fictional. The documentary mode incorporates those films relying primarily on cinema's power to relay events in the world automatically. The experimental includes the variety of approaches that have tested and played with the technological limits and capabilities of the medium, including animated (nonphotographic) and computer-generated images. The fictional is the mode most often thought of as simply "the movies." It has adopted the forms of storytelling that have always existed in culture, creating various cinematic languages to convey its tales. Each of these three modes can in turn be subdivided into genres (*i.e.,* commonly recognized types of stories or forms).

The documentary. The turn of the century witnessed

not only the invention of the motion picture but also tremendous growth of popular interest in journalism, picture postcards, lectures by travelers (frequently illustrated with slides), and so forth. The motion picture quickly came to serve society's need to learn about the geography and social conditions of the world at large. Some of the first motion pictures depicted exotic locations, contemporary events (battles, coronations), and unknown cultures. Indeed as late as 1908 such a major company as Biograph actually produced more nonfiction films than narratives. This would soon change, in part because the production of documentary films is dependent on world events and is therefore more haphazard and more difficult than the fully controlled process of making fiction films in studios. The decline of the nonfiction film has also been attributed to the belief that, after a decade, audiences were saturated with "views" and "actualities," as such films were called. Moviegoers were no longer drawn to the sheer recording ability of motion pictures; they demanded imaginative entertainment instead.

Travelogues and ethnographic films. One sort of film that has had continuous appeal, albeit for a specialized audience, has been the travel film. Much of the attraction of such films—from the crude pictures cranked out by Lumière cameramen in Japan, Africa, and the Arctic, to Robert Flaherty's films about the Eskimos, the South Sea Islands, and the wild western coast of Ireland, to National Geographic presentations on television—results simply from the thrill of seeing a foreign culture or a distant location. Flaherty proved, however, that there could also be tremendous artistry in such films. His unforgettable compositions matched the harmonious rhythm of his editing to render the lives of his subjects in a gloriously romantic tone.

Influence of travel films on fiction films

Both anthropologists and Hollywood producers immediately recognized the value of Flaherty's work, initiating several long-lived genres. In Hollywood *King Kong* (1933), one of the most famous monster movies ever made, was conceived by producer-director Merian C. Cooper, who was inspired by his experience shooting travel documentaries. The surprising success of *The Gods Must Be Crazy* (1981), a comedy about life in the Kalahari desert of Botswana, shows that audiences continue to enjoy the mixture of foreign locations and familiar dramas. The Bushmen (San) of the Kalahari are also the subject of an important ethnographic film, John Marshall's *The Hunters* (1958). Marshall's tradition dates to the 1930s and to the films the anthropologists Margaret Mead and Gregory Bateson made in the Pacific.

Most scholars prefer that all artistry be eliminated from ethnographic films so that the visual data recorded by the camera remains as fresh and uninterpreted as possible. The audience for these films typically consists of members of a university or museum community for whom entertainment is less significant than authenticity. When such films are prepared for mass television audiences, however, many concessions may be necessary, including the addition of extensive explanatory narration, musical accompaniment, and scenic photography.

Newsreels and documentaries. The argument over the role of art and artlessness in travelogues and ethnographic films is also pertinent to newsreels, where the standard principles governing journalism must apply. In the first years of cinema, reconstructions of such events as *The Dreyfus Affair* (Méliès, 1899) and *L'Assassinat de McKinley* (Pathé, 1901) were commonly accepted. Since then, viewers have required that newsreel material be neither prearranged nor fabricated, and they have become aware of the effects of the intrusiveness of the reporter and the limitations of point of view on the objectivity of any documentary film.

Newsfilms, more than any other type of motion picture, depend on their timeliness. Hence, for all of its ability to show the actual world, the motion picture failed to provide genuine news until it did so by means of television. Too stale and infrequent for day-to-day coverage, newsreels showed not news but parades, ceremonies, sporting events, bridge building, and similar events. *The March of Time,* inspired by *Time* magazine and produced by Louis de Rochemont from 1935 to 1951, was a series in which a topic of political or social importance was discussed in depth in a 30-minute film. The series was an immediate and continued success. It is television, however, that has developed the screen presentation of news, comment, and discussion beyond anything known before.

It is less in the straight presentation of reality than in its creative interpretation that the documentary has produced works of lasting value. Among the pioneers of the documentary besides Flaherty were the Russian theorist Dziga Vertov, whose films include *The Man with the Movie Camera* (1929), and the British director John Grierson, whose *Drifters* (1929) inspired a school of fine directors to produce a succession of memorable documentaries through the 1930s. With the outbreak of World War II, Humphrey Jennings' *Fires Were Started* (1943) and Harry Watt's *Target for Tonight* (1941), two among many outstanding British wartime documentaries, dramatized Britain's war effort better than fictional films could.

The British documentarists

In the United States, Pare Lorentz made dramatic documentaries about soil erosion and the dust bowl, such as *The Plow That Broke the Plains* (1936) and *The River* (1937) during the era of the Great Depression, and, during World War II, Frank Capra, who had been an outstanding director of Hollywood comedies, made a series of documentaries under the title *Why We Fight.* The later French movement, *cinéma vérité,* made films that are much closer to journalism than to the careful compositions of the English documentary school. Though often untidy, they are fresh and realistic. Television deeply affected the development of the documentary film in two major ways: by providing a training ground for documentary directors, and by building a supply of news film that could be adapted to documentary form. *Point of Order* (1964), a U.S. documentary film that ran successfully in motion-picture theatres, was made from television films of the U.S. Senate hearings on the charges and countercharges made by Senator Joseph McCarthy and the U.S. Army.

The Vietnam War gave rise to a plethora of documentary essays, some of them politically committed, some attempting a balanced exploration of the situation. American *cinéma vérité,* sometimes called "direct cinema," matured during the war, though not only in response to it. The first of the rock concert films, D.A. Pennebaker's portrait of Bob Dylan, *Don't Look Back,* first played theatrically in 1967, and that same year Frederick Wiseman's *Titicut Follies,* which exposed the horrendous conditions in a Massachusetts institution for the mentally ill, caused such an uproar that it was banned in that state. Excitement over public events and celebrations permitted this spate of documentaries to compete with fiction films for screens in larger cities. The films, which were often of inflammatory content, were kept off television but nonetheless influenced that medium tremendously. *Hearts and Minds* (Peter Davis, 1974), for example, a powerful, though one-sided, attack on U.S. Vietnam policy, had an enormous

impact just because it could not be shown on television. Conversely, in the 1980s, many documentaries were increasingly seen on television rather than on movie-theatre screens. Claude Lanzmann's *Shoah* (1985), for example, a nine-and-a-half-hour examination of the Nazi concentration camps, received limited theatrical distribution in many areas because of its length but still managed to reach wide audiences through the distribution markets provided by the growing cable-television and videocassette industries.

Henrik Gawkowski, a Polish locomotive engineer in *Shoah* (1985), Claude Lanzmann's documentary of the Nazi concentration camps. The film uses no archival footage of the camps, relying on oral descriptions from eyewitnesses and participants to create its impact.

Propaganda. In presenting a background, an environment, and characters who behave in a certain way, every motion picture may be said to be propaganda. The term is usually restricted, however, to pictures made deliberately to influence opinion or to argue a point. The most powerful and most consistent use of the cinema for propaganda was seen in the Soviet Union. After the 1917 revolution, Soviet films exploded on the screen with fervent conviction. Gradually, however, the pictures became lifeless, and in the 1930s and 1940s, during the Stalin regime, great directors such as Eisenstein and Aleksandr Dovzhenko worked under severe restraints. Nazi Germany produced its own brand of propaganda in the 1930s, the most striking being Leni Riefenstahl's *Triumph of the Will* (1936), a terrifying spectacle of a huge Nazi rally that had in effect been staged for the film made about it.

Propaganda in film

Few filmmakers would admit to making propaganda, although, in effect, many so-called educational films and all advertising or promotional shorts, whether featuring consumer products, vacation sites, or religious sects, may be seen as examples of propaganda. This form of film bears a stigma owing to its undisguised aim: to influence ideas and change behaviour. Cinematic artistry serves merely as a tool in propaganda. (R.St./D.A.)

The experimental and animated film. Films of all kinds may be the results of experiments or may contain attempts to overturn traditional genres, but the mode of experimental film has always been reserved for those endeavours produced and exhibited with the aim of questioning or revolutionizing the medium itself. The mode is by definition limited, because no real traditions can develop that do not soon cease to be experimental.

The first significant experimental film movements emerged during the 1920s, when sophisticated artists began to play with the film medium and when film societies, specialized theatres, journals, and museum lectures began to cater to audiences wanting to be disturbed or surprised. In France at that time a true avant-garde led by painters such as Marcel Duchamp, Man Ray, Fernand Léger, and Salvador Dalí scorned the mass market and sought exhibition in clubs and museums. French directors of the time, including Jean Epstein, Marcel L'Herbier, and Abel Gance, experimented with narrative structure in their films but were still involved in creating feature films for theatrical release. Although these films, especially Gance's *Napoléon* (1927), are full of experimental camera and editing techniques, they are not considered to be experimental films because of their exhibition histories.

The experimental film has been forged out of two impulses. The first has stemmed from movements in the fine arts, such as Futurism, Constructivism, Dada, Surrealism, Minimalism, and Abstract Expressionism. Artists working in these movements have often shifted to cinema as new terrain for their ideas, radically rethinking the medium to make a personal or cultural point. The other impulse has been technological. The experimentalist, curious to see what the medium can do, has explored and expanded the basic processes and techniques involved in filmmaking. The early films of Méliès were precursors of this type of cinema.

Influence of fine arts and technology on experimental films

The two impulses have rarely been seen separately. Luis Buñuel's scandalous *Un Chien andalou* (*The Andalusian Dog*, 1928) arose as much from his curiosity about film and narrative as it did from his association with the Surrealist movement. The same can be said of Maya Deren, founder of the American avant-garde during the 1940s. Other artists have rejected narrative altogether and linked up with traditions in poetry and the visual arts. During the 1950s and 1960s, the heyday of the American avant-garde, Stan Brakhage manipulated focus, lighting, and sequence in a range of distinctively personal and often mythic films. His most radical technical strategy was to eliminate photography altogether—by scratching directly on film, gluing particles on the emulsion, and even growing algae on the film before copying it—in an attempt to express himself without the mediation of character, plot, or objects. Like other filmmakers of the period, he called on the theories of action painting to justify his excesses.

Nonphotographic techniques can also be used to produce representational objects and even stories, as the experimentalist Len Lye proved with his short animated films of the 1930s. Laboriously drawing black-and-white (and later polychrome) figures on every film frame, he achieved a lightness of effect impossible in photography. Imaginative animation can also be used to demonstrate movements or changes that are difficult or impossible to photograph. It can produce striking, eye-catching effects or make a dull subject interesting and entertaining. In addition, information is often conveyed more quickly and clearly through animation than through live action. For these reasons, animated films are widely used for instructional and advertising or other promotional purposes. Animated films can, of course, exist simply to amuse, and the best-known works of animation are undoubtedly the cartoon comedies.

Whatever their length or purpose, animated films have a motion and characterization more succinct than live action. They can more freely contract or distort both time and space and defy the forces of gravity; they can be as realistic or as fantastic as their designers wish. The potentialities of animation have fascinated filmmakers since the earliest days of the motion picture.

The graphic style of early animated entertainments followed at first that of the cartoon strips of the period—hard outlines, little or no modeling, and the flat application of paint when colour was introduced. Walt Disney was responsible for improving the professionalism of the animated film and for getting it into the standard theatrical distribution system. He also helped to develop and popularize the animated feature film. Disney's feature-length *Snow White and the Seven Dwarfs* (1937) contained about 477,000 photographed drawings; it was the leading international box-office favourite of 1938, and its sound track was dubbed into 13 foreign languages.

The symbolic political fable *L'Idée* (1934), by the Austro-Hungarian animator Berthold Bartosch, represented a rare use of animation to present a serious, as distinct from a comic or legendary, subject; the approach was first achieved at feature length by the British husband-and-wife team of John Halas and Joy Batchelor in their adaptation of George Orwell's novel *Animal Farm* (1954). More recently, cartoons were used on occasion in certain Communist countries to make social statements in the guise of highly stylized anecdotes or fables. Some of the most advanced, most inventive work of this kind was done in such countries as Yugoslavia, Czechoslovakia, and Poland. In the United States, highly individual styles were pioneered in the 1940s by the United Productions

Use of serious subject matter

An illustration from Walt Disney's first animated feature film, *Snow White and the Seven Dwarfs* (1937).

of America (UPA) group under the direction of Stephen Bosustow. Among their creations were the series that featured Mr. Magoo and Gerald McBoing Boing.

Later, various kinds of graphic fantasy found expression through animation, and the older style of cartooning associated with Walt Disney was completely overtaken by artists using a diversity of contemporary graphic styles, often extremely elaborate. The work of Jiří Trnka and Karel Zeman exemplified the long-established Czech leadership in animated puppetry. Trnka's *Old Czech Legends* (1951) and *The Good Soldier Schweik* (1955) used stylized puppets in naturalistic settings to dramatize social satires, folk legends, and classics. Zeman's work used both puppets and live actors moving within real sets.

Since the 1950s, the experimental filmmakers Robert Breer and Norman McLaren, among others, have developed new styles and techniques of animation, including collage and pixilation (a technique that makes human movements look like those of animated automatons). In the 1960s the cartoon film appeared to lose ground as pure entertainment, except in the Communist countries, but it has steadily advanced in the fields of education and public relations. The growing use of computers in graphic design has further emphasized this use of animation.

(R.M./D.A.)

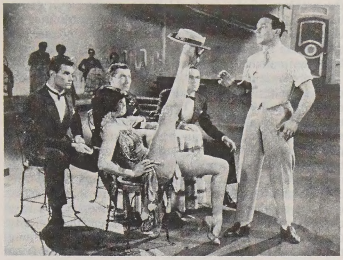
Fictional genres. Motion pictures are the most important narrative art form of the 20th century, having taken on the functions served earlier by dime novels, serial novels, staged melodramas, wax museum displays, epic paintings, and professional storytelling. These earlier forms continued into the century and were supplemented by comic books, radio, and television, but it is the motion picture that came to dominate them all. Still, most films can be seen as descendants and variants of types of stories and storytelling that predated the invention of the cinema.

Production advantages of genre films

Always plagued by the need for a constant flow of new products to satisfy patrons returning to the movies week after week, film companies quickly began to rely on genres to help regularize production and to help presell their motion pictures. A studio that decided to make half a dozen police thrillers in one year could organize its production schedule efficiently, saving time and money by reusing sets, costumes, and other items. More important, the studio could assign the same personnel to certain genres, allowing writers, directors, technical crews, and actors to establish a routine that often resulted in quicker and improved filmmaking from work to work. In addition, it was found that the initial success of a new film was frequently enhanced by the popularity of previous films in the same genre. Viewers knew, to a great extent, what to expect from a genre film; they recognized the stars, or at least the characters, in it, and they were sensitive to music, lighting, and plot devices because of long familiarity with the type of story being portrayed.

Although the movies have created their own genres, most have been derived from prototypes in the other arts, especially literature. The western, for example, has important precursors in popular painting, Wild West shows, and pulp fiction. It does not matter, however, if audiences are unfamiliar with these other media; viewers quickly learn the rules of the genre, acquiring the ability to recognize the hero from his costume, to anticipate the final shoot-out, and so forth. Genres epitomize the dilemma of the fiction film, in that they promise to deliver to a waiting audience something that is similar to what that audience has enjoyed in the past and yet something that is also quite new and different. Often the most highly acclaimed films are those that invoke the conventions of a genre only to break them down in the pursuit of ideas and visions never attained in that form before. Examples include John Ford's western *The Searchers* (1956), the comedies of Preston Sturges, Arthur Penn's gangster film *Bonnie and Clyde* (1967), and Robert Altman's comedy *M*A*S*H* (1970).

Well-formed genres typically characterize the production of highly centralized studio systems such as those of Hollywood, of Japan, or of India. They play a lesser role in countries where individual producers dominate. In France, for example, most films are treated as single-effort productions, a practice that can permit far more revolutionary films to develop, as was seen during the French New Wave of the late 1950s and early '60s. François Truffaut, Jean-Luc Godard, Claude Chabrol, Eric Rohmer, and other New Wave directors utterly overturned standards of storytelling and visualization to the delight of an international audience tired of old formulas. These directors were not oblivious to genres; rather they played with conventions, mixing comedy and pathos, suspense and spectacle. Their highly personal films confirmed the importance of genre to the fictional mode.



Hollywood genres. Most genres can be defined by their subject matter or setting—*e.g.,* the western, gangster film, police thriller, science-fiction film, or social problem film. Others are classified according to the type of narrative form they exhibit. The musical, for example, often has a show business setting or theme, but it is not so narrowly restricted; it can be about almost any subject. The melodrama also encompasses many subjects and styles; it has even been combined with other genres—for example, with the western in *Rancho Notorious* (1952) and with the problem film in *Ordinary People* (1980).

Evolution of genres

The evolution of genres can be used to trace the history of Hollywood cinema and 20th-century American popular culture. Different genres have achieved popular success in different periods. Some, termed "cycles," are short-lived (*e.g.,* the disaster cycle of the 1970s, which included *Earthquake* [1974] and *The Towering Inferno* [1974]); but even lasting genres go through phases of popularity. The western, for example, was well-established as a genre by the 1920s. It was particularly strong in the late 1940s and early '50s but not during the '30s. It resurged in the 1960s but subsided later in the '70s. Musicals came into prominence with the introduction of sound. They remained important until the late 1960s, when a number of expensive, overblown productions flooded theatres and met financial failure. Most film historians were ready to proclaim the genre dead, but several astounding successes in the late 1970s and early '80s caused them to revise their view of the musical and the culture it addresses.

The internal mutation of a genre reflects the changing tastes and mores of the public. The modern musical (*All That Jazz,* 1979; *Fame,* 1980; *Coal Miner's Daughter,* 1980) is more socially conscious and more serious than the colourful, vividly stylized, self-conscious musicals of the 1940s and '50s (*Singin' in the Rain,* 1952; *The Band Wagon,* 1953), which in turn are derived from, but upend, such early escapist masterpieces as *42nd Street* (1933) and *Top Hat* (1935). Each phase can be seen as a response to the prevailing political, social, and economic conditions of its time.

The western is the genre most scrutinized for this evolution. Its classical phase (*Stagecoach,* 1939) mutated after World War II into a variant capable of dealing with social problems (*High Noon,* 1952) or with tortured heroes (*Winchester 73,* 1950). In the 1960s the Italian "spaghetti western" announced a decadent phase. *The Good, the Bad, and the Ugly* (1966) inverted character roles and culminated in a three-man gunfight. Audiences applauded

Cyd Charisse and Gene Kelly in a dance sequence from the musical film *Singin' in the Rain* (1952).

both the attenuated spectacle of these films and their ironic perversion of the codes operating in the standard genre. Some scholars, citing the *Star Wars* trilogy (1977, 1980, 1983) as an example, have argued that in the 1970s the mutation went so far as to leap across the boundary of subject matter toward science fiction. Although some science-fiction films may share fascinating properties with the western, it is unlikely that the production or reception of such films was consciously affected by westerns. Genres with strong, well-defined iconographies rarely consciously influence or combine with one another, even when they are clearly related. When Hollywood remade Kurosawa's *Seven Samurai* (1954) into the western *The Magnificent Seven* (1960), production personnel and audiences were far more conscious of the new film's relationship to previous westerns than of its similarities to Japanese samurai pictures.

The serial. While genres implicitly rely on an audience's interest in and familiarity with earlier movies of a certain kind, the serial is a type of movie that explicitly requires an audience to return episode after episode. Also called the chapter-play or cliff-hanger, the serial flourished in the days of silent films, when cinema going was a weekly habit. Perhaps the most famous were Louis Feuillade's *Fantômas* (1913–14) and *Judex* (1916) in France and the U.S. series of the same period with Pearl White, such as *The Perils of Pauline.* Old serials have been revived since the 1960s as period pieces of popular art, with their improbable plots, exaggerated acting, and old-fashioned decor appealing to modern, sophisticated audiences. The French director Georges Franju made a modern pastiche *Judex* in 1963. Since the late 1970s new serials have appeared in the form of multiepisode sagas shown on television. *Roots* (1977) in the United States had its counterpart in Rainer Werner Fassbinder's 16-hour *Berlin Alexanderplatz* (1980), which aired in installments on German television and then played as a serial in art house theatres around the world. (D.A.)

Interpretations

Films of art and the art cinema. For want of a better term, "interpretation" may be used to describe the type of motion picture in which a play, a ballet, an opera, or some other work of another art form is kept virtually intact and recorded by the camera and microphone. Adaptations of novels or plays re-create the work in motion-picture form, but interpretations merely give the performance a wider audience. The English director Tony Richardson's version of *Hamlet* (1970) is an example of such a filmed record of a theatrical performance. Most motion pictures of operas and ballets may be classed as interpretations. Public and cable television have become obvious sponsors and disseminators of this type of film, although some interpretations, including Joseph Losey's *Don Giovanni* (1979), and numerous films of rock concerts continue to thrive in theatrical distribution.

At one time the recording of an already established work of art was deemed "uncinematic" and thought to be a doubtful use of the medium. Such arguments were made as early as 1911 in response to the French Film d'Art company, which photographed high-class stage plays. Recently, however, imaginative and innovative cinematic techniques have been employed to record operas, ballets, and stage plays. The complexity of the resulting hybrid works, such as Arnold Schoenberg's *Moses and Aaron* as filmed by Jean-Marie Straub and Danièle Huillet (1975), have made the validity of the early generalizations questionable. Important filmmakers, including Robert Altman in the United States, Eric Rohmer in France, and Carlos Saura in Spain, have turned to the filming of works of other art forms as ways to open up the motion picture to new types of experiences.

Art films versus popular films

The motion-picture recording of the acknowledged artistic successes of other media raises the important issue of the artistic stature of the cinema. As early as 1920 an audience of film connoisseurs could be identified in Europe. Ever since that time it has been possible to divide the cinema audience of any nation into a mass audience that seeks entertainment and a smaller group that is consciously concerned with artistic values in the motion picture. The films that appeal to these two groups, however, vary from one nation to another and from one period to another. The Hollywood comedies of the 1920s by Charlie Chaplin, Buster Keaton, and others, for example, were originally popular entertainment, but they were later taken up by the art film audience. The comedies of Jerry Lewis received little serious critical attention in their native United States but a great deal in France. The low-budget thrillers of directors who were adopted by auteur critics met a similar experience. The distinction between popular entertainment and high art seems indisputable in most instances, but confusions of fashion and conflicts in artistic standards resulting from experiment and change make it difficult to generalize about them.

Although there may be disagreements over what constitutes cinematic art, certain institutions have developed that foster the art of film. In the United States after World War II, "art houses" catered to sophisticated audiences in large cities, screening primarily European films, such as those directed by Fellini, Bergman, Buñuel, and Antonioni. The distribution of 16-millimetre films to museums and college campuses sparked interest in avant-garde films as well. In one sense art films represent a genre; the audience that seeks them out has precise expectations which producers have been known to exploit. In 1951 Daiei films of Japan, for example, expressly aimed to conquer the export market by winning awards at international festivals. The company, which generally produced cheap domestic genre motion pictures, reserved a portion of its budget to make lavish historical spectacles, such as Mizoguchi's *Ugetsu* (1953), that would appeal to the art audience outside of Japan. The art film usually cannot be characterized in advance, however; it does not follow prescribed conventions but prides and sells itself on its uniqueness or distinctiveness.

THE STUDY AND APPRECIATION OF MOTION PICTURES

Film criticism

Criticism of motion pictures generally follows the pattern of the other arts, though it has some peculiar features. In the criticism of painting, music, theatre, and literature, some technical knowledge of the medium has generally been required. Motion-picture reviewers, however, rarely have any experience of filmmaking. A lack of experience in filmmaking is not necessarily a handicap. Film is such a complex medium that a technician is unlikely to be expert in every aspect of it and may well be overly conscious of his specialty. In addition, even though the technique is complex, the results are plain to view, and an intelligent critic may well appreciate such technicalities as fine camera-work, tight editing, authentic location shooting, or competent direction without knowing in detail how the result was achieved.

Film periodicals and books

Besides reviews in the daily and weekly press, there are specialized monthlies and quarterlies that engage scholars, students, and enthusiasts of the medium. In the United States *Film Quarterly, Wide Angle, Quarterly Review of Film Studies,* and *Cinema Journal* have great influence, just as *Screen* does in England and *Bianco e nero* in Italy.

As a country France has made cinema a central part of its culture. The French *Cahiers du Cinéma* sustains several times the circulation of the U.S. *Film Quarterly* and is rivaled by several other serious journals and countless magazines. Aiming at a less specialized but still avid film audience, glossy magazines such as *American Film* in the United States and *Sight and Sound* in England mix serious reviews, interviews, and features. There are similar publications in Poland and India. Popular magazines, which lure a large readership with their blend of pictures and gossip, have always been a part of movie culture, as have trade papers such as *Variety*, one of the most reliable and thorough sources of information about the international film business.

Books about the cinema range from serious studies of its economic, sociological, and technical aspects to light memoirs, ephemeral gossip, and innumerable biographies and autobiographies of actresses, actors, producers, and directors. Monumental film histories and theories written by Sergey Eisenstein, Vsevolod Pudovkin, André Bazin, Lewis Jacobs, Georges Sadoul, and others have triggered a remarkable industry of book publishing on these topics in many countries. The U.S.-based Society for Cinema Studies enrolls more than 500 teachers of film, who read these books and recommend titles to students. Most major university libraries now routinely collect film books and periodicals, although certain centres of research house the most complete collections. In the English-speaking world these include the British Film Institute, the special collections libraries at the University of California at Los Angeles and the University of Southern California, the Margaret Herrick Library of the Academy of Motion Picture Arts and Sciences in Beverly Hills, Calif., and the Lincoln Center Library in New York City. Other institutions house important documentation along with archives of films. The International Museum of Photography at George Eastman House in Rochester, N.Y., is particularly rich in material on the early cinema, while the Wisconsin Center for Film and Theater Research in Madison has gathered data pertaining to its collection of films produced by Warner Bros., RKO, and United Artists.

Preservation of film. The permanence of the motion-picture medium—the fact that films can be stored and reproduced indefinitely—not only makes it an enduring theatrical art but also a vivid record of past life. Despite the fact that motion pictures can theoretically last forever, relatively few have been preserved and many of these are in poor condition. One reason is that inflammable nitrate film stock, which was generally used until the 1940s, when it was replaced by acetate, is chemically unstable. Also, as film runs through a projector, it is eventually worn, scratched, or damaged. Still another factor is that commercial conditions of filmmaking discouraged preservation; the stress was on the present and the future, not on preservation of the past. Early motion pictures were best preserved when filmmakers such as Chaplin or Disney had control over their own work and a personal interest in preserving and representing it. During the 1960s and 1970s, however, there developed a tremendous interest in old movies. Revival houses sprang up in most major U.S. cities, and distribution companies were established solely for the reissue of old films.

Film preservation that allows access to old motion pictures is costly, requiring careful scientific control of storage conditions. Few private organizations or governments have been willing to spend the necessary funds. The earliest film archive was the Swedish Film History Collection begun in 1933. Archives in Paris, London, and New York City followed shortly afterward. An international federation (FIAF; Fédération Internationale des Archives du Film) was founded with headquarters in Paris in 1938.

Problems of the archivists

The archivists' problems are many: first, selecting the motion pictures to be preserved; second, acquiring copies (a negative or a fine-grain positive if possible) in good condition; third, storing them under the best possible conditions of temperature and humidity; fourth, cataloguing them and keeping some record of their contents; and fifth, allowing them to be viewed or letting stills or extracts be taken, without damaging the copies. The ideal solution to the problem of choice would be to preserve everything, but the cost would be prohibitive. Even with a limited selection, acquisition and storage are expensive and difficult, and nitrate film requires regular testing to see whether it has deteriorated enough to require copying.

The preservation of colour films has become perhaps the most serious problem. While Technicolor films (mostly made before 1953) can be reproduced faithfully and endlessly, virtually all colour films made since 1953 are subject to fading that can be arrested only by storing prints at very low temperatures. Video technology has been used to help preserve some colour motion pictures; computer-driven viewers are able to read the original tints of films and reproduce them on videotape. Nevertheless, until the development of a suitable and inexpensive base onto which colour films can be transferred, the majority of colour motion pictures made after 1953 will continue to deteriorate.

(R.St./D.A.)

Film societies, film festivals, and awards. Predating and indispensable to the academic study of motion pictures are the linked phenomena of film societies and film festivals. These social institutions provided readership for film journals and serious film books, which eventually led to the acceptance of film study in universities. The first and most lasting function of film societies has been to foster the appreciation of the art of film. The second function has been to emphasize the social dimension of film in culture, sometimes using the film as a prop for the examination and propagation of moral and political ideas.

Functions of film societies

These two directions were evident by the 1920s. Louis Delluc and Ricciotto Canudo are credited with forming the first important *ciné-club* (as such societies are frequently called, especially when devoted to film art). The list of adherents to these clubs contains many luminaries from the film world (Epstein, Gance, L'Herbier, Germaine Dulac) and the other arts (Colette, André Gide). The Film Society of London, for example, was founded in 1925 by H.G. Wells, George Bernard Shaw, Augustus John, John Maynard Keynes, and other dignitaries who wanted to see French, German, and Soviet pictures that commercial exhibitors did not handle. The movement spread rapidly, and cinema was included in several international art forums, beginning with the 1925 Paris Exposition des Arts Décoratifs et Industriels Modernes that launched Art Deco. There, for several months, a history of cinema played in the Grand Palais and was accompanied by lectures on technique and appreciation of motion pictures.

Specialized theatres in major cities began to cater to *ciné-club* audiences. One of Jean Renoir's first films, *La Petite Marchande d'allumettes* (*The Little Match Girl*, 1928) was actually commissioned by a theatre and shot on its premises. *Ciné-clubs*, too, sponsored films made by their own members until the invention of sound made such amateur productions too expensive and technically intricate.

The political power of film societies was first recognized by Léon Moussinac, an official in Delluc's club who traveled to the Soviet Union in the 1920s and recognized immediately the importance of motion pictures in the education of the masses. Through his writing and organization, he was responsible for thousands of "average citizens" joining film clubs that featured controversial and sometimes revolutionary films. In 1928 Les Amis de Spartacus purportedly enrolled more than 75,000 subscribers. The mayor of Paris found it necessary to prohibit some of their meetings, the most important being a scheduled appearance by Sergey Eisenstein, whose *Battleship Potemkin* (1925) was officially banned in some countries.

In the 1930s enthusiasm for film societies waned, perhaps due to the Depression, although it was in this decade that the Roman Catholic Church developed networks of societies for the projection and discussion of exemplary films, particularly in parishes in Italy and France. After World War II, a resurgence of film societies occurred internationally. The French film theorist André Bazin was associated with both an artistic club headed by Jean Cocteau and a trade union club, indicating that the old split between "film art" and "film and social issues" remained. In the United States, clubs were devoted primarily to film art, fostering the American underground film movement. This

postwar flourishing must be credited in part to the marketing of convenient 16-millimetre equipment.

Decline of film societies

The importance of such societies inevitably declined after universities and museums regularly began to include motion pictures as part of their collections, and in most countries film societies eventually attached themselves to universities. In the 1980s the availability of videocassettes further dissolved the strength of the *ciné-club* by allowing would-be members to select their own films for viewing at times convenient to them.

Film festivals provide a forum for promotion and recognition of artistic achievements of national film industries. The first festival was founded at Venice in 1932. It remained unique until after World War II, when the Cannes Festival was founded, and festivals began to assume their modern-day importance. Struggling nations, rebuilding their shattered film industries, saw in festivals a chance for world recognition. The growing interest everywhere in film imports made the festivals an international marketplace for distributors. Festivals were initiated at Berlin; Moscow; Karlovy Vary, Czech.; London; San Francisco; Chicago; and New York City. Through the early 1960s, the U.S. film industry remained wary of festivals; films that won festival awards did not necessarily do well at the box office, though a poor reaction at a festival might reduce the audience for a serious film. After 1965, however, distributor attitudes changed as investments increased in films for specialized audiences, particularly in "foreign" films backed by U.S. companies, and favourable critical acclaim became a vital promotional aid. Interest in the festivals persisted, and they continued to increase in number and in size. By the early 1980s there were more than 100 scheduled annually in some 25 different countries.

Functions of film festivals

Film festivals serve several functions. They provide an international marketplace where producers and distributors can exchange ideas, view films, and sign contracts. For example, the phenomenon of the international coproduction, so important to European cinema, arose at the Cannes festivals of the late 1940s. Festivals also provide an opportunity for fans to see popular stars and other celebrities. A further function of film festivals has been to provide a cultural rendezvous for those interested in the art and influence of the movies. Festivals often showcase new films or movements, as when the Venice festivals of the early 1950s introduced the stunning accomplishments of the Japanese film industry, which had been previously unknown in the West. At other times festivals are sites of artistic and political contention. At the Cannes festivals of 1958 and 1959, for example, advocates and opponents of the French New Wave heatedly exchanged diatribes and manifestos. A decade later several key New Wave directors, most notably François Truffaut and Jean-Luc Godard, helped close the festival to protest government policies during the events of May 1968. The Venice Film Festival, generally deemed more serious and less commercial than Cannes, ceased its juried competition from1969 to 1979 because of political strife.

Festivals are regulated by the Fédération Internationale des Associations de Producteurs de Films (FIAPF), which licenses those who want to award prizes. The competition that is associated with most festivals is in many instances, however, only a publicity device. Film screenings are often not even announced. The real purpose of the festival is to allow distributors to view and bid on the latest movies.

Academy Awards

The best known of all competitions, the Academy Awards, does not take place at a festival at all. The U.S. industry, with its overwhelming control of the world's screens, long had virtually no interest in film awards except for the awards voted each year since 1929 by the Academy of Motion Picture Arts and Sciences. The academy, which represents various artistic and technical disciplines, originally intended its annual awards as modest, peer-group citations within the tightly knit Hollywood industry. After media coverage created widespread interest, however, there was an increase in box-office revenues for winning films, and the Academy Awards, or "Oscars," became valuable in merchandising. The prestige of the academy's artistic judgments, however, has failed to keep pace with its economic power. Serious students of the film tend to place more credence in the awards of the New York Film Critics (founded in 1935), and the National Society of Film Critics (1966), as well as in the oldest U.S. reviewing organization, the National Board of Review of Motion Pictures (1909). (R.St./A.D.M./D.A.)

Technology

Motion-picture technology is a curious blend of the old and the new. In one piece of equipment state-of-the-art digital electronics may be working in tandem with a mechanical system invented in 1895. Furthermore, the technology of motion pictures is based not only on the prior invention of still photography but also on a combination of several more or less independent technologies; that is, camera and projector design, film manufacture and processing, sound recording and reproduction, and lighting and light measurement.

HISTORY

Motion-picture photography is based on the phenomenon that the human brain will perceive an illusion of continuous movement from a succession of still images exposed at a rate above 15 frames per second. Although posed sequential pictures had been taken as early as 1860, successive photography of actual movement was not achieved until 1877, when Eadweard Muybridge used 12 equally spaced cameras to demonstrate that at some time all four hooves of a galloping horse left the ground at once. In 1877–78 an associate of Muybridge devised a system of magnetic releases to trigger an expanded battery of 24 cameras.

Eadweard Muybridge

The Muybridge pictures were widely published in still form. They were also made up as strips for the popular parlour toy the zoetrope "wheel of life," a rotating drum that induced an illusion of movement from drawn or painted pictures (see Figure 1). Meanwhile, Émile Reynaud in France was projecting sequences of drawn pictures onto a screen using his Praxinoscope, in which revolving mirrors and an oil-lamp "magic lantern" were applied to a zoetrope-like drum, and by 1880 Muybridge was similarly projecting enlarged, illuminated views of his motion photographs using the Zoöpraxiscope, an adaptation of the zoetrope.

Although a contemporary observer of Muybridge's demonstration claimed to have seen "living, moving animals," such devices lacked several essentials of true motion pictures. The first was a mechanism to enable sequence photographs to be taken within a single camera at regular, rapid intervals, and the second was a medium capable of storing images for more than the second or so of movement possible from drums, wheels, or disks.

A motion-picture camera must be able to advance the medium rapidly enough to permit at least 16 separate exposures per second as well as bring each frame to a full stop to record a sharp image. The principal technology

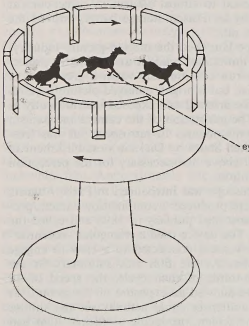

Figure 1: Zoetrope.

that creates this intermittent movement is the Geneva watch movement, in which a four-slotted star wheel, or "Maltese cross," converts the tension of the mainspring to the ticking of toothed gears. In 1882 Étienne-Jules Marey employed a similar "clockwork train" intermittent movement in a photographic "gun" used to "shoot" birds in flight. Twelve shots per second could be recorded onto a circular glass plate. Marey subsequently increased the frame rate, although for no more than about 30 images, and employed strips of sensitized paper (1887) and paper-backed celluloid (1889) instead of the fragile, bulky glass. The transparent material trade-named celluloid was first manufactured commercially in 1872. It was derived from collodion, that is, nitrocellulose (gun cotton) dissolved in alcohol and dried. John Carbutt manufactured the first commercially successful celluloid photographic film in 1888, but it was too stiff for convenient use. By 1889 the George Eastman company had developed a roll film of celluloid coated with photographic emulsion for use in its Kodak still camera. This sturdy, flexible medium could transport a rapid succession of numerous images and was eventually adapted for motion pictures.

Étienne-Jules Marey

Thomas Edison is often credited with the invention of the motion picture in 1889. The claim is disputable, however, specifically because Edison's motion-picture operations were entrusted to an assistant, W.K.L. Dickson, and generally because there are several plausible pre-Edison claimants in England and France. Indeed, a U.S. Supreme Court decision of 1902 concluded that Edison had not invented the motion picture but had only combined the discoveries of others. His systems are important, nevertheless, because they prevailed commercially. The heart of Edison's patent claim was the intermittent movement provided by a Maltese cross synchronized with a shutter. The October 1892 version of Edison's Kinetograph camera employed the format essentially still in use today. The film, made by Eastman according to Edison's specifications, was 35 millimetres (mm) in width. Two rows of sprocket holes, each with four holes per frame, ran the length of the film and were used to advance it. The image was 1 inch wide by ¾ inch high.

At first Edison's motion pictures were not projected. One viewer at a time could watch a film by looking through the eyepiece of a peep-show cabinet known as the Kinetoscope. This device was mechanically derived from the zoetrope in that the film was advanced by continuous movement, and action was "stopped" by a very brief exposure. In the zoetrope, a slit opposite the picture produced a stroboscopic effect; in the Kinetoscope the film traveled at the rate of 40 frames per second, and a slit in a 10-inch-diameter rotating shutter wheel afforded an exposure of $^1/_{6,000}$ second. Illumination was provided by an electric bulb positioned directly beneath the film. The film ran over spools. Its ends were spliced together to form a continuous loop, which was initially 25 to 30 feet long but later was lengthened to almost 50 feet. A direct-current motor powered by an Edison storage battery moved the film at a uniform rate.

The Kinetoscope

The Kinetoscope launched the motion-picture industry, but its technical limitations made it unsuitable for projection. Films may run continuously when a great deal of light is not crucial, but a bright, enlarged picture requires that each frame be arrested and exposed intermittently as in the camera. The adaptation of the camera mechanism to projection seems obvious in retrospect but was frustrated in the United States by Dickson's establishment of a frame rate well above that necessary for the perception of continuous motion.

After the Kinetoscope was introduced in Paris, Auguste and Louis Lumière produced a combination camera/projector, first demonstrated publicly in 1895 and called the *cinématographe.* The device used a triangular "eccentric" (intermittent) movement connected to a claw to engage the sprocket holes. As the film was stationary in the aperture for two-thirds of each cycle, the speed of 16 frames per second allowed an exposure of $^1/_{25}$ second. At this slower rate audiences could actually see the shutter blade crossing the screen, producing a "flicker" that had been absent from Edison's pictures. On the other hand, the hand-cranked *cinématographe* weighed less than 20 pounds (Edison's camera weighed 100 times as much). The Lumière units could therefore travel the world to shoot and screen their footage. The first American projectors employing intermittent movement were devised by Thomas Armat in 1895 with a Pitman arm or "beater" movement taken from a French camera of 1893. The following year Armat agreed to allow Edison to produce the projectors in quantity and to market them as Edison Vitascopes. In 1897 Armat patented the first projector with four-slot star and cam (as in the Edison camera).

The *cinématographe*

One limitation of early motion-picture filming was the tearing of sprocket holes. The eventual solution to this problem was the addition to the film path of a slack-forming loop that restrained the inertia of the take-up reel. When this so-called Latham loop was applied to cameras and projectors with intermittent movement, the growth and shrinkage of the loops on either side of the shutter adjusted for the disparity between the stop-and-go motion at the aperture and the continuous movement of the reels (see Figure 6).

The Latham loop

When the art of projection was established, the importance of a bright screen picture was appreciated. Illumination was provided by carbon arc lamps, although flasks of ether and sticks of unslaked calcium ("limelight") were used for brief runs.

Introduction of sound. The popularity of the motion picture inspired many inventors to seek a method of reproducing accompanying sound. Two processes were involved: recording and reproducing. Further, the sound reproduction had to be presented in an auditorium and had to be quite good. This could not be achieved without a good amplifier of electrical signals. In 1907 Lee De Forest invented the Audion, a three-element vacuum tube, which provided the basis in the early 1920s for a feasible amplifier that produced an undistorted sound of sufficient loudness.

Next came the problem of synchronization of the sound with the picture. A major difficulty turned out to be the securing of constant speed in both the recorder and reproducer. Many ingenious ideas were tried. In 1918 in Germany, the use of a modulated glow lamp in photographically recording sound and a photocell for reproduction were studied. In Denmark in 1923, an oscillograph light modulator and selenium-cell reproducer were developed. De Forest tried a gas-filled glow discharge operated by a telephone transmitter to record a synchronized sound track on the film. For loudspeakers he experimented with a variety of devices but finally chose the speaker with horn. The operating signal was obtained from a light shining through the film sound track and detected by a light-sensitive device (photocell). These were used in a system called Phonofilm, which was tried experimentally in a number of theatres. In 1927 the Fox Film Corporation utilized some of these principles in the showing of Fox Movietone News.

Meanwhile, the Western Electric Company laboratories in the United States had been making extensive studies on the nature of speech and other sounds and on techniques for recording and reproducing such sounds. They experimented with recording on a phonograph disc and developed a 16-inch (40.6-centimetre) disc rotated at 33⅓ revolutions per minute; they improved loudspeakers, introduced the moving-coil type of speaker, and generally improved the entire electronic amplification system. The Warner Bros. movie studio became interested in all these developments and formed the Vitaphone Corporation to market the complete system.

Vitaphone sound-on-disc recording

Warner Bros. premiered Vitaphone in 1926 with a program featuring short musical performances and a full-length picture, *Don Juan,* which had synchronized music and effects but no speech. In 1927 it brought out *The Jazz Singer,* which was essentially a silent picture with Vitaphone score and sporadic episodes of synchronized singing and speech. Warners presented the first "100-percent talkie," *The Lights of New York,* in 1928.

Although the Vitaphone system offered fidelity superior to sound-on-film systems at this stage, it became clear that recording on film would be much more convenient.

Among other disadvantages, it was extremely difficult with the wax discs to shoot outdoors or to edit sound. By 1931 Warner Bros. ceased production of sound-on-disc and adopted the sound-on-film option preferred by the other studios.

Sound-on-film, a system that in various guises had enjoyed several periods of popularity, underwent constant improvements in the 1910s and 1920s. Although a sound track on the picture negative was used for Movietone News, Fox's dramatic productions used a separate sound film on fine-grain print stock that could be edited apart from the picture yet in synchronism with it. One serious problem of sound-on-film systems had been the distortion of the signal introduced by the glow lamp when recording the sound track on film. The Western Electric Company devised a "double-string" light valve. A wire was looped around a post and parallel to itself. When speech current was applied to the wire in a magnetic field, the wire vibrated toward and away from itself according to the applied electrical waveform. A steady beam of white light shining through the loop was modulated in intensity by the varying gap between the wires; the modulated beam was photographed while masked by a slit perpendicular to the edge of the film. The resulting sound track appeared as darker or fainter parallel lines on the edge of the film. Known as the variable density system, this method of optically recording sound was originally used by all but one of the major Hollywood studios.

Variable area sound-on-film recording

The Radio-Keith-Orpheum Corporation (RKO) was created in 1928 to showcase the Radio Corporation of America (RCA) Photophone system of variable area recording. With this system, the sound recording was modulated by a rotating mirror and the slit was parallel to the edge of the film; reproduction employed the perpendicular slit of the variable density sound track. Minor problems of incompatibility between recording and reproduction were solved in late 1928 when the track was narrowed down to stay safely within the area scanned by the beam. Identical side-by-side tracks were employed to compensate for lateral misalignment. Initially inferior in quality, the variable area system gradually drew even with the quality of the density system and supplanted it altogether in the 1950s.

Whereas there was wide variation in the speed at which silent films were photographed and projected, sound necessitated standardization of the frame rate. In 1927 the speed was standardized at 24 frames per second, or 90 feet per minute for 35-mm film.

The development of sound technology in the first years of talking pictures focused on two areas. One involved the development of blimped cameras, directional microphones, microphone booms, and quieter lights, so that sound could be recorded more cleanly at the time of shooting. The other technologies involved the ability to add, edit, and mix sound separately from the time the picture was recorded. (P.Me./E.We./S.G.H.)

Introduction of colour. From their earliest days, silent films could be coloured using nonphotographic methods. One means was to hand-colour frames individually. Another method made it possible to use monochrome sections for mood (*e.g.*, blue for night scenes or red for passionate sequences). Monochrome stock was created by "tinting" the film base or "toning" the emulsion (by bathing the film in chemical salts).

The photography of colour was theorized decades before it was developed for motion pictures. In 1855 the British physicist James Clerk Maxwell argued that a full-colour photographic record of a scene could be made by filming three separate black-and-white negatives through filters coloured, respectively, red, green, and blue, the three primary colours. When converted to positives, the transparent exposed areas of the three films could pass light through the appropriate filter to produce three images, one red, one green, and one blue. Superimposing the three images would "rebuild" the image in its original colours.

Additive and subtractive systems of colour

In 1868 Louis Ducos du Hauron identified the additive and subtractive systems of colour. Both systems originate as red, green, and blue negative records. The difference occurs in the positive image, which may be composited from either the additive or subtractive primaries. The subtractive primaries—cyan, magenta, and yellow—are the complements of the additive primaries and can be obtained by subtracting, respectively, red, green, and blue from white. (Subtracting all three additive primaries yields black; adding all three yields white.)

In motion-picture prints, overlapping dye layers in the three subtractive primaries are simultaneously present on a clear, transparent base, and the image is projected with an exposure of white light. The dark areas of the cyan layer subtract all red colour, permitting only cyan (the mixture of blue and green) to pass through; the transparent areas pass all the white light. The magenta and yellow layers act similarly, and the original colour image is reproduced. The fineness of resolution is limited only by the structure of photographic grain or dye globules.

The first film colour systems were additive, but they were confronted by insurmountable limitations. In an additive system, the three colour records remain discrete and meet only as light rays on the screen. The best picture results when a separate film is made for each colour; however, each colour can occupy alternating frames or small, alternating portions of each frame of a single film. (A contemporary example of additive colour can be seen in projection television, in which red, green, and blue lenses converge to produce an image so enlarged that the separate colour areas, or dots, become discernible.)

The best known of the early additive processes was Kinemacolor (1906), which, for manageability, reduced the three colour records to two: red-orange and blue-green. A single black-and-white film was photographed and projected at 32 frames per second (twice the normal silent speed) through a rotating colour filter. The two colour records occupied alternate frames and were integrated by the retention characteristic of the human eye. As there were no separate red-orange and blue-green records for each image, displacement from frame to frame was visible during rapid movement, so that a horse might appear to have two tails. Inventors tried to increase the film speed, reduce the frame size, or combine two films with mirrored prisms, but additive systems continued to be plagued by excessive film consumption, poor resolution, loss of light, and registration problems.

The first subtractive process employing a single film strip in an ordinary projector without filters was Prizma Color in 1919. (Prizma Color had been introduced as an additive process but was soon revised.) The basis was an ingenious "duplitized" film with emulsion on both sides. One side was toned red-orange and the other blue-green. The stock long outlasted the Prizma company and was in use as late as the early 1950s in such low-cost systems as Cinecolor.

Similar enough to provoke litigation was an early (1922) process by Technicolor in which separate red and green films were cemented back-to-back, resulting in a thick and stiff print that scratched easily. Although only four two-colour Technicolor features were produced by the end of the silent era, Technicolor sequences were a highlight of several big-budget pictures in the mid-to-late 1920s, including *The Phantom of the Opera* (1923–25) and *Ben Hur* (1925). Technicolor devised the first of its dye-transfer, or imbibition, processes in 1928. Red and green dye images were printed onto the same side of clear film containing a black silver sound track.

Three-strip Technicolor

When Technicolor's appeal seemed on the wane, it devised a greatly improved three-register process (1932). The perfected Technicolor system used a prism/mirror beam-splitter behind a single lens to record the red, green, and blue components of each image on three strips of black-and-white film. Approximately one-third of the light was transmitted to the film behind a green filter in direct path of the lens; the film was sensitized to green light by special dyes. A partially silvered mirror (initially flecked with gold) directed the remainder of the light through a magenta (red plus blue) filter to a bi-pack of orthochromatic and panchromatic films with their emulsion surfaces in contact. The orthochromatic film became the blue record. As it was insensitive to red light, the orthochromatic film passed the red rays to the panchromatic film. A 1938 improvement added red-orange dye to the orthochromatic film so that only red light reached the panchromatic layer.

In 1941 Monopack Technicolor was introduced. This was a three-layer film from which separation negatives were made for the Technicolor dye-transfer printing process.

Using the dye-transfer method, it was necessary to make gelatin positives that contained the image in relief. Dye filled the recesses while the higher areas remained dry. Each gelatin matrix thus imprinted its complement onto the film base. As in the two-colour process, a black silver sound track was printed first on clear film. When magnetic sound became popular, the oxide strips were embossed after printing. Technicolor gave excellent results but was very expensive.

In 1936 Germany produced Agfacolor, a single-strip, three-layer negative film and accompanying print stock. After World War II Agfacolor appeared as Sovcolor in the Eastern bloc and as Anscocolor in the United States, where it was initially used for amateur filmmaking. The first serious rival to Technicolor was the single-strip Eastmancolor negative, which was introduced in 1952 by the Eastman Kodak Company but was often credited under a studio trademark (*e.g.,* Warnercolor). Eastmancolor did not require special camera or processing equipment and was cheaper than Technicolor. Producers naturally preferred the less expensive Eastmancolor, especially since they had, in response to the perceived threat of television, increased production of colour films. (After the 1960s black-and-white films were so rare that they cost more to print than colour films.) The 1950s vogue for CinemaScope and three-dimensional productions, both incompatible with the Technicolor camera, also hastened the demise of Technicolor photography.

Eastmancolor

Dye-transfer printing remained cost-effective somewhat longer, but Technicolor was forced to abandon the process in the 1970s. This has created a significant problem for film preservationists because only Technicolor film permanently retains its original colours. Other colour prints fade to magenta within seven years, yet the hard gelatin dyes of a Technicolor print remain undimmed even after the film's nitrate base has begun to decompose.

In the 1980s computerized versions of the hand-stenciled colour films of the silent era were developed to rejuvenate old black-and-white films for video. (E.We./S.G.H.)

Wide-screen and stereoscopic pictures. Until the early 1950s, the screen shape, or aspect ratio (expressed as the ratio of frame width to frame height), was generally 1.33 to 1, or 4 to 3. In the mid-1950s the ratio became standardized at 1.85 to 1 in the United States and 1.66 or 1.75 to 1 in Europe. These slightly wider images were accomplished by using the same film but smaller aperture plates in the projector and by using shorter-focal-length lenses.

Many people have felt that, while vision at the extreme sides of the vision field does not usually contribute much information to the eyes, it does add substantially to the illusion of reality when it is present. Hence, there have been periods when film producers have attempted to introduce extremely wide formats. As early as 1929, Grandeur films were presented using 70-mm instead of the standard 35-mm film to give a wider field of view.

In 1952 a radical attack was made on wide-screen projection in the form of the Cinerama, which used three projectors and a curved screen. The expanded field of view gave a remarkable increase in the illusion of reality, especially with such exciting and spectacular subjects as a ride down a toboggan slide. There were technical problems, including the necessity of carrying three cameras bolted together at the correct angles on the toboggan or other carrier, synchronization of the three separate films, and matching of the image structure and brightness at the joining edges on the screen. After 1963 Cinerama replaced its three-film process with a 70-mm anamorphic system with an aspect ratio of 2.75 to 1.

Heightening the illusion of reality

The use of anamorphic lenses for wide-screen projection was introduced by CinemaScope in 1953. An anamorphic optical system photographs with a different magnification horizontally than it does vertically. The lens seems to squeeze the image so that on the film itself figures appear tall and thin. A lens on the projector reverses the effect, so that the images on the screen reacquire normal proportions.

In 1955 Todd-AO introduced a wider film (photographed on a 65-mm negative and printed on a 70-mm positive for projection), with several sound tracks added. Like anamorphic systems, the wider format could be achieved with a single projector. The first two Todd-AO productions, *Oklahoma!* (1955) and *Around the World in 80 Days* (1956), were made at 30 frames per second for a nearly flicker-free image; 70-mm films are now photographed and projected at 24 frames per second.

Amusement parks and world's fairs have often featured 360-degree projection. The first system was presented at the Disneyland amusement park in 1955. At first, the projection involved 11 16-mm projectors and screens and, later, nine 35-mm projectors. The audience stood on a low platform in the middle. The result was extremely realistic. In one scene, showing the view from a cable car in San Francisco, the viewers were seen involuntarily to lean over on the curves, as if they were actually on the cable car. The format, however, has limited uses for general storytelling.

In the 1980s, efforts to improve picture quality took two routes: increase in frame rate (Showscan operates at 60 frames per second) or increase in overall picture size—height as well as width (IMAX and Futurevision). In these formats the sound tracks are usually printed on a separate, magnetic strip of film.

Another project intended to improve the illusion of reality in motion pictures has been stereoscopic, or three-dimensional, cinematography. "3-D" films use two cameras or one camera with two lenses. The centres of the lenses are spaced 2½ to 2¾ inches apart to replicate the displacement between a viewer's left and right eyes. Each lens records a slightly different view corresponding to the different view each eye sees in normal vision.

Stereoscopic cinematography

Despite many efforts to create "3-D without glasses" (notably in the U.S.S.R., where a screen of vertical slats was used for many years), audience members have had to wear one of two types of special glasses to watch 3-D films. In the early anaglyph system, one lens of the glasses was red and the other green (later blue). The picture on the screen viewed without glasses appeared as two slightly displaced images, one with red lines, the other with green. Each lens of the glasses darkened its opposite colour so that each eye would see only the image intended for it.

The Polaroid system, used for commercial 3-D movies since the early 1950s, is based on a light-polarizing material developed by the American inventor Edwin H. Land in 1932. In this method, known as Natural Vision, two films are recorded with lenses that polarize light at different angles. The lenses on the glasses worn by spectators are similarly polarized so that each admits its corresponding view and blocks the other. Early versions of Polaroid 3-D used two interlocked projectors to synchronize the two pictures. A later system, revived in the 1970s and 1980s, stacked the left and right components vertically on half-frames two sprocket holes high. The images were converged by means of a mirror and/or prism.

PROFESSIONAL MOTION-PICTURE PRODUCTION

Cameras. The principles of operation of modern professional motion-picture cameras are much the same as those of earlier times, although the mechanisms have been refined. A film is exposed behind a lens and is moved intermittently, with a shutter to stop the light while the film is moving. In the process, the film is unrolled from a supply reel, through the intermittent to the gate where the exposure takes place, and then on to the take-up reel.

Principal parts. Lenses have gone through a continuous evolution in the last half century, for both still and motion-picture photography. The two major objectives have been to focus properly all the colours of the image at the film plane (*i.e.,* to make the lens achromatic) and to focus portions of a beam coming from different portions of the lens, the centre or the edges, at the same point on the film (*i.e.,* anastigmatic). Both objectives require solution for as large a lens opening as possible, in order to capture maximum light for the exposure, and for as wide a field of view as will be needed in the use of the lens. In order to solve these problems, lenses have been

Achromatic and anastigmatic lenses

made with more and more components. Also, more types of glass have been discovered and developed, to give better achromatic performance. It was found, about 1939, that a special coating of the glass-to-air surface of a lens component could greatly diminish reflections from this surface without affecting other properties of the lens. The use of such coatings improved image contrast by reducing the stray rays that were produced by reflections in a multiple-component lens. Coatings also reduce loss of light by reflection in the desired rays. Coating developments have permitted the manufacture of lenses with many more components than had previously been possible.

Long experience with both motion-picture and still cameras has shown the need for a variety of focal lengths (ranging from ultrawide angle to telephoto) to photograph scenes under the best conditions. To make changing focal lengths more convenient, the lenses have sometimes been mounted on a turret, so that one out of a set of three lenses may be quickly selected. For motion pictures this would mean an interruption in the action depicted. A continuous change would be more desirable.

When two lenses are used in a tandem combination, the focal length of the combination varies according to the separation between the two components. For example, when two thin converging lenses are mounted close together, the combined focal length is shorter than when they are separated a certain distance. Thus, the focal length of the combination can be continuously varied over a range merely by changing the separation.

This observation led to the conception of camera lenses of variable focal length in which the variation is obtained by moving one or more elements. One simple design consists of two fixed convex (converging) lenses of unequal power with a movable concave (diverging) lens between them. When the central concave lens is located close to the front convex element, the combination focal length can be shorter (and the image therefore smaller) than when it is located close to the rear convex element. The design can be made such that, with the two convex elements remaining fixed, a distant view can remain almost in focus on the film as the middle element is moved. Exact focus for this arrangement, however, could not be attained. Thus, for lenses of this design, a cam device has in the past been provided to move the front convex element a short distance as the middle element is moved over its range, to keep the focus exact. This kind of lens has come to be called a zoom lens.

The zoom lens

By increasing the number of elements, the focus can be kept exact without the need of a correcting cam. Other improvements include increasing the range of focal lengths covered, increasing the effective lens aperture, increasing the angular field of view seen by the film, and improving the colour correction with radically new glass materials.

For a long time the change in focal lengths was carried out manually. More recently, the use of an electric motor drive has allowed a smoother change, with less distraction to the cameraman.

The general principles utilized in the film transport system have remained much the same over recent years, at least for the 35-mm film. The films are usually preloaded in lighttight reel cases (called magazines), with an exposed loop between the supply and take-up reels. This loop is quickly fitted into the camera mechanism when loading.

The intermittent is usually a claw-type mechanism, sometimes a "dual-fork" claw that pulls down four sprocket holes at a time. The fork protrudes and recedes to engage the sprocket holes. Some cameras are equipped with pin-registering mechanisms, which hold the film firmly in place in the exposure gate, with the pins engaging sprocket holes.

In the early days of sound films, the noise made by the intermittent and other moving parts in the camera was loud enough to interfere with the sound picked up by the microphone. Cameras were sheathed ("blimped") with outer, separate sound-absorbing materials. The sound insulation is now usually self-contained in the camera.

The film drive

Before the introduction of sound, the film and intermittent were driven by a crank operated by the cameraman. With sound, considerably more uniformity in the speed of the film drive became necessary. For this and other reasons, the film drive in modern cameras is provided by an accurately controlled electric motor, which maintains the standardized sound speed of 24 frames per second.

The shutter keeps light from striking the film while it is moving from one frame to the next. A variable shutter opening can also be used to reduce exposure when it is necessary or desirable to do this without reducing the lens aperture. The shutter is in most cases rotary and is synchronized with the intermittent.

Viewfinding for motion pictures is especially critical: whereas still photographs can be cropped during enlargement or printing, the film image must be framed as it will appear on the screen. Older cameras employed a mechanical "rack-over" that enabled the camera operator to sight directly through the aperture with the film transport out of the way. When an external viewfinder is used, the image seen through it is not exactly the same as that photographed. The viewfinder must be angled so that it and the taking lens both point at the centre of the subject. A system of cams in the focus mechanism of the camera keeps the viewfinder image free of parallax (viewpoint difference) by adjustment from infinity to the near-point of the lens with a separate cam for each focal length.

Most cameras used today are of the reflex type. A partially reflecting mirror (beam splitter) is positioned in the door of the camera body or built into the lens itself with a parallel viewing tube. The mirror diverts to the viewfinder some of the light rays coming through the lens. This method's major drawback is that it takes away part of the light that would otherwise be used for the exposure. A much-admired viewing system that allows the full amount of light to reach the film is the rotating mirror shutter employed in the Arriflex camera. Light is reflected into the viewfinder only when the shutter blade covers the film as it advances to the next frame. This arrangement, however, is not wholly free from objections. Chief among these is that the arrangement opens a return path for light from the viewer's eyepiece to reach the film. The eyepiece must fit snugly around the eye while the viewfinder is in use, and the finder must be closed completely while it is not in use. In addition, since the camera shutter is closed only once per frame, the image will be subject to a distinct flicker, to which the cameraman must adjust himself. Some cameras incorporate a "video assist" or "video tap" wherein the viewfinder image is electronically fed to a video monitor or video recorder, thus allowing evaluation of the take by videotape replay.

Focusing has also been a perennial problem for the motion-picture camera. On the camera the position of the lens is precisely indicated on a calibrated scale. The actor's location on the set was formerly marked on the floor and the exact distance to the camera measured with a tape. The actor moved to previously marked places, and an assistant to the cameraman, called a focus puller, or follow-focus assistant, kept the lens in adjustment. Various electrical devices have now been introduced for remote adjustment by the assistant. Where a through-the-lens finder is used, focusing can be done directly, using the viewfinder image. Also, experienced cameramen can estimate distances quite closely.

It is usual to generate some kind of signal in synchronism with the intermittent when an auxiliary, magnetic-tape sound recorder is used, so that the sound record can later be synchronized exactly with the picture. The sync-generator provides a record of the speed of the camera motor; each frame of picture causes 2.5 cycles of a 60-hertz pulse to be recorded on the sync-track of the sound tape. A newer system is based on the "time code" originally developed for videotape. A separate generator uses a digital audio signal to provide each frame of film with its own number. For each take the time code generator is set to zero; when the camera and film are running, the generator starts to emit numbers that represent "real-time" in hours, minutes, seconds, and frames. In one system, a light-emitting diode next to the camera aperture records the information as ordinary numbers that can be read by the eye; in others, the binary numbers are contained in a control surface of magnetic particles on the base side of the

Time-code numbers

film. One hundred feet of 35-mm film would be rendered in time code as 00:01:07:08, or one minute, seven seconds, eight frames. Corresponding information is recorded on the "address" track of the audio tape. The time code's last two digits, which represent frames, go up to either 24 or 30. Material intended for theatres is photographed at the international sound projection speed of 24 frames per second. Material filmed for American television is often shot at 30 frames per second (in countries with 50 hertz AC power, the rate is 25 frames per second).

The camera is often supplied with electric motors to perform miscellaneous functions, such as to provide smooth rotation (panning) of the camera or to change the magnification in a zoom lens (or change lenses in a turret). The camera is normally provided with footage indicators to indicate the amount of film left unexposed and with frame counters used when it is desired to superimpose a second exposure. There can also be an "inching knob" to reposition the film to a given frame for multiple exposures. When the camera is used at a speed different from standard, a tachometer may be provided to indicate the actual speed.

The cameras that have so far been described are for the standard 35-mm film. Cameras for 65-mm film are generally quite similar, though heavier. The 16-mm professional camera may differ from the 35-mm in the form of its case, in its use of a spring-operated film drive, and in its method of film loading, as a result of its development from a former amateur camera. On the other hand it may be a smaller version and have the same features as the 35-mm model by the same manufacturer.

Camera supports. The camera must be mounted on a substantial support to avoid extraneous movements while film is being exposed. In its simplest form this is a heavy tripod structure, with sturdy but smooth-moving adjustments and casters, so that the exact desired position can be quickly reached. Often a heavy dolly, holding both the camera and a seated cameraman, is used. This can be pushed or driven around the set. When shots from elevated positions are to be used, both camera and cameraman are carried on the end of a crane, also on a dolly. In some cases the assemblage is smoothly driven to follow the action being pictured, such as movement along a street. If the surface being traversed is not smooth, rails, resembling train tracks, must be laid on the floor or ground for the dolly. The camera may be freed from the tripod or dolly and carried by the operator by means of a body brace and gyroscope stabilizer. One such support is the Steadicam, which eliminates the tell-tale motions of the hand-held camera.

Film formats

Film. Film types are usually described by their gauge, or approximate width. The 65-mm format is used chiefly for special effects and for special systems such as IMAX and Showscan. It was formerly used for original photography in conjunction with 70-mm release prints; now 70-mm theatrical films are generally shot in 35-mm and blown up in printing. With some exceptions the 35-mm format is for theatrical use, 16-mm for institutional applications, and 8-mm for home movies. The more frequently encountered film formats are illustrated in Figure 2. There are some minor differences in the shape of the sprocket holes in 35-mm film between negative and positive film. The first 8-mm film was made by using 16-mm film, punched with twice as many sprocket holes of the same size and shape. One side, to the middle line, was exposed in one direction. The supply and take-up reels were then interchanged in the camera, and the other side was exposed in the other direction. After processing, the film was split into two strips, which were spliced into one. An improved version of 8-mm stock, called Super-8 film, was designed with the idea of reducing the sprocket-hole size and employing the space thus made available for a larger picture area.

Originally, the film base was some form of celluloid or cellulose nitrate. This material is highly flammable, and extensive precautions were required in projection rooms to avoid film ignition because of the proximity of the projector arc lamp to the film. In 1923, when 16-mm amateur film was introduced, cellulose acetate (or safety film), much less flammable than the nitrate, was used. It

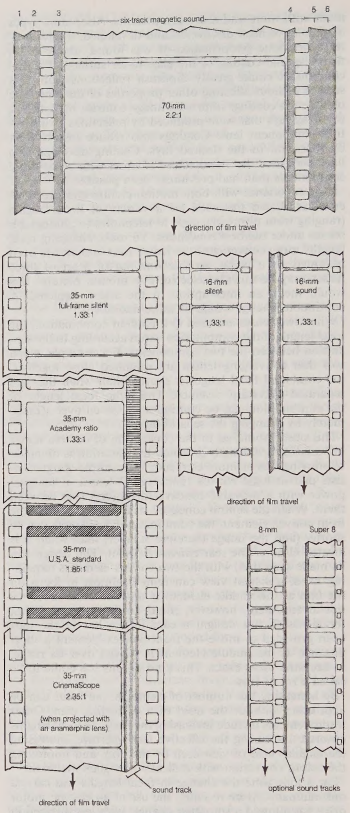

Figure 2: Film formats and usages (actual size).

was not considered desirable to adopt it for professional 35-mm film, largely because it was inferior in strength and dimensional stability. By the late 1930s an improved cellulose acetate safety film was introduced, and by the early 1950s it had generally replaced the nitrate film. Since 1956 acetate has lost ground to polyester- or mylar-based film, which is thinner, less brittle, and more resistant to tearing.

Emulsions. The film base is coated with a light-sensitive layer of silver halide emulsion; multiple layers are used for colour film. Emulsion manufacture is quite complicated and delicate. The earlier emulsions were most sensitive to violet and blue light, as shown schematically in Figure 3, curve *a*. Toward the cyan and green, sensitivity drops rapidly. Such an emulsion is called natural, or ordinary. The result of such a characteristic is that in a natural scene reds and yellows appear black in the positive, and green appears too dark. As early as 1873 it was found that dyes introduced into the emulsion could increase the sensitivity in the yellow and green (Figure 3, curve *b*). The change increased the natural appearance of the reproduced picture, and the emulsion was called orthochromatic. Later (1904) dyes were found to prolong the sensitivity into

Orthochromatic and panchromatic film

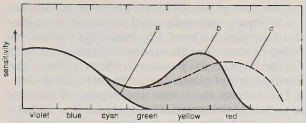

Figure 3: Sensitization of photographic emulsions (see text).

the red, and this emulsion is called panchromatic (Figure 3, curve *c*). The dates are fairly early for motion-picture application, but the development had importance in the general technology.

The overall sensitivity for picture taking has been increased greatly, from below about 10 ASA before 1930 to several hundred and even several thousand. The ASA (American Standards Association) scale is an arbitrary rating of film speed; that is, the sensitivity of the film to light. If everything else is kept constant, the required exposure time is inversely proportional to the ASA rating. Negative films designed for original picture exposure are usually faster (*i.e.,* have higher ASA ratings) than those for prints and are apt to be somewhat coarser grained.

Current technology has made use of a flatter crystal or "T-grain" that exposes more readily to light without an increase in the visible dimension of the grain. This enables use of very low light levels, especially when the film is "pushed" (given extended development) or "flashed" (prestruck with white light to accelerate exposure). When extreme sensitivity to light is not required, finer grain film may be used, particularly when it is intended to enlarge a 16-mm negative for 35-mm release or a 35-mm negative for 70-mm release.

The development of modern colour film

There are two major steps involved in making a dye image on motion-picture film. The first is to convert the negative silver image that is obtained from a normally exposed film into a positive dye image. The clue to how this can be done came from experience with a developer known as pyro (pyrogallol), once very popular with still photographers. A negative developed with pyro developer has not only a silver image but also a brown stain. Study of the process showed that the stain was caused by oxidation products given off locally by the developer in the development process. A substance in the developer reacts with these oxidation products to give an insoluble brown dye. The substance is called a dye coupler. Since the dye is not soluble, it does not wash off in the subsequent film treatment.

This suggested the possibility of bleaching to take away the silver image, leaving the dye image on the film. The first step was to find a developer and dye couplers that would produce the three dye colours that give a faithful three-colour picture rendering. The second step was to carry out the process in the film coating with three separate colours and keep them separate, all the way from exposure to the final three-colour image on the completed film.

The first portion of this second step is carried out by obtaining three emulsions that can be laid on top of one another and are sensitive, respectively, to the red, green, and blue of the exposing image without interfering with each other and that give corresponding silver layers that similarly do not interfere with each other.

It has been observed above that normal silver halide photographic emulsion is particularly sensitive to blue light and that one of the early problems was to obtain a more natural pictorial rendering by extending the sensitivity of the emulsion to green and finally to red light. The problem was solved by inserting appropriate dyes in the emulsion. The dye adds a peak of increased sensitivity, respectively, to green and red light, as in Figure 3. The triple-layer film then consists of, on the top, an ordinary blue-sensitive emulsion; below this, a yellow filter to cut off blue light; next below this, an emulsion with a sensitivity peak in the green, with the yellow filter cutting off blue sensitivity; and, finally, an emulsion with a peak sensitivity in the red, a valley in the green, and blue sensitivity cut off by the yellow filter. The sensitization can be chosen to locate and enhance the sensitivity peaks.

Thus, the blue layer responds to the blue light in the original, the green layer to the green light, and the red layer to the red light. These can be given a first development together, so that the individual responses will be indicated as silver deposits in the respective layers. The developer used is one which leaves no dye-coupler stains.

The non-substantive process

In what is called the nonsubstantive subsequent process, the dye couplers are introduced in a second development. Each colour layer is treated separately. Uniform red light is applied (from the bottom up) to expose the undeveloped silver halide in the red layer. It has no effect on the other layers because of their insensitivity to red. The film is processed with a developer containing a minus-red (or cyan) dye coupler. This leaves a silver and minus-red dye deposit wherever there was newly exposed silver halide in the red layer. Similarly, the blue layer, newly exposed with blue light from above and processed with a developer containing a minus-blue (or yellow) dye coupler, leaves a silver and minus-blue dye deposit wherever there was newly exposed silver halide in the blue layer. In the remaining green layer, a white-light exposure and development with a minus-green (or magenta) dye coupler converts the residual silver halide into a silver and minus-green dye deposit.

All the silver deposits and the yellow filter are finally bleached out. The remaining dye deposits serve to subtract from white light, in the manner that was described earlier, the correct part of the spectrum to leave the colour of the initial exposing light. For example, where this light was red, the final dyes absorb blue and green. Of the spectrum, this therefore leaves red light to go through the film.

The substantive process

In a modification called the substantive process, the appropriate dye couplers are suitably embedded in the emulsion in the appropriate colour layers to prevent their moving about during processing and contaminating the colours (an important problem). It is then possible to carry out the second exposure and development on all three layers in a single step with white light and with only one developer.

Nonsubstantive film is essentially an amateur medium that enables the camera original to be processed as a projection print. Commercial theatrical motion pictures are photographed on a colour negative stock containing dye couplers (*i.e.,* substantive type) from which prints can be made.

Lighting. The art of cinematography is, above all, the art of lighting, and the British term for the chief of the camera crew, lighting cameraman, comes closer to the matter than the Hollywood director of photography. In motion-picture photography, decisions about exposure are governed by the overall style of film, and light levels are set to expose the particular film stock at the desired f-stop.

Light sources. The earliest effective motion-picture lighting source was natural daylight, which meant that films at first had to be photographed outdoors, on open-roof stages, or in glass-enclosed studios. After 1903, artificial light was introduced in the form of mercury vapour tubes that produced a rather flat lighting. Ordinary tungsten (incandescent) lamps could not be used because the light rays they produced came predominantly from the red end of the spectrum, to which the orthochromatic film of the era was relatively insensitive. After about 1912, white flame carbon arc instruments, such as the Klieg light (made by Kliegl Brothers and used for stage shows) were adapted for motion pictures. After the industry converted to sound in 1927, however, the sputtering created by carbon arcs caused them to be replaced by incandescent lighting. Fresnel-lens spotlights then became the standard. Fresnel lenses concentrate the light beam somewhat and prevent excessive light loss around the sides. They can also, when suitably focused, give a relatively sharp beam. In the studio there are racks above and stands on the floor on which lamps can be mounted so that they direct the light where it is wanted. The advent of Technicolor led to a partial reversion to the carbon arc because incandescent light affected the colours recorded on the film. Around 1950, however, economic pressures caused Technicolor film to be rebalanced for incandescent light.

The modern era in lighting began in the late 1960s when

Tungsten-halogen lamps

tungsten-halogen lamps with quartz envelopes came into wide use. The halogen compound is included inside the envelope, and its purpose is to combine with the tungsten evaporated from the hot filament. This forms a compound that is electrically attracted back to the tungsten filament. It thus prevents the evaporated tungsten from condensing on the envelope and darkening it, an effect that reduces the light output of ordinary gas-filled tungsten lamps. The return of the tungsten to the filament means that the incandescent lamp can be run with a long life at a higher filament temperature and, more important, remain at precisely the same colour temperature. These lamps are now sometimes provided with a special multilayered filter to give a bluish light that approaches the colour of daylight. Halogen lamps give brilliant light from a compact unit and are particularly well-suited to location filming.

The principal light on a scene is called the key light. The position of the key light has often been conventionalized (*e.g.*, aimed at the actors at an angle 45 degrees off the camera-to-subject axis). Another school of cinematographers prefers source lighting, in the tradition of Renaissance and Old Master paintings; that is, a window or lamp in the scene governs the angle and intensity of light. A fill light is used to provide detail in the shadow areas created by the key light. The difference in lighting level between the key plus the fill light versus the fill light alone yields the lighting contrast ratio. The "latitude" of the film, or the spread between the greatest and least exposure that will produce an acceptable image, governs the lighting contrast ratio. For many years, the latitude of colour films was so restricted that it was thought necessary to have numerically low lighting ratios, typically 2 to 1 (a very flat lighting) and never more than 3 to 1. The introduction of Eastman 5254 colour negative in 1968 and the even more sophisticated 5247 in 1974 opened a new era in which colour film was exposed with higher ratios approaching the previous subtleties of black-and-white.

Light measurement. Precise control of exposure throughout filming is necessary to maintain consistent tones from shot to shot and to give an overall tenor of lighting that suits the pictorial style. To determine light levels in the studio and on interior locations, an incident light meter is primarily used. This type of meter is recognizable by a white plastic dome that collects light in a 180-degree pattern (the dome is an approximation of the shape of the human face). Because it measures the overall light (calibrated in footcandles) falling on the scene, it may be used without the actors present.

Reflected light readings measure the average light coming toward the camera from the scene being photographed. This works well for average subjects but gives wrong exposures if the background contains either many bright areas, as in a beach scene, or very dark areas, as in front of a dark building. In such cases the photocell must be held not at the camera but very close to the subject of interest, to eliminate the effect of the background. This is also the case when the scene contains a good deal of backlight. These shortcomings eventually led to the development of the spot meter.

Spot measurement readings measure the light coming toward the camera from selected spots in the subject being photographed. The meter for this purpose has an optical system that covers measurement of a spot of about one degree, making it extremely useful on exterior locations.

Colour temperature

Light is also measurable in terms of colour temperature. Light rich in red rays has a low reading in kelvins. Ordinary household light bulbs produce light of about 2,800 kelvins, while daylight, which is rich in rays from the blue end of the spectrum, may have readings from 5,000 to more than 20,000 K. The colour temperature meter uses a rotating filter to indicate a bias toward either red or blue; when red and blue rays are in balance, the needle does not move. Some meters also use red/blue and blue/green filters for fuller measurement.

The general practice has been to shoot the entire picture on stock balanced for artificial light at 3,200 K. Lights for filmmaking generally range between 3,200 K and 3,400 K. For daylight shooting, an orange filter is employed to counter the film's sensitivity to blue light. Although colour-correcting filters are produced in a great many gradations, the No. 85 filter is generally used to shoot tungsten-balanced colour film outdoors. For mixed-light situations where daylight enters through windows but tungsten light is used for the interior, the practice has been to cover the windows with sheets of plastic similar in colour to the No. 85 filter. This reduces the colour temperature of the natural light to that of the artificial light. When the windows are very large, blue filters are sometimes placed on the lights and the No. 85 orange filter is used on the lens, as if filming in exterior daylight. Yet another approach is to supplement natural daylight with metal halide (daylight-balanced) lights. With the increase in location shooting, daylight-balanced high-speed films have been introduced to allow shooting in mixed-light situations without light loss due to filters.

Film processing and printing. In the early days of motion pictures, films were processed by winding on flat racks and then dipping in tanks of solution. As films became longer, such methods proved to be too cumbersome. It was recognized that the processing system should have the following characteristics: it must run continuously; it must be lighttight and yet capable of being loaded in daylight; and it must be as compact as possible to provide a minimum air surface for the processing solutions. A general form evolved that is still in use.

Continuous method of film processing

For continuous operation the film must be passed continuously through the solutions and folded back over rollers that do not touch the emulsion surface. It must be handled very carefully, as the impregnation with solution weakens the support, and the sprocket holes should not be engaged. Drive should, therefore, be accomplished by a light friction force at the edges.

Splicing on a fresh film without affecting the motion of the part of the film being processed is handled by using a storage unit or reservoir. This reservoir has a variable capacity so that the output end can be giving out film while the input end is stationary as the new film is spliced. Lighttight gates prevent all but a short length of film being light-struck at the very beginning or end of the film (and leaders may be used). The take-up-reel case is fastened in a lighttight way to the storage unit so that after splicing, the film is unreeled into the storage and processing units until the other end is reached, ready for splicing to the next film after changing cases.

Many tank shapes have been tried. Long vertical tanks provide for several passes of the film through each tank. The spools are designed so as to hold the film at the edges by friction. There are a number of types of drive, but all function gently to avoid strain. Sometimes the spools have multistepped edges to accommodate various film widths. The lower spools (or "diabolos") are more or less free but guided in a loose fashion so that they will not jam or tangle. The long vertical tanks give a minimum of air surface to the solution. The motion of the film through the liquid can be sufficient for proper contact of the film with the solutions, but sometimes submerged sprays with small jets of fine nitrogen bubbles are provided to increase the agitation.

The last receptacle in the processing sequence is a drying oven. There are several designs, some of which generally resemble the tank but without solution and are provided with heating elements. This receptacle does not need to be lighttight.

The processing steps for the many different types of film are similar in principle, though there are variations in specific solutions and treatments. One variation is known as reversal processing. After partial development, the camera original is bleached and given a second exposure of uniform white light. This yields a positive rather than a negative image and thus saves the cost of an additional generation.

In laboratory parlance, the major functions are divided into "front end" and "release print" work and may be performed at different facilities. Front end work begins even before shooting with tests by the cinematographer on the same film stocks that will be used for the production. These will be used as a guide when takes from the camera negative that come in from each day's shooting

are printed. A colour video analyzer reads the red, blue, and green records of the tests over a range of six f-stops to establish "printer lights." As desired, the work print may be "one light" (given uniform exposure) or "timed" (exposure corrected for scene-to-scene variations).

The original negative is stored until postproduction is finished. Positive work print is furnished in 1,000-foot rolls for editing. When all editing, including the insertion of optical effects and titles, is completed, the negative cutter matches the original camera film frame by frame at each editing point. The edited camera negative is combined with the synchronized sound track negative into a composite print called the answer print. (The first answer print is rarely the same as the final release print.) After all colour-correction and timing takes place, the information is recorded on perforated paper tape that serves to control both the exposure for each shot and the louvered filters that add red, green, and blue values.

The answer print

For theatrical distribution, exhibition release prints are not normally struck from the original camera negative. The original negative is used to make a master positive, sometimes known as the protection positive, from which a printing negative is then made to run off the release prints. Alternatively, a "dupe" negative can be made by copying the original camera negative through the reversal process. This yields a colour reversal intermediate (CRI) from which prints can be struck.

Printing takes a number of different forms. In contact printing, the master film (or negative) is pressed against the raw stock; this combination is exposed to light on the master film side. In optical printing, the master film is projected through a lens to expose the raw stock. In continuous printing, the master film and the raw stock both run continuously. Continuous printing is usually contact printing but can be optical, through a projected slit. In intermittent, or step-by-step, printing, each frame of the master film is exposed as a whole to a corresponding frame space on the raw film.

It is possible to print from one size master film to another size raw stock, such as 35-mm to 16-mm, or vice versa. In such cases the printing must, of course, be optical, and in the examples cited must be intermittent if there is a sound track. This is because 35-mm sound film has a spacing between frames and 16-mm does not. The sound track must be printed separately. The preferred method for making 16-mm versions of 35-mm films is to make a 16-mm negative by reduction from the 35-mm negative. Sometimes a 35-mm release print is reduced and printed by reversal, but this yields a coarser image. When 16-mm film is "blown up," the 16-mm negative is immersed in a solution that conceals scratches and grain as it is being rephotographed; this process is called wet-gate printing.

Film prints to be used for projection are given a coat of wax over the sprocket-hole areas. This eases the film passage between the pressure plates at the projection aperture.

Sound-recording techniques. The art of sound recording for motion pictures has developed dramatically. Most of the improvements fall into three areas: fidelity of recording; separation and then resynchronization of sound to picture; and ability to manipulate sound during the postproduction stage.

Optical recording. Until the early 1950s the normal recording medium was film. Sound waves were converted into light and recorded onto 35-mm film stock. Today the principal use of optical recording is to make a master optical negative for final exhibition prints after all editing and rerecording have been completed.

Magnetic recording. Magnetic recording offers better fidelity than optical sound, can be copied with less quality loss, and can be played back immediately without development. Magnetic tracks were first used by filmmakers in the late 1940s for recording music. The physical principles are the same as those of the standard tape recorder: the microphone output is fed to a magnet past which a tape coated with iron oxide runs at a constant speed. The changes in magnetic flux are recorded onto the tape as an invisible magnetic "picture" of the sound.

At first the sound was recorded onto 35-mm film that had a magnetic coating. Today sprocketed 35-mm magnetic tape is used during the editing stages. For onset recording, however, the film industry converted gradually to the same unperforated quarter-inch tape format widely used in broadcasting, the record industry, and even the home. Documentary and independent filmmakers were the first to develop and use the portable, more compact apparatus. Improvements in magnetic recording have paralleled those in the recording industry and include the development of multiple-track recording and Dolby noise reduction.

Double-system recording. Although it is possible to reproduce sound, either optically or magnetically, in the same camera that is photographing a scene (a procedure known as single-system recording), there is greater flexibility if the sound track is recorded by a different person and on a separate unit. The main professional use for single-system recording is in filming news, where there is little time to strive for optimal sound or image quality. Motion-picture sound recording customarily uses a double system in which the sound track remains physically separate from the image until the very last stages of postproduction.

Double-system shooting requires a means of rematching corresponding sounds and images. The traditional solution is to mark the beginning of each take with a "clapper," or "clapstick," a set of wooden jaws about a foot long, snapped together in the picture field. The instant of clacking then is registered on both picture and sound tracks. Each new take number is identified visually by a number on the clapper board and aurally by voice. A newer version of the clapper is a digital slate that uses light-emitting diodes and an audio link to synchronize film and tape.

Synchronizing sound and image recording

Precise synchronism must be maintained between camera and recorder so that sound can be kept perfectly matched to the visuals. (Lack of perfect synchronism is most conspicuous in close-up shots in which a speaker's lips do not match his voice.) On some occasions several cameras shoot a scene simultaneously from different points of view while only one sound recording is made, or several sound records may be taken of a single shot. Thus, to maintain synchronism, all sound and picture versions of a particular scene must be recorded at the same speed; the camera and the recorder cannot fluctuate in speed. One way to achieve this is to drive all cameras and recorders from a common power supply. Alternatively, synchronization may be achieved through the automatic, continual transmission from cameras to recorders of a sync-pulse signal sent by cable or wireless radio. More convenient yet is crystal sync, whereby the speed of both cameras and recorders is controlled through the use of the oscillation of crystals installed in each piece of equipment. The most advanced system uses a time-code generator to emit numbers in "real-time" on both film and tape.

The sound recordist. The main task of the recordist during live recording is to get "clean" dialogue that eliminates background noise and seems to correspond to the space between speaker and camera. Most of the nonsynchronous dialogue, sound effects, and music can be added and adjusted later. During shooting the sound recordist adjusts the sound by setting levels, altering microphone placement, and mixing (combining signals if there is more than one microphone). Major technical and aesthetic reshaping is left for the postproduction phase when overhead is lower, the facilities are more sophisticated, and alternative versions can be created. It is also the job of the sound personnel to record wild sound (important sound effects and nonsynchronous dialogue) and ambient sound (the inherent sound of the location). Ambient sound is added to the sound track during postproduction to maintain continuity between takes. Usually, wild sound and music are also adjusted and added then.

Microphones. Microphones of many different types have been used for sound recording. These may differ in sound quality, in directional characteristics, and in convenience of use. Conditions that may dictate the choice of a particular microphone include the presence of minor echoes from objects in the set or reproduction of speech in a small room, as distinct from that in a large hall. Painstaking adjustments are made by careful attention to the choice of microphones, by the arrangement and sound absorbency of walls and furniture on the set, and by the

Choice of microphones

exact positioning of the actors. For recording a conversation indoors, the preferred microphone is sensitive in a particular direction in order to reduce extraneous noises from the side and rear. It is usually suspended from a polelike "boom" just beyond camera range in front of and above the actors so that it can be pivoted toward each actor as he speaks. Microphones can also be mounted on a variety of other stands. A second way to cut down background noise is to use a chest (or lavaliere) microphone hidden under the actor's clothing. For longer shots, radio microphones eliminate the wires connecting actors to recorders by using a miniature transistor radio to send sound to the mixer and recorder. (P.Me./E.We./S.G.H.)

Editing. The postproduction stage of professional filmmaking is likely to last longer than the shooting itself. During this stage, the picture and the sound tracks are edited; special effects, titles, and other optical effects are created; nonsynchronous sounds, sound effects, and music are selected and devised; and all these elements are combined.

Picture editing. The developed footage comes back from the laboratory with one or more duplicate copies. Editors work from these copies, known as work prints, so that the original camera footage can remain undamaged and clean until the final negative cut. The work prints reproduce not only the footage shot but also the edge numbers that were photographically imprinted on the raw film stock. These latent edge numbers, which are imprinted successively once per foot on the film border, enable the negative matcher to conform the assembled work print to the original footage.

Work prints

Before a day's work, or rushes, are viewed it is usual to synchronize those takes that were shot with dialogue or other major sounds. Principal sound is transferred from quarter-inch to sprocketed magnetic tape of the same gauge as the film (*i.e.*, 16-mm or 35-mm) so that once the start of each shot is matched, sound and image will advance at the same rate, even though they are on separate strips. Once synchronism is established, the sound and image tracks can be marked with identical ink "rubber" numbers so that synchronism can be maintained or quickly reestablished by sight.

The editor first assembles a rough cut, choosing with the director one version of each shot and providing one possible arrangement that largely preserves continuity and the major dialogue. The work print goes through many stages from rough to fine cut, as the editor juggles such factors for each shot and scene as camera placement, relation between sound and image, performance quality, and cutting rhythm. While the work print is being refined, decisions are made about additions or adjustments to the image that could not be created in the camera. These "opticals" range from titles to elaborate computer-generated special effects and are created in special laboratories.

Editing equipment. Rushes are first viewed in a screening room. Once individual shots and takes have been separated and logged, editing requires such equipment as viewers, sound readers, synchronizers, and splicers to reattach the separate pieces of film. Most work is done on a console that combines several of the above functions and enables the editor to run sound and picture synchronously, separately at sound speed, or at variable speeds. For decades the Hollywood standard was the Moviola, originally a vertical device with one or more sound heads and a small viewplate that preserves much of the image brightness without damaging the film. Many European editors, from the 1930s on, worked with flatbed machines, which use a rotating prism rather than intermittent motion to yield an image. Starting in the 1960s flatbeds such as the KEM and Steenbeck versions became more popular in the United States and Great Britain. These horizontal editing systems are identified by how many plates they provide; each supply plate and its corresponding take-up plate transports one image or sound track. Flatbeds provide larger viewing monitors, much quieter operation, better sound quality, and faster speeds than the vertical Moviola.

Electronic editing. Despite the replacement of the optical sound track by sprocketed magnetic film and the introduction of the flatbed, the mechanics of editing did not change fundamentally from the 1930s until the 1980s. Each production generated hundreds of thousands of feet of work print and sound track on expensive 35-mm film, much of it hanging in bins around the editing room. Assistants manually entered scene numbers, take numbers, and roll numbers into notebooks; cuts were marked in grease pencil and spliced with cement or tape. The recent application of computer and video technology to editing equipment, however, has had dramatic results.

The present generation of "random access" editing controllers makes it likely that physical cutting and splicing will become obsolete. In these systems, material originated on film is transferred to laser videodiscs. Videotape players may also be used, but the interactive disc has the advantage of speed. It enables editors to locate any single frame from 30 minutes of program material in three seconds or less. The log that lists each take is stored in the computer memory; the editor can call up the desired frame simply by punching a location code. The image is displayed without any distracting or obstructing numbers on a high-resolution video monitor. The editor uses a keypad to assemble various versions of a scene. There is neither actual cutting of film nor copying onto another tape or disc; computer numbers are merely rearranged. The end product is computer output in which the "edit decision" list exists as time code numbers (see above *Cameras*).

Electronic editing also simplifies the last stage in editing. Instead of assembling the camera negative with as many as 2,000 or more splices, an editor can match the time code information on a computer program against the latent edge numbers on the film. Intact camera rolls can then be assembled in order without cutting or splicing. Electronic editing equipment has been used primarily with material photographed at the standard television rate of 30 frames per second. Material shot at the motion-picture rate of 24 frames per second can be adapted for electronic editing by assigning each film frame three video fields, of which only two are used.

Special effects. Special effects embrace a wide array of photographic, mechanical, pyrotechnic, and model-making skills.

The most important resource of the special effects department is the optical printer, essentially a camera and projector operating in tandem, which makes it possible to photograph a photograph. In simplest form this apparatus is little more than a contact printer with motorized controls to execute simple transitions such as fades, dissolves, and wipes. A 24-frame dissolve can be accomplished by copying the end of one film scene and the beginning of another onto a third film so that diminished exposure of the first overlaps increased exposure of the second. Slow motion can be created by reprinting each frame two or three times. Conversely, printing every other frame (skip printing) speeds up action to create a comic effect or to double the speed when filming action such as collisions. A freeze frame is made by copying one frame repeatedly.

The optical printer can also be used to replace part of an image. For example, a high-angle long shot in a western may reveal what looks like an entire frontier town surrounded by wilderness. Rather than take the time and trouble to actually build and film on location for a shot that may last less than a minute, filmmakers can make the shot using standing sets on the studio backlot, with skyscrapers and freeway traffic visible in the distance. One frame of the original scene is then enlarged so that a matte artist can trace the outline of the offending area on paper. When the copy negative is made, the offending area is masked and remains unexposed. The negative can then be rewound to film a matte painting of suitable location scenery. In addition to combining artwork with live action, optical printing can combine two or more live-action shots.

Optical printing

In the aerial image optical printer, the camera is aimed straight down at a ground glass easel on which an image is projected from below. The large image allows the artist to make a very precise alignment of the artwork and live action so that they can be filmed in one pass.

Optical printing can be combined with blue-screen photography to produce such effects as characters flying through the air. Ordinary superimposition cannot be used

Blue-screen photography

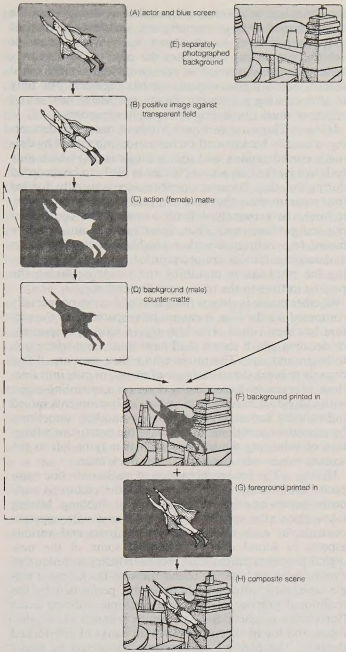

Figure 4: Steps in a blue-screen effect.

for this effect because the background will bleed through as the character moves. To create a traveling matte shot, it is necessary to obtain an opaque image of the foreground actors or objects against a transparent background. This is done by exploiting film's special sensitivity to blue light. In a traditional blue-screen process the actor is posed before a primary blue background, which, to avoid shadows, is illuminated from behind (see Figure 4A). Eastman No. 5247 colour negative is used to film the shot because its blue-sensitive layer yields a dense black-silver image in the area of the blue screen. On the positive print, the foreground action appears against a transparent field (see 4B). This image, printed with red light onto high-contrast panchromatic film, produces the action, or female, matte (see 4C). An additional generation yields a countermatte known as the background, or male, on which the action appears as an opaque silhouette (see 4D). This silhouette is placed with a separately photographed background (see 4E) in an optical printer. In the first pass through the optical printer, the background is "printed in" (see 4F). In the second pass, the actor and action matte are combined and the foreground is printed in (see 4G). All the elements are thus composited on one film (see 4H). There are many variations using more or fewer generations. In some systems the foreground is printed first. With a negative, or reverse, matte, the action matte is made from the camera negative and is opaque against a transparent background. The blue-screen process, in a form more complex than that described here, was used to create many spectacular effects in such films as *Star Wars* (1977) and *E.T.—The Extraterrestrial* (1982). The term blue-screen need not be taken literally. Blue-garbed Superman required a differentiated backing, and sodium vapour (yellow) light was used on the screen to yield a transparent background for the flight scenes in *Mary Poppins* (1964).

In the past two actors talking in a car were likely to be filmed in the studio using rear projection (process) shots; that is, the actors were photographed in front of a translucent screen through which previously filmed footage of passing scenery was projected. Location shooting and lightweight sound equipment have all but eliminated this formerly common practice in feature films, although it survives in television. When routine background replacement is still used in expensive productions, it is more likely to be done with blue-screen than with rear projection.

Front projection

The light loss and lack of sharpness (especially noticeable in colour) that made rear projection shots obvious has also inspired some interest in front projection. The camera is placed facing the screen, and the background projector is positioned in front of and to the side of the camera so that the beam it projects is perpendicular to the camera's line of sight. A semitransparent mirror is angled at 45 degrees between camera and projector; the camera photographs the scene through the glass while the mirror particles reflect the projection beam onto the screen. The screen is made of Scotchlite, the trade name for a material that was originally devised to make road signs that would reflect light from a car's headlight to the driver's eyes. Because camera and projector are in the same optical axis in the front projection process, the background illumination is reflected directly to the camera lens so brilliantly that it is not washed out by the lighting on the actors. The actors also mask their own shadows. Front projection was used to great effect in "The Dawn of Man" sequence in *2001* (1968) wherein a leopard's eyes lit up in facing the camera. Scotchlite screens have been used to reflect powerful lights that have been shone through tanks of dyed water to produce large-scale blue-screen effects.

To reduce the graininess that each generation of film adds to the original, concerns such as George Lucas' Industrial Light and Magic produce their effects on 65-mm film. Others, notably Albert Whitlock, have revived the old practice of making matte effects on the camera negative. In the silent film days, this was achieved using a glass shot in which the actors were photographed through a pane of glass on which the background had been painted. The Whitlock method employs a black matte in front of the camera. A hole is cut in the matte to expose the live action, which may account for only a small portion of the image. The partially exposed negative is rewound, and the background is photographed from a matte painting on glass on which the corresponding area of live action is absent.

Miniatures and models

Miniatures (scale models) are often used in special effects work because they are relatively inexpensive and easy to handle. Great care is needed to maintain smooth, proportionate movement to keep the miniatures from looking as small and insubstantial as they really are. Models may be filmed at speeds greater than 24 frames per second (*i.e.*, in slow motion) to achieve more realistic-looking changes in perspective and time scale. John Dykstra's Apogee, Inc., is a leader in the field of motion control, the use of computer-controlled motors to regulate the movement of models and camera in relation to one another, thereby improving the illusion of motion. The model aircraft or spacecraft can even be made to swoop and turn as they approach the camera.

Until recently it was difficult to introduce camera movement into special effects shots. Limited camera movement was achieved by moving the camera in the optical printer, thereby creating an optical zoom, but this method did not create a convincing illusion of three-dimensionality because the foreground and background elements, as well as the grain pattern in the film, were enlarged or reduced at the same rate. When a crane or dolly was used to shoot the live portion of the scene, the background had to be animated frame-by-frame, involving considerable expense in draftsmanship. Computer-enhanced animation has made it possible to store and recall the algorithms needed to model shapes and surfaces at varied perspectives.

The increased interface of film and video techniques has great implications in the effects area. The ease with which

colour components can be separated and reformed makes the electronic medium especially well suited to blue-screen and similar image replacement techniques. The creation of mattes through computer graphics rather than the laborious process of laboratory development is an obvious area of cost savings. Digital image storage on laser videodiscs, as in the Abekas system, enables images to be manipulated with ease.

Sound editing. Less than 25 percent of the sound track of a feature film may have been recorded at the time of photography. Much of the dialogue and almost all of the sound effects and music are adjusted and added during postproduction. Most sound effects and music are kept on separate magnetic tracks and not combined until the rerecording session.

Dialogue. Because of drastic changes in microphone placement from one shot to another, excessively "live" acoustics, background noise, and other difficulties, part or all of the dialogue in a scene may have to be added during postproduction. Production sound is used as a cue or guide track for replacing dialogue, a procedure commonly known as dubbing, or looping. Looping involves cutting loops out of identical lengths of picture, sound track, and blank magnetic film. The actor listens to the cue track while watching the scene over and over. The actor rehearses the line so that it matches the wording and lip movements and then a recording is made. The cutting of loops has largely been replaced by automatic dialogue replacement (ADR). Picture and sound are interlocked on machines that can run forward or backward. In the 1980s digitalized systems were developed that could, with imperceptible changes in pitch, stretch or shrink the replacement dialogue to match the waveforms in the original for perfect lip sync.

Dubbing

Dubbing also refers to the process of substituting one language for another throughout the entire picture. If this is to be done credibly, it is necessary to make the speech in the second language fit the character and cadence of the original. If the actor's face is visible in the picture it is also necessary to fit the words of the translation so that the lip movements are not too disparate. In the United States and England pictures intended for foreign distribution are prepared in a version with an M&E (music and effects) track separate from the dialogue to facilitate dubbing. In certain other countries, notably Italy, most dialogue recorded during production is meant merely to serve as a guide track, and nearly all sound is added during postproduction. One last form of speech recorded separately from photography is narration or commentary. Although images may be edited to fit the commentary, as in a documentary using primarily archival footage, most narration is added as a separate track and mixed like sound effects and music.

Sound effects. All sounds other than speech, music, and the natural sounds generated by the actors in synchronous filming are considered sound effects, whether or not they are intended to be noticed by the audience. Although some sounds may be gathered at the time of shooting, the big studios and large independent services maintain vast libraries of effects. Still other effects may be generated by re-creating conditions or by finding or creating substitute noises that sound convincing.

An expedient way of generating mundane effects is the "foley" technique, which involves matching sound effects to picture. For footsteps, a foley artist chooses or creates an appropriate surface in a studio and records the sound of someone moving in place on it in time to the projected image. Foleying is the effects equivalent of looping dialogue.

Background noise (room tone or presence) from the original location must be added to all shots that were not recorded live so that there is continuity between synchronous and postsynchronized shots. Continuous noises, such as wind or waves, may be put on separate tracks that are looped (the beginning of a track is spliced to follow its end), so that the sound can be run continuously.

Sound effects can be manipulated with the use of digital technology known as audio signal processing (ASP). The sound waveform is analyzed 44,000 times per second and converted into binary information. The pitch of a sound may be raised or lowered without altering the speed of the tape transport. Thus, engineers can simulate the changes in pitch perceived as an object, such as an arrow or vehicle, approaches and passes the camera. Sounds may be lengthened, shortened, or reversed without mechanical means. Some digital systems enable engineers not only to alter existing sounds but also to synthesize new sound effects or music, including full symphonic scores.

Music. There are two basic kinds of music; underscoring is usually background orchestration motivated by dramatic considerations, and source music is that which may be heard by the characters. Neither is likely to be recorded during shooting. Because a performance is usually divided into separate shots that take minutes or hours to prepare, it would be extremely difficult to produce a continuous musical performance. Thus, most musical numbers are filmed to synchronize with a playback track. The songs and accompaniment are prerecorded, so that during filming the musician is mouthing the words or faking the playing in time to the track recorded earlier.

Underscoring and source music

Whether music is chosen from music libraries or specially composed for the film, it cannot be prepared until the picture has been edited. The first step in scoring is spotting, or deciding which scenes shall have music and where it is to begin and end. The music editor then uses an editing console to break down each use of music, or cue, into fractions of seconds. Recording is done on a recording stage, with individual musicians or groups of instruments miked individually and separated from one another, sometimes by acoustical partitions. In this case the conductor's function of balancing the instrumentalists may be left to the scoring mixer, who can adjust each track later.

Mixing. The final combination of tracks onto one composite sound track synchronous with the picture is variously known as mixing, rerecording, or dubbing. Mixing takes place at a special console equipped with separate controls for each track to adjust loudness and various aspects of sound quality. Although some of the new digital processes employ the record-industry technique of overdubbing, or building sound track-by-track onto a single tape, most mixing in films is still performed by the traditional practice of threading multiple dubbing units (sprocketed magnetic film containing separate music, dialogue, and sound effects elements) on banks of interlocked dubbers. The playback dubbers are connected by selsyn motors to one another, as well as to the rerecorders that produce the master, or parallel music/dialogue/effects (M/D/E), track on full-coat magnetic stock. Also in interlock are a projector that allows the mixer to work from the actual image and a footage counter that allows the mixer to follow cue sheets, or logs, which indicate by footage number when each track should be brought in and out.

The mixer strives to strike the right dramatic balance between dialogue, music, and effects and to avoid monotony. Mixing procedures vary widely. Some studios use one mixer for each of the three main tracks, in which case the effects tracks have probably been mixed down earlier onto one combined track. In the early days of magnetic recording, stopping the rerecording equipment produced an audible click on the track; if a mistake were made, mixing would have to be redone from the beginning of the tape reel. The advent of back-up recording in the 1960s eliminated the click, making it possible for mixers to work on smaller segments and to correct mistakes without starting over. This enables the mix to be controlled by one person, who may be combining as many as 24 tracks. An even greater advance is the computerized console that enables the mixer to go back and correct any one track without having to remix the others.

Back-up recording

For monaural release, a composite music/dialogue/effects master on full-coat 35-mm magnetic film is converted to an optical sound negative. For stereo, four-track submasters for M/D/E are mixed down to a two-track magnetic matrix encoded to contain four channels of sound information. Optical sound negatives are copied from the magnetic master, and they are then composited with the picture internegative so that they are in projection sync (on 35-mm prints the sound is placed 21 frames in advance of its corresponding image; on 16-mm

prints the sound is 26 frames in advance of the picture).

Because of narrow track width, optical stereo sound tracks require a system of noise reduction such as Dolby Type A. The Dolby system works by responding to changing amplitudes in various regions of the frequency spectrum of an audio signal. The quieter passages are boosted to increase the spread between the signal (desired sound) and the unwanted ground noise. When played back, normal levels are restored, and the ground noise drops below the threshold of audibility.

Projection technology and theatre design. *Projectors.* The projector is the piece of motion-picture equipment that has changed the least. Manufacturers produce models virtually identical to those of the 1950s, and even the 1930 model Super Simplex is still in wide use. The essential mechanism is still the four-slot Maltese cross introduced in the 1890s. The Maltese cross provides the intermittent Geneva movement that stops each frame of the continuously moving film in front of the picture aperture, where it can be projected (or, in a camera, exposed). The movement starts with a continuously rotating gear and cam (see Figure 5, top). Each 360-degree rotation of the gear and cam causes a pin to engage one of the slots of the Maltese cross. The pin rotates the cross, which in turn rotates a shaft, one quarter turn. As the shaft rotates, four of the 16 teeth on the intermittent sprocket advance and engage the perforations (sprocket holes) on one frame of the film. The sprocket moves only when the pin is fully engaged in the Maltese cross slot (see Figure 5, bottom). This is the "pull-down" phase; in the other phases the curved surfaces of the cam and the cross are in contact and the movement is in the "dwell" position. The Geneva movement is also called a 3:1 movement because there are three quarter-cycles of dwell for every one quarter-cycle of pull-down.

Intermittent Geneva movement

Sound, unlike images, cannot be reproduced intermittently; sound must be continuous to be realistic. The optical-sound-reading equipment on a projector is therefore

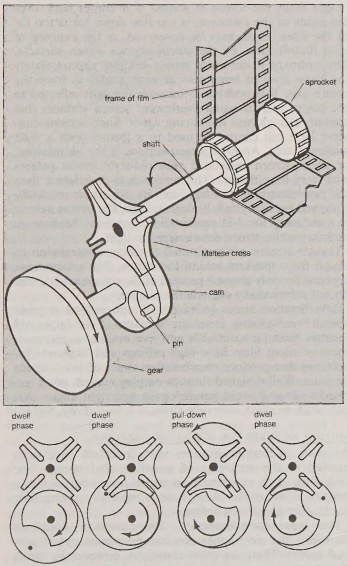

Figure 5: (Top) Intermittent Geneva movement. (Bottom) Successive positions of the Maltese cross.

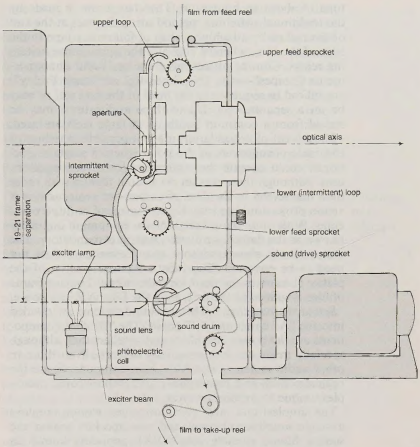

Figure 6: Film path in a typical 35-mm theatrical projector with optical sound reproducer (doors removed).

located below the picture aperture (see Figure 6), and the sound on an optical 35-mm print is located 21 frames ahead of its corresponding image. A light beam (supplied by a direct current for stability) is shone through a rectangular slit and focused by a lens to dimensions of .001 by .084 inch onto the sound track. The sound track's varying bands of light and dark then modulate the amount of light from the beam that is allowed to pass to the optical pickup. In older equipment this pickup was a photoelectric cell that changed electrical resistance under exposure to light. Newer designs employ a solar cell of photovoltaic material to convert light energy to electric energy.

An important element of picture quality on the screen is brightness. For decades the standard light source was the carbon-arc lamphouse, which used disposable electrodes (positive and negative carbon-clad rods) that would be moved together as they burned; the rods needed to be replaced every hour or so. Xenon lamps were introduced in West Germany in the 1950s, and carbon-arc projection is now found only in older theatres. Both carbon-arc and xenon lamps are run off a direct-current power supply in order to minimize brightness variations due to fluctuations in voltage. The xenon bulb replaces the positive and negative carbons with a tungsten anode and cathode in a quartz envelope filled with xenon gas under pressure. Light from xenon bulbs has a colour temperature closer to that of daylight than carbon-arc light does; that is, it is bluer and is therefore particularly well suited to colour films.

Carbon-arc and xenon lamps

Projection techniques. A 35-mm exhibition print is furnished to the theatre mounted on 2,000-foot (22-minute) reels. Thus, a typical feature film consists of five or six reels. For decades, the 2,000-foot reel was the basic unit of projection, and each screening required four or five changes of projector. Circular cue marks printed in the upper right corner of the picture indicated when each changeover should take place. Today the 2,000-foot reel is used primarily in single-screen theatres and in archival and repertory theatres that may present only a single screening of a film. Theatrical exhibition increasingly requires the film to be "made up"—that is, reels must be spliced together to enable the projectionist to make a single changeover between large reels or to use external transports that contain an entire feature without changeovers. For the former, a feature film of six 2,000-foot reels would be reassembled onto two 6,000-foot reels with a running

Changeovers

time of about an hour each. The changeover is made by the traditional switching method using the cues at the end of the reel or by attaching a strip of foil sensor tape to the edge of the film, where it activates the appropriate switching relays. Coming attractions ("trailers") and announcements ("snipes"—*e.g.,* "No Smoking" or "Starts Friday") are spliced in sequence at the head of the first reel or may be on a separate reel. Up to three auditoriums may be served from a common booth when large reels are used.

The advent of xenon lamps made it possible to reduce or eliminate changeovers to the point where a single projectionist could operate the equipment for several auditoriums. Although there was an occasional theatre with more than one screen in the days of carbon-arc projection, it is xenon projection that truly began the age of multiplex cinemas. With more than three screens, equipment popularly known as the flatbed, or platter, system is mandatory. The entire film is shown without changeovers and does not need to be rewound. The most advanced version of the platter eliminates the need for rethreading. The last frame of film is spliced to the first, as in the Edison Kinetoscope.

Sound reproduction. Theatre sound systems are divided into the "A" chain and "B" chain. The "B" chain components are the power amplifiers and speakers that, although specially made, are not essentially different from those in other audio systems. The "A" chain components are the optical pickup and preamplifier and employ some principles unique to motion pictures.

The simplest and most common sound system employs a single amplifier channel and one speaker behind the screen. Stereo variable area (SVA), popularly known as Dolby, though in fact made by several manufacturers, employs a split optical pickup for two sets of wires for the left and right channels. Three stage speakers (left, right, and centre) are mounted behind the screen, and an array of speakers is spread along the side and rear of the auditorium for "surround" sound. Most feature films are prepared so that dialogue issues from the centre speaker, music and on-screen sound effects from the left and right, and off-screen sounds from the surrounds. A processor decodes the four channels from dual variable area tracks; information appearing on the left track is sent to the left speaker, on the right track to the right speaker, while information on both tracks is combined in the centre channel. The surround channel is derived from inversion phase relationships between the left and right tracks.

In monaural systems, a treble cut is employed in accordance with the Standard Electrical Characteristic of 1938, or Academy Curve, so that frequencies above 8,000 hertz (Hz) are "rolled off." This practice dates from an era when sound tracks had a large degree of ground noise and vacuum tube amplifiers produced an audible hiss concentrated in the upper frequencies. A treble boost is added during rerecording so that monaural sound tracks sound shrill and sibilant when played without the Academy filter. The introduction of Dolby noise reduction in conjunction with optical tracks made it possible for frequencies to range up to about 12,000 Hz. With the replacement of tube power amplifiers by solid state ones, large wattages are easily obtainable, and theatre sound is generally louder than it was formerly. The normal level for dialogue in a monaural film is 80 decibels (dB) in the centre of the auditorium; the normal Dolby level is 85 dB, or nearly double that.

SVA is a direct replacement for the four-track magnetic sound introduced in 1953 in conjunction with CinemaScope. Today, magnetic sound is used only with 70-mm prints where six tracks are contained in four stripes of magnetic oxide embossed on the film. The magnetic reproducer, called a penthouse, is mounted above the projector. On a magnetic print, the sound displacement is behind the picture (28 frames in 35 mm and 23 frames in 70 mm).

Until recently, theatre speakers were not capable of reproducing sounds below 80 Hz. The standard theatre speaker was a two-way system with a high-frequency horn mounted atop a cabinet containing a wide, shallow paper cone woofer. The impetus given to 70-mm six-track sound by the great success of *Star Wars* led to the development of the THX system for exhibition. In the six-track system, five stage speakers are mounted in a flat baffle wall behind the screen; each has double 15-inch woofers for low-frequency reproduction down to 40 Hz. For frequencies down to 30 Hz, sub-woofers are connected to a bass extension module that augments signals below 100 Hz on the tracks. At this level, sound is not heard but felt as vibration in the viewer's diaphragm. The THX system delivers undistorted sound up to a level of 108 dB per channel.

THX system

Auditorium design. The most crucial consideration of theatre design is the relationship of picture size to the seating area. In the 1940s the Society of Motion Picture Engineers propounded the "two and six rule," which stated that the first row of seats should be at a distance from the screen equal to twice the picture width and the last row at six picture widths. This rule was based on the Academy picture ratio of 1.33 to 1, which is no longer used except for revival showings. The rule is still valid, however, because the wide-screen formats derive their impact from extension of the picture into the viewer's peripheral vision, and proper installation will maintain constant picture height through all formats.

Depending upon the seating capacity of the auditorium, the image may be made larger or smaller by changing the focal length of the lens. The lens size is calculated by multiplying the "throw" (distance from lens to screen) by the width of the aperture and dividing the total by the picture width. Thus, to produce a picture 18.5 feet wide in 1.85 format (aperture width .825 inch) in an auditorium having a 90-foot throw would require a 4-inch lens.

Screen brightness

The recommended level of screen brightness is 16 foot lamberts in the centre of the screen (with no film in the aperture), but a level of 12 to 14 foot lamberts is more typical for commercial cinemas. It is difficult to illuminate a large picture, because screen brightness decreases in proportion to the square of the increase in screen size; *i.e.,* the light source used to produce a 30-foot-wide picture will have to be not twice but four times as bright as that for a 15-foot image.

Light from the screen is wasted if it comes back over the heads of the audience, is too low down, or is too far to the sides. Light may be conserved, at the expense of even illumination, by the use of various screen surfaces. The ordinary matte-white screen exhibits approximately the same level of brightness at wide angles as from the centre axis. It is possible to increase the light reflected to the centre axis by using pearlescent screen surfaces that contain a brightness enhancing agent. Such screens conserve light but cannot be used in a theatre with a wide audience area. Another screen surface is the aluminized, or silver, screen associated with old-style movie palaces with very long throws. This screen is even brighter than the pearlescent version but loses its brightness markedly if viewed from beyond 20 degrees from the centre axis. It is mandatory for 3-D presentation, however, because an ordinary white screen depolarizes the light.

Theatre screens are perforated to allow transmission of sound from speakers behind the screen. The perforations account for only about 8 percent of the screen surface and do not substantially degrade the picture.

Reverberation times in excess of one second degrade speech intelligibility from the speakers. Very large, old theatres built for vaudeville and live musical accompaniment of silent films have high ceilings and large interior volumes that produce reverberation times of two seconds or more. Well-designed theatres employ curved, often serrated walls and avoid parallel walls and right angles that can produce short-path reflections. (E.We./S.G.H.)

MOTION PICTURES FOR SCIENTIFIC PURPOSES

As soon as motion pictures were invented, they were applied in the recording of scientific phenomena. The recording of an experiment in which a number of things happen at about the same time is especially appropriate for motion-picture recording.

Time-lapse cinematography. There are many occasions on which the cinematography can be carried out at normal speeds. There are other situations, however, in which the changes occur very slowly, so slowly that the eye does not discern the change. One example is the opening of

a flower blossom. In such a situation the technique used is to take successive pictures at intervals of, for example, an hour, taking great care not to move the camera or the plant and to project the resulting film at normal motion-picture speed. The projected picture will disclose many details in the development from the bud to the completed flower that are not apparent in ordinary visual observation. Other phenomena can be studied in this way.

These techniques require merely a standard camera that can take single exposures, plus a timed triggering device that can take the exposures at the desired intervals. The rest of the technique is mostly a matter of preventing undesired motions of camera and subject.

High-speed cinematography. Motion pictures have also been used to study phenomena that occur so fast that they cannot be recorded on normal cameras. An immense amount of ingenuity has been applied to the solution of many problems in this field.

Optical systems outside the camera. Shadowgraph film can show sharp shadows of fast-moving bodies, indicating their speed and any changes of attitude they undergo. With a rapid enough exposure this procedure can also show the sharp shadow of a wave front in air.

Schlieren optics show changes in the condition of a test area of space in the optical path, even when it remains fully transparent. A simplified outline of the arrangement is shown in Figure 7. A source sends out a beam of light through the apparatus to a film. Half the field is cut off by a knife-edged screen, K_1, which is imaged by a lens, L_1, to a position, K_1', in the same plane as a matching screen, K_2. The knife-edges of image and screen exactly coincide. A test position, T, is sharply focused on the film. Thus the light flow past K_1 to K_2 is all cut off from the film if the space at T is completely uniform. Any nonuniformity, such as caused by a wave front in the air at T, causes a scattered light beam to evade the screen, K_2 (path *a*), and reach the film.

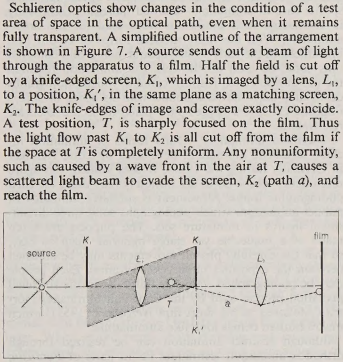

Figure 7: Schlieren optical system (see text).

The Schlieren interferometer is a modification of the system shown in Figure 7. An apparatus that polarizes the light beam—separating it into two slightly different paths and then reintegrating it into one path—is inserted before and after the area T to bring out details of the phase of the light as it progresses from left to right. These details appear in the form of light and dark phase bands, or fringes. They outline the disturbance of the wave by any nonuniformity existing at T. Counting the number of fringes displaced gives a measure of how great the nonuniformity is. The arrangement is especially adaptable to detecting and measuring irregular flow phenomena and wave fronts in the air (or another fluid) at T.

Spectrometric studies

A spectrum of a self-luminous subject is often obtained. Sometimes the spectrum varies quickly, as in an explosion, and it is desired to study the variation. The light output from the spectrometer is led into a motion-picture camera that can handle the speed needed, and a film record is taken. The film can then be studied at leisure.

Framing. The normal-speed camera records on the film a succession of frames, each showing a complete picture but taken at successive instants of time. Not all high-speed cameras record in this way, but some do, and the various methods of separating the frames and recording them represent key elements in the technology.

When a cube (or many-sided prism) is rotated in the optical path in a camera, it moves the image periodically past the picture aperture. If the film is moved in the same direction at the same speed, the image, while it is appearing, is fixed on the film. The problems are that, during its appearance, the image does not move with an exactly constant velocity, and the prism introduces some optical distortion of the image. These can be partially remedied by a variety of modifications, but there are still residual imperfections. The rotating prism device is used, however, up to about 10,000 frames per second. A variation, in which an internal mirror drum with many facets is used instead of a glass prism, is usable up to about 40,000 frames per second. In evaluating the performance of the system, the size of the frames and sharpness of the images must be considered, as well as the number of frames per second.

Rotating-mirror systems

Rotating-mirror systems take a number of forms, but Figure 8 shows a reasonably typical arrangement. The objective lens forms a primary image at the rotating-mirror position. The mirror reflects this image through an arc of fixed, individual relay lenses in succession on the stationary film. The relay lenses having the primary and final images both in focus keep the final image fixed at each place in succession on the film as the beam traverses each lens. With some rotating-mirror systems it is possible to go to some 5,000,000–10,000,000 frames per second (again keeping in mind that frame size and image sharpness are important as well). The arrangement wastes light, so that bright original subjects are necessary for a satisfactory exposure. The system has been used to study explosions and plasmas and to study subjects by reflected light with very high-intensity illuminants.

The central idea of the image dissector technique is to cut up a picture in the same way that a television picture is cut into horizontal scanning lines. The bright lines are made very narrow, with black or empty spaces between them, which permits superimposing other, similar pictures—also cut into fine lines separated by empty spaces. A number of pictures can be superimposed in this way without the lines interfering with each other. Lenticulations (embossed lenslike shapes) on the film form the scanning lines and concentrate the incoming light into fine lines on the film, according to where the light comes from on the objective lens.

The method will also work with two sets of lenticulations, one horizontal and the other vertical and superposed. This permits the storing of more pictures on the record film—in this case, as dots instead of thin lines. A number of devices based on these general ideas have been used. The frame speeds achievable vary with the specific arrangements but are generally lower than with the moving-mirror mechanisms.

The number of frames in Figure 8 may be increased to infinity by changing the optical system to put the primary image on the film and leaving out the relay lenses or, more simply, to replace the mirror with the film on a rotating drum. This requires compressing the individual frame from a two-dimensional into a one-dimensional image or slit. The equipment becomes a "streak camera." It is useful when there are one or more distinct demarcations in the one-dimensional view of the subject and it is desired to record their motion along a more or less straight line.

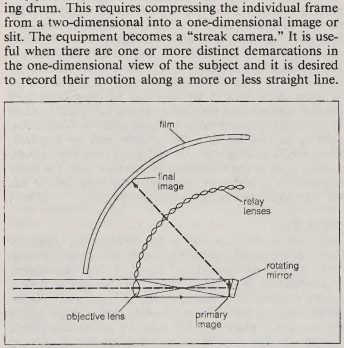

Figure 8: Arrangement of the principal parts of a rotating-mirror system (see text).

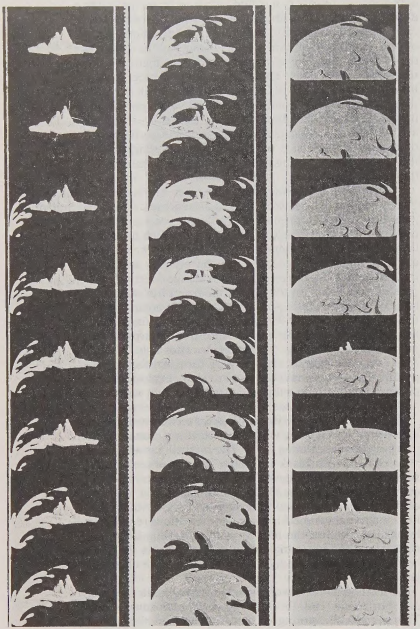

Figure 9: Twenty-four frames, the length of film projected each second, from *If You Could See the Earth*, an educational film. The jagged white line to the right of each frame is the sound track.
EB Inc

This is useful, for example, in recording the motion of the front of an explosion cloud or of a projectile. It leaves no unexplored areas of time, as does a framing record.

Illumination. The need for sufficient light is a most important requirement in high-speed cinematography. This need is so great that it is often undesirable to keep the light on longer than absolutely necessary, so that in many cases the light being turned on and off acts as a shutter. High-intensity, short-time sources have been studied extensively. Most sources consist of electrical discharges or, in some cases, arcs in air or a gas. In most cases they involve sophisticated electronic control methods. In cases in which the original subject is sufficiently self-luminous, such as in explosions, a fast shutter may be required. Since mechanical shutters do not go to very high speeds, various types of electro-optical shutters are used. On some occasions it is necessary to amplify the light after it has left the subject and before it reaches the film. (P.Me.)

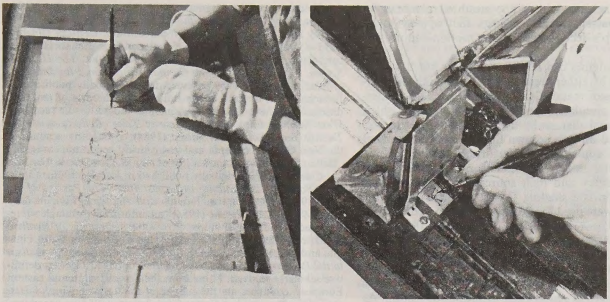
ANIMATION

The basis of all animation is the building up, frame by frame, of the moving picture by exact timing and choreography of both movement and sound. All film movement is achieved by projecting during every second of time a certain number of frames, normally 24, each a still photograph minutely varied from its predecessor, which record the successive phases of the subject's movement before the camera. The same motion, or a stylized or caricatured version of it, can be achieved by "stop-motion" or "stop-action" cinematography, the frame-by-frame photographing of a similarly phased series of drawings (see Figure 9) or the phased movement of such objects as puppets, marionettes, or commercial products. And, as in live filming, the camera itself can create movement by tracking into a scene or panning across it. The great majority of animated films are short and have always been so for obvious reasons. When each second of action requires, for the fullest animation, 24 adjustments of the image, a minute's action may call for many hundreds of drawings.

The range of techniques in animation production is broad. The basic form is the simple, outlined figure, however, that moves against a simple, outlined background.

Figural basis of animation. The development of cel (or cell) animation permitted the phased movements of the figures to be traced onto a succession of transparent celluloid sheets and superimposed, in turn, onto a single static drawing representing the background. With this technique the background could be drawn in somewhat greater detail and tonal qualities introduced through shading, while the figure itself became a black silhouette, blotting out the background when the cels were superimposed. Multiple cel animation—the superimposition of several cel layers, each carrying different figures or parts of figures requiring special care in animation—allowed increased complexity in the image with minimum work load for the artist-animators. With the more modern forms of colour film introduced in the early 1930s, opaque paints and coloured inks could be used on the cels. Cel animation required the use of a so-called rostrum camera, which photographs downward onto the background with its series of superimposed cel layers pegged into place to secure accurate registration.

Cel animation



Noncellular animation. Other forms of animation include silhouette animation, developed by Lotte Reiniger in Germany during the 1920s. It uses jointed, flat-figure marionettes whose poses are minutely readjusted for each photographic frame. Movement is similarly simulated in puppet animation, which photographs solid three-dimensional figures in miniature sets. The puppets are often made of a malleable yet stable material, such as clay, so that the carefully phased movements may be adjusted between the exposures of successive frames. Even people may be photographed frame by frame, as in the so-called pixilation process used by the Canadian filmmaker Norman McLaren in his short film *Neighbors* (1952), which makes human beings look like automatons.

Although abstract animation can be realized through orthodox animation techniques (as in parts of *Fantasia*, 1940), it may also be inked or painted directly onto the film. This form of abstract animation was pioneered in the 1920s with the individual and collaborative work of the German Hans Richter and the Swede Viking Eggeling and continued in the 1930s with the films of Len Lye, a New Zealander also known for his abstract sculpture. McLaren, too, experimented with a wide range of techniques for animating directly on film; he even created many of his scores by stenciling directly onto the sound track rather than recording in the traditional manner. Since the 1970s, computers have often been used to generate abstract or stylized patterns, and means were developed to circumvent photography by transferring the results directly to 35 mm.

Abstract animation

Planning. The preparation of these films, whatever their length or form, follows a similar process. First comes the story, plot, action, or situational idea, which may be a written treatment with or without supporting sketches. It describes the continuity of what it is proposed should take place on the screen, the nature of the cartoon or puppet characters, the graphic stylization of the film as a whole, and similar considerations. Such a treatment, perhaps very brief, precedes any fuller scripting or other elaboration that may take place.

Since visual emphasis is the key to animation, and sound its close counterpart, the sooner ideas are translated into pictures the better. The "storyboard" provides the continuity of the action, which is worked out scene by scene simultaneously with the animation script. In the storyboard the story is told and to some extent graphically styled in a succession of key sketches with captions and fragments of dialogue, much like a cartoon strip but with much

Techniques of animation art.

fuller treatment. A feature-length film could easily require a final continuity of several hundred such sketches.

Meanwhile, an animation director is also preparing modeling drawings for the principal characters and drawings establishing the backgrounds, or settings, for the film. These begin to indicate the general graphic style and, when colour is involved, the colour scheme and decor to be used. The modeling drawings must indicate the nature and temperament of the characters as well as their appearance when seen from a variety of angles and using a number of characteristic gestures. These will act as guides for the key animators, who with their assistants must bring the figures to dramatic life through the succession of final drawings created on the drawing board.

Animated films are, in effect, choreographed; since mobility involves time, the movements must be exactly timed and so deployed through the right number of successive drawings, like notes in music deployed through bars in a score. When the characters speak or sing, their lip movements must be synchronized with the words they appear to utter. When sound tracks, both dialogue and music, are prerecorded, the animators have an exact time scheme to follow; if the tracks are not prerecorded, then the "scoring" of the action will control the subsequent timing of the speech and music at recording stage. The timing in either case is predetermined on paper in a workbook, which grades the progression of the animators' drawings frame by frame with the same precision as a musical score. A similar control in the form of a time chart may be created by the director as a guide for the composer. A third control, the so-called dope sheet or camera exposure chart, guides the rostrum cameraman in the frame-by-frame setups and sequence of cels or backgrounds.

Sound synchronization

Execution. When the exacting labour of animation is under way, difficult moments in the choreography of the figures may be "line-tested"—that is, outlined in pencil, photographed, and tested out on the screen for rhythm and characterization. The key, or senior, animators draw, or "cartoon," the highlights, or salients, of the movement, perhaps the five or more drawings out of the 24 per second that will give the special edge of liveliness or characterization to the movements. Assistant animators, sometimes called in-betweeners, close the gaps by completing the intermediate drawings. The smaller the animation unit, the greater the burden each artist has to bear in the preparation of final drawings. These drawings, the backgrounds of which remain on drawing paper, are transferred to the cels by specialized artists, who trace the animators' work and paint over it with opaque colouring. The work of tracing and painting can be saved when the animators draw directly on the cels with coloured chinagraph pencils, which they can rub out or correct without harm. When the picture track and the sound track with speech, sound effects, and music dubbed together are completed under the control of the director and the editor, a "married print" can be made, with the track recorded optically. (R.M./E.We.)

Newer techniques. In the 1950s, animation studios such as Hanna-Barbera sought to lessen the extraordinary labour and costs of animation so that they could quickly produce cartoons for television. To do so, they employed the technique of limited animation, in which each drawing is repeated for two to five frames. The resultant movements are jerky, rather than smoothly gradated, and often only part of a body is animated and the remaining parts of the figure do not change at all. Another shortcut, cycling (reusing the same series of drawings over and over) is maximized in limited animation, especially when characters are walking or talking. Since the early 1980s, however, the use of computers has supplanted limited animation as a cost- and labour-saving method.

Today computers are used in virtually every step of sophisticated animation. Computers have been used, for example, to automate the movement of the rostrum camera or to supply the in-between drawings for full animation. They can also be used to modify or enhance a drawing that has been created by hand. If a three-dimensional figure is translated into computer terms (*i.e.*, digitized), the computer can move or rotate the object convincingly through space. Hence, computer animation can demonstrate highly complex movements for medical or other scientific researchers.

The various techniques used by computer animators range from simple graphics generation (for such effects as a waving flag or a "flying" television show title) to the sophisticated structure animation required for rendering humans or animals in action. The degree to which computers are employed in the making of an animated film depends on the nature of the task. The animator can use the computer to define each individual element of a film, or the computer can generate its own animated effects by assigning programmed behaviour to a given object or to a set of objects, such as a flock of birds in flight.

Computers can render two- or three-dimensional images based on either live-action models or line drawings. The most common method of creating animated images from live-action models is a motion-capture system, in which small reflective or magnetic sensors are attached to an actor's body at key positions (head, hands, feet, and most of the joints). The actor undergoes the series of movements to be performed by his computer-generated image in the finished film, and the markers feed a stream of data to a host computer, which in turn constructs a three-dimensional image based on the position and orientation of each marker. Such techniques were employed in the motion picture *Titanic* (1997) in order to obtain sweeping overhead shots of the title ship that would have been difficult or cost-

prohibitive to achieve with crane-mounted cameras. In these scenes, passengers and officers that appear to be strolling the ship's decks were actually motion-capture animations.

Computer animators can render characters not based on real-life models by either creating and employing an interconnected series of metaballs (software devices for rendering spherical or circular-shaped objects) and splines (which interconnect metaballs), or by using the computer to create images based on hand-drawn line art or mathematical models. In both approaches, the algorithm that creates the three-dimensional image also considers such matters as background scenery and light sources in order to determine the appropriate shading for the finished rendering. Such methods were used for the popular animated features *Toy Story* (1995), *A Bug's Life* (1998), *Antz* (1998), and *Toy Story 2* (1999).

Although traditional cel animation and keyframing were still being employed at the turn of the 21st century, they were increasingly replaced or aided by computer programs based on principles of physics and dynamic simulation. As the field expands to incorporate such innovations as synthetic actors capable of real-time interaction with humans, it would appear that computers offer animators heretofore unimaginable possibilities. (R.M./E.We./Ed.)

BIBLIOGRAPHY

General histories: ARTHUR KNIGHT, *The Liveliest Art: A Panoramic History of the Movies,* rev. ed. (1979), an influential history; GERALD MAST, *A Short History of the Movies,* 4th ed. (1986); DAVID A. COOK, *A History of Narrative Film* (1981), a wide-ranging historical survey of international film; ERIC RHODE, *A History of the Cinema from Its Origins to 1970* (1976, reprinted 1985), an international critical history providing detailed though opinionated coverage; KENNETH MACGOWAN, *Behind the Screen: The History and Techniques of the Motion Picture* (1965), a dated but still valuable history by an industry insider; EPHRAIM KATZ, *The Film Encyclopedia* (1979), an informative reference source. Perhaps the most exhaustive study of American film history is CHARLES HARPOLE (ed.), *History of the American Cinema* (1990–).

Historical studies of specific periods: Early developments are studied in TERRY RAMSAYE, *A Million and One Nights: A History of the Motion Picture,* 2 vol. (1926, reissued in 1 vol., 1986), a romantic account covering the period to 1925, with emphasis on American film between 1890 and 1915; MICHAEL CHANAN, *The Dream That Kicks: The Prehistory and Early Years of Cinema in Britain,* 2nd ed. (1995), an extraordinary study of the cultural/ideological "site" of cinema at the moment of its birth; and WILLIAM K. EVERSON, *American Silent Film* (1978, reissued 1998).

Further developments are presented in GEORGES SADOUL, *Histoire générale du cinéma,* 6 vol. in varied editions (1973–75), a detailed study of the epoch of silent film; KEVIN BROWNLOW, *The Parade's Gone By* (1968, reissued 1988), a well-illustrated study of American silent films and stars, based on interviews with survivors; JOHN KOBAL, *Hollywood: The Years of Innocence* (1985), a pictorial work on the period; GRAHAM PETRIE, *Hollywood Destinies: European Directors in America, 1922–1931* (1985); and BENJAMIN B. HAMPTON, *A History of the Movies* (1931, reissued as *History of the American Film Industry from Its Beginnings to 1931,* 1970). An excellent, well-researched account of the coming of sound is found in ALEXANDER WALKER, *The Shattered Silents: How the Talkies Came to Stay* (1978, reissued 1986); see also LEONARD QUART and ALBERT AUSTER, *American Films and Society Since 1945* (1984), a brief, penetrating study; and WILLIAM LUHR (ed.), *World Cinema Since 1945* (1987).

Historical and critical studies of national film movements: British filmmaking is the subject of ROY ARMES, *A Critical History of the British Cinema* (1978); RACHAEL LOW, *The History of the British Film,* 7 vol. (1948–79), a detailed study of the silent film; ERNEST BETTS, *The Film Business: A History of British Cinema, 1896–1972* (1973), a standard, compact history; and SARAH STREET, *British National Cinema* (1997). For France, see RICHARD ABEL, *French Cinema: The First Wave, 1915–1929* (1984), a definitive scholarly study of avant-garde and commercial cinema of the era, superbly illustrated; JAMES MONACO, *The New Wave: Truffaut, Godard, Chabrol, Rohmer, Rivette* (1976, reprinted 1980), an excellent critical study; and ALAN WILLIAMS, *Republic of Images: A History of French Filmmaking* (1992). For Germany, see SIEGFRIED KRACAUER, *From Caligari to Hitler: A Psychological History of the German Film* (1947, reissued with additions, 1974), a psychological, sociological, and political analysis; DAVID STEWART HULL, *Film in the Third Reich: A Study of the German Cinema, 1933–1945* (1969, reissued 1973), an exploration of the cinema's role in Nazi propaganda; DAVID WELCH, *Propaganda and the German Cinema, 1933–1945* (1983); JULIAN PETLEY, *Capital and Culture: German Cinema, 1933–45* (1979), a discussion of the economic and social structure of the Nazi film industry; LOTTE H. EISNER, *The Haunted Screen: Expressionism in the German Cinema and the Influence of Max Reinhardt* (1969, reissued 1973; originally published in French, 1965), a study of the influence of the arts of painting, drama, and the novel on the cinema; and ERIC RENTSCHLER, *West German Film in the Course of Time: Reflections on the Twenty Years Since Oberhausen* (1984), a scholarly account of the New German Cinema and its historical-economic contexts.

Italian filmmaking is the subject of PIERRE LEPROHON, *The Italian Cinema* (1972; originally published in French, 1966); JAMES HAY, *Popular Film Culture in Fascist Italy: The Passing of the Rex* (1987); MIRA LIEHM, *Passion and Defiance: Film in Italy from 1942 to the Present* (1984), an informative though sometimes eccentric critical study; ROY ARMES, *Patterns of Realism* (1971, reprinted 1986), a standard study of the Neorealist cinema; and PETER BONDANELLA, *Italian Cinema: From Neorealism to the Present,* new expanded ed. (1990, reissued 1999), a definitive scholarly analysis. Films from the Soviet Union and eastern European countries are the subject of JAY LEYDA, *Kino: A History of the Russian and Soviet Film,* 3rd ed. (1983), a broad, authoritative study of developments beginning with tsarist times; MIRA LIEHM and ANTONÍN J. LIEHM, *The Most Important Art: Eastern European Film After 1945* (1977), a survey of Soviet, Polish, Czechoslovak, Hungarian, Yugoslav, East German, Romanian, and Bulgarian cinema, illustrated with many rare stills; RONALD HOLLOWAY, *The Bulgarian Cinema* (1986), a well-illustrated study; PETER HAMES, *The Czechoslovak New Wave* (1985); GRAHAM PETRIE, *History Must Answer to Man: The Contemporary Hungarian Cinema* (1978); and DANIEL J. GOULDING, *Liberated Cinema: The Yugoslav Experience* (1985), a critical history of the postwar period. For other European countries, see PETER COWIE, *Swedish Cinema* (1966) and *Swedish Cinema from Ingeborg Holm to Fanny and Alexander* (1985); and PETER BESAS, *Behind the Spanish Lens: Spanish Cinema Under Fascism and Democracy* (1985).

For a survey of Australian movies, see GRAHAM SHIRLEY and BRIAN ADAMS, *Australian Cinema: The First Eighty Years,* rev. ed. (1989), a standard scholarly history, covering developments to 1975; and BRIAN MCFARLANE, *Australian Cinema 1970–1985* (1987), a valuable account of Australia's unprecedented film explosion. Filmmaking in Asian and African countries is discussed in NOËL BURCH, *To the Distant Observer: Form and Meaning in the Japanese Cinema,* revised and edited by ANNETTE MICHELSON (1979); AUDIE BOCK, *Japanese Film Directors* (1978, reprinted 1985), a scrupulously researched critical study of 10 directors spanning the history of the industry; THOMAS WEISSER and YUKO MIHARA WEISSER, *Japanese Cinema: The Essential Handbook*; 4th rev. ed. (1998); JAY LEYDA, *Dianying. An Account of Films and the Film Audience in China* (1972); ERIK BARNOUW and S. KRISHNASWAMY, *Indian Film,* 2nd ed. (1980), an authoritative study; T.M. RAMACHANDRAN (ed.), *70 Years of Indian Cinema, 1913–1983* (1985), a well-illustrated, extended history; ASHISH RAJADHYAKSHA and PAUL WILLEMEN, *Encyclopedia of Indian Cinema*; new rev. ed. (1999).

Book-length works on Latin America, Cuba, and Mexico include JORGE A. SCHNITMAN, *Film Industries in Latin America: Dependency and Development* (1984), an economic analysis from the silent era through the 1980s; RANDAL JOHNSON and ROBERT STAM (eds.), *Brazilian Cinema* (1982), a definitive English-language history; MICHAEL CHANAN, *The Cuban Image: Cinema and Cultural Politics in Cuba* (1985); and CARL J. MORA, *Mexican Cinema: Reflections of a Society, 1896–1980* (1982), a scholarly critical history; and CHON A. NORIEGA (ed.), *Visible Nations: Latin American Cinema and Video* (2000). The cinema of the United States is the subject of ROBERT SKLAR, *Movie-Made America: A Social History of American Movies* (1975); LEWIS JACOBS, *The Rise of the American Film, a Critical History,* expanded ed. (1968, reissued 1974), a detailed study with emphasis on trends and audience preference; DAVID BORDWELL, KRISTIN THOMPSON, and JANET STAIGER, *The Classical Hollywood Cinema: Film Style & Mode of Production to 1960* (1985); DOUGLAS GOMERY, *The Hollywood Studio System* (1985); ANDREW SARRIS, *The American Cinema: Directors and Directions, 1929–1968* (1968, reissued 1996), a classic definition of the auteur theory and its critical application to American films and filmmakers; and TINO BALIO (ed.), *The American Film Industry,* rev. ed. (1985), an anthology of historical scholarship and primary documents from the origins to the 1980s.

Genre studies: THOMAS SCHATZ, *Hollywood Genres: Formulas, Filmmaking, and the Studio System* (1981), examines prevalent styles and forms. Nonfiction films are discussed in RICHARD MERAN BARSAM, *Nonfiction Film: A Critical History* (1973), which focuses on British and American documentaries; RICHARD MERAN BARSAM (ed.), *Nonfiction Film: Theory and Criticism*

(1976); and ERIK BARNOUW, *Documentary: A History of the Non-Fiction Film.* 2nd rev. ed. (1993). War themes are explored in CRAIG W. CAMPBELL, *Reel America and World War I: A Comprehensive Filmography and History of Motion Pictures in the United States, 1914–1920* (1985); and JEANINE BASINGER, *The World War II Combat Film: Anatomy of a Genre* (1986).

Studies of the western, crime movies, and film noir include WILLIAM K. EVERSON, *The Hollywood Western: 90 Years of Cowboys and Indians, Train Robbers, Sheriffs and Gunslingers, and Assorted Heroes and Desperados* (1992, rev. ed. of *A Pictorial History of the Western Film*, 1969); JIM KITSES, *Horizons West: Anthony Mann, Budd Boetticher, Sam Peckinpah: Studies of Authorship Within the Western* (1969); JON TUSKA, *The Filming of the West* (1976); LAWRENCE ALLOWAY, *Violent America: The Movies, 1946–1964* (1971); CARLOS CLARENS, *Crime Movies: From Griffith to The Godfather and Beyond* (1980), a historical cross-genre survey; ALAIN SILVER and ELIZABETH WARD (eds.), *Film Noir: An Encyclopedic Reference to the American Style,* 3rd rev. and expanded ed. (1992), a critical reference work; FOSTER HIRSCH, *The Dark Side of the Screen: Film Noir* (1981, reprinted 1983), an in-depth study; and JON TUSKA, *Dark Cinema: American Film Noir in Cultural Perspective* (1984). Experimental cinema is the subject of SHELDON RENAN, *An Introduction to the American Underground Film* (1967). The social-issue movie is explored in PETER ROFFMAN and JIM PURDY, *The Hollywood Social Problem Film: Madness, Despair, and Politics from the Depression to the Fifties* (1981). For feminist studies of Hollywood films, see MARY ANN DOANE, *The Desire to Desire: The Woman's Film of the 1940s* (1987); and E. ANN KAPLAN, *Women and Film: Both Sides of the Camera* (1983), which also covers independent films.

Two surveys of specific genres are KALTON C. LAHUE, *Continued Next Week: A History of the Moving Picture Serial* (1964) and *World of Laughter: The Motion Picture Comedy Short, 1910–1930* (1966, reprinted 1972). Other works on comedy include WALTER KERR, *The Silent Clowns* (1975, reprinted 1990); GERALD MAST, *The Comic Mind: Comedy and the Movies,* 2nd ed. (1979); and ANDREW HORTON (ed.), *Comedy/Cinema/Theory* (1991). Musicals are discussed in JOHN KOBAL, *A History of Movie Musicals: Gotta Sing, Gotta Dance,* rev. ed. (1983); TED SENNETT, *Hollywood Musicals* (1981, reprinted 1985); and RICK ALTMAN, *The American Film Musical* (1987, reissued 1989); and COLIN LARKIN, *The Virgin Encyclopedia of Stage and Film Musicals* (1999). For an overview of animated films, see LEONARD MALTIN, *Of Mice and Magic: A History of American Animated Cartoons,* rev. ed. (1987); DONALD CRAFTON, *Before Mickey: The Animated Film, 1898–1928* (1982), a scholarly discussion of pre-Disney works; and CHRISTOPHER FINCH, *The Art of Walt Disney: From Mickey Mouse to the Magic Kingdoms* (1973, reprinted 1983), a richly illustrated study. (D.A.C.)

The art of film: There are numerous primers to film study, but the best systematic introductions are DAVID BORDWELL and KRISTIN THOMPSON, *Film Art,* 2nd ed. (1986); and BRUCE F. KAWIN, *How Movies Work* (1987). The essential and classical books concerned with the nature of the film include the following: SERGEI EISENSTEIN, *The Film Sense* (1947), and *Film Form* (1949), two essays in film theory, translated from Russian and available in various later editions of the author's theoretical essays; BÉLA BALÁZS, *Theory of the Film: Character and Growth of a New Art* (1952, reprinted 1972; originally published in Hungarian, 1948); RUDOLF ARNHEIM, *Film as Art* (1957, reprinted 1971; originally published in German, 1932); SIEGFRIED KRACAUER, *Nature of Film: The Redemption of Physical Reality* (1961, reissued as *Theory of Film,* 1974); ANDRÉ BAZIN, *What Is Cinema?,* 2 vol., trans. from French (1967–71); HUGO MÜNSTERBERG, *The Photoplay: A Psychological Study* (1916; reissued as *The Film, a Psychological Study: The Silent Photoplay in 1916,* 1970); PETER WOLLEN, *Signs and Meaning in the Cinema,* new ed. (1972); CHRISTIAN METZ, *Film Language: A Semiotics of the Cinema* (1974; originally published in French, 1968), and *The Imaginary Signifier: Psychoanalysis and the Cinema* (1982; originally published in French, 1977); and NÖEL BURCH, *Theory of Film Practice* (1973, reissued 1981; originally published in French, 1969). Of these Bazin and Eisenstein have proved the most fertile and lasting. An overview of classical theories can be found in J. DUDLEY ANDREW, *The Major Film Theories: An Introduction* (1976); for more recent ideas see his *Concepts in Film Theory* (1984). Several anthologies of essays stemming from the academic era of film study put the reader in touch with issues such as semiotics, psychoanalysis, feminism, ideology, and structuralism as they influence the cinema. See GERALD MAST and MARSHALL COHEN, *Film Theory and Criticism: Introductory Readings,* 3rd ed. (1985); BILL NICHOLS (ed.), *Movies and Methods: An Anthology,* 2 vol. (1976–85); and PHILIP ROSEN (ed.), *Narrative, Apparatus, Ideology: Film Theory Reader* (1986). Individual modern theories have been advanced in DAVID BORDWELL, *Narration in the Fiction Film* (1985); STEPHEN HEATH, *Questions of Cinema* (1981); BRUCE F. KAWIN, *Mindscreen: Bergman, Godard, and First-Person Film* (1978); and TERESA DE LAURETIS, *Alice Doesn't: Feminism, Semiotics, Cinema* (1984). The most thorough study of experimental cinema remains P. ADAMS SITNEY, *Visionary Film: The American Avant-Garde,* 2nd ed. (1979). (D.A.)

Technology: *The Focal Encyclopedia of Film & Television Techniques* (1969), is a fairly complete reference source; RAYMOND FIELDING (comp.), *A Technological History of Motion Pictures and Television: An Anthology from the Pages of the Journal of the Society of Motion Picture and Television Engineers* (1967, reprinted 1983), provides a remarkable survey. The society's own invaluable publications include DON V. KLOEPFEL (ed.), *Motion-Picture Projection and Theatre Presentation Manual* (1969); FRANK P. CLARK, *Special Effects in Motion Pictures: Some Methods for Producing Mechanical Special Effects* (1966); and *Widescreen Motion-Picture Systems* (1965). See also RAYMOND FIELDING, *The Technique of Special Effects Cinematography,* 4th ed. (1985). Other works include BARRY SALT, *Film Style and Technology: History and Analysis* (1983), the evolution of film equipment; STEVE NEALE, *Cinema and Technology: Image, Sound, Colour* (1985), an economic and aesthetic context for the emergence of the motion-picture technologies; and R.W.G. HUNT, *The Reproduction of Colour,* 3rd ed. (1975), an extended discussion of specific technology. CHARLES G. CLARKE, *Professional Cinematography,* rev. ed. (1968), is an older but still valuable brief summary; BARBARA CLARK and SUSAN J. SPOHR, *Guide to Post-production for TV and Film: Managing the Process* (1998). DOMINIC CASE, *Film Technology in Post Production* (1997), is a definitive text; PAUL M. HONORÉ, *A Handbook of Sound Recording: A Text for Motion Picture and General Sound Recording* (1980), covers sound production; and GLEN BALLOU (ed.), *Handbook for Sound Engineers: The New Audio Cyclopedia* (1987), is an extended reference manual. Works on editing techniques include KAREL REISZ and GAVIN MILLAR, *The Technique of Film Editing,* 2nd enlarged ed. (1968, reprinted 1982); WILLIAM B. ADAMS, *Handbook of Motion Picture Production* (1977); and ERNEST WALTER, *The Technique of the Film Cutting Room,* 2nd rev. ed. (1982). Detailed techniques in high-speed and scientific cinematography are discussed in J.S. COURTNEY-PRATT (ed.), *Proceedings of the Fifth International Congress on High-Speed Photography* (1962); and WILLIAM G. HYZER and WILLIAM G. CHACE (eds.), *Proceedings of the Ninth International Congress on High-Speed Photography* (1970). JOHN HALAS and ROGER MANVELL, *The Technique of Film Animation,* 4th ed. (1976), is the standard text on the subject, and *Art in Movement: New Directions in Animation* (1970), explores the link between animation and kinetic art forms. THOMAS W. HOFFER, *Animation, a Reference Guide* (1981), is a scholarly guide with many bibliographic essays. Information on state-of-the-art technologies is provided in the *SMPTE Journal* (monthly); *Image Technology: Journal of the BKSTS* (10/yr.); *Millimeter* (monthly); *On Location* (monthly); and *American Cinematographer* (monthly). (E.We./S.G.H./P.Me./R.M.)

Human Motivation

Motivation in human psychology is the term used to describe forces acting either on or within a person to initiate behaviour. The word motivation is derived from the Latin term *motivus* ("a moving cause"), which suggests the activating properties of the processes involved in psychological motivation. Psychologists study motivational forces to help explain observed changes in behaviour that occur in an individual. Thus, for example, the observation that a person is increasingly likely to open the refrigerator door to look for food as the number of hours since the last meal increases can be understood by invoking the concept of motivation. As the above example suggests, motivation is not typically measured directly but rather inferred as the result of behavioral changes in reaction to internal or external stimuli. It is also important to understand that motivation is primarily a performance variable. That is, the effects of changes in motivation are often temporary. An individual, highly motivated to perform a particular task because of a motivational change, may later show little interest for that task as a result of further change in motivation.

Motives are often categorized into primary, or basic, motives, which are unlearned and common to both animals and humans; and secondary, or learned, motives, which can differ from animal to animal and person to person. Primary motives are thought to include hunger, thirst, sex, avoidance of pain, and perhaps aggression and fear. Secondary motives typically studied in humans include achievement, power motivation, and numerous other specialized motives.

Unlearned and learned motives

Motives have also sometimes been classified into "pushes" and "pulls." Push motives concern internal changes that have the effect of triggering specific motive states. Pull motives represent external goals that influence one's behaviour toward them. Most motivational situations are in reality a combination of push and pull conditions. For example, hunger, in part, may be signaled by internal changes in blood glucose or fat stores, but motivation to eat is also heavily influenced by what foods are available. Some foods are more desirable than others and exert an influence on our behaviour toward them. Behaviour is, thus, often a complex blend of internal pushes and external pulls.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 433, and the *Index*.

The study of motivation

PHYSIOLOGICAL, PSYCHOLOGICAL, AND PHILOSOPHICAL APPROACHES

Motivation has been studied in a variety of ways. For instance, it has been analyzed at the physiological level using electrical and chemical stimulation of the brain, the recording of electrical brain-wave activity with the electroencephalograph, and lesion techniques, where a portion of the brain (usually of a laboratory animal) is destroyed and subsequent changes in motivation are noted. Physiological studies performed primarily on animals other than humans have demonstrated the importance of certain brain structures in the control of basic motives such as hunger, thirst, sex, aggression, and fear.

Motivation may also be analyzed at the individual psychological level. Such analyses attempt to understand why people act in particular ways and seek to draw general conclusions from individual cases. Through studies of individuals, for example, it has been found that both men and women proceed through a series of identifiable stages of arousal during behaviours leading to and culminating in sexual intercourse. The finding may be applied to people in general.

Motivation of an individual is also influenced by the presence of other people. Social psychologists have been active in discovering how the presence of others in a given situation influences motivation. For example, students and teachers behave in predictable ways in the classroom. Those behaviours are often quite different, however, from the way students and teachers behave outside the classroom. Studies of conformity, obedience, and helping behaviours (which benefit others without reward) are three areas in this field that have received considerable attention.

Finally, motivation is sometimes also approached from a more philosophical direction. That is, analyses of motivation are understood, at least in part, by examining the particular philosophical point of view espoused by the theorist. For example, some motivational theorists conceive motivation to be an aversive state: one to be avoided. Sigmund Freud's view of motivational processes could be applied within this framework; his contention that blocked sexual energy could be displaced into acceptable behaviours implies that accumulation of sexual energy (motivation) is aversive. Other theorists see motivation as a much more positive experience. That is, motivation can produce behaviours that lead to increases in future motivation. The American psychologist Abraham H. Maslow's concept of self-actualization could be applied within this framework (see below).

Aversive and positive views

DEBATES IN MOTIVATIONAL STUDY

The nomothetic versus ideographic approach. However motivation is studied, certain fundamental debates have typified the positions taken by researchers. One such debate concerns the question of whether it is better to study groups of individuals and attempt to draw general conclusions (termed the nomothetic approach) or to study the behaviours that make individuals unique (termed the ideographic approach). Although both approaches have added to the understanding of motivational processes, the nomothetic approach has dominated motivational research.

Innate versus acquired processes. A second debate among theorists concerns the degree to which motivational processes are innate (genetically programmed) versus acquired (learned). Since the 1890s this debate has swung from one extreme to the other and then back toward the middle. Early approaches viewed motivation as largely or entirely instinctive. When the instinctive approach fell into disfavour during the 1920s, the idea that all behaviours were learned largely replaced the instinctive approach. By the 1960s, and continuing to the present, research indicated that the answer to the debate is that both positions are correct. Some motives, in some species, do appear to be largely innate, as, for example, in the courting behaviour of the three-spined stickleback, a small fish of the Northern Hemisphere (see below). Other motives, such as achievement motivation, seem more closely associated with learning. Some motive states, such as extreme shyness, seem to result from an innate predisposition coupled with a particular environment where learning interacts with the predisposition.

Internal needs versus external goals. Another dimension along which debates concerning motivational processes have flourished is the question of whether motivation is primarily the result of internal needs or external goals. As noted earlier, this dimension describes differences between push and pull motives. Research suggests that some motive states are best classified as internal (push motives) while other motive states develop from goals external to the individual (pull motives). Many real-life situations are undoubtedly a combination of both internal and external motives.

Mechanistic versus cognitive processes. Finally, researchers have tended to view motivational processes as either mechanistic or cognitive. The first of these assumes that motivational processes are automatic; that is, the organism, human or otherwise, need not understand what it is doing in order for the processes to work. This point of view has achieved considerable popularity. Neither conscious awareness nor intent is assumed to be operative in the mechanistic approach. Researchers taking the mechanistic point of view are often interested in studying internal need states and genetically programmed behaviours. The second and newer approach, promoted by researchers more often interested in external and acquired motives, has emphasized the importance of cognition in motivational processes. The cognitive approach assumes that the way in which one interprets information influences motives. Cognitive motivational approaches assume that the active processing of information has important influences on future motivation. Given the complexity of motivational processes, most theorists feel safe in assuming that some motive states are relatively mechanistic while others are more cognitive.

The mechanistic approach

Historical overview

PHILOSOPHERS' CONTRIBUTIONS

The history of motivational thought reflects the considerable influence of philosophers and physiologists. For example, the concept of free will as proposed by Aristotle and others was a widely accepted philosophical position until it was generally rejected in favour of determinism. Determinism, as the term is used by psychologists, holds that every behaviour has some antecedent cause. One antecedent to which particular behaviours are often attributed is motivation. Thus, if one sees a woman hurriedly eating a sandwich while continually glancing at her watch, one might infer that she is late for an appointment rather than that she is ravenously hungry. Regardless of the eventual explanation that would allow us to understand her behaviour, we do not assume that she is behaving randomly. Rather, we assume some motive is causing her to behave as she does.

Descartes's mind-body dualism

Aristotle's belief that the mind is at birth a blank slate upon which experience writes was the basis for studying the effects of learning on behaviour. The 17th-century philosopher René Descartes proposed the concept of mind-body dualism, which implied that human behaviour could be understood as resulting from both a free, rational soul and from automatic, nonrational processes of the body. His proposition that nonrational, mechanistic processes of the body could motivate behaviour under some circumstances led to the development of the concept of instinct and provided a counterpoint to Aristotle's emphasis on learning as the most important concept in the control of behaviour. Today, the mechanistic component of Descartes's dualism can be seen as the distant forerunner of the study of genetic components of motivation, while his other view of rational choices can be regarded as a precursor of modern cognitive approaches to motivation.

British empiricist philosophers, as exemplified by John Locke, also contributed to the development of modern motivational theory. Locke's emphasis on the importance of sensory experience can be understood as underlying the modern focus on external stimulation as motivating. Many psychologists believe that goals become valuable to us because of the sensory experience associated with these goals. Thus, for example, the motivating properties that cause a person to drive across the city to eat a particular food are thought to result from the desirable taste, smell, and perhaps texture of the food itself. If the food tasted and smelled like cardboard, it would not motivate future trips across the city to obtain it. Locke also provided the important concept of association. As proposed by Locke, one idea can become associated, or linked, to another to produce a new, more complex idea. The concept of association provides an explanation for how nonmotivating experiences can become motivating. If one pairs a nonmotivating stimulus with a highly motivating object several times, the formerly neutral stimulus begins to motivate behaviour in a fashion similar to the original object. Research has shown that, under some circumstances, phobias and other motives may be acquired through such association. The associative mechanism can serve as an example of Pavlovian classical conditioning. (Ivan P. Pavlov was a Russian scientist who taught dogs to associate food with the sound of a bell; the dogs learned to salivate at the sound of a bell, demonstrating what has been termed a conditioned response.) Perhaps the most commonly associated stimulus in Western society that is recognized for its strong motivational properties is money. Because money is paired with many strong motivators, it often becomes strongly motivating itself.

PHYSIOLOGISTS' CONTRIBUTIONS

Motivational research has also progressed through discoveries made in the field of physiology. The discovery of separate nerve fibers for sensory and motor information first suspected by the Greek physician Galen and separately confirmed by the English anatomist Sir Charles Bell in 1811 and the French physiologist François Magendie in 1822 led naturally to the development of the stimulus-response approach to motivation, which has become fundamental to the field.

Galvani's and Du Bois-Reymond's experiments

The discovery of the electrical nature of the nerve impulse, first suggested by the Italian physician and physicist Luigi Galvani's experiments in the 1770s and '80s with frogs and later directly measured by the German physiologist Emil Du Bois-Reymond in 1848–49 using a galvanometer, showed that nerves are not canals by which animal spirits flow through the body, as had been commonly thought, but are rather the conveyors of signals sent from one area of the body to another. The German psychologist Georg E. Müller added the concept of specific nerve energies, which proposed that the electrical signals passing along the nerves were specific, coded messages, while the German scientist Hermann von Helmholtz measured the speed of

the nerve impulse and found it to be about 100 miles (160 kilometres) per hour. These discoveries made it clear that the nervous system could be studied and paved the way for examination of its role in the motivation of behaviour.

Studies of the localization of function within the nervous system, especially the brain, derived at least in part from the phrenology of the German physician Franz Josef Gall during the early 1800s. Although phrenology has been thoroughly discredited, it indirectly contributed to the localization of motivational systems within such brain areas as the hypothalamus.

BEHAVIOURISM

The contributions from philosophical and physiological sources have generated several stages of evolution in motivational theory since the late 19th century. In the 1800s Descartes' dualism was often used to distinguish between animal and human motivation. By the end of the 19th century, behavioral theorists such as the American psychologists William James and William McDougall had begun to emphasize the instinctive component of human behaviour and to de-emphasize, and in some cases eliminate from discussion, the more mentalistic concept of will. Other behaviourists, as exemplified by the American psychologist John B. Watson, rejected theories of both instinct and will and emphasized the importance of learning in behaviour. This group conceived behaviour to be a reaction or response (R) to changes in environmental stimulation (S); their S-R psychology subsequently gained popularity, becoming the basis for the school of behaviourism. By the 1920s, the concept of instinct as proposed by theorists such as James and McDougall had been roundly criticized and fell into disrepute. Behaviourism dominated the thinking of motivational theorists and a new motivational concept, drive, congenial to behaviourism's S-R approach, was born. Drive, initially proposed by the American psychologist Robert S. Woodworth, was developed most fully by Clark Hull, an American psychologist who conceived motivation to result from changed internal bodily needs, which were in turn satisfied by obtaining specific items from the environment. Thus, hunger motivation was thought to occur as a result of a changed internal need for energy that motivated food-seeking behaviour in the environment.

Decline of the instinct concept

Behaviourism dominated motivational research until the 1960s, but even in the 1920s and '30s dissenting voices were heard. Researchers such as the American psychologist Edward C. Tolman and the German psychologist Wolfgang Köhler argued for the existence of a more active processing of information in both humans and animals and rejected the mechanistic S-R psychology. These early cognitive psychologists opened the way for other researchers to examine motivation resulting from the expectation of future events, choices among alternatives, and attributions concerning outcomes. In other words, with the advent of cognitive explanations of motivated behaviour, it became possible to argue that behaviours were sometimes purposive. The cognitive approach has proved useful in the analysis of several types of motivation, among them achievement behaviour, dissonance motivation, and self-actualization (see below).

Changing perspectives and research on motivation have led away from large, all-encompassing theories of motivation to smaller, discrete theories that explain specific motives or specific aspects of motivation under particular conditions. These microtheories of motivation are conveniently categorized as falling within three major areas: biological, behavioristic, and cognitive explanations.

Biological approaches to motivation

The biological microtheories of motivation can be divided into three categories: genetic contributions to motivated behaviour, arousal mechanisms, and biological monitoring systems.

GENETIC CONTRIBUTIONS

As indicated above, the idea that some motivated behaviours are the result of innate programs manifested in the nervous system had been proposed by James and McDougall in the late 1800s and early 1900s. These early instinct approaches fell into disfavour during the 1920s because of their proponents' inability to discriminate between instinctive and learned behaviours and because of the realization that labeling an observed behaviour as instinctive did not explain why the behaviour occurred. In Europe, however, a group of biologists interested in the evolutionary significance of animal behaviours kept the concept alive and continued to study the genetic basis of behaviour. Three of these researchers (the Austrians Karl von Frisch and Konrad Lorenz and the Netherlander Nikolaas Tinbergen) were awarded a Nobel Prize in 1973 for their work on the subject. They were early entrants in the field of study known as ethology, which studies the behaviour patterns of animals in their natural habitat. Ethologists argue that the evolutionary significance of a particular behaviour can best be understood after a taxonomy of behaviours for that species has been developed as a result of observation in nature. They propose further that the significance of a behaviour is often clearer when observed in the context of other behaviours of that animal. Ethologists use naturalistic observation and field studies as their most common techniques.

Ethology

The research conducted by the ethologists showed that some behaviours of some animal species were released in an automatic and mechanical fashion when conditions were appropriate. These behaviours, known as fixed-action patterns, have several salient characteristics: they are specific to the species under study, occur in a highly similar fashion from one occurrence to the next, and do not appear to be appreciably altered by experience. Furthermore, the stimulus that releases these genetically programmed behaviours is usually highly specific, such as a particular colour, shape, or sound. Such stimuli are termed key stimuli or sign stimuli and when provided by a conspecific organism (a member of the same species) are known as social releasers.

One thoroughly researched example of this type of genetically programmed behaviour is the courtship behaviour of the three-spined stickleback, a small fish. During the reproductive season, male sticklebacks become territorial and defend a portion of the streambed against other intruding stickleback males. Ethological analysis of this aggressive behaviour reveals that it is a series of fixed-action patterns released by the reddish coloration of the ventral (under) surface of the intruding males. A female stickleback entering the territory is not attacked because she does not possess the red coloration. Instead she is courted through a complex series of movements termed the zigzag dance. This behaviour pattern performed by the male stickleback is released by the shape of the ventral surface of the female, which is distended as a result of the eggs she carries. (See BEHAVIOUR, ANIMAL: *Nature and patterns of animal behaviour: Components of behaviour: Movement*).

Although the largest number of studies conducted by ethologists has been on nonhuman animals, some ethological researchers have applied the same kinds of analyses to human behaviour. Prominent among these is the Austrian ethologist Irenäus Eibl-Eibesfeldt. In a book entitled *Love and Hate: The Natural History of Behavior Patterns,* he summarized many years of cross-cultural research on human genetic behaviour patterns. Interestingly, research on the facial expressions associated with emotion has provided some support for the existence of innate motivations in humans.

MOTIVATION AS AROUSAL

The James-Lange theory. A second biological approach to the study of human motivation has been the study of mechanisms that change the arousal level of the organism. Early research on this topic emphasized the essential equivalency of changes in arousal, changes in emotion, and changes in motivation. It was proposed that emotional expressions and the motivation of behaviour are the observable manifestations of changes in arousal level. One of the earliest arousal theories suggested that one's perception of emotion depends upon the bodily responses

Study of the arousal level

the individual makes to a specific, arousing situation. This theory became known as the James-Lange theory of emotion after the two researchers, William James and the Danish physician Carl Lange, who independently proposed it in 1884 and 1885 respectively. The theory argued, for example, that experiencing a dangerous event such as an automobile accident leads to bodily changes such as increased breathing and heart rate, increased adrenaline output, and so forth. These changes are detected by the brain and the emotion appropriate to the situation is experienced. In the example of the automobile accident, fear might be experienced as a result of these bodily changes.

The Cannon-Bard theory. Walter B. Cannon, a Harvard physiologist, questioned the James-Lange theory on the basis of a number of observations; he noted that the feedback from bodily changes can be eliminated without eliminating emotion; that the bodily changes associated with many quite different emotional states are similar, making it unlikely that these changes serve to produce particular emotions; that the organs supposedly providing the feedback to the brain concerning these bodily changes are not very sensitive; and that these bodily changes occur too slowly to account for experienced emotions.

Cannon and a colleague, Philip Bard, proposed an alternative arousal theory, subsequently known as the Cannon-Bard theory. According to this approach, the experience of an event, such as the automobile accident mentioned earlier, leads to the simultaneous determination of emotion and changes to the body. The brain, upon receiving information from the senses, interprets an event as emotional while at the same time preparing the body to deal with the new situation. Thus, emotional responses and changes in the body are proposed to be preparations for dealing with a potentially dangerous emergency situation.

The cognitive-physiological theory

The Schachter-Singer model. In 1962 the American psychologists Stanley Schachter and Jerome Singer performed an experiment that suggested to them that elements of both the James-Lange and Cannon-Bard theories are factors in the experience of emotion. Their cognitive-physiological theory of emotion proposed that both bodily changes and a cognitive label are needed to experience emotion completely. The bodily changes are assumed to occur as a result of situations that are experienced, while the cognitive label is considered to be the interpretation the brain makes about those experiences. According to this view, one experiences anger as a result of perceiving the bodily changes (increased heart rate and breathing, adrenaline production, and so forth) and interpreting the situation as one in which anger is appropriate or would be expected. The Schachter-Singer model of emotional arousal has proved to be popular although the evidence for it remains modest. Other researchers have suggested that bodily changes are unnecessary for the experience of emotional arousal and that the cognitive label alone is sufficient.

The inverted-U function. The relationship between changes in arousal and motivation is often expressed as an inverted-U function (also known as the Yerkes-Dodson law). The basic concept is that, as arousal level increases, performance improves, but only to a point, beyond which increases in arousal lead to a deterioration in performance. Thus some arousal is thought to be necessary for efficient performance, but too much arousal leads to anxiety or stress, which degrades performance.

The search for a biological mechanism capable of altering the arousal level of an individual led to the discovery of a group of neurons (nerve cells) in the brain stem named the reticular activating system, or reticular formation. These cells, which are found along the center of the brain stem, run from the medulla to the thalamus and are responsible for changes in arousal that move a person from sleeping to waking. They are also believed to function in relation to an individual's attention factor.

Sleep processes and stress reactions. Research on arousal mechanisms of motivation has furthered understanding of both sleep processes and stress reactions. In the case of sleep, arousal levels generally seem lower than during waking; however, during one stage of sleep arousal levels appear highly similar to those in the waking state. Sleep itself may be considered a motivational state. The biological motivation to sleep can become so overpowering that individuals can fall asleep while driving an automobile or while engaged in dangerous tasks.

Five stages of sleep have been defined using the electroencephalograph (EEG). The EEG records the electrical activity of neurons in the outermost portion of the brain known as the cerebral cortex.

The five stages of sleep

According to EEG-based findings, everyone cycles through five stages during sleep. A complete cycle averages approximately 90 minutes. The two most interesting stages of sleep from a motivational point of view are stages 4 and 5. Stage 4 represents the deepest sleep in that the brain-wave activity as measured by the EEG is farthest from the activity seen when a person is awake. The brain-wave pattern is characterized by delta waves, which are large, irregular, and slow; breathing, heart rate, and blood pressure are also reduced. Because the overall activity of the individual in stage 4 is greatly reduced, it has been suggested by some researchers that stage 4 (and perhaps also stage 3) sleep serves a restorative function. However, a potential problem with such an explanation is that stage 4 sleep drops dramatically after age 30 and may be entirely absent in some people aged 50 or over who nevertheless appear to be perfectly healthy. Additionally, studies have shown that in the typical individual physical exhaustion does not lead to increases in stage 4 sleep as might be expected if it were serving a restorative function. The purpose of stage 4 sleep remains unknown.

Stage 5 sleep is also known as rapid eye movement (REM) sleep because during this stage the eyes begin to move rapidly under the eyelids. Interest in stage 5 sleep has been considerable since it was discovered that most, if not all, dreaming occurs during this stage. During stage 5 sleep the EEG pattern of brain-wave activity appears very similar to the brain-wave activity of an awake, alert person. Breathing, heart rate, and blood pressure rise from the low levels observed during stage 4 and can fluctuate rapidly. In addition to eye movements, fast, small, and irregular brain waves, and autonomic changes indicative of an aroused state, individuals in stage 5 sleep display a large loss in skeletal muscle tone that amounts to a temporary paralysis. Researchers have suggested that the muscle paralysis prevents the "acting out" of our dreams.

Another aspect of arousal processes concerns the high levels of arousal leading to a triggering of the stress reaction. The stress reaction can be triggered by a challenge to the physical integrity of the body, or it can occur as a result of some psychological challenge. Furthermore, the body appears to react in a similar fashion regardless of whether the demands made upon it are physical or psychological. Hans Selye, a Viennese-born Canadian medical researcher, showed that stressors trigger a chain of processes that begins with what is called the alarm reaction, may proceed to a second stage called the stage of resistance, and, if the stressor has still not been removed, may lead to a final stage called exhaustion.

The three stages of stress reaction

The alarm reaction occurs when a stressor is first detected and activates a brain structure called the hypothalamus. The hypothalamus, in turn, stimulates the sympathetic nervous system and also produces a substance called corticotropin-releasing hormone that activates the pituitary to produce adrenocorticotropic hormone (ACTH). Both ACTH and activation of the sympathetic nervous system stimulate the adrenal glands. ACTH stimulates the adrenals to produce hydrocortisone, or cortisol, an anti-inflammatory substance, while the sympathetic nervous system stimulates the centre portion of the adrenals to produce epinephrine and norepinephrine (adrenaline and noradrenaline). All these hormones are secreted into the bloodstream and have the effect of mobilizing the body to deal with the stressor. This initial mobilization is a whole-body response and leads to increases in heart rate, blood pressure, and respiration and other responses associated with high arousal. The person so aroused is, in effect, in a high state of readiness. The alarm reaction often succeeds in changing the situation so that the stressor is no longer present, as would be the case, for example, if one were to run away from a physical threat.

In the second stage, the stage of resistance, localized responses within appropriate areas of the body replace the whole-body response of the alarm reaction, and blood levels of hydrocortisone, epinephrine, and norepinephrine return to just slightly above normal levels. During this stage the ability to fight off the stressor is high and may remain so for considerable periods of time.

If these localized responses to a stressor prove to be inadequate, eventually the third stage of stress, that of exhaustion, will be triggered, during which hormonal levels rise once more and the whole body becomes mobilized again. Selye proposed that if the stressor is not quickly defeated during this last stage, the individual can become withdrawn, maladjusted, and even die.

This three-part mechanism for coping with a stressor is called the general adaptation syndrome and appears to have evolved primarily to deal with systemic stressors. As noted earlier, however, this same set of processes is also triggered by psychological stressors and is often inappropriate to the situation. For example, the stress of an important upcoming test can trigger the alarm reaction, yet it is not apparent how increased levels of hydrocortisone, epinephrine, and norepinephrine would facilitate removing the stress-provoking test. It has been suggested that overstimulation of the stress response, in which psychological stressors produce physical changes in the body, can lead to psychosomatic illness. When the stress response, especially the alarm reaction, is triggered too often, it can lead to physical deterioration.

The relationship between stress and illness has been investigated most thoroughly in regard to the effect life changes have on the likelihood of subsequent illness. The pioneer in the field was Adolph Meyer, a Swiss-born American psychiatrist. Several life-change scales have been developed that measure the number and severity of various life changes, such as the death of a spouse, divorce, retirement, change in living conditions, and so forth. High scores on these scales have been found to be consistently associated with an increased probability of future illness, although the relationship is not especially strong. Presumably the life changes lead to increased stress, which in turn promotes an increased likelihood of illness.

The Meyer scale of life-change stress

Some research has also been conducted on the ways in which the negative effects of stressors can be reduced. A personality characteristic called hardiness has been associated with the ability to better withstand the effects of stress. People who score high in hardiness appear to have high levels of commitment toward the things they do, a strong need to control the events around them, and a willingness to accept challenges. These characteristics may serve to protect individuals from the effects of stress related to major life changes. Exercise, especially in conjunction with hardiness, was reported to relieve stress stemming from physiological and psychological causes. Other factors unrelated to hardiness, such as social support from others, optimism, and humour in the face of difficulty, also have been reported to reduce the stressful effects of life changes.

BIOLOGICAL MONITORING SYSTEMS

For some basic motives such as hunger, thirst, and sex, a biological approach emphasizing regulatory mechanisms has dominated the thinking of researchers. The fundamental premise has been that such basic motives are homeostatically regulated—that is, the nervous system monitors levels of energy, fluid balance, and hormone production (in the case of sex) and alters motivation when these levels deviate too far from some optimum level.

Hunger. The question of why we eat when we do appears to involve two separate mechanisms. The first mechanism, typically called short-term regulation, attempts to take in sufficient energy to balance what is being expended. It is usually assumed that time between meals and meal size are determined by this short-term mechanism. A second mechanism, called long-term regulation, is directed toward storing away sufficient energy for possible later use should the short-term mechanism fail to adequately replenish energy expended. Energy for long-term use is stored in the form of fat within the fat cells of the body. Short-term regulation processes have generally been assumed to monitor the blood glucose (blood sugar) level and to initiate eating when this level falls below some predetermined optimum. Long-term regulation processes appear to monitor fat levels and to initiate eating when fat stores fall below some optimal level.

Explanations of short-term regulation of hunger motivation have revolved around two basic ideas. The earlier of these two, known as the local theory of hunger, suggested that the hunger signals that initiate eating originate in the gastrointestinal tract, specifically the stomach. Hunger pangs were thought to be the result of stomach contractions. Considerable research has shown that such an analysis is inadequate to explain hunger motivation. For example, it is known that much of the stomach can be removed without the loss of hunger motivation. Similarly, it is known that severing the vagus nerve, which causes stomach contractions to cease, does not eliminate the experience of hunger.

The local theory of hunger

When it became apparent that the local theory of hunger was incomplete, researchers began to look for the hunger-initiating mechanism in the brain. It was quickly discovered that the hypothalamus, a small structure lying below the thalamus of the brain, is involved in the regulation of eating. Damage to the ventromedial (lower, middle) area of the hypothalamus produces a condition known as hyperphagia, in which animals overeat and gain enormous amounts of weight. Damage to a different area known as the lateral hypothalamus (located on the sides of the hypothalamus) produces a total lack of eating known as aphagia, as well as a lack of drinking, or adipsia. It was assumed that these two areas share in the control of hunger motivation by activating and deactivating hunger as glucose levels within the blood change. It was further assumed that the specialized cells (glucoreceptors) monitoring the levels of blood glucose reside in these two hypothalamic areas. This belief was weakened, however, when these glucoreceptors could not definitely be located in the brain. Additional research suggests that such glucoreceptors may reside in the liver, where new arrivals of glucose are first received and whence signals about glucose content are sent to these hypothalamic areas.

Less is known about the long-term regulation of hunger motivation, but one suggestion has been that there exists in each individual a genetically programmed body-weight set point that determines how much energy is stored away as fat within the fat cells. According to this theory, hunger motivation would serve to keep individuals close to this set point, even though the fat level maintained may not be what the individual desires nor what society dictates as beautiful or healthy. Such a system would help to explain why weight loss is so hard to maintain in many persons.

Theory of long-term hunger regulation

Thirst. Processes similar to the physiological control mechanisms of hunger are thought to regulate thirst motivation and sexual behaviour. In the case of thirst, the desire to drink appears to be initiated by fluid loss from within specialized brain cells known as osmoreceptors and also from fluid loss from the area outside of cells, such as from bleeding. Thirst, therefore, would seem to be triggered by mechanisms controlling the fluid integrity both within and around the cells of the body. Cells within the hypothalamus also seem to be involved in the control of thirst motivation.

Sexual motivation. In most animals sexual motivation is under stricter hormonal control than is the case in humans. The female of most species is not interested in sexual behaviour until cyclic hormonal changes produce estrus. The male, however, is usually sexually ready but is prevented from engaging in sexual behaviour by the female until estrus occurs. Research indicates that the anterior (front) portion of the hypothalamus is involved with the estrous cycle of female mammals; it has been demonstrated that destruction of these hypothalamus cells eliminates estrus. Similarly, destruction of the anterior region of the hypothalamus reduces or eliminates sexual behaviour in male rats. Since hormone replacement therapy in both males and females is ineffective in reestablishing sexual behaviours reduced by anterior hypothalamic damage, it has been suggested that this region contains receptors sensitive to changes in the levels of circulating

sex hormones. Damage to the ventromedial hypothalamus (VMH) also arrests estrus in females and sexual behaviour in males, but hormone replacement therapy successfully restores these functions, suggesting that VMH is involved with the expression of sexual behaviour when hormonal conditions are appropriate.

Behavioristic approaches to motivation

The behavioristic approach examines how motives are learned and how internal drives and external goals interact with learning to produce behaviour. Learning theorists have taken a somewhat more global perspective when studying motivation than researchers using the biological approach. These researchers have regarded motivation as one component out of several that combine to cause behaviour. Thus, for example, one major theory regards learning and motivation as combining multiplicatively to determine behaviour. Among the behavioristic approaches, three concepts are especially prominent: drive, learned motives, and incentives.

DRIVE

Although in many respects Freud's psychoanalytic theory of behaviour was a drive theory, the term drive was first used by Robert S. Woodworth, an American psychologist, in 1918. The concept of drive is closely tied to the concept of homeostasis. It was assumed that drive would be triggered when internal conditions changed enough to be detected and to initiate the motivational changes that amounted to drive. Thus it was assumed that some tissue need within the body would instigate drive, which would, in turn, instigate behaviours aimed at reducing the drive. According to this sort of analysis, energy depletion would lead to a hunger drive, which would in turn lead to food-seeking behaviours. Drive, then, would serve to energize appropriate behaviours, either innate or learned, which would effect a lowering of the need state of the individual.

Woodworth's early concept of drive theory

The most extensive theoretical model of drive was developed by Clark Hull in the 1940s. Hull argued that drive is general in nature and that various motives such as hunger, thirst, or sex may add to the overall drive level of an individual. Since drive was regarded as the instigator of behaviour, increases in drive level were expected to lead to increases in activity. According to Hull's model, drive is directed by what he termed drive stimuli. These internal stimuli were thought to be different for different motives and to direct the activity of an individual in ways appropriate for the particular motive state present. Thus, for example, a hungry person might go to the refrigerator seeking food because drive stimuli linked with hunger had been associated with responses of obtaining food from the refrigerator in the past.

Finally, Hull suggested that learning itself depends upon adequate drive. Responses were thought to be strengthened when followed by drive or drive-stimulus reduction. If drive or drive stimuli were not reduced, then learning would not occur.

Assessment of Hull's drive theory

Hull's drive theory generated a tremendous body of research, but the model of motivation he evolved was not more effective than others in explaining behaviour. For example, studies showed that increases in activity that occur when subjects are deprived depend largely on the species of the subject and the manner in which the activity is tested. Some species do not become more active when deprived, and changes in activity that are apparent when one type of apparatus is used (*e.g.*, a running wheel) are not seen when other types of apparatus (*e.g.*, a stabilimeter cage—for measuring caged animal activity) are used. Furthermore, drive stimuli, the proposed directional mechanism in Hull's model, have proved to be very elusive, and it is not clear that under normal circumstances their presence, if they exist, is crucial to the direction of behaviour. Finally, several studies have shown that learning can occur under circumstances that would seem to preclude any reduction in drive or drive stimuli. Since Hull's model tied learning to a reduction in drive, these studies pose a problem. Although explicit theoretical models of drive have not proved to be any better at explaining motivation than other approaches, the drive concept, in general, would seem to have some validity if only because people often express their subjective feelings of motivation in terms that suggest they are driven. In particular, the drive concept would often seem to apply to feelings associated with human sexual motivation. The drive theory no longer has wide acceptance in the motivational field.

LEARNED MOTIVES

One of the most significant contributions that the learning approach has made to the study of motivation is its emphasis on the ability of individuals to learn new motives. It has been demonstrated that new motives may be acquired as a result of three learning techniques: classical, instrumental, and observational learning.

Classical conditioning. In classical conditioning, also called Pavlovian conditioning, a neutral stimulus gains the ability to elicit a response as a result of being paired with another stimulus that already causes that response. Such learning situations can then lead to changes in motivated behaviour. Pavlov, for example, showed that dogs would develop what appeared to be neurotic behaviour if they were required to make finer and finer discriminations between stimuli in a classical conditioning discrimination experiment. The dogs became motivated to avoid the experiment room, were restless during the experimental session, and sometimes bit the apparatus. The neurosis developed when the dogs were no longer able to discriminate between the two stimuli presented to them. Later researchers have noted that this motivational change may have resulted from a lack of predictability or control on the part of the animal rather than from the classical conditioning process per se.

In 1920 the American psychologists John B. Watson and Rosalie Rayner demonstrated the development of an emotional response in a young boy using classical conditioning techniques. The presentation of a white rat was paired with the striking of a steel bar, which induced fear in the little boy. After only a few pairings, the white rat became capable of inducing fear responses similar to those produced by striking the bar. This early demonstration of learned emotional responses has suggested to psychologists that many human motives may result from the accidental pairing of events. It has been proposed that some fears, phobias, taste aversions, and even eating problems can result from classical conditioning.

Inducement of a fear response through conditioning

Instrumental learning. The second type of learning technique is instrumental learning, or conditioning, also called operant conditioning. In this type of conditioning a response is followed by some consequence which then changes the future probability of that response. For example, instrumental conditioning appears to be one way in which aggressive motivation can be changed. If an aggressive response by one child toward another child is followed by some positive event such as the aggressor getting to play with a desired toy, then the motivation to behave aggressively can be expected to increase in the future. Furthermore, through a process called conditioned reinforcement, neutral stimuli associated with a reinforcer can become reinforcers in their own right. These stimuli can then be used to motivate behaviour. Perhaps the most common example of a conditioned reinforcer is money. A piece of paper with numbers and intricate drawings on it can motivate all sorts of behaviour if that paper has previously been associated with important reinforcers such as food, clothing, sex, and so forth. Money is in effect a token of the things it can buy. Psychologists have used different types of tokens as rewards to implement reinforcement, and token economies, involving the principles of conditioned reinforcement, have been successfully used to alter behaviour in schools, institutions, and hospitals (see below).

Observational learning. In the third type of learning technique, observational learning, or modeling, a new behaviour is learned simply by watching someone else behave. In a very real sense, such learning is the ability to profit from another's successes or mistakes. This type of learning is important because the learning can occur without an individual ever having to perform the behaviour.

Thus, watching another child put a finger in an electrical outlet and get shocked is often enough to keep the observing child from behaving the same way. Similarly, noticing that friends do well in school because they study hard may be a sufficient stimulus to motivate students. Albert Bandura, a Canadian psychologist, has proposed, and provided a wealth of support for, the observational learning of aggression in humans. He has shown that young children will mimic the aggressive responses they see performed by adults. Such aggressive responses can potentially be learned by observation of violent acts on television or in movies or by reading or hearing about violent behaviour. If the observed violent acts are further perceived to lead to desired goals, then the observed aggressive behaviours may be utilized at some future date by the observer.

Learned aggressive responses in children

Research indicates that persons also learn their society's rules of sexual conduct through observation. These sexual values are taught in part by parents, clergy, political leaders, books, movies, and television. Although the learning is often indirect, people nevertheless learn how to express their sexuality. The rules for sexual behaviour in a given culture appear to be learned during adolescence. In monkeys, social isolation impairs sexual functioning. Although isolated monkeys seem to have adequate sexual motivation, the lack of appropriate social skills results in inappropriate behaviours. Thus, learning would appear to be a significant factor in normal sexual behaviour. It is generally thought that certain sexual preferences are also learned, by one technique or another. In one experiment a boot fetish was established in three males by pairing pictures of boots with pictures of nude women (at the conclusion of the experiment the fetish was extinguished). Such a demonstration would seem to indicate that some sexual preferences are learned.

INCENTIVE MOTIVATION

One area within the study of human motivation that has proved fruitful is research on incentives. Incentive motivation is concerned with the way goals influence behaviour. For example, a person might be willing to travel across the city to dine at a special restaurant that served a favourite dish. On the other hand, that same person might not be willing to travel the same distance to eat an ordinary frankfurter. The two meals have different incentive values and motivate behaviour to differing degrees.

It is often assumed that the stimulus characteristics of the goal are what produce the goal's motivating properties. Thus, the taste, smell, and texture of one food would motivate behaviour better than these qualities in another food. Unlike drives, which were thought to be innate, incentives are usually considered to be learned. An individual is not born preferring one goal over another, but rather these preferences develop as new goals are experienced. Incentive motivation is not restricted to goals associated with the primary motives of hunger, thirst, sex, or avoidance of pain. Indeed, one of the most important aspects of this type of motivation is that any goal one seeks can motivate behaviour. For example, the goal of obtaining a high-paying job could serve as a strong motivator for studying hard in school. Goals serving as incentive motivators do not even need to physically exist at the time they activate behaviour, such as might be the case for someone who is motivated to get high grades now in order to eventually get into medical school.

Effect of goal-seeking on behaviour

Theoretical explanations of incentive motivation have ranged from mechanical stimulus-response approaches based on classical conditioning to cognitive approaches emphasizing the learning of expectancies, as discussed in the section below. Several theories have emphasized the role of predictive cues in the development of incentive motivation. Researchers concerned primarily with human motivation have suggested that much of human behaviour can be understood as being directed toward specific goals.

Cognitive motivation

Cognitive theories of motivation assume that behaviour is directed as a result of the active processing and interpretation of information. Motivation is not seen as a mechanical or innate set of processes but as a purposive and persistent set of behaviours based on the information available. Expectations, based on past experiences, serve to direct behaviour toward particular goals.

Important concepts of cognitive motivation theory include expectancy-value theory, attribution theory, cognitive dissonance, self-perception, and self-actualization.

EXPECTANCY-VALUE THEORY

According to expectancy-value theory, behaviour is a function of the expectancies one has and the value of the goal toward which one is working [expressed as $B = f(E \times V)$]. Such an approach predicts that, when more than one behaviour is possible, the behaviour chosen will be the one with the largest combination of expected success and value. Expectancy-value theory has proved useful in the explanation of social behaviours, achievement motivation, and work motivation. Examination of its use in achievement motivation can serve to represent the various types of expectancy-value motivations.

Achievement was initially recognized as an important source of human motivation by the American psychologist Henry Murray in the late 1930s. Although Murray identified achievement motivation as important to the behaviour of many people, it was the American psychologists David McClelland and John Atkinson who devised a way of measuring differences in achievement motivation. These researchers used Murray's Thematic Apperception Test (TAT), a series of ambiguous pictures about which people were asked to write stories (as a determination of personality traits), to measure differences in achievement motivation. Using a technique known as content analysis, the stories were scored for achievement imagery. Based on a substantial body of research, a theoretical model was developed that rested upon the fundamental concepts of expectancy and goal value.

The expectancy-value model of achievement motivation proposes that the overall tendency to achieve in a particular situation depends upon two stable motives—a motive for success and a motive to avoid failure—and the subjective evaluation of the probability of success in the situation. The motive for success is regarded as a relatively stable personality characteristic by the time adulthood is reached. One's motive for success is believed to result from learning in prior achievement situations where the individual has performed successfully. Thus, someone who has, for the most part, had successful experiences in the past is thought to be highly achievement-oriented. The motive to avoid failure is also assumed to be relatively stable by adulthood and represents the compilation of those prior instances where achievement behaviours were unsuccessful. It is argued that someone who has made many unsuccessful attempts in achievement situations will develop a strong motive to avoid failure.

The motive for success

Since almost everyone has experienced both successes and failures during development, the theory assumes that each person has differing degrees of both motivation for success and motivation to avoid failure. These two motivations are opposing tendencies, and as a result the difference in strength between the two will determine whether a given individual is an "achiever" or not. People with high motivation for success and low motivation to avoid failure will be achievement-oriented, while people with strong motivation to avoid failure and weak motivation for success will try to avoid most achievement situations if possible.

The expected probability of success in a particular achievement situation is also important in this achievement theory. The theory predicts that persons highly motivated for success will tend to choose to participate in achievement situations that they judge to be moderately difficult, while the theory also predicts that people highly motivated to avoid failure will tend to choose tasks that they judge to be either very easy or extremely difficult. The choices made by people either highly motivated to achieve success or to avoid failure differ because of the differing value of easy, moderate, and difficult goals for these two types of people. The model mathematically predicts that goals that require moderate effort to achieve will have the greatest value for persons highly motivated

for success. Stated another way, high achievers want to obtain goals that are difficult enough to have some value but not so difficult as to be impossible or so easy as to be worthless. Persons with strong motivation to avoid failure believe they are likely to be unsuccessful. For this reason, the theory predicts that they would prefer easy tasks where success is likely or tasks so difficult that little embarrassment would ensue if they fail.

Attempts to test these predictions have met with mixed results. Some studies have found that people scoring high in motivation for success do often choose tasks that they consider moderately difficult, while other studies have failed to find such results. Also, persons scoring high in motivation to avoid failure do sometimes choose very easy tasks, as the theory predicts, but often do not choose very difficult tasks as also predicted. Clearly much research remains to be done before the model's accuracy in predicting achievement behaviour can be judged.

ATTRIBUTION THEORY

Rejection of the expectancy-value concept

A second major approach to achievement motivation rejects the expectancy-value formulation and analyzes instead the attributions that people make about achievement situations. In general, attribution theory concerns how people make judgments about someone's (or their own) behaviour—that is, the causes to which they attribute behaviour. Considerable research has found that people typically attribute behaviour either to stable personality characteristics, termed dispositions, or to the situations that were present at the time the behaviour occurred.

In regard to achievement behaviour, the attributions of ability, effort, task difficulty, and luck are argued to be especially important in determining future achievement motivation. For example, when a person is successful at a task and attributes that success to ability, that person is likely to approach new achievement situations in the future. Similarly, if the success was attributed to an intense effort, future achievement behaviour would depend upon a willingness to expend such effort in the future. Task difficulty appears to be judged from social norms. If most people are unsuccessful at a task, it is judged to be difficult, and, if most people are successful, the task is judged to be easy. The attribution of success to task difficulty therefore, would be expected to modify future achievement behaviour. If success was judged to be due to the fact that the task was very easy, future achievement behaviour would not be expected to change much; however, success in a task judged to be very difficult might prompt a person to expand the range of tasks he or she is willing to attempt. Ascriptions of luck in an achievement task would also influence future achievement behaviour. Basically, luck is assumed when a person expects to have no control over the outcome in the task. Success attributed to luck is not expected to increase future achievement behaviour much, nor would failure attributed to bad luck be expected to decrease it much.

Locus, stability, and controllability

Research on the attributions people make in achievement-related situations suggests that the four causal ascriptions mentioned above and perhaps other ascriptions as well can best be understood as falling along three dimensions: locus, stability, and controllability. Locus refers to the location, internal or external, of the perceived cause of a success or failure. Ability and effort, for example, are seen as internal dispositions of a person, while task difficulty and luck are situational factors external to the person. Stability refers to how much a given reason for success or failure could be expected to change. Ability and task difficulty are stable and therefore not expected to change much, while effort and luck are unstable and could therefore change dramatically over time. Controllability refers to how much control the individual has over the events of the situation. Causes such as effort are considered to be controllable, whereas luck is uncontrollable.

COGNITIVE DISSONANCE

One of the most popular cognitive approaches to the study of motivation has been the theory of cognitive dissonance, first systematically studied by the American psychologist Leon Festinger. This theory proposed that people attempt to maintain consistency among their beliefs, attitudes, and behaviours. According to this theory, a motivational state termed cognitive dissonance is produced whenever beliefs, attitudes, and behaviours are inconsistent. Cognitive dissonance is considered to be an aversive state that triggers mechanisms to bring cognitions back into a consistent relationship with one another. Much of the research on cognitive dissonance has centred around what happens when attitudes and behaviours are inconsistent. This research suggests that behavior inconsistent with one's beliefs—if there is insufficient justification for the behaviour—will often bring about modification of those beliefs. Suppose, for example, that a person is required to undergo a stressful initiation in order to join a select group. After undergoing this initiation the person discovers that becoming a member of the group does not provide the satisfaction originally expected. Such an outcome should produce cognitive dissonance because the behaviours required and the current belief about the group are inconsistent. As a result, the theory suggests that motivation will be triggered to bring the dissonant elements back into a consistent relationship. The behaviour cannot be changed because it has already occurred; the belief, on the other hand can be changed. Under these conditions dissonance theory predicts that the person's attitude will change and that he will actually come to believe that he likes the group more. Several studies have supported this prediction.

SELF-PERCEPTION THEORY

Cognitive dissonance approaches have not gone unchallenged. An alternative approach, known as self-perception theory, suggests that all individuals analyze their own behaviour much as an outside observer might and, as a result of these observations, make judgments about why they are motivated to do what they do. Thus, in the example above, self-perception theory would argue that the person, in observing his own behaviour, assesses the effort involved and decides that the initiation was endured because he really wanted to be a member of this group. Dissonance theory and self-perception theory are not necessarily mutually exclusive; several studies suggest that both processes can and do occur but under different conditions.

SELF-ACTUALIZATION

Cognitive motivational approaches have also explored the idea that human motivation is heavily influenced by a need for competence or control. Although there are several varieties of these theories, most have in common the idea that human behaviour is at least partially motivated by a need to become as much as one can possibly become. One example of this approach is the self-actualization theory of Abraham Maslow previously mentioned.

Maslow's hierarchy of needs

Maslow has proposed that human motivation can be understood as resulting from a hierarchy of needs. These needs, starting with the most basic physiological demands, progress upward through safety needs, belonging needs, and esteem needs and culminate in self-actualization. Each level directs behaviour toward the need level that is not being adequately met. As lower-level needs are met, the motivation to meet the higher-level needs becomes active. Furthermore, as an individual progresses upward, it becomes progressively more difficult to successfully fulfill the needs of each higher level. For this reason Maslow believed that very few people actually reach the level of self-actualization, and it is a lifelong process for the few who do.

Based on his observations of individuals he believed to be self-actualized, including historical figures such as the U.S. presidents Abraham Lincoln and Thomas Jefferson, Maslow outlined a cluster of 14 characteristics that distinguish self-actualized individuals. Summarized, these characteristics define individuals who are accepting of themselves and others, are relatively independent of the culture or society in which they live, are somewhat detached but with very close personal ties to a few other people, and are deeply committed to solving problems that they deem important. Additionally, self-actualized individuals intensely appreciate simple or natural events, such as a sunrise, and they sometimes experience profound changes

that Maslow termed peak experiences. Although difficult to describe, peak experiences often involve a momentary loss of self and feelings of transcendence. Reports of peak experiences also include the feeling of limitless horizons opening up and of being simultaneously very powerful, yet weak. Peak experiences are extremely positive in nature and often cause an individual to change the direction of his or her future behaviour. Maslow believed that everyone is capable of having peak experiences, but he believed that self-actualized persons have these experiences more often. (H.L.P.)

Applications in society

Attempts have been made in society to use motivational methods to achieve certain goals. In the control of animal behaviour, for example, it is clear that depriving an organism of food is a powerful means for accomplishing reinforcement. Appropriate use of food under these circumstances is an effective procedure for shaping an animal's behaviour, maintaining it, and controlling the rate of its occurrence. Likewise, it is clear that animals have preferences (within, for example, the range of foodstuffs) and that their behaviour can be controlled with relatively greater effectiveness by the proper selection of preferred substances for use in training.

Behavioral control through motivational reinforcement

In many cultures, deprivation cannot be used so readily with human beings as it can be with other animals, although there are many human examples. Thus, some success has been reported in effecting desired behaviour in the classroom by depriving children of some of their recess time when they behave in ways deemed undesirable by the school authorities. Economies based on the use of tokens (*e.g.,* poker chips) have been set up in schools, psychiatric hospitals, and institutions for retarded people. The result typically has been an improvement in the subjects' behaviour and personal care and in the ease with which they may be managed. In such economies, tokens can be exchanged for privileges and commodities (*e.g.,* candy and toys). The individual's ability to obtain tokens is made contingent on socially desirable acts, such as making beds, being personally clean, being cooperative, and being generally acceptable to others. There have been reports of marked improvement in scholastic achievement among institutionalized juvenile delinquents who have been placed in such token economies.

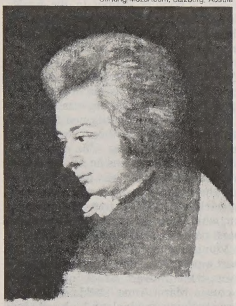
The effectiveness of these and similar procedures has been most easily demonstrated in institutions, in which the situation permits a great deal of control over the subjects' conditions of life and over their activities. In society at large, of course, this degree of control is effectively not feasible. There also are widely endorsed moral or ethical concerns about the desirability of instituting such control even if it were possible. The use of particular kinds of motivational devices in the control of human behaviour seems to many to be incompatible with the ethical idea of personal freedom and fraught with potential for immoral misuse in the hands of those who seek to manipulate others for ends that are politically or socially conformist.

On the other hand, it often is observed that many of society's problems are motivational. This observation usually means that the goals and values of economically affluent groups in the Americas, Europe, and Asia are not shared by members of deprived urban populations or by millions of poor people in industrially less-developed countries. Or, it may mean that the goals of those who own or control profit-seeking enterprises (to make a product or deliver a service for the investors' profit) are not shared by workers below the level of middle management. Many techniques have been tried in business and industry to effect so-called motivational involvement with production on the part of ordinary employees. Some of them have had success. Incentive systems, employee participation in company planning and decisions, and human-relations training exemplify the procedures used. A substantial corps of specialists throughout the world provides programs to industry designed to improve the motivation, morale, and satisfaction of workers at all levels. Although these programs have wide acceptance, most of them have received very little objective evaluation. (C.N.C.)

Motivational techniques in business and industry

Summary

Motivation is a complex topic that spans virtually all areas of psychology. No one theory is capable of explaining all that we know about motivational processes. Some motives such as hunger, thirst, and sexual activity seem best understood from a biological viewpoint. Other motives appear to be learned, and such motives help to account for the diversity and complexity of human activities. Still other motives are influenced by the cognitive processes in which we engage. Our interpretation of the events around us influences our future motivation.



A complicating factor in human motivation is the fact that even basic motives are influenced by a variety of elements. For example, we may eat because of energy needs, but some people also eat when stressed or anxious, when depressed or alone, or because of social influences such as other people eating. The taste qualities of certain foods may also cause us to eat when not hungry. This interaction of many factors in determining the motivation of behaviour seriously hinders our ability to understand even basic motivational processes; the contribution of various motivational components must be carefully separated and analyzed. When the study of more subtle motives is attempted, these complicating factors hinder understanding even more. In spite of the large amount of information we have on motivation, much yet remains to be understood. (H.L.P.)

BIBLIOGRAPHY. The following works are broad studies in psychology, and they, if not cover, then at least touch upon many aspects of the subject of motivation. CHARLES N. COFER, *Motivation & Emotion* (1972), is a concise discussion of the basic relevant psychological concepts. Good overviews of the major approaches to motivation are presented in HERBERT L. PETRI, *Motivation: Theory, Research, and Applications,* 3rd ed. (1991); and DAVID C. MCCLELLAND, *Human Motivation* (1985). NIKO TINBERGEN, *The Study of Instinct* (1951, reissued with a new preface by the author, 1989), offers an excellent survey of early research using the ethological approach. Development of the ethological school in the behavioral sciences is exemplified in KONRAD LORENZ and PAUL LEYHAUSEN, *Motivation of Human and Animal Behavior* (1973; originally published in German, 1968). IRENÄUS EIBL-EIBESFELDT, *Love and Hate; On the Natural History of Basic Behaviour Patterns* (1971; originally published in German, 1970), examines the role of instinctive behaviour in human motivation. CHARLES N. COFER and M.H. APPLEY, *Motivation: Theory and Research* (1964), is a monumental survey, which for years was considered a standard in the field. Another broad survey of developments in the period until the mid-1960s, though not as extensive, is M.D. VERNON, *Human Motivation* (1969). CLARK L. HULL, *Principles of Behavior: An Introduction to Behavior Theory* (1943, reissued 1966), includes a discussion of the learning approach, excluded from Vernon's book. ROBERT C. BOLLES, *Theory of Motivation,* 2nd ed. (1975), provides a review of the drive concept and its failure to explain all aspects of motivated behaviour. JOHN JUNG, *Understanding Human Motivation: A Cognitive Approach* (1978), covers also all traditional motivational approaches. HANS SELYE, *The Physiology and Pathology of Exposure to Stress: A Treatise Based on the Concepts of the General-Adaptation-Syndrome and the Diseases of Adaptation* (1950), and *The Stress of Life,* rev. ed. (1976, reissued 1984), provide a good introduction to the understanding of the concept of stress and the body's reaction to it. JOHN W. ATKINSON and DAVID BIRCH, *An Introduction to Motivation,* 2nd ed. (1978), examines the expectancy-value model of achievement motivation and the relevant research. ABRAHAM H. MASLOW (ed.), *New Knowledge in Human Values* (1959, reissued 1970), and the two books authored by Maslow, *Eupsychian Management: A Journal* (1965), and *The Farther Reaches of Human Nature* (1971), outline his ideas concerning self-actualization. NATHAN BRODY, *Human Motivation: Commentary on Goal-Directed Action* (1983), provides an overview of all mainstream scientific theories of motivation beginning with Hull. EDWARD L. DECI and RICHARD M. RYAN, *Intrinsic Motivation and Self-Determination in Human Behavior* (1985), offers a comprehensive look at the literature of motivation from Freud to the latest working theories. (H.L.P.)

Mozart

Wolfgang Amadeus Mozart is widely recognized as one of the greatest composers in the history of Western music. With Haydn and Beethoven he brought to its height the achievement of the Viennese Classical school. Unlike any other composer in musical history, he wrote in all the musical genres of his day and excelled in every one. His taste, his command of form, and his range of expression entitle him to be considered the most universal of all composers.

Mozart, unfinished oil portrait by Joseph Lange, 1789. In the Internationale Stiftung Mozarteum, Salzburg, Austria.

Early life and works. Mozart was born in Salzburg, now in Austria, then in church lands, on Jan. 27, 1756. Although baptized Joannes Chrysostomus Wolfgangus Theophilus, he most commonly called himself Wolfgang Amadè or Wolfgang Gottlieb. His father, Leopold, came from a family of good standing, which included architects and bookbinders, and was the author of a famous violin-playing manual; his mother, Anna Maria Pertl, was born of a middle-class family active in local administration. Mozart and his sister Maria Anna ("Nannerl") were the only two of their seven children to survive.

The boy's early talent for music was remarkable. At three he was picking out chords on the harpsichord, at four playing short pieces, at five composing. There are anecdotes about his precise memory of pitch, about his scribbling a concerto at the age of five, and about his gentleness and sensitivity (he was afraid of the trumpet). Just before he was six, his father took him and Nannerl, also highly talented, to Munich to play at the Bavarian court, and a few months later they went to Vienna and were heard at the imperial court and in noble houses.

"The miracle which God let be born in Salzburg" was Leopold's description of his son, and he was keenly conscious of his duty to God, as he saw it, to draw the miracle to the notice of the world (and incidentally to profit from doing so). In mid-1763 he obtained a leave of absence from his position as deputy Kapellmeister at the prince-archbishop's court at Salzburg, and the family set out on a prolonged tour. They went to what were all the main musical centres of western Europe—Munich, Augsburg, Stuttgart, Mannheim, Mainz, Frankfurt, Brussels, and Paris (where they remained for the winter), then London (where they spent 15 months), returning through The Hague, Amsterdam, Paris, Lyon, and Switzerland, and arriving back in Salzburg in November 1766. In most of these cities Mozart, and often his sister, played and improvised, sometimes at court, sometimes in public or in a church. Leopold's surviving letters to friends in Salzburg tell of the universal admiration that his son's achievements aroused. In Paris they met several German composers, and Mozart's first music was published (sonatas for keyboard and violin, dedicated to a royal princess); in London they met, among others, Johann Christian Bach, Johann Sebastian Bach's youngest son and a leading figure in the city's musical life, and under his influence Mozart composed his first symphonies—three survive (K 16, K 19, and K 19a—K signifying the work's place in the catalog of Ludwig von Köchel). Two more followed during a stay in The Hague on the return journey (K 22 and K 45a).

First European tour

After little more than nine months in Salzburg the Mozarts set out for Vienna in September 1767, where (apart from a 10-week break during a smallpox epidemic) they spent 15 months. Mozart wrote a one-act German singspiel, *Bastien und Bastienne,* which was given privately. Greater hopes were attached to his prospect of having an Italian opera buffa, *La finta semplice* ("The Feigned Simpleton"), done at the court theatre—hopes that were, however, frustrated, much to Leopold's indignation. But a substantial, festal mass setting (probably K 139/47a) was successfully given before the court at the dedication of the Orphanage Church. *La finta semplice* was given the following year, 1769, in the archbishop's palace in Salzburg. In October Mozart was appointed an honorary Konzertmeister at the Salzburg court.

La finta semplice

Still only 13, Mozart had by now acquired considerable fluency in the musical language of his time. The early Paris and London sonatas, the autographs of which include Leopold's helping hand, show a childlike pleasure in patterns of notes and textures. But the London and The Hague symphonies attest to his quick and inventive response to the music he had encountered, as, with their enrichment of texture and fuller development, do those he produced in Vienna (such as K 43 and, especially, K 48). And his first Italian opera shows a ready grasp of the buffo style.

The Italian tours. Mastery of the Italian operatic style was a prerequisite for a successful international composing career, and the Austrian political dominion over northern Italy ensured that doors would be open there to Mozart. This time Mozart's mother and sister remained at home, and the family correspondence provides a full account of events. The first tour, begun on Dec. 13, 1769, and lasting 15 months, took them to all the main musical centres, but as usual they paused at any town where a concert could be given or a nobleman might want to hear Mozart play. In Verona Mozart was put through stringent tests at the Accademia Filarmonica, and in Milan, after tests of his capacities in dramatic music, he was commissioned to write the first opera for the carnival season. After a stop in Bologna, where they met the esteemed theorist Giovanni Battista Martini, they proceeded to Florence and on to Rome for Holy Week. There Mozart heard the Sistine Choir in the famous *Miserere* of Gregorio Allegri (1582–1652), which was considered the choir's exclusive preserve but which Mozart copied out from memory. They spent six weeks in Naples; returning through Rome, Mozart had a papal audience and was made a knight of the order of the Golden Spur. The summer was passed near Bologna, where Mozart passed the tests for admission to the Accademia Filarmonica. In mid-October he reached Milan and began work on the new opera, *Mitridate, rè di Ponto* ("Mithradates, King of Pontus"). He had to rewrite several numbers to satisfy the singers, but, after a series of rehearsals (Leopold's letters provide fascinating insights as to theatre procedures), the premiere at the Regio Ducal

Rome

Teatro on December 26 was a notable success. Mozart, in the traditional way, directed the first three of the 22 performances. After a brief excursion to Venice he and his father returned to Salzburg.

Plans had already been laid for further journeys to Italy: for a theatrical serenata commissioned for a royal wedding in Milan in October 1771 and for a further opera, again for Milan, at carnival time in 1772–73. Mozart was also commissioned to write an oratorio for Padua; he composed *La Betulia liberata* during 1771, but there is no record of a performance. The second Italian visit, between August and December 1771, saw the premiere of his *Ascanio in Alba,* which, Leopold gleefully reported, "completely overshadowed" the other new work for the occasion, an opera (*Ruggiero*) by Johann Adolph Hasse, the most respected opera seria composer of the time. But hopes that Leopold had entertained of his son's securing an appointment in Milan were disappointed. Back in Salzburg, Mozart had a prolific spell: he wrote eight symphonies, four divertimentos, several substantial sacred works, and an allegorical serenata, *Il sogno di Scipione.* Probably intended as a tribute to the Salzburg prince-archbishop, Count Schrattenbach, this work may not have been given until the spring of 1772, and then for his successor Hieronymus, Count Colloredo; Schrattenbach, a tolerant employer generous in allowing leave, died at the end of 1771.

Third Italian journey

The third and last Italian journey lasted from October 1772 until March 1773. *Lucio Silla* ("Lucius Sulla"), the new opera, was given on Dec. 26, 1772, and after a difficult premiere (it began three hours late and lasted six) it proved even more successful than *Mitridate,* with 26 performances. This is the earliest indication of the dramatic composer Mozart was to become. He followed *Lucio Silla* with a solo motet written for its leading singer, the castrato and composer Venanzio Rauzzini, *Exsultate, jubilate* (K 165), an appealing three-movement piece culminating in a brilliant "Alleluia." The instrumental music of the period around the Italian journeys includes several symphonies; a few of them are done in a light, Italianate style (*e.g.,* K 95 and K 97), but others, notably the seven from 1772, tread new ground in form, orchestration, and scale (such as K 130, K 132, and the chamber musical K 134). There are also six string quartets (K 155–160) and three divertimentos (K 136–138), in a lively, extroverted vein.

Early maturity. More symphonies and divertimentos, as well as a mass, followed during the summer of 1773. Then Leopold, doubtless seeking again a better situation for his son than the Salzburg court (now under a much less sympathetic archbishop) was likely to offer, took him to Vienna. No position materialized, but Mozart's contact with the newest Viennese music seems to have had a considerable effect on him. He produced a set of six string quartets in the capital, showing in them his knowledge of Haydn's recent Opus 20 in his fuller textures and more intellectual approach to the medium. Soon after his return he wrote a group of symphonies, including two that represent a new level of achievement, the "Little" G Minor (K 183) and the A Major (K 201). Also dating from this time was Mozart's first true piano concerto (in D, K 175; earlier keyboard concertos were arrangements of movements by other composers).

The year 1774 saw the composition of more symphonies, concertos for bassoon and for two violins (in a style recalling J.C. Bach), serenades, and several sacred works. Mozart was now a salaried court Konzertmeister, and the sacred music in particular was intended for local use. Archbishop Colloredo, a progressive churchman, discouraged lavish music and set a severe time limit on mass settings, which Mozart objected to but was obliged to observe. At the end of the year he was commissioned to write an opera buffa, *La finta giardiniera* ("The Feigned Gardener Girl"), for the Munich carnival season, where it was duly successful. It shows Mozart, in his first comic opera since his childhood, finding ways of using the orchestra more expressively and of giving real personality to the pasteboard figures of Italian opera buffa.

La finta giardiniera

A period of two and a half years (from March 1775) began in which Mozart worked steadily in his Salzburg post. The work was for him undemanding and by no means compatible with his abilities. During this period he wrote only one dramatic work (the serenata-like *Il rè pastore,* "The Shepherd King," for an archducal visit), but he was productive in sacred and lighter instrumental music. His most impressive piece for the church was the *Litaniae de venerabili altaris sacramento* (K 243), which embraces a wide range of styles (fugues, choruses of considerable dramatic force, florid arias, and a plainchant setting). The instrumental works included divertimentos, concertos, and serenades, notably the *Haffner* (K 250), which in its use of instruments and its richness of working carried the serenade style into the symphonic without prejudicing its traditional warmth and high spirits. The five concertos for violin, all from this period (No. 1 may be slightly earlier), show a remarkable growth over a few months in confidence in handling the medium, with increasingly fanciful ideas and attractive and natural contexts for virtuoso display. The use of popular themes in the finales is typically south German. He also wrote a concerto for three pianos and three piano concertos, the last of them, K 271, showing a new level of maturity in technique and expressive range.

Mannheim and Paris. It must have been abundantly clear by this time to Mozart as well as his father that a small, provincial court like that at Salzburg was no place for a genius of his order. In 1777 he petitioned the archbishop for his release and, with his mother to watch over him, set out to find new opportunities. The correspondence with his father over the 16 months he was away not only gives information as to what he was doing but also casts a sharp light on their changing relationship; Mozart, now 21, increasingly felt the need to free himself from paternal domination, while Leopold's anxieties about their future assumed almost pathological dimensions.

They went first to Munich, where the elector politely declined to offer Mozart a post. Next they visited Augsburg, staying with relatives; there Mozart struck up a lively friendship with his cousin Maria Anna Thekla (they later had a correspondence involving much playful, obscene humour). At the end of October they arrived at Mannheim, where the court of the Elector Palatine was musically one of the most famous and progressive in Europe. Mozart stayed there for more than four months, although he soon learned that again no position was to be had. He became friendly with the Mannheim musicians, undertook some teaching and playing, accepted and partly fulfilled a commission for flute music from a German surgeon, and fell in love with Aloysia Weber, a soprano, the second of four daughters of a music copyist. He also composed several piano sonatas, some with violin. He put to his father a scheme for traveling to Italy with the Webers, which, naive and irresponsible, met with an angry response: "Off with you to Paris! and that soon, find your place among great people—aut Caesar aut nihil." The plan had been that he would go on alone, but now Leopold felt that he was not to be trusted and made the ill-fated decision that his mother should go too. They reached Paris late in March 1778, and Mozart soon found work. His most important achievement was the symphony (K 297) composed for the Concert Spirituel, a brilliant D Major work in which he met the taste of the Parisian public (and musicians) for orchestral display without sacrifice of integrity; indeed he exploited the devices they admired (such as the opening coup d'archet—a forceful, unanimous musical gesture) to new formal ends.

Mother's death

By the time of its premiere, on June 18, his mother was seriously ill, and on July 3 she died. Mozart handled the situation with consideration, first writing to his father of her grave illness, then asking an abbé friend in Salzburg to break the news. He went to stay with Friedrich Melchior, Baron von Grimm, a German friend. Soon after, Grimm wrote pessimistically to Leopold about his son's prospects in Paris, and Leopold negotiated a better post for him in Salzburg, where he would be court organist rather than violinist as before, though still nominally Konzertmeister. Summoned home, Mozart reluctantly obeyed, tarrying en route in Mannheim and in Munich—where the Mannheim musicians had now mostly moved and where

he was coolly received by Aloysia Weber. He reached Salzburg in mid-January 1780.

Salzburg and Munich. Back in Salzburg, Mozart seems to have been eager to display his command of international styles: of the three symphonies he wrote in 1779–80, K 318 in G Major has a Parisian premier coup d'archet and crescendos of the type favoured in Mannheim, and K 338 in C Major shows many features of the brilliant Parisian manner. His outstanding orchestral work of this period was, however, the sinfonia concertante for violin and viola K 364; the genre was popular in both cities, and there are many features of the Mannheim style in the orchestral writing, but the character of the work, its ingenious instrumental interplay, and its depth of feeling are unmistakably Mozartian. Also from this time came the cheerful two-piano concerto and the two-piano sonata, as well as a number of sacred works, including the best-known of his complete masses, the *Coronation Mass*.

But it was dramatic music that attracted Mozart above all. He had lately written incidental music to a play by Tobias Philipp von Gebler, and during 1779–80 he composed much of a singspiel, known as *Zaide*, although with no sure prospects of performance. So Mozart must have been delighted, in the summer of 1780, to receive a commission to compose a serious Italian opera for Munich. The subject was to be Idomeneus, king of Crete, and the librettist the local cleric Giambattista Varesco, who was to follow a French text of 1712. Mozart could start work in Salzburg as he already knew the capacities of several of the singers, but he went to Munich some 10 weeks before the date set for the premiere. Leopold remained at home until close to the time of the premiere and acted as a link between Mozart and Varesco; their correspondence is accordingly richly informative about the process of composition. Four matters dominate Mozart's letters home. First, he was anxious, as always, to assure his father of the enthusiasm with which the singers received his music. Second, he was concerned about cuts: the libretto was far too long, and Mozart had set it spaciously, so that much trimming—of the recitative, of the choral scenes, and even of two arias in the final acts—was needed. Third, he was always eager to make modifications that rendered the action more natural and plausible. And fourth, he was much occupied with accommodating the music and the action to the needs and the limitations of the singers.

Idomeneo

In *Idomeneo, rè di Creta* Mozart depicted serious, heroic emotion with a richness unparalleled elsewhere in his operas. Though influenced by Christoph Gluck and by Niccolò Piccinni and others, it is not a "reform opera": it includes plain recitative and bravura singing, but always to a dramatic purpose, and, though the texture is more continuous than in Mozart's earlier operas, its plan, because of its French source, is essentially traditional. Given on Jan. 29, 1781, just after Mozart's 25th birthday, it met with due success. Mozart and his father were still in Munich when, on March 12, he was summoned to join the archbishop's retinue in Vienna, where the accession of Joseph II was being celebrated.

Vienna: the early years. Fresh from his triumphs in Munich, where he had mixed freely with noblemen, Mozart now found himself placed, at table in the lodgings for the archbishop's entourage, below the valets if above the cooks. Furthermore, the archbishop refused him permission to play at concerts (including one attended by the emperor at which Mozart could have earned half a year's salary in an evening). He was resentful and insulted. Matters came to a head at an interview with Archbishop Colloredo, who, according to Mozart, used unecclesiastical language; Mozart requested his discharge, which was eventually granted at a stormy meeting with the court steward on June 9, 1781.

Mozart, who now went to live with his old friends the Webers (Aloysia was married to a court actor and painter), set about earning a living in Vienna. Although eager for a court appointment, he for the moment was concerned to take on some pupils, to write music for publication, and to play in concerts (which in Vienna were more often in noblemen's houses than in public). He also embarked on an opera, *Die Entführung aus dem Serail* (*The Abduction from the Seraglio*). (Joseph II currently required that German opera, rather than the traditional Italian, be given at the court theatre.) In the summer of 1781, rumours began to circulate, as far as Salzburg, that Mozart was contemplating marriage with the third of the Weber daughters, Constanze; but he hotly denied them in a letter to his father: "I have never thought less of getting married . . . besides, I am not in love with her." He moved lodgings to scotch the gossip. But by December he was asking for his father's blessing on a marriage with Constanze, with whom he was now in love and to whom, probably through the machinations of her mother and her guardian, he was in some degree committed. Because Constanze later destroyed Leopold's letters, for reasons that are easy to imagine, only one side of the correspondence exists; Leopold's reactions can, however, be readily inferred, and it would seem that this period marked a low point in the relationship between father and son.

Die Entführung aus dem Serail

Musically, Mozart's main preoccupation was with *Die Entführung* in the early part of 1782. The opera, after various delays, reached the Burgtheater stage on July 16. The story of the emperor's saying "very many notes, my dear Mozart" may not be literally true, but the tale is symptomatic: the work does have far more notes than any other then in the German repertory, with fuller textures, more elaboration, and longer arias. Mozart's letters to his father give insight into his approach to dramatic composition, explaining, for example, his use of accompanying figures and key relationships to embody meaning. He also had the original text substantially modified to strengthen its drama and allow better opportunities for music. Noteworthy features are the Turkish colouring, created by "exotic" turns of phrase and chromaticisms as well as janissary instruments; the extended Act 2 finale, along the lines of those in opera buffa but lacking the dramatic propulsion of the Italian type; the expressive and powerful arias for the heroine (coincidentally called Constanze); and what Mozart called concessions to Viennese taste in the comic music, such as the duet "Vivat Bacchus."

Die Entführung enjoyed immediate and continuing success; it was quickly taken up by traveling and provincial companies—as *La finta giardiniera* had been, to a lesser degree—and carried Mozart's reputation widely around the German-speaking countries. Later in the year he worked on a set of three piano concertos and began a set of six string quartets. He also started work on a mass setting, in C Minor, which he had vowed to write on his marriage but of which only the first two sections, "Kyrie" and "Gloria," were completed. Among the influences on this music, besides the Austrian ecclesiastical tradition, was that of the Baroque music (Bach, Handel, and others) that Mozart had become acquainted with, probably for the first time, at the house of his patron Baron Gottfried van Swieten, a music collector and antiquarian. The Baroque influence is noticeable especially in the spare textures and austere lines of certain of the solo numbers, though others are squarely in the decorative, south German late Rococo manner (this interest in "old-fashioned" counterpoint can also be seen in some of Mozart's piano music of the time and in his string arrangements of music from Bach's *The Well-Tempered Clavier*). Mozart and his wife visited Salzburg in the summer and autumn of 1783, when the completed movements were performed, with (as always intended) Constanze singing one of the solo soprano parts, at St. Peter's Abbey. On the way back to Vienna Mozart paused at Linz, where he hastily wrote the symphony known by that city's name for a concert he gave there.

The Baroque influence

The central Viennese period. Back in Vienna Mozart entered on what was to be the most fruitful and successful period of his life. He had once written to his father that Vienna was "the land of the piano," and his greatest triumphs there were as a pianist-composer. During one spell of little more than five weeks he appeared at 22 concerts, mainly at the Esterházy and Galitzin houses but including five concerts of his own. In February 1784 he began to keep a catalog of his own music, which suggests a new awareness of posterity and his place in it (in fact his entries are sometimes misdated). At concerts he would normally play the piano, both existing pieces and improvisations;

his fantasias—such as the fine C Minor one (K 475) of 1785—and his numerous sets of variations probably give some indication of the kind of music his audiences heard. He would also conduct performances of his symphonies (using earlier Salzburg works as well as the two written since he had settled in Vienna, the *Haffner* of 1782, composed for the Salzburg family, and the *Linz* [*Symphony No. 36 in C Major*]); but above all the piano concertos were the central products of his concert activity.

In 1782–83 Mozart wrote three piano concertos (K 413–415), which he published in 1785 with string and optional wind parts (so that they were suitable for domestic use) and described as "a happy medium between what is too easy and too difficult." Six more followed in 1784, three each in 1785 and 1786 and one each in 1788 and 1791. With the 1784 group he established a new level of piano concerto writing; these concertos are at once symphonic, melodically rich, and orchestrally ingenious, and they also blend the virtuoso element effectively into the musical and formal texture of the work. Much melodic material is assigned to the wind instruments, and a unique melodic style is developed that lends itself to patterns of dialogue and instrumental interplay. After the relatively homogeneous 1784 group (K 449, 450, 451, 453, 456, and 459), all of which begin with themes stated first by the orchestra and later taken up by the piano, Mozart moved on in the concertos of 1785 (K 466, 467, and 482) to make the piano solo a reinterpretation of the opening theme. These concertos are increasingly individual in character—one a stormy and romantic D Minor work, the next a closely argued concerto in C Major with a slow movement remarkable for its troubled beauty, and the third, in E-flat Major, notable for its military rhythms and wind colouring. The 1786 group begins with the refined but conservatively lyrical K 488, but then follow two concertos with a new level of symphonic unity and grandeur, that in C Minor (K 491), using the largest orchestra Mozart had yet called for in the concert hall, and the imperious concerto in C Major (K 503). The two final concertos (K 537 and 595) represent no new departures.

Mozart's other important contributions of this time come in the fields of chamber and piano music. The outpouring of 1784 included the fine piano sonata K 457 and the piano and violin sonata K 454 (written for a visiting violin virtuoso, it was produced in such haste that Mozart could not write out the piano part and played from blank paper at the premiere). He also wrote, in a style close to that of the concertos, a quintet for piano and wind instruments (K 452), which he considered his finest work to date; it was first heard at a concert in the house of his pupil Barbara Ployer, for whom two of the 1784 concertos had been written (K 449 and 453). The six string quartets on which he had embarked in 1782 were finished in the first days of 1785 and published later that year, dedicated to Haydn, now a friend of Mozart's. In 1785 Haydn said to Leopold Mozart, on a visit to his son in Vienna, "Your son is the greatest composer known to me in person or by name; he has taste, and what is more the greatest knowledge of composition."

Haydn's praise

From Figaro to Don Giovanni. In spite of his success as a pianist and composer, Mozart had serious financial worries, and they worsened as the famously fickle Viennese found other idols. One may calculate his likely income during his last five years, 1786–91, as being far larger than that of most musicians though much below that of the section of society with which he wanted to be associated; Leopold's early advice to be aloof ("like an Englishman") with his fellow musicians but friendly with the aristocracy had its price. His sense of being as good a man as any privileged nobleman led him and his wife into tastes that for his actual station in life, and his income, were extravagant. He saw a court appointment as a possible source of salvation but knew that the Italian musical influence at court, under the Kapellmeister Antonio Salieri, was powerful and exclusive—even if he and Salieri were never on less than friendly terms personally.

Success in the court opera house was all-important. Joseph II had now reverted to Italian opera, and since 1783 Mozart had been seeking suitable librettos (he had even started work on two but broke off when he came to realize their feebleness for his purpose). He had become acquainted with Lorenzo da Ponte, an Italian abbé-adventurer of Jewish descent who was a talented poet and librettist to the court theatre. At Mozart's suggestion he wrote a libretto, *Le nozze di Figaro,* based on Beaumarchais's revolutionary comedy, *Le Mariage de Figaro,* but with most of the political sting removed. Nonetheless, the music of *Figaro* makes the social distinctions clear. *Figaro,* as well as the later opera *Don Giovanni,* treats the traditional figure of the licentious nobleman, but the earlier work does so on a more directly comic plane even though the undercurrents of social tension run stronger. Perhaps the central achievement of *Figaro* lies in its ensembles with their close link between music and dramatic meaning. The Act 3 Letter Duet, for instance, has a realistic representation of dictation with the reading back as a condensed recapitulation. The act finales, above all, show a broad, symphonic organization with each section worked out as a unit; for example, in the B-flat section of the Act 2 finale the tension of the count's examination of Figaro is paralleled in the tonal scheme, with its return to the tonic only when the final question is resolved: a telling conjunction of music and drama. These features, coupled with the elaborate commentary on character and action that is embodied in the orchestral writing, add depth to the situations and seriousness to their resolution and set the work apart from the generality of Italian opere buffe.

Le nozze di Figaro

Figaro reached the stage on May 1, 1786, and was warmly received. There were nine performances in 1786 and a further 26 when it was revived in 1789–90—a success, but a modest one compared with certain operas of Martín y Soler and Giovanni Paisiello (to whose *Il barbiere di Siviglia* it was a sequel, and planned in direct competition). The opera did, however, enjoy outstanding popularity in Prague, and at the end of the year Mozart was invited to go to the Bohemian capital; he went in January 1787, giving a new symphony there and accepting a further operatic commission. He returned to Vienna in February 1787.

Mozart's concert activities in Vienna were now on a modest scale. No Viennese appearances at all are recorded for 1787. In April he heard that his father was gravely ill. Mozart wrote him a letter of consolation putting forward a view of death ("this best and truest friend of mankind") based on the teachings of Freemasonry, which he had embraced at the end of 1784. Leopold died in May 1787.

Mozart's music from this time includes the two string quintets K 515–516, arguably his supreme chamber works. Clearly this genre, with the opportunities it offered for richness of sonority and patterns of symmetry, had a particular appeal for him. The quintet in C Major (K 515) is the most expansive and most richly developed of all his chamber works, while the G Minor (K 516) has always been recognized for its depth of feeling, which in the circumstances it is tempting to regard as elegiac. From this period come a number of short but appealing lieder and three instrumental works of note: the *Musikalischer Spass* (*Musical Joke*), a good-humoured parody of bad music, in a vein Leopold would have liked (it was thought to have been provoked by his death until it was found that it was begun much earlier); *Eine kleine Nachtmusik,* the exquisite and much-loved serenade, probably intended for solo strings and written for a purpose that remains unknown; and a fine piano and violin sonata, K 526.

But Mozart's chief occupation during 1787 was the composition of *Don Giovanni,* commissioned for production in Prague; it was given on October 29 and warmly received. *Don Giovanni* was Mozart's second opera based on a libretto by da Ponte, who used as his model a libretto by Giovanni Bertati, set by Giuseppe Gazzaniga for Venice earlier in 1787. Da Ponte rewrote the libretto, inserting new episodes into the one-act original, which explains certain structural features. A difference in Mozart's approach to the work—a *dramma giocoso* in the tradition of Carlo Goldoni that, because of its more serious treatment of character, had a greater expressive potential than an opera buffa—is seen in the extended spans of the score, with set-piece numbers often running into one another.

Don Giovanni

As in *Figaro,* the two act finales are again remarkable: the first for the three stage bands that play dances for different social segments, the second for the supper scene in which the commendatore's statue consigns Giovanni to damnation, with trombones to suggest the supernatural and with hieratic dotted rhythms, extreme chromaticism, and wildly lurching harmony as Giovanni is overcome. But it remains a comic opera, as is made clear through the figure of Leporello, who from under a table offers the common man's wry or facetious observations; and at the end the surviving characters draw the moral in a cheerful sextet. The "demonic" character of the opera has caused it to exercise a special fascination for audiences, and it has given rise to a large critical, interpretative, and purely fanciful literature.

The last travels. On his return from Prague in mid-November 1787, Mozart was at last appointed to a court post, as *Kammermusicus,* in place of Gluck, who had died. It was largely a sinecure, the only requirement being that he should supply dance music for court balls, which he did, in abundance and with some distinction, over his remaining years. The salary of 800 gulden seems to have done little to relieve the Mozarts' chronic financial troubles. Their debts, however, were never large, and they were always able to continue employing servants and owning a carriage; their anxieties were more a matter of whether they could live as they wished than whether they would starve. In 1788 a series of letters begging loans from a fellow Freemason, Michael Puchberg, began; Puchberg usually obliged, and Mozart seems generally to have repaid him promptly. He was deeply depressed during the summer, writing of "black thoughts"; it has been suggested that he may have had a cyclothymic personality, linked with manic-depressive tendencies, which could explain not only his depression but also other aspects of his behaviour, including his spells of hectic creativity.

Financial difficulties

During the time of this depression Mozart was working on a series of three symphonies, in E-flat Major (K 543), G Minor (K 550), and C Major (the *Jupiter,* K 551), usually numbered 39, 40, and 41; these, with the work written for Prague (K 504), represent the summa of his orchestral output. It is not known why they were composed; possibly Mozart had a summer concert season in mind. The Prague work was a climax to his long series of brilliant D Major orchestral pieces, but the closely worked, even motivic form gives it a new power and unity. The E-flat Major work, scored with clarinets and more lyrical in temper, makes fewer departures, except in the intensity of its slow movement, where Mozart used a new palette of darker orchestral colours, and the epigrammatic wit of its finale. In the G Minor work the tone of passion and perhaps of pathos, in its constant falling figures, is still more pronounced. The *Jupiter* (the name dates from the early 19th century) summarized the series of C Major symphonies, with their atmosphere of military pomp and ceremony, but it went far beyond them in its assimilation of opera buffa style, profundity of expression (in its andante), and richness of working—especially in the finale, which incorporates fugal procedures and ends with a grand apotheosis in five-voice counterpoint.

Early in 1789 Mozart accepted an invitation to travel to Berlin with Prince Karl Lichnowsky; they paused in Prague, Dresden (where he played at court), and Leipzig (where he improvised on the Thomaskirche organ). He appeared at the Prussian court and probably was invited to compose piano sonatas for the princess and string quartets with a prominent cello part for King Friedrich Wilhelm II. He did in fact write three quartets, in parts of which he allowed the individual instruments (including the royal cello) special prominence, and there is one sonata (his last, K 576) that may have been intended for the Prussian princess. But it is unlikely that Mozart ever sent this music or was paid for it.

The summer saw the composition of the clarinet quintet, in which a true chamber style is warmly and gracefully reconciled with the solo writing. Thereafter Mozart concentrated on completing his next opera commission, the third of his da Ponte operas, *Così fan tutte,* which was given on Jan. 26, 1790; its run was interrupted after five performances when theatres closed because of the death of Joseph II, but a further five were given in the summer. This opera, the subtlest, most consistent, and most symmetrical of the three, was long reviled (from Beethoven onward) on account of its subject, female fickleness; but a more careful reading of it, especially in light of the emotional texture of the music, which gains complexity as the plot progresses, makes it clear that it is no frivolous piece but a penetrating essay on human feelings and their mature recognition. The music of Act 1 is essentially conventional in expression, and conventional feeling is tellingly parodied in certain of the arias; but the arias of Act 2 are on a deeper and more personal level. Features of the music of *Così fan tutte*—serenity, restraint, poise, irony—may be noted as markers of Mozart's late style, which had developed since 1787 and may be linked with his personal development and the circumstances of his life, including his Masonic associations, his professional and financial situation, and his marriage.

Così fan tutte

The year 1790 was difficult and unproductive: besides *Così fan tutte,* Mozart completed two of the "Prussian" quartets, arranged works by Handel for performance at van Swieten's house (he had similarly arranged *Messiah* in 1789), and wrote the first of his two fantasy-like pieces, in a variety of prelude-and-fugue form, for a mechanical organ (this imposing work, in F Minor [K 594], is now generally played on a normal organ). In the autumn, anxious to be noticed in court circles, he went to Frankfurt for the imperial coronation of Leopold II, but as an individual rather than a court musician. His concert, which included two piano concertos and possibly one of the new symphonies, was ill timed, poorly attended, and a financial failure. Anxieties about money were a recurrent theme in his letters home.

The last year. But 1791 promised to be a better year. Music was flowing again: for a concert in March Mozart completed a piano concerto (K 595) begun some years before, reeled off numerous dances for the Redoutensaal, and wrote two new string quintets, the one in D (K 593) being a work of particular refinement and subtlety. In April he applied successfully for the role of unpaid assistant to the elderly Kapellmeister of St. Stephen's Cathedral, Leopold Hofmann (with the expectation of being duly appointed his successor, but Hofmann was to live until 1793).

An old friend of Mozart's, Emanuel Schikaneder, had in 1789 set up a company to perform singspiels in a suburban theatre, and in 1791 he engaged Mozart to compose a score to his *Die Zauberflöte* (*The Magic Flute*); Mozart worked on it during the spring and early summer. Then he received another commission, anonymously delivered, for a requiem, to be composed under conditions of secrecy. In addition he was invited, probably in July, to write the opera to be given during Leopold II's coronation festivities in September. Constanze was away taking a cure at Baden during much of the summer and autumn; in July she gave birth to their sixth child, one of the two to survive (Carl Thomas, 1784–1858, and Franz Xaver Wolfgang, 1791–1844, a composer and pianist). Mozart's letters to her show that he worked first on *Die Zauberflöte,* although he must have written some of the Prague opera, *La clemenza di Tito* ("The Clemency of Titus"), before he left for the Bohemian capital near the end of August. Pressure of work, however, was such that he took with him to Prague, along with Constanze, his pupil Franz Xaver Süssmayr, who almost certainly composed the plain recitatives for the new opera. The work itself, to an old libretto by Pietro Metastasio, condensed and supplemented by the Dresden court poet Caterino Mazzolà, was long dismissed as a product of haste and a commission unwillingly undertaken; but in fact the spare scoring, the short arias, and the generally restrained style are better understood in terms of Mozart's reaction to the neoclassical thinking of the time and the known preferences of Leopold II. The opera was indifferently received by the court but quickly won over the Prague audiences and went on to become one of Mozart's most admired works over the ensuing decades.

Die Zauberflöte

Mozart was back in Vienna by the middle of September; his clarinet concerto was finished by September 29, and the next day *Die Zauberflöte* had its premiere. Again,

early reactions were cautious, but soon the opera became the most loved of all of Mozart's works for the stage. Schikaneder took its plot from a collection of fairy tales by Christoph Martin Wieland but drew too on other literary sources and on current thinking about Freemasonry—all viewed in the context of Viennese popular theatre. Musically it is distinguished from contemporary singspiels not merely by the quality of its music but also by the serious ideas that lie below what may seem to be merely childish pantomime or low comedy, welding together the stylistically diverse elements.

Mozart had been ill during the weeks in Prague, but to judge by his letters to Constanze in October he was in good spirits and, with some cause, more optimistic about the future. He wrote a Masonic cantata for his lodge and directed a performance of it on November 18. He was also working steadily on the commissioned requiem. Later in November he was ill and confined to bed; some apparent improvement on December 3 was not sustained, and on Dec. 5, 1791, he died. "Severe miliary fever" was the certified cause; later, "rheumatic inflammatory fever" was named. Other diagnoses, taking account of Mozart's medical history, have been put forward, including Schönlein–Henoch syndrome. There is no evidence to support the tale that he was poisoned by Salieri (a colleague and friend, hardly a real rival) or anyone else. He was buried in a multiple grave, standard at the time in Vienna for a person of his social and financial situation; a small group of friends attended the funeral.

Completion of the requiem

Constanze Mozart was anxious to have the requiem completed, as a fee was due; it had been commissioned, in memory of his wife, by Count von Walsegg-Stuppach to pass off as his own. She handed it first to Joseph Eybler, who supplied some orchestration but was reluctant to do more, and then to Süssmayr, who produced a complete version, writing several movements himself though possibly basing them on Mozart's sketches or instructions. Although subject to criticism for its technical weaknesses, which editors have sought to remedy, this must remain the standard version by dint of its position as the only one with a source close to Mozart. The sombre grandeur of the work, with its restrained instrumental colouring and its noble choral writing, hints at what might have been had Mozart lived to take on the Kapellmeistership of St. Stephen's.

Mozart's place. At the time of his death Mozart was widely regarded not only as the greatest composer of the time but also as a bold and "difficult" one; *Don Giovanni* especially was seen as complex and dissonant, and his chamber music as calling for outstanding skill in its interpreters. His surviving manuscripts, which included many unpublished works, were mostly sold by Constanze to the firm of André in Offenbach, which issued editions during the 19th century. But Mozart's reputation was such that even before the end of the 18th century two firms had embarked on substantial collected editions of his music. Important biographies appeared in 1798 and 1828, the latter by Constanze's second husband; the first scholarly biography, by Otto Jahn, was issued on Mozart's centenary in 1856. The first edition of the Köchel catalog followed six years later, and the first complete edition of his music began in 1877.

First edition of the Köchel catalog

The works most secure in the repertory during the 19th century were the three operas least susceptible to changes in public taste—*Le nozze di Figaro, Don Giovanni,* and *Die Zauberflöte*—and the orchestral works closest in spirit to the Romantic era—the minor-key piano concertos (Beethoven wrote a set of cadenzas for the one in D Minor) and the last three symphonies. It was only in the 20th century that Mozart's music began to be reexamined more broadly. Although up to the middle of the century Mozart was still widely regarded as having been surpassed in most respects by Beethoven, with the increased historical perspective of the later 20th century he came to be seen as an artist of a formidable, indeed perhaps unequaled, expressive range. The traditional image of the child prodigy turned refined drawing-room composer, who could miraculously conceive an entire work in his head before setting pen to paper (always a distortion of the truth), gave way to the image of the serious and painstaking creative artist with acute human insight, whose complex psychology demanded exploration by writers, historians, and scholars. But regardless of such shifting currents of interpretation, in public esteem and affection Mozart's place more than equals that of any other composer.

MAJOR WORKS

Mozart's works are listed in the catalog of LUDWIG RITTER VON KÖCHEL, *Chronologisch-thematisches Verzeichniss sämtlicher Tonwerke Wolfgang Amade Mozarts* (1862). It was twice significantly revised and enlarged, namely, for the 3rd ed., edited by ALFRED EINSTEIN (1937), with suppl. (1947), and the 6th ed., edited by FRANZ GIEGLING, ALEXANDER WEINMANN, and GERD SIEVERS (1964, reprinted 1983).

The following list excludes works that are lost, of doubtful authenticity, or substantially incomplete.

Vocal works

SACRED WORKS: 7 long masses (1 incomplete); 7 short masses; *Requiem,* K. 626, 1791 (incomplete); 4 litanies; 2 vespers; 22 motets and miscellaneous works (including *Exsultate, jubilate,* K. 165, 1773); 17 church sonatas.

ORATORIOS AND CANTATAS: 2 oratorios; 1 act of a sacred drama; Passion cantata; 4 Masonic cantatas.

DRAMATIC WORKS: 15 operas (including *Idomeneo, rè di Creta,* K. 366, 1781; *Die Entführung aus dem Serail,* K. 384, 1782; *Le nozze di Figaro,* K. 492, 1786; *Don Giovanni,* K. 527, 1787; *Così fan tutte,* K. 588, 1790; *Die Zauberflöte,* K. 620, 1791; *La clemenza di Tito,* K. 621, 1791); 2 serenatas; 1 ballet; 1 Latin intermezzo; incidental music.

MISCELLANEOUS VOCAL: 17 pieces for 2 to 4 voices with orchestra, ensemble, or piano; 48 songs and arias with orchestra (some for insertion into operas); 31 songs with piano; 15 vocal and 20 unspecified canons.

Instrumental works

SYMPHONIES: 56 symphonies, with some adapted from overtures and serenades (the traditional numbering up to 41 omits many and includes three not by Mozart), including *No. 38 in D Major (Prague),* K. 504, 1786; *No. 39 in E-flat Major,* K. 543, 1788; *No. 40 in G Minor,* K. 550, 1788; *No. 41 in C Major (Jupiter),* K. 551, 1788.

OTHER ORCHESTRAL AND ENSEMBLE MUSIC: 21 serenades (including *Serenata notturna,* K. 239, 1776; *Serenade in D Major [Haffner],* K. 250, 1776; *Serenade in D Major [Posthorn],* K. 320, 1779; *Eine kleine Nachtmusik,* K. 525, 1787), cassations, and divertimentos; 17 serenades and divertimentos for wind instruments; 13 marches, 105 minuets, 56 German dances, 47 contredanses.

CONCERTOS: For piano, 21, 7 arrangements of music by other composers, and 2 rondos (the traditional numbering includes 2 multiple concertos and 4 arrangements); 1 for 2 pianos; 1 for 3 pianos; 5 for violin; 1 *Concertone,* K. 190, 1774, for two violins; 1 *Sinfonia concertante,* K. 364, 1779, for violin and viola; 2 for flute; 1 for oboe; 1 for clarinet; 1 for bassoon; 3 and 1 incomplete for horn.

CHAMBER MUSIC: 6 string quintets; 26 string quartets and *Adagio and Fugue,* K. 546, 1788; 2 string trios; 2 string duos; 1 duo for bassoon and cello; 4 flute quartets; 1 oboe quartet; 1 clarinet quintet; 1 horn quintet; 1 quintet for piano and winds; 2 piano quartets; 7 piano trios (1 with clarinet); adagio and rondo for glass harmonica, wind, and strings; 32 sonatas and 2 sets of variations for piano and violin.

KEYBOARD MUSIC: 19 piano sonatas; 5 sonatas for piano duet; 1 two-piano sonata; 16 sets of variations for piano; 1 set of variations for piano duet; 27 pieces for piano; fugue for 2 pianos; 3 pieces for mechanical organ; adagio for glass harmonica.

BIBLIOGRAPHY. The Mozart literature is vast. Sources and documents of his lifetime begin with his numerous letters that are available in a critical edition of the family correspondence, *Mozart, Briefe und Aufzeichnungen: Gesamtausgabe,* 7 vol., ed. by WILHELM A. BAUER and OTTO ERICH DEUTSCH (1962–75); and in WOLFGANG AMADEUS MOZART, *Briefe,* ed. by ALBRECHT GOES (1979). For the English translation of the correspondence, see EMILY ANDERSON (ed.), *The Letters of Mozart and His Family,* 3rd ed. (1985, rev. 1989).

A comprehensive bibliography of secondary sources appeared as the *Mozart-Jahrbuch 1975* and in 1976 was published as *Mozart-Bibliographie (bis 1970),* RUDOLPH ANGERMÜLLER and OTTO SCHNEIDER (comps.). These compilers have continued the bibliography in *Mozart-Bibliographie, 1971–1975* (1978), *Mozart-Bibliographie, 1976–1980* (1982), and *Mozart-Bibliographie, 1981–1985* (1987). More selective bibliographies are included in many of the biographical works cited here.

Basic secondary sources begin with a biography-obituary that appeared in the periodical *Nekrolog auf das Jahr 1791,* ed. by FRIEDRICH SCHLICHTEGROLL (1793), vol. 2, pp. 82–112, and supplement, 2, pp. 159ff. Other early biographies are FRANZ

XAVER NIEMETSCHEK, *Life of Mozart* (1956, reprinted 1979; originally published in German, 1798); and GEORG NIKOLAUS VON NISSEN, *Biographie W.A. Mozarts* (1828, reprinted 1984). The first scholarly biography is OTTO JAHN, *Life of Mozart*, 3 vol. (1882, reissued 1970; originally published in German, 1856–59). This work was later thoroughly revised and greatly enlarged for the 5th edition by HERMANN ABERT (ed.), *W.A. Mozart*, 2 vol. (1919–21, reissued 1983), but this edition has not been translated into English. Documentary sources are compiled and annotated in OTTO ERICH DEUTSCH, *Mozart: A Documentary Biography*, 2nd ed. (1966; originally published in German, 1961); it is supplemented by JOSEPH HEINZ EIBL (comp.), *Mozart: Die Dokumente seines Lebens: Addenda und Corrigenda* (1978). MAXIMILIAN ZENGER and OTTO ERICH DEUTSCH, *Mozart and His World in Contemporary Pictures* (1961), is a pictorial account with parallel English and German text.

Other studies of the composer's life include ALFRED EINSTEIN, *Mozart, His Character, His Work*, trans. from German (1945, reissued 1971), a sympathetic and perceptive, if a little dated, work; ARTHUR HUTCHINGS, *Mozart, the Man, the Musician* (1976), a generously illustrated exploration of the life and the career; WOLFGANG HILDESHEIMER, *Mozart* (1982; originally published in German, 1977), a speculative psychological exploration; MICHAEL LEVEY, *The Life and Death of Mozart*, rev. ed. (1988), an attempt to discover new links between life and music; IVOR KEYS, *Mozart: His Music in His Life* (1980), a general introduction; STANLEY SADIE, "Wolfgang Amadeus Mozart," in *The New Grove Dictionary of Music and Musicians*, vol.12 (1980), pp. 680–752, a biography with an exhaustive list of Mozart's works, available also as a monograph; and H.C. ROBBINS LANDON, *1791, Mozart's Last Year* (1988), a new interpretation of documentary sources.

Discussions of Mozart's music include CHARLES ROSEN, *The Classical Style: Haydn, Mozart, Beethoven*, rev. ed. (1976), a study of both the technicalities and aesthetics of the music. H.C. ROBBINS LANDON and DONALD MITCHELL (eds.), *The Mozart Companion* (1956, reprinted 1981); and PAUL HENRY LANG (ed.), *The Creative World of Mozart* (1963), are collections of essays by specialists. Operas are surveyed in WILLIAM MANN, *The Operas of Mozart* (1977), treating all of the composer's dramatic works; and CHARLES OSBORNE, *The Complete Operas of Mozart: A Critical Guide* (1978, reprinted 1986), an introductory guide. New standpoints on the operas are seen in FRITS NOSKE, *The Signifier and the Signified: Studies in the Operas of Mozart and Verdi* (1977); WYE JAMISON ALLANBROOK, *Rhythmic Gesture in Mozart: Le Nozze di Figaro & Don Giovanni* (1983); BRIGID BROPHY, *Mozart the Dramatist: The Value of His Operas to Him, to His Age, and to Us*, rev. ed. (1988), a psychoanalytical study; and ANDREW STEPTOE, *The Mozart-Da Ponte Operas: The Cultural and Musical Background to Le nozze di Figaro, Don Giovanni, and Così fan tutte* (1988). The "Cambridge Opera Handbooks" series offers valuable surveys of individual operas: JULIAN RUSHTON, *W.A. Mozart: Don Giovanni* (1981); TIM CARTER, *W.A. Mozart: Le Nozze di Figaro* (1987); and THOMAS BAUMAN, *W.A. Mozart: Die Entführung aus dem Serail* (1987).

For instrumental music, see ARTHUR HUTCHINGS, *A Companion to Mozart's Piano Concertos*, 2nd ed. (1950, reprinted 1980), an enthusiastic, personal survey; and the works from the useful "BBC Music Guides" series: A. HYATT KING, *Mozart Chamber Music* (1968, reprinted 1986), and *Mozart Wind and String Concertos* (1978, reprinted 1986); STANLEY SADIE, *Mozart Symphonies* (1986); and ERIK SMITH, *Mozart Serenades, Divertimenti, and Dances* (1982). ALAN TYSON, *Mozart: Studies of the Autograph Scores* (1987), offers fascinating glimpses into Mozart's creative workshop; while A. HYATT KING, *Mozart in Retrospect: Studies in Criticism and Bibliography* (1955, reprinted with revisions, 1976). looks at his changing image and reputation over the years. (S.Sa.)

Muscles and Muscle Systems

Movement, the intricate cooperation of muscle and nerve fibres, is the means by which an organism interacts with its environment. The innervation of muscle cells, or fibres, permits an animal to carry out the normal activities of life. An organism must move to find food or, if it is sedentary, must have the means to bring food to itself. An animal must be able to move nutrients and fluids through its body, and it must be able to react to external or internal stimuli. Muscle cells fuel their actions by converting chemical energy in the form of adenosine triphosphate (ATP), which is derived from the metabolism of food, into mechanical energy.

Muscle is contractile tissue grouped into coordinated systems for greater efficiency. In humans, the muscle systems are classified by gross appearance and location of cells. The three types of muscles are striated (or skeletal), cardiac, and smooth (or nonstriated). Striated muscle is almost exclusively attached to the skeleton and constitutes the bulk of the body's muscle tissue. The multinucleated fibres are under the control of the somatic nervous system and elicit movement by forces exerted on the skeleton similar to levers and pulleys. The rhythmic contraction of cardiac muscle is regulated by the sinoatrial node, the heart's pacemaker. Although cardiac muscle is specialized striated muscle consisting of elongated cells with many centrally located nuclei, it is not under voluntary control. Smooth muscle lines the viscera, blood vessels, and dermis, and, like cardiac muscle, its movements are operated by the autonomic nervous system and thus are not under voluntary control. The nucleus of each short, tapering cell is located centrally.

Unicellular organisms, simple animals, and the motile cells of complex animals do not have vast muscle systems. Rather, movement in these organisms is elicited by hairlike extensions of the cell membrane called cilia and flagella or by cytoplasmic extensions called pseudopodia.

This article consists of a comparative study of the muscle systems of various animals, including an explanation of the process of muscle contraction and an account of the human muscle system as it relates to upright posture. A brief survey of the diseases that affect human muscle is also included.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 421 and 423, and the *Index*. (W.F.W./R.McN.A./Ed.)

General features of muscle and movement

Muscle powers the movements of multicellular animals and maintains posture. Its gross appearance is familiar as meat or as the flesh of fish. Muscle is the most plentiful tissue in many animals; for example, it comprises 50 to 60 percent of the body mass in many fishes, and 40 to 50 percent in antelopes. Some muscles are under conscious control and are called voluntary muscles. Other muscles, called involuntary muscles, are not consciously controlled by the organism; for example, in vertebrates, muscles in the walls of the heart contract rhythmically, pumping blood around the body; muscles in the walls of the intestines move food along by peristalsis; and muscles in the walls of small blood vessels constrict or relax, controlling the flow of blood to different parts of the body. (The effects of muscle changes in the blood vessels are apparent in blushing and paling due to increased or decreased blood flow, respectively, to the skin.)

Non-muscular movement

Muscles are not the only means of movement in animals. Many protists (unicellular organisms) move instead by using cilia or flagella (actively beating processes of the cell surface that propel the organism through water). Some unicellular organisms are capable of amoeboid movement, in which the cell contents flow into extensions (pseudopodia) from the cell body. Some of the ciliated protozoans move by means of rods called myonemes, which are capable of shortening rapidly.

Nonmuscular methods of movement are important for multicellular animals as well. Many microscopic animals

swim by means of beating cilia. Some small mollusks and flatworms crawl using cilia on the underside of the body. Some invertebrates that feed by filtering particles from water use cilia to create the necessary water currents. In higher animals, white cells use amoeboid movements, and cilia from cells lining the respiratory tract remove foreign particles from the delicate membranes.

Muscles consist of long, slender cells (fibres) each of which is a bundle of finer fibrils (Figure 1). Within each fibril are relatively thick filaments of the protein myosin and thin ones of actin and other proteins. When a muscle fibre lengthens or shortens, the filaments remain essentially constant in length but slide past each other as shown in Figure 2. Tension in active muscles is produced by cross bridges (*i.e.*, projections from the thick filaments that attach to the thin ones and exert forces on them). As the active muscle lengthens or shortens and the filaments slide past each other, the cross bridges repeatedly detach and reattach in new positions. Their action is similar to pulling a rope in hand over hand. Some muscle fibres are several centimetres long, but most other cells are only a fraction of a millimetre long. Because these long fibres cannot be served adequately by a single nucleus, numerous nuclei are distributed along their length.

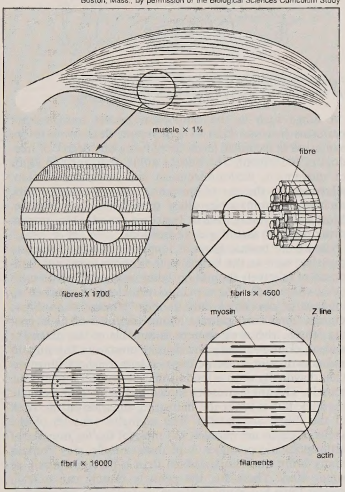

Figure 1: Striated muscle structure in increasingly magnified drawings.

Energy requirements

The work done by muscle requires chemical energy derived from the metabolism of food. When muscles shorten while exerting tension and performing mechanical work, some of the chemical energy is converted to work and some is lost as heat. When muscles lengthen while exerting tension (such as in slowly lowering a weight), the chemical energy that is used along with the mechanical energy absorbed by the action is converted to heat. Generation of heat is an important function of muscle in warm-blooded animals. Shivering is muscle activity that generates heat and warms the body. Similarly, some insects vibrate their wings for a while before flight, heating the muscles to the temperature at which they work best.

DIVERSITY OF MUSCLE

Muscle fibres differ from species to species of animal and between parts of the same animal. Apart from the distinction between voluntary and involuntary muscles, muscles differ in structure and activity.

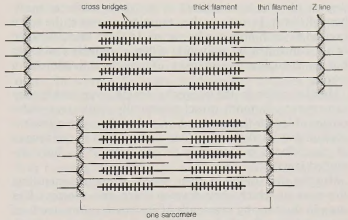

Figure 2: *The arrangement of the myofilaments in a striated muscle.*
The muscle is extended in the upper diagram and contracted in the lower one. The thick filaments are 1.6 micrometres (0.0016 millimetre) long in vertebrate striated muscle but up to six micrometres long in some arthropods.

Types of muscle fibres

Muscles differ in the arrangement of their myofilaments. The principal types of muscle are striated muscle, in which the filaments are organized in transverse bands as in Figure 2; obliquely striated muscle, in which the filaments are staggered, making the bands oblique (Figure 3); and smooth muscle, in which the filaments are arranged irregularly. In vertebrates, all voluntary muscles are striated and all involuntary muscles are smooth, except for cardiac muscle, which is involuntary but striated. Obliquely striated muscle is found only in some invertebrate groups (the nematodes, annelids, and mollusks) and has the protein paramyosin in the thick filaments as well as myosin.

Muscles differ in the stimuli required to activate them. In vertebrates, voluntary muscles require action potentials (electrical signals) in their nerves to initiate every contraction. Some involuntary muscles are spontaneously active, and the action potentials in their nerves only modify the natural rhythm of contraction. The leg muscles of all insects, and the wing muscles of many, require action potentials to initiate every contraction; however, the wing muscles of other insects consist of fibrillar muscle, which requires only occasional action potentials to maintain its rapid rhythmic contractions. The wings of these insects are attached to the body in such a way as to have a resonant frequency of vibration (like a guitar string that vibrates, when plucked, at its resonant frequency). When fibrillar muscles are active, they contract so as to maintain the vibrations of the resonant system.

Stress

Muscles differ in the ability to exert stress. Muscles that exert large stresses have long, thick filaments that carry larger numbers of cross bridges. The result is more cross bridges than in other muscles. This means that more force can be transmitted from each thick filament to the adjacent thin filaments, and larger stresses can be exerted. Less stress can be exerted when the fibres are shortening than when they are maintaining constant length, and more when they are being forcibly stretched.

Muscles differ in the manner in which their forces are controlled. Most of the fibres in the voluntary muscles of mammals can only be switched on or off, and different

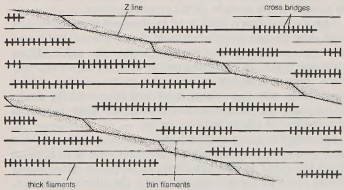

Figure 3: The arrangement of the myofilaments in obliquely striated muscle.

degrees of force are obtained by activating different numbers of fibres. In many other muscles, however, the force exerted by each fibre can be varied. In these muscles, force is not controlled by activating different numbers of fibres but by changing the intensity of muscle activation as a whole.

Muscles differ in the ranges of length over which they can operate. Smooth muscles generally work over wider ranges of length than striated ones, but there are a few exceptional striated muscles. One such muscle in the tongue of chameleons can shorten to one-sixth of its fully extended length.

Muscles also differ in their speed of action, including the rates at which they develop force and shorten. If a muscle shortens by one-tenth of its length in one-tenth of a second, its rate of shortening is one length per second. Maximum rates of shortening vary between species and between muscle fibres in a single animal. For example, two muscles in the limbs of mice have maximum shortening speeds (at 37° C) of 24 and 13 lengths per second.

Metabolism

Finally, muscles differ in their metabolism. The adenosine triphosphate (ATP) that they use as their immediate energy source may be produced either by oxidative reactions, in which food is oxidized to carbon dioxide and water, or by processes that do not require oxygen (anaerobic). Vertebrates and crabs use the anaerobic process of glycolysis, converting the carbohydrate glycogen to lactic acid, for short bursts of vigorous activity such as sprinting. The burst of activity is followed by a recovery period in which oxygen is used to oxidize some of the lactic acid, releasing the energy needed to convert the rest back to glycogen. The advantage of using anaerobic metabolism in this way is that the intensity of activity during the burst is not limited by the rate at which the blood can bring oxygen to the muscles.

In vertebrates, many muscle fibres perform only oxidative metabolism or only glycolysis, though some perform both. Oxidative fibres are commonly red, owing to the presence of the pigment myoglobin. Most fishes show an obvious distinction between the main bulk of white swimming muscle and a narrow strip of red muscle along the side of the body. Slow swimming is powered by the red (oxidative) muscle and bursts of fast swimming by the white (glycolytic) muscle. Red and white muscles are also easy to distinguish in the domestic chicken, in which the pale meat of the breast consists mainly of white fibres and the dark meat of the legs the red fibres. The breast muscles are the main muscles of the wings, which are used by chickens only for occasional short bursts of flight. Other birds that practice sustained flight (*e.g.*, hummingbirds) mainly have red breast muscles.

MUSCLES THAT WORK SKELETONS

Figure 4 shows a simple system, in which a skeleton is worked by muscles. The two rigid parts of the clam shell (Figure 4A) are hinged together. They can be closed to protect the animal within or allowed to open. A block of rubbery protein, the inner hinge ligament, lies just inside the hinge. When the adductor muscle contracts it closes the shell, but in so doing it compresses the inner hinge ligament. When it relaxes, the ligament recoils elastically, reopening the shell. This is an unusual system, in that it is worked by just one muscle. Most other skeletal systems need muscles in antagonistic pairs, in which each muscle is paired with a muscle of the opposite effect.

Human ankle joint

This antagonism is illustrated by the human ankle (Figure 4B). The tibialis anterior muscle flexes the ankle (raising the toes) and the soleus muscle extends the ankle. These muscles make up an antagonistic pair. In this particular case there is another muscle, the gastrocnemius, which cooperates with the soleus, helping it to extend the ankle. (The gastrocnemius, however, crosses the knee as well as the ankle and affects both joints.)

The ankle is not a simple hinge joint. As well as flexion and extension, it can exhibit inversion (the sole of the foot faces the other leg) or eversion (the opposite movement). These movements are controlled by the tibialis posterior, which inverts the ankle, and the peronaeus muscles, which are antagonistic and evert it (Figure 4B).

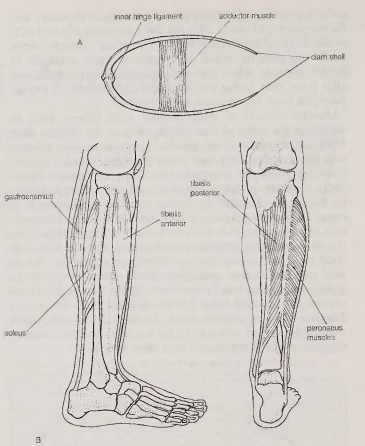

Figure 4: *Rigid skeletons worked by muscles.*
(A) Cross section of a clam shell. (B) Human lower leg.

A hinge such as the clam joint or the human knee performs just one kind of movement, flexion/extension, expressed in technical terms as allowing one degree of freedom of movement. The human ankle performs two kinds of movement, flexion/extension and inversion/eversion, allowing two degrees of freedom. Ball-and-socket joints, such as the human hip, allow three degrees of freedom. Most animal joints have at least two muscles (an antagonistic pair) for each degree of freedom.

Seldom are muscle fibres as long as a muscle, but many muscles, such as the biceps in the human arm, are composed of relatively long fibres lying nearly parallel to each other (Figure 5). These parallel muscles are attached to tendons or apodemes only at their extreme ends. Since muscle fibres can contract about one-third of their resting length, this arrangement is suitable to an extensive and quick movement. The deltoid muscle in the human shoulder is said to be pennate: relatively short fibres attach diagonally onto a tendon that penetrates far into the muscle. The ankle muscles shown in Figure 4 are pennate muscles, but most of the hamstring muscles (at the back of the thigh) are parallel. The adductor muscles of the shells of clams are parallel, but most of the leg muscles of arthropods are pennate. A pennate muscle may contain many more and shorter fibres than a parallel muscle of equal mass. Therefore, the pennate muscle can exert a greater force but cannot shorten a great deal; the parallel-fibred muscle can exert only a relatively small force but can shorten significantly. The presence of pennate muscle in a given structure may have the same effect as a longer lever arm. In the slender legs of arthropods, with insufficient space for bulky muscles or long lever arms, many of the muscles are pennate.

Pennate muscle

Tendons and apodemes (in arthropods, chitinous rods that serve as sites for muscle attachment) have elastic properties. Tendons in the legs of mammals serve as springs, reducing the energy cost of running: energy that is lost as the foot hits the ground and decelerates the body is stored as elastic strain energy in tendons and is subsequently returned in an elastic recoil. An apodeme in the hind legs of locusts is one of the important elastic elements in the catapult mechanism that powers jumping.

MUSCLE IN SOFT ANIMALS

Slugs, worms, and many other invertebrate animals have no skeleton, and thus movement is not produced by lever

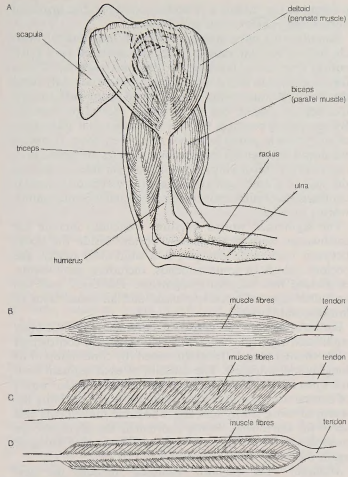

Figure 5: *Gross muscle structure.*

action. Even vertebrates have parts of the body that have muscles but no skeletal component (for example, the tongue). Many soft-bodied animals have muscle systems based on the principle illustrated in Figure 6, which shows a simple wormlike animal. The longitudinal muscle fibres run lengthwise along the body and the circular fibres encircle it. The body contents are liquids or tissues that can be deformed into different shapes, but they maintain a constant volume. If longitudinal muscles contract and the body shortens, it must widen to accommodate its volume; if the circular muscles contract and the body thins, it must lengthen. Thus the longitudinal and circular muscles are antagonistic, and shortening of either extends the other.

Antagonism of muscles

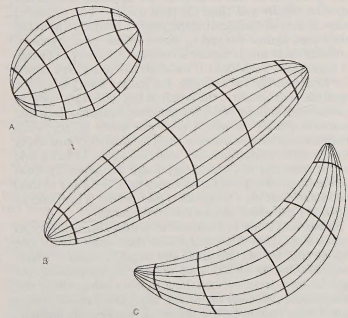

Figure 6: *Changes in body form in wormlike soft-bodied animals.*
(A) The longitudinal muscle contracting. (B) The circular muscle contracting. (C) The longitudinal muscle above contracting while the circular muscles maintain a constant length, stretching the longitudinal muscles below.

Further, if the length of a circular muscle remains constant while the longitudinal muscle of one side of the body shortens, the body bends and the longitudinal muscle of the other side is stretched. Thus the longitudinal muscles of the left and right sides can be antagonistic toward each other. In worms the body fluids render muscles antagonistic through hydrostatic forces. The principle involved is sometimes called the principle of the hydrostatic skeleton.

The principle of the hydrostatic skeleton can apply to individual muscles as well if their fibres run in several directions. For example, in a muscle that has some fibres running longitudinally and others running circularly and/or radially, when the longitudinal fibres shorten, the muscle becomes shorter and fatter; and when the circular and radial fibres shorten, it becomes longer and thinner. There are many examples of muscle structure like this in the mollusks. One such is the shell muscle of the abalone *Haliotis*, which connects the domed shell of the animal to its adhesive foot. When the muscle shortens, with the foot attached to a rock, the shell is pulled down over the animal to protect it. When the muscle lengthens (by contraction of circular and radial fibres) the shell is raised from the rock, allowing respiratory water currents to circulate.

Muscle systems

INVERTEBRATE MUSCLE SYSTEMS

Cnidarians. The phylum Cnidaria includes the hydras, jellyfishes, and sea anemones. Cnidarians have two main body forms, the cylindrical tentacled polyp exemplified by the hydra and the sea anemone, and the bell-shaped (or inverted saucer-shaped) medusa. Hydras are some of the simplest multicellular animals to have muscle. They are hollow, cylindrical, freshwater creatures about 10 millimetres long. One end attaches to a plant or some other support, and the other end is free and has a mouth surrounded by tentacles. The body wall consists of two layers of cells with a middle gelatinous layer (mesoglea). In hydras and other two-layered animals one kind of cell serves as both muscle and epithelial cells. The compact body of each cell is packed closely with the adjacent cells to form an epithelium, and the base of each cell, where it meets the mesoglea, is drawn out into a long muscle fibre. Hydras and medusae

In the hydra the musculoepithelial cells that cover the outer surface of the body have longitudinal muscle fibres; those that line the gut cavity (the gastrodermis) have circular muscle fibres. Sea anemones have all of the muscle fibres in the gastrodermis, though some of the fibres are longitudinal and some are circular. When the mouth of the sea anemone is closed, the water in the gut cavity acts as a hydrostatic skeleton, permitting the animal to grow longer and thinner or shorter and fatter, or to bend in any direction. These changes result from the interaction of the longitudinal and circular muscles through movements that are not as simple as those of the schematic worm of Figure 6. The hydra can reduce its volume by using its muscles to squeeze water out of the gut cavity through the open mouth. It can reinflate using cilia to circulate water into the gut cavity. Its movements are also influenced by the viscoelastic properties of the mesogleal jelly.

The largest and most familiar medusae are the jellyfishes of the class Scyphozoa, some of which grow to a diameter of two metres. Though large, the scyphozoan jellyfishes have only a single layer of cells on the outer surface of the body and a single layer lining the gut cavity; most of the volume of the animal is occupied by the gelatinous mesoglea. The epidermis of the undersurface of the bell includes the musculoepithelial cells responsible for the animal's weak swimming movements. The muscle fibres contract, reducing the diameter of the bell and forcing out a stream of water. The bell then returns to its original shape by elastic recoil of the mesoglea. These movements are performed in a regular rhythm with a period of a few seconds, propelling the animal through the water. Medusae are among the simplest animals that use muscles to make rhythmic movements. In at least some medusae the circular muscles, which do most of the work of swimming, are striated. In contrast, most of the other muscles of cnidarians are smooth. Jellyfishes

Multilayered animals. *Worms.* Although all worms have more than two layers of cells and most have long, slender bodies, the various groups of worms are different from each other in other respects.

The simplest worms are the flatworms (phylum Platyhelminthes), most of which have flattened shapes like leaves or ribbons. Although musculoepithelial cells have been found in some flatworms, the muscle cells in most are distinct from the epithelial cells. There is a layer of circular muscle fibres immediately under the epidermis, a layer of diagonal fibres, and a still deeper longitudinal layer (Figure 7C). There are also dorsoventral muscle fibres running from the upper to the lower epidermis of the flattened body. These sets of muscle fibres act in various combinations to make the body long and thin, short and fat, or bent to one side or the other. These muscles are also used by some of the larger flatworms to pass waves of muscular contraction along the body, enabling the worm to crawl in a snaillike fashion.

Many flatworms have a mouth opening connected to the pharynx, a muscular tube that conveys food from the mouth to the intestine. In some flatworms the pharynx is protruded and inserted into invertebrate prey, to digest and suck out the contents. The sucking is done by peristalsis, waves of muscular contraction that move along the tube from the mouth toward the gut. Although the muscle cells of flatworms are generally not musculoepithelial, their nuclei are found in large cell bodies. The muscle fibres of vertebrates and higher invertebrates, on the other hand, have no projecting cell body.

Roundworms

Roundworms (phylum Nematoda) also have large cell bodies on their muscle cells, but these muscle cells are unique in that nerve fibres do not travel to them as they do in the muscles of other animals. Instead, narrow projections of the muscle cell bodies extend to the principal nerves and contact nerve cells there.

Roundworms have obliquely striated, longitudinal muscle but no circular muscle. They are enclosed in a thick cuticle that allows bending but prevents swelling. Therefore, contraction of the longitudinal muscle can only bend the body. Roundworms do not bend from side to side like eels or snakes, but up or down (dorsal or ventral). By preventing swelling, the cuticle ensures that shortening of one muscle group stretches the other; thus, it makes the dorsal and ventral longitudinal muscles antagonistic to one another. Most crawl between soil particles or among the villi of a host's gut by undulating waves of muscular contraction. Similar movements also enable some roundworms to swim.

The segmented worms (phylum Annelida) include the earthworms and many marine worms. Inside the body, between body wall and gut, is a fluid-filled cavity, the coelom, which in some annelids, including earthworms, is divided into successive segments. The body wall has an outer layer of circular muscle and an inner layer of longitudinal muscle.

Earthworms crawl by peristaltic contractions of the body wall. Each segment is alternately elongated (by contraction of its circular muscles) and shortened (by contraction of its longitudinal muscles). The muscles of each segment contract just after those of the segment in front, so that waves of contraction pass backward along the body, enabling the worm to move slowly forward. The same movements also serve for burrowing. While shortened, the segments are pushed against the burrow wall, and when they elongate again the worm moves forward.

Mollusks. The phylum Mollusca includes the gastropods (snails, slugs, periwinkles), the bivalves (clams, oysters, mussels, and scallops), the cephalopods (octopods and squids), and other smaller classes. All mollusks, except the cephalopods, have a highly muscular organ called the foot, through which muscle fibres run in all directions. The foot of a gastropod is a flat structure used for crawling. Waves of muscular contraction travel along its length, moving the animal slowly over the ground. The foot of a bivalve mollusk is a bulbous or tonguelike organ that is used for burrowing in sand or mud. The foot pushes down into the substrate, then swells to anchor itself and pulls the rest of the animal down behind it.

In addition to the muscles of the foot, gastropod and bivalve mollusks have large muscles attached to their shells. The columellar (shell) muscles of gastropods pull the foot and other parts of the body into the shell. The adductor muscles of bivalves (Figure 4) shorten to close the shell or relax to allow the shell to spring open, enabling the mollusk to extend its foot or to feed. The adductor muscle can shorten rapidly and close the shell quickly. The muscle is also capable of maintaining the tension needed to hold the shell shut against the spring action of the hinge ligament without using much metabolic energy. Economy of energy is particularly important if the shell has to be kept closed for long periods; for example, for several hours while the mollusk is exposed on the beach at low tide. Fast muscles can shorten rapidly because their cross bridges detach and reattach quickly; however, they use much energy while maintaining tension because there is an energy cost every time a cross bridge detaches and reattaches. Muscles that are economical in their energy usage are generally slow. Accordingly, most bivalve mollusks have two parts to their adductor muscles, a translucent part, which is fast, and an opaque part, which is slow but economical.

Squids and cephalopods

Squids and other cephalopod mollusks also swim by jet propulsion. They draw water into the mantle cavity (the cavity that houses the gills) and expel it rapidly. Vigorous movements of this kind provide jet propulsion, but gentler ones serve for breathing by circulating water, and thus oxygen, through the mantle and gills. Fast-swimming squid have mantle cavities whose muscular walls make up as much as 35 percent of the mass of the body.

These walls mainly consist of circular muscle fibres that squeeze water out of the mantle cavity when they contract. Other fibres run radially through the thickness of the wall. These fibres make the wall thinner when they

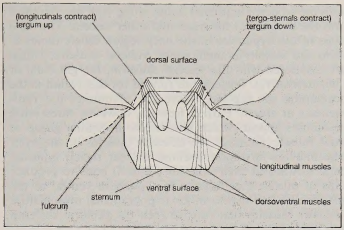

Figure 8: Muscles involved in insect flight (see text).
From C.A. Villee, W.F. Walker, and F.E. Smith, General Zoology (1963), W.B. Saunders Company

contract, stretching the circular muscle and enlarging the cavity again. Cephalopods do not have longitudinal muscle fibres; however, layers of collagen fibres on the outer and inner surfaces of the muscle prevent the animal from lengthening when the muscles contract. Thus the circular and radial muscle fibres are antagonistic. Enlargement of the cavity, however, is not solely due to the radial muscle fibres: the cavity tends to expand by elastic recoil of the tissues, when the circular muscles relax.

Though many mollusks have shells, most molluscan muscle systems depend on the principle of the hydrostatic skeleton. In some cases body fluids are involved, for example, in the feet of clams, which are extended and inflated by inflow of blood. In other cases the muscle itself serves as the incompressible element that must thicken as it shortens or become slender as it elongates, to maintain constant volume. Examples include the shell muscle of the abalone and the tentacles of squid, which are shortened by contraction of longitudinal muscle fibres and lengthened by circular and transverse ones.

Arthropods. Arthropoda is the largest phylum of invertebrate animals and comprises the crustaceans, insects, arachnids (spiders and scorpions), and other classes. Some arthropods have soft-bodied young stages in which the principle of the hydrostatic skeleton is important. Most adult arthropods are encased in a skeleton with jointed appendages formed from a stiff cuticle that is divided into separate plates to assist in movement. This skeleton, working as a system of levers, is largely responsible for making muscles antagonistic.

Insect wings

The wing muscles of dragonflies (Odonata) and those of some other insects are worked in simple, direct ways by pulling on the wing bases and making them pivot about their joints. More advanced insects, including flies (Diptera), work their wings indirectly by muscles that attach to other parts of the skeleton. Although the details of the mechanisms are complicated, the basic principle is simple. Each wing-bearing segment of the body is enclosed by two main plates of cuticle, a tergum above and a sternum below (Figure 8). These plates are flexible enough to be distorted by muscle action. Distortions of the tergum are particularly important in the wing mechanism.

The principal wing muscles are the dorsoventral muscles, which run vertically from the sternum to the tergum, and the longitudinal muscles, which run lengthwise along the segment. Contraction of the longitudinal muscles makes the tergum bow upward, and contraction of the dorsoventral muscles pulls it down again. The wings have joints connecting them to the tergum and to the sternum. Upward movement of the tergum (from contraction of the longitudinal muscles) lowers the wings and downward movement (from contraction of the dorsoventral muscles) raises them.

All arthropod muscles seem to be striated, not obliquely striated or smooth, and the sarcomeres are of varying lengths. In locusts the sarcomeres (the primary structural and functional unit responsible for contraction; see below *Striated muscle: The myofilament*) of wing muscles are 3.9 micrometres long, but the sarcomeres of leg muscles (which do not have to contract so quickly) are 8.5 micrometres long. Wing muscles in many other insects have shorter sarcomeres, often about the same length as those in mammalian muscle (about 2.5 micrometres).

The force exerted by the muscle is controlled by varying the frequency of action potentials in the axons (an extension of the nerve cell that conducts nerve impulses away from the cell body). The higher the frequency, the larger the force, within limits. In contrast, in vertebrates each muscle is served by many motor axons, each of which is connected to only a small group of muscle fibres. In the twitch muscles that predominate in vertebrates, each muscle fibre is either inactive or fully active and force is varied by recruiting different numbers of muscle fibres. Like those of other animals, most arthropod muscles require an action potential to initiate each contraction.

Fibrillar muscle

Fibrillar muscle is found in the sound-producing, or tymbal, muscles of some cicadas and in the wing muscles of several orders of insects including the Diptera (flies), Coleoptera (beetles), Hymenoptera (wasps), and Hemiptera (bugs). Most fibrillar muscles work at high frequencies, often of several hundred cycles per second, but they are kept working by action potentials arriving at much lower frequencies. They contract at the resonant frequency of the tymbal or of the wing system. Clipping the wings of an insect that has fibrillar wing muscles increases the frequency of the wing beat, because reduction of the vibrating mass increases the resonant frequency.

All insect wing muscles work aerobically and produce high power outputs. Consequently they need many mitochondria, which may occupy 40 percent or more of their volume both in fibrillar and in non-fibrillar muscles. Non-fibrillar muscles that work at high frequencies also need large sarcoplasmic reticulums, but fibrillar ones do not.

Although insect muscles seem always to work aerobically, some crustacean muscles can work anaerobically. The leg muscles that the crab *Callinectes* uses for swimming include two types of fibres. One type resembles the red muscle fibres of vertebrates in that it is deep pink and contains a high proportion of mitochondria. The other resembles vertebrate white fibres because it is white with far fewer mitochondria, and presumably works anaerobically. Similar differences occur in other crustacean muscles. Crabs use anaerobic metabolism for short bursts of violent activity in the way that vertebrates do.

Echinoderms. The phylum Echinodermata comprises the starfishes, sea urchins, and their relatives. Their internal skeletons are made of porous blocks of calcium carbonate and they have muscles to work their skeleton. Echinoderms also have a hydraulic system, the water-vascular system, with movable projections from the body called tube feet.

Tube feet

The details of the tube feet differ among the different groups of echinoderms, but Figure 9 shows the arrangement in sea urchins. Five double rows of tube feet project through the test, so that every part of the body surface has tube feet near it. The tube feet are slender tubes, with

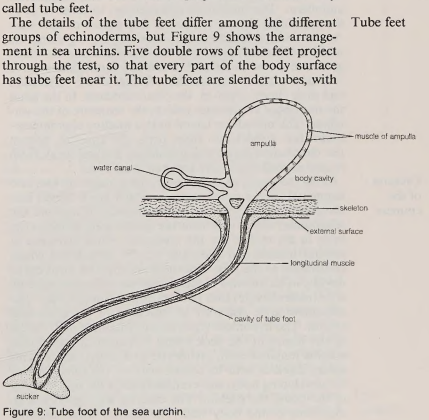

Figure 9: Tube foot of the sea urchin.

a sucker on the closed end. Muscles in the sucker enable it to attach to objects, so the tube feet can be used by the animal to anchor, to move, or to manipulate its prey. Connective tissue in the tube feet limits their diameter but allows them to lengthen, to shorten, and to bend. The tube feet have only longitudinal muscles, which extend the length of the cavity of the tube foot. They are extended by water that has been forced into them by muscles in the wall of the ampulla at their bases. (W.F.W./R.McN.A.)

VERTEBRATE MUSCLE SYSTEMS

Major types of vertebrate muscle. In terms of its microscopic structure, the musculature of vertebrates is usually divided into three types: striated, cardiac, and smooth muscle. Smooth and cardiac muscle are under the control of the involuntary, or autonomic, nervous system. Striated muscle, on the other hand, is mainly under the control of the voluntary, or central, nervous system. Smooth and cardiac muscle are also similar in their development, being generally associated with the yolk sac. Striated muscle develops directly from the middle of the three embryonic layers, arising largely from the mesodermal somites (see below). In the adult, smooth and cardiac muscle are associated with organs or tubes (viscera), and striated (skeletal) muscle with the bony or cartilaginous skeleton.

Although some evidence suggests that a twofold division of the musculature into visceral and skeletal muscle might be appropriate, one set of striated muscles is distinct in development and in innervation from all other striated muscle. In humans these include both the muscles of the jaw and some of the muscles of the shoulder and are called the branchiomeric, or branchial, muscles. Branchiomeric muscles, even in humans, are innervated by visceral nerve fibres as is the case with smooth and cardiac muscle, not the somatic nerve fibres (those that supply the outer body wall or soma), and thus are usually grouped with the smooth and cardiac muscles despite their striated nature.

Vertebrate muscle divisions

The two major divisions of the vertebrate musculature are thus the visceral musculature (smooth, cardiac, and branchiomeric) and the somatic musculature (the striated muscles of the body wall). Somatic musculature may be divided into appendicular, or limb, muscles and axial muscles. The axial muscles include the muscles of the tail, trunk, and eyeballs as well as a group of muscles called hypobranchial muscles, which separate and migrate from the others during development.

Basic pattern of development. The gastrula is the stage of embryonic development at which the embryo appears as three distinct layers of cells (the germ layers): the exterior ectoderm, the middle mesoderm, and the interior endoderm. The mesoderm differentiates to form most of the remaining tissues, structures, and organs of the body. As the embryo lengthens, the mesoderm lying along the midline differentiates to form the chordamesoderm, which gives rise to the notochord, a hollow, cartilaginous nerve tube and a major distinguishing feature of the vertebrates and their closest relatives, the protochordates. In the adult the notochord contributes only to the structure of the vertebrae. The mesoderm lateral to this midline chordamesoderm then divides into three parts: the epimere, nearest the chordamesoderm; the hypomere, farthest away from it; and a small mesomere between these two.

Division of the epimere

Along the length of the embryo, the epimere divides into segmental blocks called somites, which again divide into three cell blocks: closest to the notochord appears the sclerotome, which will form the greater part of the vertebrae; in the middle lies the myotome, which gives rise to somatic muscle; and to the side lies the dermatome, which contributes to the skin. Appendicular muscles form either directly as outgrowths of the myotomes or from wandering cells (mesenchyme) that bud off from the myotomes. The mesomere gives rise only to structures of the urogenital system. The hypomere remains unsegmented, and, except in the region of the neck where it remains a solid mass, it splits longitudinally, giving rise to a central space. This space, together with its counterpart on the other side of the developing body, will eventually form the major cavity of the body, the coelom. The exterior layer gives rise to the lining of the body wall. The interior layer, together with the adjacent epithelial lining of the yolk sac, develops into the muscles of the heart and other viscera. The solid mass of the hypomere in the neck region differentiates to form the various branchiomeric visceral muscles, which are associated with the visceral skeleton, the gill bars, or their derivatives. Posterior to (dorsal to) this region is the developing ear capsule, where the myotomes are rudimentary or absent. Farther forward, however, three more myotomes appear, which give rise to a distinct group of axial muscles, namely the external muscles of the eyes. The first few myotomes behind the ear region typically bend forward at their anterior (ventral) ends to produce slips of muscle that migrate to a position ventral to the gill pouches and that form the hypobranchial musculature (somatic muscles that run between the pectoral skeleton and the jaw).

Comparative anatomy. One problem in discussing the differences in arrangement of muscles between the various vertebrate groups is in deciding which muscles in each species are homologous; that is, which have the same evolutionary and developmental origin. The problem arises because the position and attachment of muscles change during evolution: a muscle lying in the same position and attached to the same bone or cartilage in one vertebrate may have different origins from those of another vertebrate species. Comparison of the development of muscles in the embryo of each species, and of their nerve supply, probably will give the best clues. No single method may be relied upon in all cases, and many different types of evidence are considered before the homology is decided upon.

Origin of muscle names

Vertebrate muscles are given names derived from Latin according to their attachments. In this system, the Latin names of the bony points of attachment are either joined, as in the human "sternocleidomastoid," which runs from the sternum and clavicle to the mastoid region of the skull, or they may be named for their form or their gross function. There are several standard terms that describe form and function. A muscle may have more than one point of origin: thus it may be described as having, for example, two "heads" as in "biceps femoris" (*bi* for two, *-ceps* for heads, *femoris* meaning "of the femur"). It may be long, "longus," or short, "brevis." It may run transversely across a body segment "transversus," or obliquely, "obliquus." It may lie close to the surface, "superficialis," or deep, "profundus." In describing function, flexors are muscles that tend to close the angle made by the two bones to which they are attached, extensors tend to increase the angle. Adductors pull a bone or cartilage closer to the axis of the body, or limb, while abductors pull away from the axis. Rotators turn one bone or cartilage with respect to another, or turn it with respect to the midline. Pronators turn the sole of the foot or the palm of the hand to face the ground, while the opposite function is performed by supinators. Constrictors and sphincters diminish the volume of spaces or the area of structures, and dilators increase them. Because human anatomy is better understood than that of other species, the names of muscles in humans often have been applied to grossly equivalent muscles in animals, a situation that often causes confusion.

Jawless fishes. The earliest known vertebrates were jawless fishes of the class Agnatha, and their only living representatives are the cyclostomes—the lampreys and the hagfishes. The modern agnathans retain much of the general organization of the ancestral vertebrates, and therefore, much of their musculature is relevant to an understanding of the evolution of muscles in more advanced vertebrates.

Cyclostomes

The cyclostomes are free-swimming animals with prominent axial somatic musculature, which during contraction produces undulating waves that propagate from head to tail to produce thrust. The axial muscles form a single segmented mass in which each embryonic myotome has given rise to a strip of muscle running vertically down the side of the fish. These muscle segments, known as myomeres, consist of relatively short fibres that insert into septa of connective tissue, the myocommata, between the adjacent myomeres. There is only a rudimentary axial skeleton and no appendicular skeleton, so there are no limb muscles. The eyes of cyclostomes are degenerate

structures, and the six axially derived muscles normally found associated with vertebrate eyes are diminished or absent. The branchiomeric muscles in cyclostomes are represented by a sheet of constrictors that compresses the gill pouches and helps the pumping mechanism draw water through the pharynx to the gills. Other muscles of the branchiomeric series have been modified for specialized feeding functions.

Chondrichthyes

The branchiomeric musculature of more primitive jawless fishes would probably have been similar for each of the gill arches. The sharks and other cartilaginous fishes (the class Chondrichthyes) have modified the structure of the first two arches, the cartilages of the anterior arch forming the mandible and upper jaw (palatoquadrate), and modifications also having taken place in the second, hyoid arch. The posterior five gill arches of more primitive sharks, however, are a good model for the condition in the ancestral jawless fishes. Each arch has a visceral skeleton comprising five cartilages named, from dorsal to ventral, the pharyngobranchial, epibranchial, ceratobranchial, hypobranchial, and basibranchial. The cartilages are arranged at angles to each other. Each cartilaginous arch is provided with a set of branchial muscles, which receives separate, visceral innervation. Superficially, a thin sheet comprising dorsal and ventral constrictor muscles runs in the flap of skin that covers each gill slit and forms the gill septum. Most fibres attach, dorsally and ventrally, to connective tissue sheathing the body (fascia). Some of the deeper fibres attach to the gill bar and may run between adjacent bars. These thin, broad muscles squeeze the pharynx closed as part of the pumping action necessary for gill breathing. Dorsal and deep to this layer, a levator muscle runs from the sheathing fascia to the pharyngobranchial, and it can elevate the gill arch. In some sharks, however, the most posterior sets of levator muscles, whose fibres run diagonally down and back, may join adjacent levators, become enlarged, and attach to the pectoral girdle. This mass is known as the trapezius and evolves into the tetrapod muscle of the same name. Adductor muscles are positioned so as to close the angle between the epibranchial and ceratobranchial, and an interarcual muscle performs the same function for the angle between the pharyngobranchial and epibranchial cartilages.

Jawed fishes. In the jawed fishes, including the sharks, the axial musculature of the trunk and tail (a single block in cyclostomes) differentiates into dorsal and ventral components, which are separated by connective tissue. The dorsal block of muscle is known as the epaxial musculature, and the ventral block, the hypaxial (Figure 10A). The epaxial block runs from the back of the skull to the end of the tail, while the hypaxial block is not present any farther forward than the pectoral (shoulder) girdle (because of the presence of the branchial [gill] apparatus). The hypaxial musculature in the tail forms a solid block of muscle, while in the trunk it encloses the body cavity. Ribs develop in the horizontal septum separating the two blocks of muscle and usually lie in the myocommata, the fascial tissue separating each myomere (Figure 10B). In fishes, the ribs primarily serve to improve the leverage of the myomeres in producing the undulatory movements of swimming. The ribs are short in sharks but may develop to considerable length in bony fishes. Unlike the cyclostomes, where the myomeres form a series of essentially vertical strips of muscle, the myomeres of all jawed fishes are folded in a complex fashion. This development is related to the development of a more powerful swimming ability in the jawed fishes. The myomeres are folded in a zigzag pattern, projecting strongly forward halfway down the side of the fish, with a smaller, backward projection both dorsal and ventral to this point: the effect is of a W on its side. These projections become sharper and more cone-shaped deep to the surface of the fish and thus come both to be overlapped by the folds of several anterior myomeres and to overlap those of several more posterior myomeres. The folding and overlapping of myomeres has the effect that contraction of a single myomere produces curvature over a considerable part of the body of the fish. The fishes who swim faster thus tend to have a greater degree of folding and overlapping. In the tunny, for example,

Myomeres

Neal and H.W. Rand, Copyright © 1944 by McGraw-Hill Book Co. Used with permission of McGraw-Hill Book Company

one myomere may have an overlap with 20 others. The undulations of the body and caudal (tail) fin produced by these axial muscles can produce much greater thrust than is produced by the beating of the appendicular fins. The latter are mostly used in slow "precision" swimming, as when a fish is investigating food, while undulations of the body are used for faster, powerful swimming. The axial musculature of fishes contributes up to half the weight of the fish, while the appendicular muscle contributes less than a fifth of the fish's mass.

Eye muscles

In all higher vertebrates the most anterior element in the axial musculature is the set of six eye muscles derived

from the three pre-otic somites (those anterior to the ear region of the embryo). The rectus muscles move the eyes about the longitudinal axis of the body, that is superiorly (upward), or inferiorly (downward), or about a vertical axis, in other words, laterally (backward) or medially (forward), according to their position relative to the eyeball. They take appropriate names. The oblique muscles, superior and inferior, rotate the eyes about a transverse axis.

Jawed fishes have single midline fins and two sets of paired fins. The unpaired dorsal and anal fins of teleosts (advanced bony fishes) have axially derived muscle sheets on either side, which, when contracted, may change their angle and even fold the fins. The paired pectoral fins and the weaker pair of pelvic fins, however, have a mass of musculature both dorsal and ventral to them that is derived from mesenchymal cells. The dorsal muscle mass lifts the fin or pulls it posteriorly; the ventral mass pulls it down or forward. The two major muscle masses are attached at one end to the pectoral or pelvic girdle and on the other to the base of the fin. The amount of downward or upward movement of the fin versus the amount of backward or forward movement can be adjusted, in some fishes, by small slips of muscle derived from the major dorsal and ventral masses, which twist the fin.

The hypobranchial muscles of jawed fishes are straplike muscles running from the pectoral girdle to the structures of the visceral skeleton, the jaws, and gill bars. Some muscles, like the coracomandibularis, are specialized as jaw openers, although most of the work of jaw opening is done by gravity.

In bony fishes the gill septum of the hyoid arch is greatly modified to become a single, movable, bony covering for the whole gill chamber: the operculum. The individual gill septa are lost, and there is a great modification of the posterior branchial muscles, with many of the elements found in sharks (levators, adductors) becoming reduced or absent. The superficial constrictor of the hyoid arch in sharks is remodeled in bony fishes to control the opening and closing of this protective cover.

Electric organs

Electric organs appear to have arisen independently in several fishes. They are modifications of the axial musculature of the tail, as in the electric "eel" *Gymnotus,* a teleost, or of the muscles of the pectoral fins, as in the ray *Torpedo.* In a few cases electric organs lie superficially to the musculature and may be derived from modified glandular tissue, as in the Nile catfish *Malapterurus.*

Origins of the tetrapod limbs. The invasion of the land led to a complete change in emphasis in the propulsive elements of the muscular system. In fish the axial musculature is much more important as a mover of the body than is the appendicular musculature. The evolution of land vertebrates is characterized by an increasing emphasis on the limbs for propulsion and by a corresponding deemphasis on the axial musculature. The limbs of tetrapods are generally similar in overall pattern. Primitively, at least, most major groups have similar characteristic features: the fore and hind feet have five digits; there is one bone in the proximal part of the limb (nearest to the body) and two in the distal part (away from the body); and there are a wrist or ankle joint, an elbow or knee joint, and a shoulder or hip joint. Although most muscles have several roles, the major actions of tetrapod limb muscles are similar: some primarily resist the downward force of the body at hip and shoulder; others press the supporting fore or hind feet down onto the ground at wrist or ankle or pull back on the supporting limbs (at all three joints) to create thrust; others primarily pull the "swing" limbs forward into a new support position.

The limbs may originally have developed more as supportive struts. Structurally, the tetrapod limb can be derived from the pattern found in the paired fins of Sarcopterygii, a class of lobe-finned fishes. These were once a large radiation but largely have been replaced by the Actinopterygii, the class of ray-finned fishes. Today, the lobe-finned fishes are represented by *Latimeria,* the coelacanth, and the lungfishes, or *Dipnoi.* The lungfishes, denizens of shallow and seasonal waters, habitually use their fins as supports, but propulsion is largely achieved by undulations of the body as is the case with other fish.

Amphibians

Tetrapod musculature. In the living urodeles (the newts and salamanders) of the class Amphibia, the axial muscles are most important for propulsion. The limbs of urodeles are quite weak and tend to be carried forward passively with the undulations of the body. As the primary propulsive force is provided by the muscles of the trunk, urodeles retain large axial muscles. The axial muscles are still segmented, separated by myocommata, although the myomeres run vertically and without the elaborate folding seen in jawed fishes. The epaxial muscles, given the name "dorsalis trunci" in tetrapods, are little changed, although some modification has taken place to promote a facility for dorsoventral bending of the spine that occurs in tetrapods but rarely in fishes.

The anurans (frogs and toads) have rather similar, but considerably reduced, epaxial muscles. There is, however, a trend in tetrapods toward finer control of muscular action with increasing complexity. In the reptiles the epaxial muscles, although still retaining a semisegmental structure, are divided into several structural and functional units. The deepest set of muscles, the transversospinalis group, are short and run obliquely forward, over one to four vertebrae, from the transverse process of one vertebra to the lamina (the flat plate of bone at the base of the vertebral spine) of a more anterior vertebra (Figure 10C). The transversospinalis group is particularly responsible for rotatory movements of the spine. Superficial to transversospinalis lies longissimus, with much longer fibres, which is important in extension of the back. More superficially still, and lateral to these muscle blocks, iliocostalis is a flat, sheetlike muscle that runs from the pelvic girdle upward and laterally to attach to the ribs. It is particularly important in lateral flexion (bending) of the spine. This general pattern is further complicated in snakes, which have secondarily returned to the propulsive use of the axial muscles. In birds the vertebral column of the trunk region undergoes much fusion, and this complexity is reduced, as indeed it is in chelonians (turtles and tortoises). Mammals retain the broad pattern of the reptile epaxial musculature but (with the exception of the innervation of the musculature) have greatly reduced the segmentation that is present in reptiles (Figure 10D and 10E).

In the tails of urodeles the hypaxial muscles are also largely unchanged. As with all land vertebrates, however, the demands of support of the viscera when living in an air environment have brought about major modifications of the hypaxial musculature of the trunk. In typical tetrapods a strong series of ribs has developed for the same reason. Although urodeles have secondarily reduced their ribs, they show many of the typically tetrapod features of the hypaxial musculature. The muscles fall into three groups. A group of subvertebral muscles forms ventral to the vertebrae, in the region of their joints with the ribs at the transverse processes. It acts in ventral and lateral flexion (bending) of the spine. A rectus abdominis muscle runs longitudinally along the ventral aspect of the body wall between the pectoral and pelvic girdles, and laterally this is associated with the third group, the lateral hypaxial muscles. This consists of three major layers of muscle whose fibres are oriented in differing directions, a feature that gives additional strength to the body wall. Superficially lies the external oblique muscle, with fibres running longitudinally but somewhat ventrally; deep to this lies the internal oblique, with fibres running longitudinally and somewhat dorsally; and deepest lies the transversus muscle, whose fibres run dorsoventrally.

Trunk modifications

In the higher tetrapods the external and internal obliques tend to become further divided into layers in the abdominal region. The thoracic representatives of these muscles tend to become divided into discontinuous, rather thin muscle layers between the ribs (external and internal intercostals), superficial to the ribs (supercostals), and deep to the ribs (subcostals). While only the rectus abdominis tends to retain visible evidence of segmental origin, in its tendinous intersections (which are present even in humans) the segmental innervation of the hypaxial muscles is retained in all tetrapods.

Pectoral girdle

In tetrapods, unlike fishes, the pectoral girdle does not have a solid bony connection to the axial skeleton but

rather is supported by a series of muscles derived from the outer layer of hypaxial trunk muscles. This is no doubt another adaptation to life in an air environment, where the cushioning effect of water has been lost. These muscular slings are not readily demonstrated in the living amphibians, which are either skeletally degenerate as in urodeles or highly specialized toward leaping, as in the anurans (frogs and toads). In more typical tetrapods, there are two major derivatives of the external oblique attaching the scapula (shoulder blade) to the body: first, the serratus, made up of numerous fingerlike slips running from the scapula to the neighbouring ribs; second, levator scapulae, which are fused with serratus along its caudal (tail-end) border. Levator scapulae consist of fibres running more anteriorly to ribs or transverse processes of the neck. Mammals, and some reptiles, have a third such muscle, attaching the pectoral girdle to the region of the spine, called rhomboideus. The mammals also have utilized part of the hypaxial musculature to form a muscular septum between the region of the lungs and heart (the thoracic cavity) and the region of the digestive and reproductive viscera (the abdominal cavity). This is the diaphragm, which is the most important respiratory muscle in the mammalian body.

Eye movements

The six axially derived eye muscles of fishes undergo only small modifications in tetrapods. Eye movements are changed, partly according to changes in the orientation of the orbit such as the trend toward orbital frontality that is typical in the primates. Additional eye muscles may be derived by splitting some of these six muscles. An example of this is the retractor bulbi muscle, which is derived from the lateral rectus muscle. In amphibians and some reptiles it pulls the eyeball deeper into the orbit for protection, and in amphibians it is an aid in swallowing. Another example is the levator palpebrae superioris, derived from the superior rectus, which elevates the upper eyelid to open the eye.

The limb muscles of typical tetrapods are derived from the dorsal and ventral muscle blocks of the paired fins of fishes. In tetrapod development, this pattern of derivation from dorsal and ventral muscle blocks is repeated. As a consequence, the homologies of the muscles of the typical tetrapod limb often can be traced by considering the source of innervation of each muscle from the nerves of the dorsal (or extensor) compartment or the ventral (or flexor) compartment.

Latissimus dorsi

In the pectoral limb, the dorsal, extensor group of muscles includes several that appear consistently and with similar roles. Beginning with the muscles that act on the humerus (the proximal bone of the limb), all tetrapods have a large, sheetlike muscle, known as the latissimus dorsi, which runs from the side of the trunk to the humerus. The latissimus dorsi muscle retracts the humerus and thus propels the body forward. Acting to rotate, flex, or adduct the humerus, depending on limb posture, is a muscle known as subcoracoscapularis in amphibians, reptiles, and birds and subscapularis in mammals. It runs from the deep surface of the shoulder girdle to the humerus. In amphibians, the dorsalis scapulae arise from the anterior edge of the scapula. The same muscle is known as the deltoideus in reptiles and mammals, and in the latter, part of its origin moves from the scapula to the clavicle (collar bone). It is a major abductor of the shoulder in most tetrapods. At the elbow joint, all tetrapods have a muscle called triceps as the major extensor. It arises in several heads from the shoulder girdle and humerus. There are always a variable number of extensor muscles for the wrist and digits (fingers and toes) arising from the region of the elbow joint, on the lateral aspect of the humerus.

On the ventral, flexor aspect of the pectoral limb, the pectoralis is found in all tetrapods. The pectoralis runs from the chest wall to the humerus, on which it acts to pull the humerus downward and backward. This muscle is not only important in providing forward thrust in quadrupedal locomotion but is the chief depressor of the forelimb in birds and bats. The major elevator of the wing in birds, supracoracoideus, is present in all tetrapods. In mammals, the supracoracoideus retains its attachment to the humerus, but its previous point of origin (the coracoid plate) disappears and the muscle now appears as two separate blocks of muscle arising on either side of the spine of the scapula as an abductor muscle (supraspinatus) and a rotator and flexor (infraspinatus). Coracobrachialis and (except in amphibians) biceps arise from the tip of the coracoid and act to flex the elbow. In this they are aided by the brachialis muscle, which arises from the humerus. As on the extensor aspect, there are always a number of flexors of the wrist and digits. These arise on the medial side of the distal humerus.

Effect of limb posture

The muscles of the pelvic limb cannot be readily compared beyond the reptiles and mammals. Even in these cases, changes in limb posture have led to major changes in the arrangement and function of muscles. On the dorsal aspect, a single, large muscle in reptiles, puboischiofemoralis, runs from the bones of the pelvis to the femur (the proximal bone of the hind limb). This reptilian muscle appears to be represented by three mammalian hip muscles: psoas, iliacus, and pectineus. Iliofemoralis acts as an abductor of the hip in reptiles and appears to be represented by the gluteal muscles in mammals, but the function of the gluteal muscles is different. More similar in reptiles and mammals is the quadriceps or quadratus femoris, which consists of multiple heads (four in mammals) that arise from the pelvic girdle and femur and insert by a common tendon into the tibia (the larger bone of the distal pectoral limb). It is the sole extensor of the knee joint in both the reptiles and the mammals. The extensors of the ankle and digits in both reptiles and mammals are not dissimilar to those of the pectoral limb and take origin from the lateral and anterior surfaces of the two distal bones of the pelvic limb. On the ventral aspect of the hind limb, small, deep muscles run from the internal and external pelvis to the head of the femur and help in adduction and rotation. Of these, the puboischiofemoralis externus of reptiles appears to be represented by the obturator externus of mammals, and similarly the ischiotrochantericus of reptiles appears to be the homologue of the obturator internus of mammals. Again, the major adductor of the hip of reptiles, adductor femoris, appears to be homologous with some of the muscles called the adductors in mammals. There seem to be some homologies between the major flexors of the hip and thigh in reptiles, such as puboischiotibialis, and two deeper muscles, flexor tibialis externus and internus, and some functionally equivalent muscles in mammals: the gracilis, semimembranosus, and semitendinosus. In reptiles, the axial muscle of the tail is strong, and the caudifemoralis, a powerful flexor of the thigh which originates in the tail, is consequently large. The tail in mammals, although usually present, is much more gracile, and as a result caudofemoralis is represented by only a few small muscles. Another major change is in the flexors of ankle and digits. In reptiles, these insert by long tendons passing below the ankle joint, much as in the forelimb. In mammals, however, the equivalent long flexor, gastrocnemius, inserts on a new bony process, the calcaneal tuberosity or heel bone, which gives more efficient leverage.

Reptile and mammal homologies

The hypobranchial muscles of tetrapods are both reduced and modified in comparison with those of jawed fishes. In tetrapods these straplike muscles still arise from elements of the pectoral girdle but now pass to the new derivatives of the gill arches of fishes: the hyoid bone and laryngeal cartilages. They act primarily in the gross movements of these structures in swallowing and the production of sound—for example, as depressors of the hyoid (sternohyoid, omohyoid) or of the larynx (sternothyroid). Fibres of the hypobranchial muscles in the region of the hyoid are utilized to form the internal musculature of the tongue.

The branchial musculature is also modified in tetrapods from the condition seen in jawed fishes. The development of a shoulder muscle, the trapezius, from the levator muscles of the gill arches of fishes, as previously discussed, is taken further in tetrapods, by the separation of further slips of muscle to form muscles such as sternocleidomastoid, a muscle important for humans in movements of the head and in breathing. In mammals that lose the clavicle, these slips may further be modified to form muscles running from the head to the pectoral limb. Tetrapods,

with the exception of mammals, utilize part of the constrictor muscle of the hyoid arch to form the depressor mandibulae, which replaces the hypobranchial muscles as the major jaw-opening muscle. The restructuring of the posterior jaw in mammals leads to the further replacement of this new muscle by the digastric, which is a compound muscle made up of parts of the constrictors of the first and second branchial arches. Thus it is partly innervated by the mandibular division of the fifth cranial nerve (as is the case with other jaw muscles and the tensor tympani, one of the muscles of the ear), and partly by the seventh cranial nerve, the facial nerve (which also supplies an ear muscle associated with the stapes, an ear bone derived from the hyoid arch). The levator palatoquadrati, which elevates the upper jaw in jawed fishes, is retained as a jaw muscle in birds and in some reptiles, as they share the ability of fishes to move the upper jaw. The adductor mandibulae is much altered in tetrapods, although its overall function is retained. During the course of tetrapod evolution it becomes a superficial muscle, and in mammals it splits into several functional units arising from the undersurface and side of the skull and attaching to various points on the mandible. These are: the lateral pterygoid, which pulls the jaw forward; the medial pterygoid and its partner, the masseter, which close the jaw and move it from side to side; and the temporalis, which closes the jaw and pulls it backward. All are innervated by the first-arch cranial nerve, the fifth nerve. The intermandibularis of jawed fishes is retained as the mylohyoid of tetrapods, which is an elevator of the tongue.

Restructuring of the mammal jaw

Finally, the constrictor muscle of the hyoid arch, which in bony fishes is used to control the operculum, is remodeled in tetrapods as a sheathing superficial muscle of the neck, the sphincter colli. It derives its innervation from the nerve of the hyoid arch, the seventh, or facial, nerve. This cranial nerve is named from the further adaptation of the sphincter colli muscle in mammals, particularly in higher primates, as the many small muscles of facial expression, which allow people to smile, laugh, and frown.

MODIFICATIONS FOR UPRIGHT POSTURE AND HUMAN MUSCULATURE

Human muscles

Human muscle can be divided into striated (or skeletal), smooth, and cardiac. With a very few exceptions, the arrangement of smooth and cardiac muscle has undergone little modification with the assumption of the upright posture. A discussion of the changes in the striated, or somatic, muscles follows.

Evolutionary context. The arrangement of striated muscle in modern humans conforms to the basic pronograde (horizontal) quadrupedal vertebrate and mammaliam plan that was outlined in an earlier section. The primates inherited the primitive quadrupedal stance and locomotion, but since their appearance in the Cretaceous Period, several groups have modified their locomotor system to concentrate on the use of the arms for propulsion through the trees. The most extreme expression of this skeletal adaptation in living primates is seen in the modern gibbon family. Their forelimbs are relatively elongated; they hold their trunk erect; and for the short periods that they spend on the ground they walk only on their hind limbs (in a bipedal fashion).

Modern humans are most closely related to the living great apes, the orangutan, chimpanzee, and gorilla. Their most distant relative in the group, the orangutan, has a locomotor system that is adapted for moving among the vertical tree trunks of the Asian rain forests. It grips these trunks equally well with both fore and hind limbs and was at one time aptly called quadrumanal, or "four-handed."

There is little direct fossil evidence about the common ancestor of modern humans, chimpanzees, and gorillas, so inferences about its habitat and locomotion must be made. The ancestor was most likely a relatively generalized tree-dwelling animal that could walk quadrupedally along branches as well as climb between them. From such an ancestor, two locomotor trends were apparently derived. In one, which led to the gorillas and the chimpanzees, the forelimbs became elongated so that when these modern animals come to the ground they support their trunks by placing the knuckles of their outstretched forelimbs on the ground. The second trend involved shortening the trunk, relocating the shoulder blades, and, most importantly, steadily increasing the emphasis on hind limb support and truncal erectness. In other words, this trend saw the achievement of an upright bipedal, or orthograde, posture instead of a quadrupedal, or pronograde, one. The upright posture probably was quite well established by 3,000,000 to 3,500,000 years ago, as evidenced both by the form of the limb bones and by the preserved footprints of early hominids found from this time.

Human ancestor

Muscles of the lower limb. The major muscular changes directly associated with the shift to bipedal locomotion are seen in the lower limb. The obvious skeletal changes are in the length of the hind limb, the development of the heel, and the change in the shape of the knee joint so that its surface is flat and not evenly rounded (Figures 11, 12, and 13). The hind limbs of modern humans are proportional to body size, while the hind limbs of the apes are relatively short for their body size. The changes that occur in the bones of the pelvis are not all directly related to the shift in locomotion, but they are a consequence of it. Bipedality, by freeing the hands from primary involvement with support and locomotion, enabled the development of manual dexterity, and thus the manufacture and use of tools, which has been linked to the development in human ancestors of language and other intellectual capacities. The result is a substantially enlarged brain. Large brains clearly

Effect of bipedality

affect the form of the skull, and thus the musculature of the head and neck. A larger brain also has a direct effect on the pelvis because of the need for a wide pelvic inlet and outlet for the birth of relatively large-brained young. The larger pelvic cavity means that the hip joints have to be farther apart. Consequently, the hip joints are subjected to considerable forces when weight is taken on one leg, as it has to be in walking and running.

To counteract this, the muscles (gluteus minimus and gluteus medius) that are used by the chimpanzee to push the leg back (hip extensors) have shifted in modern humans in relation to the hip joint so that they now act as abductors to balance the trunk on the weight-bearing leg during walking. Part of a third climbing muscle (gluteus maximus) also assists in abduction as well as in maintaining the knee in extension during weight bearing. The gluteal muscles are also responsible for much of the rotation of the hip that has to accompany walking. When the right leg is swung forward and the right foot touches the ground, the hip joint of the same side externally rotates whereas that of the opposite side undergoes a similar amount of internal rotation. Both these movements are made possible by rearrangements of the muscles crossing the hip.

The bones of the trunk and the lower limb are so arranged in modern humans that to stand upright requires a minimum of muscle activity. Some muscles, however, are essential to maintaining balance, and the extensors of the knee have been rearranged and realigned, as have the muscles of the calf.

Human foot

The foot is often, but erroneously, considered to be a poor relation of the hand. Although the toes in modern humans are normally incapable of useful independent movement, the flexor muscles of the big toe (hallux) are developed to provide the final push-off in the walking cycle. Muscles of all three compartments of the modern human lower leg contribute to making the foot a stable platform, which nonetheless can adapt to walking over rough and sloping ground.

Muscles of the upper limb. The major changes in the musculature of the upper limb involve the secondary effects that result from freeing the forelimb from a major supportive or propulsive role. The hand of a chimpanzee is dexterous, but the proportions of the digits and the rearrangement and supplementation of muscles are the major reasons for the greater manipulative ability of modern humans. Most of these changes are concentrated on the thumb. For example, modern humans are the only living great apes to have a separate long thumb flexor, and the short muscle that swings the thumb over toward the palm is particularly well developed in humans. This contributes to the movement of opposition that is crucial for the so-called precision grip; *i.e.,* the bringing together of the tips of the thumb and forefinger.

Pronation and supination of the forearm, which allows the palm of the hand to rotate 180 degrees, is not peculiar to humans. This movement depends upon the possession of both a small disk in the wrist joint and on an arrangement of the muscles such that they can rotate the radius to and fro. Both the disk and the muscle arrangement are present in other great apes.

Muscles of the head and neck. The muscle group of the head and neck is most directly influenced by the change to an upright posture. This group constitutes the muscles of the back (nape) and side of the neck. Posture is not the only influence on these muscles, for the reduction in the size of the jaws in modern humans also contributes to the observed muscular differences. Generally, these involve the reduction in bulk of nuchal (or nape) muscles. In the upright posture the head is more evenly balanced on the top of the vertebral column, so less muscle force is needed, whereas in a pronograde animal with large jaws, the considerable torque developed at the base of the skull must be resisted by muscle force. The poise of the human head does pose other problems, and the detailed attachment and role of some neck muscles (*e.g.,* sternocleidomastoid) is different in humans than in the apes.

Muscles of the trunk. The consequences of an upright posture for the support of both the thoracic and abdominal viscera are profound, but the muscular modifications in the trunk are few. Whereas in pronograde animals the abdominal viscera are supported by the ventral abdominal wall, in the orthograde posture most support comes from the pelvis. This inevitably places greater strain on the passage through the muscles of the anterior abdominal wall, the inguinal canal, which marks the route taken by the descending testicle in the male. Weakness in the canal can result in herniation.

Differences are also seen in the musculature (the levator ani) that supports the floor of the pelvis and that also controls the passage of feces. The loss of a tail in all the apes has led to a major rearrangement of this muscle. There is more overlap and fusion between the various parts of the levator ani in modern humans than in the apes, and the muscular sling that comprises the puborectalis in humans is more substantial than in the apes. (B.Wo./R.H.C.)

Muscle types

PRIMITIVE CONTRACTILE SYSTEMS

Cilia and flagella. Unicellular organisms such as the paramecium, a protozoan that lives in freshwater ponds and streams, propel themselves by the action of cilia. Cilia occur in large numbers and move in a coordinated way. Ciliated cells within the vertebrate body propel fluid and mucus along interior passages, such as the lining of the respiratory tract.

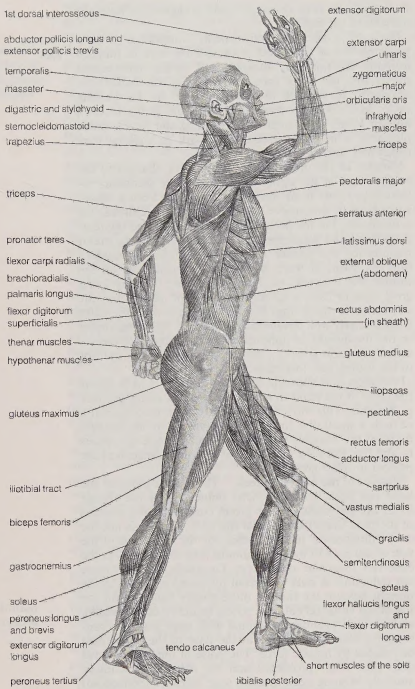

Figure 13: Lateral aspect of the human muscular system.

Reprinted by permission of Faber and Faber Ltd from *Anatomy of the Human Body* by R.D. Lockhart, G.F. Hamilton, and F.W. Fyfe (second edition) 1965.

Flagella are structurally similar to cilia, except that they are longer (sometimes up to 50 times longer) than cilia and usually number only one or two per cell. Sperm cells of most higher organisms move using flagella. Many types of unicellular algae and protozoans use flagella in swimming through the water.

Pattern of tubules

Both cilia and flagella contain a regular pattern of tubules extending along their lengths; there is an outer ring of nine pairs of tubules surrounding a central pair of tubules. Each tubule is composed of filaments comprising a string of globular subunits. The movement of a cilium or a flagellum requires energy, which is obtained from the breakdown of adenosine triphosphate (ATP), catalyzed by a protein attached to the outer tubules, dynein.

Some types of bacteria have flagella whose motion seems to depend on a cellular particle called the basal body, to which the flagellum is attached. Such flagella derive their energy from a difference in hydrogen ion concentration across the cell membrane.

Amoeboid motion. Amoeboid movement occurs as an extension of the cytoplasm, called a pseudopod ("false foot"), flows outward, deforms the cell boundary, and is followed by the rest of the cell. Many pseudopodia may be formed at the same time, and their actions do not seem to be coordinated.

Although amoeboid motion is characteristic of the amoeba, a unicellular protozoan, it is also found in non-muscle cells of multicellular organisms. These cells contain myosin and actin, which differ in some aspects of their structure from the corresponding proteins in muscles because of variations in the genes that encode them.

STRIATED MUSCLE

Whole muscle. Striated, or striped, muscle constitutes a large fraction of the total body weight in humans. Striated muscle contracts to move limbs and maintain posture. Both ends of most striated muscles articulate the skeleton and thus are often called skeletal muscles. They are attached to the bones by tendons, which have some elasticity provided by the proteins collagen and elastin, the major chemical components of tendons.

Associated structures

Each striated muscle has blood vessels and nerves associated with it. The vessels transport blood to and from the muscle, supplying oxygen and nutrients and removing carbon dioxide and other wastes. The signals that initiate contraction are sent from the central nervous system to the muscle via the motor nerves. Muscles also respond to hormones produced by various endocrine glands; hormones interact with complementary receptors on the surfaces of cells to initiate specific reactions. Each muscle also has important sensory structures called stretch receptors, which monitor the state of the muscle and return the information to the central nervous system. Stretch receptors are sensitive to the velocity of the movement of the muscle and the change in length of the muscle. They complete a feedback system that allows the central nervous system to assess muscular movement and to adjust motor signals in light of the movement.

The muscle fibre. Muscle is composed of many long, cylindrical-shaped fibres from 0.02 to 0.08 millimetre in diameter (Figure 14). In some muscles the fibres run the entire length of the muscle (parallel fibres), up to several tens of centimetres long. In others a tendon extends along each edge, and the fibres run diagonally across the muscle between the tendons (pennate fibres). Considerable variation can be found among the different skeletal muscles, the actual arrangement of the fibres depending on the function of the muscle.

There is a high degree of organization within the living fibre, a series of alternately dark and bright bands. Each band extends perpendicular to the length of the fibre. Each fibre is surrounded by a complex, multilayered structure called the sarcolemma. The outermost layer is a fine network of fibrils, which, at the ends of the muscle, extend into the tendons and form the structural link with them. The next layer of the sarcolemma is a foundation, or basement, membrane. The innermost layer is a plasma membrane similar to the ones that surround most cells. The plasma membrane consists of a lipid bilayer with proteins embedded in it. Some of the proteins are embedded entirely within the lipid layer; others extend to one or the other surface; still others span the whole width of the two layers. These proteins represent enzymes, receptors, and various channels (such as those involved in the movement of ions between the exterior and interior of the cell). The plasma membrane maintains the electrical potential, which plays a major role in stimulating muscle contraction.

Sarcoplasm

Sarcoplasm is the cytoplasm of a muscle fibre. It is a water solution containing ATP and phosphagens, as well as the enzymes and intermediate and product molecules involved in many metabolic reactions. The most abundant metal in the sarcoplasm is potassium. Sodium and magnesium are present in lower concentrations. Most of the calcium of muscle is bound to proteins or stored in the sarcoplasmic reticulum. Contraction is initiated by the release of calcium ions (Ca^{2+}) upon the depolarization of the membrane, which is induced by nerve impulses.

Each striated muscle cell, or fibre, contains many nuclei. This is the result of the fusion of singly nucleated cells that occurs during the embryological development of striated muscle. After fusion, the cells never again divide.

Mitochondria in the sarcoplasm of the muscle fibre contain the enzymes involved in the Krebs cycle and in oxidative phosphorylation. Granules in the sarcoplasm of muscle cells contain glycogen, the storage form of carbohydrate. The breakdown of glycogen and the metabolism of

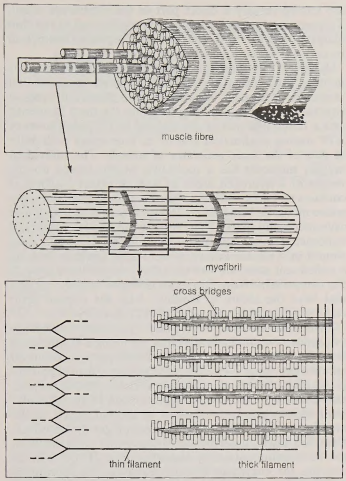

Figure 14: The spatial relationships of a striated muscle fibre, myofibrils, and sarcomeres (see text).
From E.P. Hammel, V.M.D., and K.M. Friedenberg, J. Vet. Med., M.R.C.V.S., in *Equine Medicine and Surgery*, ed. by E.J. Catcott (1972); American Veterinary Publications

the individual units of the resulting carbohydrate through glycolysis, the Krebs cycle, and oxidative phosphorylation are important sources of ATP, the immediate source of energy for muscle contraction. Muscles that contain many fibres that operate at a steady, low level of activity are red, owing to the presence of cytochromes (molecules involved in oxidative phosphorylation) and myoglobin (an oxygen-carrying molecule in the sarcoplasm). Muscles that work in bursts of activity contain fibres that have fewer mitochondria and fewer molecules of cytochromes or myoglobin, are white, and depend more heavily on reactions that do not require oxygen to make ATP.

The myofibril. Electron micrographs of thin sections of muscle fibres reveal groups of filaments oriented with their axes parallel to the length of the fibre. There are two sizes of filaments, thick and thin. Each array of filaments, called a myofibril, is shaped like a cylindrical column. Along the length of each myofibril alternate sets of thick and thin filaments (Figure 14) overlap, or interdigitate, presenting alternate bands of dark regions (with thick filaments and overlapping thin ones) and light regions (with only thin filaments). Within a fibre all the myofibrils are in register, so that the regions of similar density lie next to each other, giving the fibre the characteristic striated appearance it shows in the phase-contrast or polarized light microscope. Each light region is divided in two by a dark band. The unit between two dark bands is known as a sarcomere.

Each myofibril is about one or two micrometres (or microns; one micrometre = 10^{-6} metre) in diameter and extends the entire length of the muscle fibre. The number of myofibrils per fibre varies. At the end of the fibre the myofibrils are attached to the plasma membrane by the intervention of specialized proteins.

Forty to 80 nanometres usually separate adjacent myofibrils in a fibre. This space contains two distinct systems of membranes involved in the activation of muscle contraction (Figure 15). One system is a series of channels that open through the sarcolemma to the extra-fibre space. These channels are called the transverse tubules because they run across the fibre. The transverse tubular system is a network of interconnecting rings, each of which surrounds a myofibril. It provides an important communication pathway between the outside of the fibre and the myofibrils, some of which are located deep inside the fibre. The exact spatial relationship of the tubules to the filaments in the myofibril depends on the species of animal.

Transverse tubules

The other membrane system that surrounds each myofibril is the sarcoplasmic reticulum, a series of closed saclike membranes. Each segment of the sarcoplasmic reticulum forms a cufflike structure surrounding a myofibril. The portion in contact with the T tubule forms an enlarged sac (terminal cisterna).

Associated cisternae

In most vertebrates each transverse tubule has two cisternae closely associated with it, forming a three-element complex called a triad. The number of triads per sarcomere depends on the species: in frog muscle there is one per triad; in mammalian muscle there are two. In fishes and crustaceans only one cisterna is associated with each transverse tubule, thus forming a dyad. The sarcoplasmic reticulum controls the level of calcium ions in the sarcoplasm. The terminal cisternae apparently are the sites from which the calcium ions are released when the muscle is stimulated, and the longitudinal tubules are the sites at which calcium ions are effectively removed from the sarcoplasm. The removal of calcium ions (Ca^{2+}) from the sarcoplasm is accomplished by a protein that catalyzes the breakdown of ATP making the free energy of hydrolysis available for the energy-requiring process of Ca^{2+} transport.

The myofilament. As mentioned earlier, the myofibril is a columnlike array of filaments. Figure 15 is a diagram of a longitudinal section through a group of myofibrils. In the centre of the I band (the light band, of low density) there is a prominent dense line called the Z line, though in reality, considering the three-dimensional structure of the myofibril, it is more appropriate to speak of Z disks. The area between two Z lines, a sarcomere, can be considered to be the primary structural and functional unit directly responsible for muscle contraction. The myofibril can thus be thought of as a stack of sarcomeres. The A band, which contains thick filaments partly overlapped with thin filaments, appears dark.

Cross bridges. At high magnification small bridgelike structures can be seen on the thick filaments extending toward the thin filaments in the overlap region (Figure 14). They are called cross bridges and are believed to be responsible for the movement and force developed during contraction (for the relation of cross bridges to the molecular architecture of thick filaments, see below). In the middle of the A band, where only thick filaments are present, is a region called the H zone; it looks somewhat

From *Journal of Cell Biology* (1965)

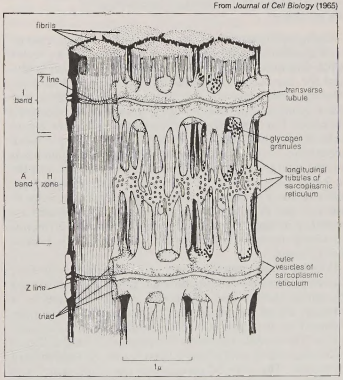

Figure 15: Ultrastructure of a group of myofibrils, showing the sarcoplasmic reticulum and transverse tubules, which constitute the two membrane systems within a muscle fibre.

lighter than the overlap region of the A band. Also in the A band is a narrow, lightly stained region that contains bare thick filaments without cross bridges and is called the pseudo-H zone. In the centre of the A band is a narrow, darkly stained region called the M band, in which occur fine bridges between the thick filaments. These bridges differ from the cross bridges between the thick and thin filaments and are in fact composed of an entirely different protein.

If cross sections of the myofibril at different levels of the sarcomere are examined in the electron microscope, the filaments can be seen end-on, and the three-dimensional nature of the lattice of filaments can be appreciated (Figure 16). The I band contains only thin filaments, with a diameter of six to eight nanometres. In the A band, in the overlap region, the thin filaments appear with thick ones (diameter of 12 nanometres) in an extremely regular pattern or lattice. In vertebrates the thick filaments are arranged in a hexagonal lattice and the thin ones are located at the centre of the equilateral triangles formed by the thick filaments. Sections through the H zone contain only thick filaments arranged in the same hexagonal pattern they form in the overlap region. In the M band the hexagonal array of thick filaments can be seen with M bridges running between them.

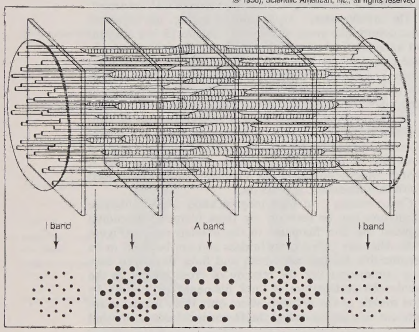

Figure 16: Muscle fibril, showing perspective model of the sarcomere.

Sliding of filaments. The discovery that during contraction the filaments do not shorten but that the two sets—thick and thin—merely move relative to each other is crucial for our current understanding of muscle physiology.

Filaments during contraction

During contraction the thin filaments move deeper into the A band, and the overlap of the thick and thin filaments increases. If a longitudinal section of the sarcomere is considered, the thin filaments on the left side of the A band would move to the right into the A band and the filaments on the right of the A band would move to the left into the A band. Directionality of the motion partly results from the structural polarity of both the thick filaments, since in the two halves of the filament the myosin molecules are oriented in opposite directions, and the actin filaments, in which the actin molecules are oriented with respect to the Z bands.

Proteins of the myofilaments. To understand the finer structural details of the myofilaments and the mechanism by which sliding, and ultimately muscle contraction, is brought about one must turn to the molecular components of the filaments and of the structures associated with them. The myofilaments are composed of several different proteins, constituting about 50 percent of the total protein in muscle. The other 50 percent consists of the proteins in the Z line and M band, the enzymes in the sarcoplasm and mitochondria, collagen, and the proteins in membrane structures. Of the myofilament proteins, myosin and actin are known to play a direct part in the contractile event. Troponin and tropomyosin, which are located in the thin filaments together with calcium ions, regulate contraction by controlling the interaction of myosin and actin.

Myosin. The main constituent of the thick filaments is myosin. Each thick filament is composed of about 250 molecules of myosin. Myosin has two important roles: a structural one as the building block for the thick filaments; and a functional one as the catalyst of the breakdown of ATP during contraction and in its interaction with actin as part of the force generator of muscle. The individual myosin molecule has a molecular weight (based on the weight of a hydrogen atom as one) of about 500,000; it contains two major protein chains and four small ones, the entire molecule being about 160 nanometres in length and asymmetrically shaped. The rodlike tail region, about 120 nanometres long, consists of two chains of protein each wound into what is known as an α-helix together forming a coiled-coil structure. At the other end of the molecule the two protein chains form two globular headlike regions that have the ability to combine with the protein actin and carry the enzymatic sites for ATP hydrolysis.

Role of myosin

The myosin molecule can be split by proteolytic cleavage to produce two fragments, light meromyosin (LMM) and heavy meromyosin (HMM). The LMM portion, about 80 nanometres long, contains most of the α-helical tail region of the original myosin molecule. The HMM portion, also about 80 nanometres long, consists of two globular head regions attached to a part of the tail region of the myosin molecule. It forms the cross bridges that protrude from the thick filaments (see below) and interacts with the thin actin-containing filaments. The HMM portion contains the enzymatic site that catalyzes the splitting of ATP. Under appropriate conditions single myosin heads (subfragment-1, or S-1) and actin binding ability also can be obtained.

There are some structural differences in myosins isolated from different muscles within the same animal and from muscles at different stages of development. These so-called isoforms are products of genes belonging to a family. Some differences in corresponding protein components are due to different ways of processing the messenger RNA produced by the same gene. While the basic pattern of myosin structure is preserved, there are many differences in the sequence of amino acids (primary structure). Many other proteins involved in muscle contraction (*e.g.*, actin, troponin) also have isoforms characteristic of different types of muscle.

Isoforms

Thick filament assembly. In the middle portion of the thick filament the molecules are assembled in a tail-to-tail fashion. Along the rest of the filament they are arranged head to tail. The tail parts of the molecules form the core of the filament: the head portions project out from the filament. The cross bridges are actually the globular head regions of myosin molecules extending outward from the filament, and the smooth pseudo-H zone is the region of tail-to-tail aggregation in which there are only tails and no heads.

The precise three-dimensional arrangement of the cross bridges projecting from the thick filament cannot be seen easily in electron micrographs but can be determined from X-ray diffraction study of living muscle (Figure 17). The three bridges project 120 degrees from the opposite sides of the filament every 14.3 nanometres along the length of the filament. Each successive set of bridges is located in a position rotated 40 degrees farther around the filament. The pattern of nine bridges (three sets of three bridges) repeats itself every 42.9 nanometres along the thick filament. Some variation may exist from species to species and muscle to muscle.

Thin filament proteins. The thin filaments contain three different proteins—actin, tropomyosin, and troponin. The latter is actually a complex of three proteins.

Actin, which constitutes about 25 percent of the protein of myofilaments, is the major component of the thin filaments in muscle. An individual molecule of actin is a single protein chain coiled to form a roughly egg-shaped unit. Actin in this form, called globular actin or G-actin, has one calcium or magnesium ion and one molecule of

Actin

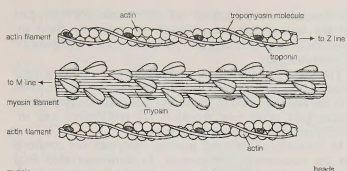

Figure 17: *The structure of actin and myosin filaments.* Actin filaments consist of globular (not strictly spherical) actin monomers, long strands of tropomyosin molecules, and the regulatory protein complex troponin. The myosin filament consists of a backbone made up of the rod parts of many myosin molecules (at bottom), with two myosin heads in each molecule projecting from the surface of the backbone.
Adapted from J.M. Squire, *Muscle: Design, Diversity, and Disease* (1986). The Benjamin/Cummings Publishing Co.

ATP bound to it. Under the proper conditions G-actin is transformed into the fibrous form, or F-actin, that exists in the thin filament in muscle. When the G-to-F transformation takes place, the ATP bound to G-actin breaks down, releasing inorganic phosphate (P_i) and leaving an adenosine diphosphate (ADP) molecule bound to each actin unit. Actin molecules repeat every 2.75 nanometres along the thin filament. They give rise to a helical structure that can be viewed as a double or single helix. The apparent half-pitch is about 40 nanometres long. Actin is believed to be directly involved in the process of contraction since the cross bridges can become attached to it.

Tropomyosin is a rod-shaped molecule about 40 nanometres long with a molecular weight of about 70,000. Two strands of tropomyosin molecules run diametrically opposed along the actin filaments. Tropomyosin has a structure similar to that of the myosin tail, being a coiled unit of two protein chains. Each tropomyosin molecule is in contact with seven actin units.

Troponin is a complex of three different protein subunits. One troponin complex is bound to every tropomyosin molecule. A troponin molecule is located approximately every 40 nanometres along the filament. Troponin and tropomyosin are both involved in the regulation of the contraction and relaxation of muscles. One of the subunits (TnC) is the receptor for Ca^{2+} released from the sarcoplasmic reticulum on activation of the muscle. It is thought that calcium-binding then causes further structural changes in the interaction of actin, tropomyosin, and another troponin subunit (TnI) that lead to contraction by activating the actin-myosin interaction.

Z lines and M bridges

The exact structure of the Z line has not yet been completely established, but it is thought that four filaments extend from the end of each thin filament to four different thin filaments on the other side of the Z line. This type of arrangement would give the Z line a three-dimensional structure resembling a series of pyramid-like units. The Z line contains proteins that form links with actin and establish lateral connections among Z disks (α-actinin, desmin) and establish connections between the Z disks and the cell membrane (*e.g.*, vinculin).

The fine M bridges are composed of proteins that have not yet been fully characterized. The M bridges run between sites on the thick filaments at which myosin molecules are joined tail to tail. It may be that the M bridges keep the filaments in register during contraction. A continuous network of filaments extending from Z disk to Z disk has also been identified; it contains some large proteins (titin, nebulin).

Actin-myosin interaction and its regulation. Mixtures of myosin and actin are used in the test tube to study the relationship between the ATP breakdown reaction and the interaction of myosin and actin. The ATPase reaction can be followed by measuring the change in the amount of phosphate present in the solution. The myosin-actin interaction also changes the physical properties of the mixture. If the concentration of ions in the solution is low, myosin molecules aggregate into filaments. As myosin and actin interact in the presence of ATP, they form a tight, compact gel mass; the process is called superprecipitation. Actin and myosin interaction can also be studied on muscle fibres whose membrane is destroyed by glycerol treatment; these fibres still develop tension when ATP is added. A form of ATP that is inactive unless irradiated with a laser beam has been found to be useful in the study of the precise time course underlying contraction.

Superprecipitation

If troponin and tropomyosin are also present, however, the actin and myosin do not interact, and ATP is not broken down. This inhibitory effect corresponds to the state of relaxation in the intact muscle. When calcium ions are added, they combine with troponin, inhibition is released, actin and myosin interact, and ATP is broken down. This corresponds to the state of contraction in intact muscle. The exact mechanism by which troponin, tropomyosin, and calcium ions regulate the myosin-actin interaction is not fully agreed upon. In the thin filament there are one troponin and one tropomyosin molecule for every seven actin units. According to one view, Ca^{2+} binding to troponin, actually the TnC subunit, induces a change in the position of tropomyosin, moving it away from the site where myosin also binds (steric blocking). Alternatively, the calcium-induced movement of tropomyosin in turn induces changes in the structure of actin, permitting its interaction with myosin (allosteric model). In smooth muscles, Ca^{2+} activates an enzyme (kinase) that catalyzes the transfer of phosphate from ATP to myosin, and the phosphorylated form is then activated by actin.

A somewhat different scheme of regulation operates in the muscle of mollusks. As in vertebrate muscles, calcium ions act as the initiator of contraction. The difference is that the component that binds calcium ions in the molluscan muscle is myosin rather than a component of the actin-containing thin filaments. The interaction of actin and myosin provides a basis for molecular models of force generation and contraction in living muscle.

(R.E.Da./N.A.C./J.Ge.)

The neuromuscular junction. The signal for a muscle to contract originates in the nervous system and is transmitted to the muscle at the neuromuscular junction, a point of contact between the motor nerve and the muscle. In higher organisms each muscle fibre is innervated by a single motor nerve fibre; in other species (*e.g.*, crustaceans) inhibitory fibres are also present. As the nerve approaches the muscle, it loses its myelin coat but remains partially covered by processes of the Schwann cells, which elsewhere surround the nerve and produce myelin. The nerve then branches several times, indenting the surface of the muscle to form the end plate that occupies only a small region of the total surface area of the muscle. The narrow (50 nanometres) synapse separates the nerve from the muscle and contains the basement membrane (basal lamina). In the subneural region the muscle membrane is deeply folded, forming secondary synaptic clefts into which the basement membrane penetrates.

Schwann cells

The neural signal is an electrical impulse that is conducted from the motor nerve cell body in the spinal cord along the nerve axon to its destination, the neuromuscular junction. No electrical continuity exists between the nerve and the muscle; the signal is transmitted by chemical means that require specialized presynaptic and postsynaptic structures.

Storage of acetylcholine in the nerve terminal. The nerve terminal contains many small vesicles (membrane-enclosed structures) about 50 nanometres in diameter, each of which contains 5,000–10,000 molecules of acetylcholine. Mitochondria are also present, providing a source of energy in the form of ATP. Acetylcholine is formed in the nerve terminal from choline and acetyl-CoA through the catalytic action of the enzyme choline acetyltransferase. Choline is obtained by the active uptake of extracellular choline, a breakdown product of previously released acetylcholine. Concentrations of acetylcholine (and ATP) in the cytoplasm are several hundredfold lower than in the vesicles. Packaging of the transmitter into the vesicles occurs within the nerve terminal and is an energy-requiring process.

Vesicles

Release of acetylcholine from the nerve terminal. The

vesicles cluster close to specialized regions of the nerve terminal membrane called the active zones. Freeze-fracture electron microscopy reveals an orderly array of small particles (about 10 nanometres in diameter) within these active zones, which are believed to represent voltage-gated calcium channels. The channels are opened by depolarization (increase in membrane potential) of the nerve terminal membrane and selectively allow the passage of calcium ions.

The nerve impulse is a wave of depolarization traveling along the axon of the motor nerve such that the resting membrane potential of about −70 millivolt is reversed, becoming briefly positive. At the nerve terminal the nerve impulse causes voltage-gated calcium channels at the active zones to open until depolarization subsides. This allows calcium ions to enter the nerve terminal along their concentration gradient. The region of raised calcium concentration within the nerve terminal is localized close to the active zones and, by a process that is not yet understood, causes vesicles in this region to fuse with the nerve terminal membrane and to open outward (exocytosis), thereby discharging their contents into the synaptic cleft. A nerve impulse causes the release of about 50–100 vesicles of acetylcholine in humans, and somewhat more in some other species.

Discharge of acetylcholine

At high rates of stimulation, sufficient to cause a smooth contraction (tetanus) of the muscle, the quantity of transmitter released per impulse declines for the first few impulses (synaptic depression), which may be due to a reduction in the number of vesicles ready for release.

Following the voltage-dependent influx of calcium into the nerve terminal, it is necessary for calcium to be removed to prevent continuous discharge of neurotransmitter. Mechanisms underlying this process are likely to involve sodium–calcium exchange across the nerve terminal membrane and possibly calcium uptake by mitochondria.

Acetylcholine is released from the nerve terminal by two other processes, independently of the nerve impulse. Neither of these processes leads to muscle contraction. The first occurs spontaneously when individual vesicles randomly fuse with the nerve terminal membrane and discharge their contents, generating a small potential change (about 0.5–1 millivolt), the miniature end plate potential. This potential is below the threshold at which an action potential is triggered in the muscle cell and thus does not lead to muscle contraction. The frequency of such events varies; in humans they occur at each end plate about once every five seconds. The second process of acetylcholine release occurs as a continuous "molecular leakage" of neurotransmitter from the nerve terminal rather than from vesicles. The overall amount released in resting muscle by this means greatly exceeds the spontaneous release of individual vesicles.

The acetylcholine molecules diffuse across the synaptic cleft and react with the acetylcholine receptors. The number of available acetylcholine binding sites greatly exceeds the number of acetylcholine molecules released. Acetylcholine is either rapidly broken down by the enzyme acetylcholinesterase, which is anchored in the basement membrane, or diffuses out of the primary cleft, thus preventing constant stimulation of acetylcholine receptors. Drugs that inactivate acetylcholinesterase and thereby prolong the presence of acetylcholine in the cleft can lead to repetitive firing of the muscle cell in response to a single nerve stimulus.

Acetylcholine receptors. Acetylcholine receptors are ion channels that span the postsynaptic membrane, and they have extracellular, intramembranous, and cytoplasmic portions. They are located principally over the peaks of the postsynaptic folds, where they are present at high density. They consist of five subunits arranged around the central ion channel. One of the subunits is represented twice. The different subunits are products of separate genes. This implies that the acetylcholine receptor has been highly conserved in evolution and suggests that the genes coding for the different subunits may have evolved from a single primeval acetylcholine receptor gene.

Structure

Models of acetylcholine receptors indicate that its structure contains an extracellular *N*-terminal portion, several intramembranous portions (of which one provides part of the wall of the ion channel) separated by short intracellular and extracellular portions, and a cytoplasmic *C*-terminal part.

The supply of junctional acetylcholine receptors is continuously renewed. Receptors are internalized by the muscle cell and degraded in lysosomes (specialized cytoplasmic organelles), while new receptors are synthesized and inserted into the muscle membrane.

In normally innervated muscle, receptors are confined to the neuromuscular junction. In non-innervated fetal muscle and in denervated adult muscle, however, acetylcholine receptors are found elsewhere as well. These receptors have slightly different properties from junctional receptors, notably a much higher rate of turnover.

Acetylcholine/acetylcholine receptor interaction. The resting membrane potential of the muscle cell is held at about −80 millivolt. Binding of acetylcholine to each of the two alpha subunits causes the receptor molecule to alter its configuration so that the ion channel is opened for about one millisecond (0.001 second). This permits the entry of small positive ions, mainly sodium. The resulting local depolarization (the end plate potential) causes voltage-gated sodium channels located around the end plate to open. At a critical point (the firing threshold for the muscle cell) a self-generating action potential is triggered, causing the membrane potential to reverse and become briefly positive. The action potential propagates over the muscle fibre membrane to activate the contractile process.

Firing threshold

The amplitude of the end plate potential is normally sufficient to bring the membrane potential of the muscle cell well above the critical firing threshold. The extent to which it does so represents a "safety factor" for neuromuscular transmission. The safety factor will be reduced by any event that, by interfering with presynaptic or postsynaptic function, reduces the size of the end plate potential. (J.M.N.-D.)

Mechanical properties. *The physical aspects.* Vertebrates are able to move about and to exert and bear forces because of the contraction of the striated muscles. These activities usually involve several structures operating in different ways. The skeleton to which the muscles are attached operates as a lever system. When a muscle shortens, it moves the joints that it spans. In addition, in coordinated movement usually several muscles contract in different ways. As some muscles shorten, others develop a force while at a fixed length, and still others may be lengthened by an external force even as they contract.

The force that a muscle develops is a "pulling" force, never a "pushing" force. If the load is small enough, the muscle can shorten and produce a pulling motion (an isotonic condition). If the load is just equal to the maximum force the muscle can develop, the length of the muscle will remain the same (an isometric condition). An even larger load will stretch the muscle.

The size and the rate of the mechanical responses to stimulation, whether by a nerve in the body or by direct electrical shocks of an isolated muscle, depend on the muscle and the temperature. In a frog sartorius muscle (of the leg) at 0° C (32° F), the action potential reaches its peak of depolarization about 1.5 milliseconds after the stimulus (Figure 18).

Time course of contraction

The very early tension changes require much more rapid and sensitive measuring and recording instruments than are necessary for studying other aspects of the contraction process. The latent period, the first seven milliseconds, is the amount of time needed for the electrical signal, which appears as an action potential at the surface membrane, to be translated and travel to the contractile apparatus within the muscle fibres. The explanation for latency relaxation (a four-millisecond period during which the tension drops slightly), however, is not so clear. It may be related to a change in shape of the sarcoplasmic reticulum, which releases a large amount of calcium ions at about the time latency relaxation occurs. The tension begins to rise after 15 milliseconds.

Twitch and tetanus responses. Skeletal muscles respond to a single electric shock of sufficient magnitude by rapid,

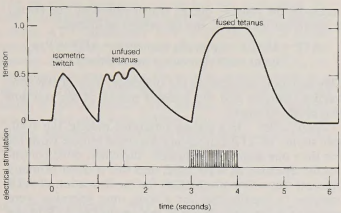

Figure 18: The effect of the rate of stimulation on the development of force in a frog muscle (at 0° C, or 32° F).

intense contractions called phasic contractions. If the ends of a frog sartorius muscle (at 0° C) are fixed to prevent shortening, the tension increases for about 200 milliseconds and then begins to decrease, at first rather rapidly and then more slowly. More happens during this mechanical response to a single stimulation, called a twitch, than the tension record suggests.

Absolute refractory period

The mechanical response to repeated stimulation depends on the rate of the stimulation. Muscle, like other excitable tissues, has a period following its action potential during which the membrane will not respond to stimulation regardless of the strength. This absolute refractory period in the frog sartorius at 0° C lasts about 10 milliseconds after stimulation. Therefore, a second pulse coming within that time span will not elicit any response. If, however, the pulses are 300 milliseconds apart, the muscle will be relaxing when the second pulse is given, and the tension will appear in waves in phase with the stimulation, causing an unfused tetanus. It is possible to stimulate the muscle at a frequency between these extremes so that the tension developed by the muscle remains constant. This latter type of contraction is called a fused tetanus, and the rate of stimulation that produces it is called the fusion frequency. The exact rate depends upon the particular muscle and the temperature.

Usually, the maximum tetanus tension is from 1.2 to 1.8 times greater than the maximum tension during a twitch. Within the muscle many elastic structures, connected in series with the contractile elements, are stretched during contraction. The attachment of the muscle fibres to the tendons at the end of the muscle and the attachment of the thin filaments to the Z line contribute to this elastic component. In single fibres, however, most of the elasticity of the series elastic elements is contributed by the actin-myosin cross bridges themselves. Full maximum tension is not apparent at the end of the muscle until the contractile elements have shortened enough to stretch the elastic elements—somewhat like taking up the slack in rope before a pull on one end can be felt at the other end. In a twitch, the activity of the muscle is so brief that the contractile elements cannot extend the elastic elements completely before relaxation begins; as a result, the tension at the ends of the muscle does not reach the maximum possible level. During a tetanus, on the other hand, the activity of the contractile elements is maintained, and they can eventually shorten enough to extend fully the series elastic elements. When this has been accomplished, the maximum tension is apparent at the ends of the muscle.

Effects of series elasticity

Length-tension relationship. The force developed by a muscle, whether it is contracting or resting, is strongly dependent on the length of the muscle (Figure 19). Resting skeletal muscle does not exert any force at lengths less than the normal length of the resting muscle in the body (l_o). When resting skeletal muscle is extended somewhat beyond l_o, however, a passive force begins to assert itself. The exact length at which this passive force occurs depends on the particular muscle. This force is characterized as passive because it is developed in noncontracting or inactive muscles by the elastic elements of the muscle.

Skeletal muscles do not develop any force when they are stimulated at lengths of less than about 50 percent l_o. The amount of force developed, however, increases during isometric contractions at lengths from 50 to 100 percent of l_o. Once beyond l_o, the passive force becomes a factor: the total force has two components, a passive one, resulting from elasticity, and an active one, resulting from contraction. For isometric contractions the active force developed during contraction decreases beyond l_o at about 150 percent l_o, the muscle fails to develop any active force.

The structural basis for the dependence of the magnitude of active force on the length of skeletal muscle has been established in experiments with single fibres rather than whole muscles. The active force has been correlated with the relative position of thick and thin filaments during contraction at each sarcomere length. The tension increases as the sarcomere length shortens from 3.65 to 2.25 μ (Figure 19A, 1 and 2) because more sites for actin-myosin cross-bridge interaction become available as the overlap of the thick and thin filaments increases (19B, 1 and 2). The force is constant from sarcomere length 2.25 to 2.00 μ (19A, 2 and 3) as the thin filaments move over the bare region devoid of cross bridges in the centre of the thick filaments (19B, 2 and 3). As the sarcomeres shorten further, from 2.00 to 1.67 μ (19A, 3 to 5), the thin filaments overlap each other, preventing effective interaction with myosin in the thick filaments (19B, 3 and 5) and consequently diminishing the force. Finally, from sarcomere length 1.67 to 1.27 μ (19A, 5 to 6) the thick filaments run up against the Z lines (19B, 6), and internal resistance causes an even greater diminution of the force.

From *Journal of Physiology* (1966)

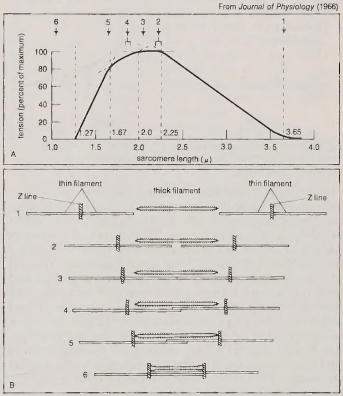

Figure 19: (A) The amount of force developed during an isometric tetanus of a single muscle fibre at various sarcomere lengths. (B) Relative positions of the thick and thin filaments at various sarcomere lengths.

Load–velocity relation. When a muscle is to lift a constant load (isotonic conditions) after stimulation starts, the force increases, just as in an isometric contraction, and, when the force is equal to the load, the muscle begins to shorten and lifts the load. When the activity of both the muscle and the force in it begin to decline, the load stretches the muscle back to its initial length. The tension in the muscle is equal to the load during the shortening and the lengthening of the muscle, except during brief periods of acceleration as the muscle begins to move. Only after the muscle has returned to its initial length does the tension begin to diminish. The size of the load also determines the velocity of shortening, and this relationship between load and velocity also applies to cardiac and smooth muscle. It can be mathematically described by Hill's equation:

$$V = \frac{(P_o - P)b}{P + a},$$

in which V is the velocity of shortening: P_o is the maximum force developed under isometric conditions; P is the force developed at a particular muscle length; and b and a are physical constants. A graphic interpretation of these values results in a rectilinear hyperbola called the force–velocity curve (Figure 20). From this curve can be determined both the velocity of shortening when the load is known and the force developed to overcome the load when the velocity is known.

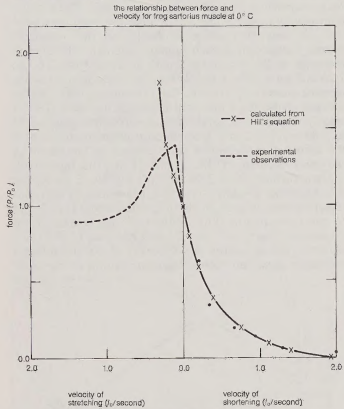

Figure 20: The force–velocity curve: relationship of the velocity of movement to the amount of force developed during tetanic stimulation (see text).

Energy transformations. When a chemical reaction occurs, energy is absorbed or released. In a contracting muscle, chemical reactions release energy that appears either as mechanical work or as heat. The first law of thermodynamics, or the law of conservation of energy, states that the heat and work produced must equal the energy released by the chemical reactions. The muscles that shorten and do external work liberate more energy as heat and work than do those that contract under isometric conditions and do not shorten or do external work. In light of the law of conservation of energy (first law of thermodynamics), this finding means that the amount of chemical reaction that takes place during contraction depends on the type of contraction performed by the muscle. In other words, the flow of energy is subject to regulation.

The mechanical work of muscles

The efficiency of the process of muscle contraction depends on the fate of the free energy released in chemical reactions; *i.e.*, whether it is converted primarily into work or degraded into heat. The second law of thermodynamics sets limits to the amount of energy that can be transformed into mechanical work. Although the production of heat can detract from the efficiency of working muscle, energy that appears as heat is not always wasted. In warm-blooded animals, for example, the heat released by muscles maintains a constant body temperature regardless of the environmental temperature. When an animal shivers in the cold a large amount of heat is generated in the muscles. The muscles alternately contract and relax, releasing energy chiefly as heat.

Source of energy for muscle work. Muscles use the free energy released by chemical reactions by coupling the chemical reaction to physical changes in the contractile proteins. The exact molecular details of this fundamental coupling process are not yet completely known. Of the reactions that have been identified, the splitting of ATP is the energy-yielding reaction nearest to the contractile event. Water participates in this reaction in which ATP is broken down to ADP and phosphate (P_i); the reaction that occurs in the muscle, during which chemical free energy is converted into work, can be written as follows:

$$\text{ATP} + \text{H}_2\text{O} + \text{contractile elements} \rightarrow \text{ADP} + \text{P}_i + \text{contractile elements} + \text{work} + \text{heat.}$$

This equation emphasizes the obligatory role of the contractile elements and the coupled nature of the reaction that produces work.

Energy stores. In a resting vertebrate muscle, the available supply of ATP can sustain maximal muscle work for less than one second. The muscle, therefore, must continuously replenish its ATP store, and this is done in many different ways. One mechanism for the formation of ATP operates so rapidly that for a long time scientists were unable to detect any change in the amount of ATP in the muscle as a result of contraction. This immediate rebuilding of ATP is accomplished by the reactions of compounds called phosphagens. All of them contain phosphorus in a chemical unit called a phosphoryl group, which they transfer to ADP to produce ATP (these compounds are also referred to as high-energy phosphates). Whereas different phosphagens occur in various animals, all of them contain two common chemical units—a guanidino group and a phosphoryl group.

Phosphagens

The reaction for the rebuilding of the ATP utilized during contraction in vertebrate muscle can be written as follows:

$$\text{ADP} + \text{PCr} \rightarrow \text{ATP} + \text{Cr.}$$

The phosphagen, phosphorylcreatine (PCr), gives rise to creatine (Cr) upon the formation of ATP. This reaction is catalyzed by the enzyme ADP : creatine phosphoryl transferase.

Resting skeletal muscle has about 10 times more phosphagen compound than ATP. During rapid and intense contraction, the phosphagen can be utilized to rebuild ATP rapidly and maintain its level as long as the phosphagen lasts, which in a maximally working human muscle is just a few seconds. After contraction ATP is utilized to form phosphagen (PCr) from creatine (Cr); ADP is also formed.

$$\text{ATP} + \text{Cr} \rightarrow \text{ADP} + \text{PCr}$$

This formation of PCr occurs at the same time that ATP is produced by various reactions that are described in a later section.

As mentioned earlier, changes in the ATP level during contraction are difficult to measure since it is rapidly reformed from ADP and Cr. Such changes can be observed, however, when the muscle is treated with the chemical 2,4-dinitro–fluorobenzene (DNFB), which inhibits the enzyme ADP : creatine phosphoryl transferase. In DNFB-treated muscles, the ATP level decreases during contraction; the ADP and phosphate (P_i) levels increase, and phosphorylcreatine and creatine levels remain constant. The mechanical properties of DNFB-treated muscle during maximal contraction are the same as those of untreated muscles, except that DNFB-treated muscle runs out of ATP sooner and therefore contracts for a shorter time.

The amount of phosphagen is higher in skeletal muscle than it is in cardiac or smooth muscle. This correlates with the type of activity of the muscles. Skeletal muscle operates in bursts of activity, whereas cardiac and smooth muscle contract in a regular pattern. Skeletal muscle needs an immediate supply of a large amount of ATP, which is provided by the phosphagen reaction; cardiac and smooth muscle, which use ATP at a lower rate, rely on slower reactions to fill their energy requirements.

Metabolic pathways producing ATP. *ATP from glucose.* In skeletal muscle most of the ATP is produced in metabolic pathways involving reactions of the sugar glucose or some other carbohydrate derived from glucose. During contraction, for example, glucose is made available for these reactions by the breakdown of glycogen, the storage form of carbohydrate in animal cells. The concentration of Ca^{2+} is transiently increased on activation of muscle. The ions are also activators of the process of glycogen breakdown. During the recovery period the glycogen supply is replenished by synthesizing glycogen from glucose supplied to the muscle tissue by the blood.

The glycolytic pathway. In all but the most brief, intense contractions—during which phosphagen is utilized to form ATP—additional ATP is supplied by a set of chemical reactions called the glycolytic pathway, or the Embden–Meyerhof–Parnas pathway. These reactions are especially important when the muscle is doing work at a high rate. The enzymes that catalyze these reactions are located in the sarcoplasm, as is glucose, the major starting material. The glycolytic pathway can be summarized as follows: reactions of glucose to lactate are coupled to formation of ATP from ADP and phosphate.

$$\underset{\text{glucose}}{C_6H_{12}O_6} + 2ADP + 2P_i \rightarrow \underset{\text{lactate}}{2C_3H_6O_3} + 2ATP + 2H_2O$$

As already indicated, ATP is broken down in the contractile reaction to form ADP and P_i, which can then be recycled into the pathway. The lactate, a waste product, diffuses out of the muscle and is transported by the blood to the liver. The removal of lactate from the muscle is slower than its production; if the muscle contracts for an extended period, the accumulation of lactate in the muscle causes fatigue and ultimately muscle cramps.

Most of the lactate taken to the liver is converted to glucose, from which glycogen is formed in a series of reactions that require ATP to provide more ATP. About one-sixth of the lactate is oxidized to carbon dioxide by reactions that require oxygen (see below) after the exercise is done; a so-called oxygen debt accumulates during brief intense exercise. Animals breathe hard after intense exercise to supply the oxygen needed for the reconversion of lactate.

The relative speed of glycolysis

The glycolytic pathway can operate up to 1,000 times faster in a contracting muscle than it does in a resting muscle. Two regulatory mechanisms play roles in the increase in the rates of these reactions. First, reacting compounds (reactants) accumulate; for example, more glucose is available because glycogen breakdown increases during contraction, and ADP and P_i accumulate. The second type of regulation depends on the activity of the enzyme phosphofructokinase, which catalyzes one of the early steps in glycolysis. This enzyme can bind either ATP or adenosine monophosphate (AMP). When ATP is bound, the activity of the enzyme is low; that is, the reaction it catalyzes proceeds slowly. When AMP is bound, the enzyme has a high activity. During contraction the ATP level drops and that of ADP increases; ADP, in turn, produces AMP as well as ATP, in a reaction catalyzed by the enzyme adenylate kinase, or myokinase. The AMP then can bind with the phosphofructokinase, thereby accelerating glycolysis and the production of ATP. The formation of ATP in the myokinase reaction enables the muscle to use the energy in the ADP formed during contraction.

The oxidative pathways. A large amount of ATP is produced by the complete oxidation of carbon-containing compounds (*e.g.*, glucose) to carbon dioxide and water in reactions of the Krebs cycle and oxidative phosphorylation. These reactions take place inside the membrane-bound components of cells called mitochondria. Carbohydrate can enter the oxidative pathways at a branch point in the glycolytic pathway. At the branch point, two kinds of reaction can occur: pyruvate, a three-carbon compound, can either react to form lactate or lose a carbon dioxide molecule to form a two-carbon unit, which then enters the Krebs cycle. If the muscle is working hard and using ATP rapidly, lactate is formed. If it is working slowly, a larger fraction of the carbon enters the oxidative pathways.

During reactions of the Krebs cycle, carbon dioxide and hydrogen atoms are removed from the compounds that enter the cycle. The carbon dioxide diffuses out of the muscle and is carried by the blood to the lungs, where it is exhaled. The electrons from the hydrogen atoms are passed through an electron-transport chain consisting of the series of reactions involving cytochrome molecules. These events occur in the mitochondria, in which ADP is also combining with phosphate (P_i) to form ATP. In the last step of this reaction sequence, the hydrogen atoms combine with oxygen to form water. The net reaction for each glucose molecule that enters the glycolytic pathway and proceeds through the Krebs cycle and oxidative phosphorylation is summarized below.

$$\underset{\text{glucose}}{C_6H_{12}O_6} + 6O_2 + 36ADP + 36P_i \rightarrow 6CO_2 + 36ATP + \underset{}{6H_2O}$$

Efficiency of oxidative pathways

Although the oxidative pathways result in the formation of more ATP from each glucose molecule than does the glycolytic pathway, the complete process is much slower than glycolysis. The slowest steps are those involving the passage of the carbon-containing compounds from the sarcoplasm into the mitochondria and the delivery of oxygen, which ultimately comes from the air that is breathed. In red blood cells oxygen is combined with hemoglobin, a protein containing four identical subunits, during its transfer from the lungs to the muscles. Muscle contains myoglobin, which has a structure similar to a single subunit of hemoglobin. Myoglobin, which combines with and can store oxygen, is responsible for transporting much of the oxygen through the sarcoplasm to the mitochondria. Myoglobin is especially important in the heart and "red" muscles, which rely heavily on oxidative metabolism for the production of ATP.

During intense exercise of skeletal muscle, ATP is supplied almost entirely by carbohydrate metabolism. During rest or very light exercise, however, skeletal muscle depends largely on the oxidation of stored fats—actually of their breakdown products, fatty acids—for the production of ATP. Two-carbon units and hydrogen atoms are removed from fats in a stepwise fashion. The two-carbon units enter the Krebs cycle, as do the identical units derived from carbohydrates, as the compound acetyl coenzyme A. The hydrogen atoms from the breakdown of the fat and from the reactions of the Krebs cycle proceed through oxidative phosphorylation, and ATP is produced.

Heart muscle, which operates constantly but at a lower level of intensity than does skeletal muscle, depends on oxidative reactions for ATP. Most of the two-carbon units are derived from either fatty acids or ketones, components of fat, brought to the heart by the blood.

Molecular mechanisms of contraction. *Excitation–contraction coupling.* The nerve impulse that ultimately results in muscle contraction appears as an action potential at the sarcolemma, the membrane that surrounds the muscle fibre. This electrical signal is communicated to the myofilaments inside the fibre in the following way. When the action potential reaches the opening of the transverse tubules (channels that open through the sarcolemma to the space outside the fibre; see above *The myofibril*) in the surface of the fibre, it travels down into the fibre along the tubular membranes, which are continuous with the surface membrane, to within a fraction of a micrometre of each functional contractile unit (Figure 15). In frog muscle the transverse tubules surround the myofibril at the level of each Z line, and in mammalian muscles they are located at the edge of the A bands and I bands. At the triads (the three-element complex consisting of one transverse tubule and two cisternae, which are enlarged saclike membranes) the transverse tubule walls are close to the membranes of the terminal cisternae of the sarcoplasmic reticulum.

The effect of calcium ions

By some as yet unknown mechanism, the change in the electrical properties of the transverse tubule during an action potential causes the rapid release by the terminal cisternae of relatively large amounts of calcium ions into the sarcoplasm. As the concentration of calcium ions increases in the sarcoplasm, they become bound to the troponin in the thin filaments. This releases (or removes) the troponin–tropomyosin-mediated inhibition of the myosin-actin interaction. As the stimulation of the muscle continues, the terminal cisternae continue to release calcium ions. At the same time, however, some of the calcium ions are being removed from the sarcoplasm by another portion of the sarcoplasmic reticulum, the longitudinal tubules. Once the calcium ions are inside the lumen (cavity) of the longitudinal tubules, many of them slowly diffuse back to the terminal cisternae, where they are bound to a protein, calsequestrin, as a storage site. The removal of calcium ions from the sarcoplasm by the sarcoplasmic reticulum is energy requiring. The breakdown of ATP is the chemical reaction that supplies the energy, and two calcium ions are apparently removed from the sarcoplasm for each ATP molecule that is split.

The development of muscular force. In the early 1950s it became clear that there were two types of filaments in muscle and that neither extended the entire length of the muscle (see Figure 14). Furthermore, it was found that the overall length of the filaments did not change during contraction. Those findings ruled out most of the then existing theories about the mechanism of muscle contraction and, based on shape or length changes in structural elements, provided the basis for the now widely accepted sliding-filament theory.

Sliding-filament theory

Shortening of the entire muscle occurs as the thin filaments on both sides of the A band slide farther into the A band. As the sliding progresses, the areas of the sarcomere containing only one type of filament—that is, the I band and the H zone—decrease in size because more and more of the thin and thick filaments overlap each other. On the other hand, the A band remains the same length because the thick filaments do not change in length except in extreme shortening. The distance from the Z line to the edge of the H zone also remains virtually the same length because that distance is determined by the length of the thin filaments. The sliding-filament theory must be expanded to explain certain aspects of contraction: how the force that moves the filaments past each other is generated and how ATP takes part in the process of contraction.

Cross-bridge theories

The sliding of the filaments is thought to result from the interaction of the cross bridges with the thin filaments during contraction. Each time a bridge links to a thin filament and operates in a specific way (see below), it causes a small movement of the thin filament along the thick filament. Since muscles are able to shorten considerably, requiring sliding of the filaments through large distances, there must be repeated cycles of interaction between a given cross bridge and successive sites on the thin filament.

The myosin heads attached to the actin filament are thought to change their angle with respect to the thin filaments. This change leads to force development, the elastic element residing in some part of the cross bridge (*i.e.*, the portion of myosin connecting the core of the thick filaments to actin) or in the actin-myosin junction itself. The precise connection between various chemical steps in the hydrolysis of ATP and force generation is still under investigation. Similarly, the precise nature of the structural change that corresponds to force generation is not fully understood—instead of the rotation of the whole myosin head about the point of contact between actin and myosin, a bending motion may take place within the head. Some theories suggest purely electrostatic interactions between thick and thin filaments without specific interaction between actin and the myosin heads. The many similarities, however, between factors that affect actin and myosin interactions in solution and those that modulate the behaviour of whole muscle fibres make models of contraction and force development based on specific protein–protein interaction more fruitful. (R.E.Da./N.A.C./J.Ge.)

CARDIAC MUSCLE

The heart is the pump that keeps blood circulating throughout the body and thereby transports nutrients, breakdown products, antibodies, hormones, and gases to and from the tissues. The heart consists mostly of muscle, the myocardial cells (collectively termed the myocardium), arranged in ways that set it apart from other types of muscle. The outstanding characteristics of the action of the heart are its contractility, which is the basis for its pumping action, and the rhythmicity of the contraction.

Contractility and rhythmicity

Heart muscle differs from its counterpart, skeletal muscle, in that it exhibits rhythmic contractions. The amount of blood pumped by the heart per minute (the cardiac output) varies to meet the metabolic needs of the peripheral tissues (muscle, kidney, brain, skin, liver, heart, gastrointestinal tract). The cardiac output is determined by the contractile force developed by the muscle cells of the heart (myocytes; Figure 21) as well as the frequency at which they are activated (rhythmicity). The factors affecting the frequency and force of heart muscle contraction are critical in determining the normal pumping performance of the heart and its response to changes in demand.

Structure and organization. The heart is a network of highly branched cardiac cells 110 micrometres in length and 15 micrometres in width, which are connected end to end by intercalated disks (Figure 21). The cells are organized into layers of myocardial tissue that are wrapped around the chambers of the heart. The contraction of the individual heart cells produces force and shortening in these bands of muscle with a resultant decrease in the heart chamber size and the consequent ejection of the blood into the pulmonary and systemic vessels. Important components of each heart cell involved in excitation and metabolic recovery processes are the plasma membrane and transverse tubules in registration with the Z lines, the longitudinal sarcoplasmic reticulum and terminal cisternae, and the mitochondria. The thick (myosin) and thin (actin, troponin, and tropomyosin) protein filaments are arranged into contractile units (that is to say, the sarcomere extending from Z line to Z line) that have a characteristic cross-striated pattern similar to that seen in skeletal muscle.

Myocyte excitation and recovery

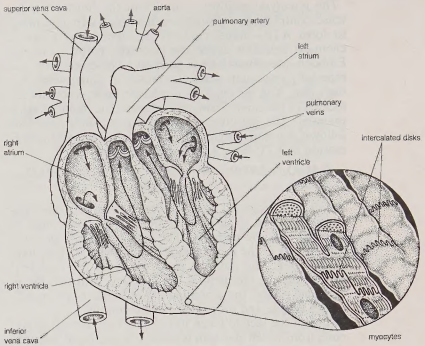

Figure 21: The four-chambered mammalian heart consisting of the right and left atria and the right and left ventricles. Blood enters the right atrium from the superior and inferior venae cavae, passes from the right atrium to the right ventricle, and then is pumped to the lungs through the pulmonary artery. The blood is returned to the left atrium from the lungs through the pulmonary veins, passes to the left ventricle, and then is pumped to the peripheral tissues through the aorta. Inset shows the heart muscle cells (myocytes).

The frequency of contraction. The rate at which the heart contracts and the synchronization of atrial and ventricular contraction required for the efficient pumping of blood depend on the electrical properties of the myocardial cells and on the conduction of electrical information from one region of the heart to another. The action potential (activation of the muscle) is divided into five phases (0–4) and is graphed in Figure 22. Each of the phases of the action potential is caused by time-dependent changes in the permeability of the plasma membrane to potassium ions (K^+), sodium ions (Na^+), and calcium ions (Ca^{2+}). The resting potential of the myocytes of the ventricle (phase 4) begins with the outside of the cell being positive—*i.e.*, having a greater concentration of positive ions. Atrial and ventricular myocytes are normally quiescent (non-rhythmic); however, when the resting membrane potential is depolarized to a critical potential (E_{crit}), a self-generating action potential follows, leading to muscle contraction. Phase 0, the upstroke, is associated with a sudden increase in membrane permeability to Na^+. Phases 1, 2, and 3 result from changes in membrane permeability and conductance to Na^+, K^+, and Ca^{2+}.

The electrical activity of heart muscle cells differs substantially from that of skeletal muscle cells in that phases 1, 2, and 3 are considerably prolonged (200 milliseconds versus five milliseconds, respectively). Another significant

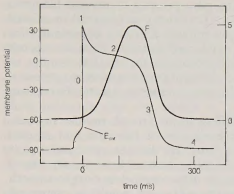

Figure 22: The time course of each of the phases of the ventricular action potential (0–4) and the isometric force (F) developed by an isolated heart muscle bundle.

difference in excitability is that heart muscle cannot be tetanized (*i.e.,* induced to spasm) by the application of repetitive stimuli (see above *Striated muscle*), thus ensuring the completion of the contraction/relaxation cycle and the effective pumping of blood.

Sources of myocyte excitation

Because atrial and ventricular cells are normally quiescent, exhibiting action potentials only after the muscle is depolarized to the critical membrane potential (E_{crit}), the source of the rhythmic contractions of the heart must be sought elsewhere. In contrast to atrial and ventricular myocytes, the myocytes of the sinoatrial (SA) node, the atrioventricular (AV) node, the bundle branches, and the Purkinje fibre system are made up of specialized cardiac muscle cells that exhibit a spontaneous upward drift in the resting potential toward E_{crit}, resulting in the generation of the action potential with all of its phases. The normal rhythmicity of cells from each of these regions depends on the rate at which spontaneous depolarization occurs and the resting membrane potential from which it starts. The region with the fastest intrinsic rate, the SA node, sets the pace for the whole heart. The pacemaker activity is propagated to the rest of the heart by means of the low electrical resistance pathways through the muscle cells (*e.g.,* intercalated disks) and the presence of specialized conducting tissue (bundle branches, Purkinje system). The time course of activation and the shape of the action potentials in different parts of the heart are responsible for the synchronous activation and contraction of the muscles of the atrium followed by those of the ventricle.

The normal rhythm of the heart (*i.e.,* the heart rate) can be altered by neural activity. The heart is innervated by sympathetic and parasympathetic nerves, which have a profound effect on the resting potential and the rate of diastolic depolarization in the SA nodal region. The activity of the sympathetic nervous system may be increased by the activation of the sympathetic nerves innervating the heart or by the secretion of epinephrine and norepinephrine from the adrenal gland. This decreases the resting potential of the myocytes of the SA node while increasing the rate of diastolic depolarization. The result is an increase in the heart rate. Conversely, stimulating the parasympathetic nervous system (vagal nerves to the heart) increases the resting potential and decreases the rate of diastolic depolarization; under these circumstances the heart rate slows. The sympathetic nervous system is activated under conditions of fright or vigorous activity (the so-called "fight or flight" reaction), where the increase in force and rate of heart contraction are easily felt; the parasympathetic system exerts its influence during periods of rest.

Excitation/contraction coupling. Immediately following depolarization of the plasma membrane and the ensuing action potential, the heart muscle develops force and then relaxes. The surface action potential is transmitted to the interior of the muscle by means of the T tubular system. Calcium ions enter the muscle cell during the plateau phase of the action potential (phase 2), triggering the release of calcium from the terminal cisternae of the sarcoplasmic reticulum. Calcium diffuses to the myofilaments and combines with the troponin-tropomyosin system (associated with the thin actin filaments), producing a conformational change that allows actin and myosin to interact. This interaction in the presence of ATP results in cross-bridge cycling and ATP hydrolysis. The force developed in the whole muscle is the sum of all the forces developed by each of the millions of cycling cross bridges of the muscle. The free calcium ions in the cytosol are removed by an energy-dependent calcium uptake system involving calcium ion pumps located in the longitudinal sarcoplasmic reticulum. These calcium pumps lower the concentration of free calcium in the cytosol, resulting in the dissociation (release) of calcium from the troponin-tropomyosin system. The troponin-tropomyosin system is then transformed back to its original state, preventing myosin and actin from interacting and thus causing relaxation of the muscle. At the same time calcium is extruded from the cell into the surrounding medium.

Cross-bridge cycling

Force and velocity of contraction. There are a number of factors that change the force developed by heart muscle cells. In a manner similar to that seen in skeletal muscle, there is a relationship between the muscle length and the isometric force developed. As the muscle length is increased, the active force developed reaches a maximum and then decreases. This maximum point is the length at which the heart normally functions. As with skeletal muscle, changes in length alter the active force by varying the degree of overlap of the thick myosin and thin actin filaments. The force developed by heart muscle also depends on the frequency at which the muscle is stimulated. As the stimulus frequency is increased, the force is increased until the maximum is reached, at which point it begins to decrease. An increase in the level of circulating epinephrine and norepinephrine from the sympathetic nervous system also increases the force of contraction. All of these factors can combine to allow the heart to develop more force when required. At any given length the velocity of contraction is a function of the load lifted, with the velocity decreasing as the load is increased. The force–velocity relationship is similar to that of skeletal muscle and takes the shape of a rectangular hyperbola. When force–velocity curves are measured at different lengths, there is a change in maximum force while the maximum velocity of shortening (V_{max}) remains unchanged. Under conditions where there is an increase in inotropic performance of the muscle (frequency, epinephrine or norepinephrine) there is a shift in both the maximum velocity and maximum force developed.

Response of the heart to stress. Demands on the heart vary from moment to moment and from day to day. In moving from rest to exercise the cardiac output may be increased tenfold. Other increases in demand are seen when the heart must pump blood against a high pressure such as that seen in hypertensive heart disease. Each of these stresses requires special adjustments. Short-term increases in demand on the heart (*e.g.,* exercise) are met by increases in the force and frequency of contraction. These changes are mediated by increases in sympathetic nervous system activity, an increase in the frequency of contraction, and changes in muscle length. The response to long-term stress (hypertension, thyrotoxicosis) results in an increase in the mass of the heart (hypertrophy) providing more heart muscle to pump the blood, which helps meet the increase in demand. In addition, subtle intracellular changes affect the performance of the muscle cells. In the pressure overload type hypertrophy (hypertensive heart disease) the pumping system of the sarcoplasmic reticulum responsible for calcium removal is slowed while the contractile protein myosin shifts toward slower cross-bridge cycling. The outcome is a slower, more economical heart that can meet the demand for pumping against an increase in pressure. At the molecular level the slowing of calcium uptake is caused by a reduction in the number of calcium pumps in the sarcoplasmic reticulum. The change in V_{max} and economy of force development occur because each myosin cross-bridge head cycles more slowly and remains in the attached force-producing state for a longer period of time. In the thyrotoxic type of hypertrophy, calcium is removed more quickly while there is a shift in myosin. At the molecular level there are more sarcoplasmic reticular calcium pumps, while the myosin cross-bridge head cycles

Short- and long-term stress

more rapidly and remains attached in the force-producing state for a shorter period of time. The result is a heart that contracts much faster but less economically than normal and can meet the peripheral need for large volumes of blood at normal pressures.

SMOOTH MUSCLE

Because vertebrate smooth muscle is located in the walls of many hollow organs (Figure 23), the normal functioning of the cardiovascular, respiratory, gastrointestinal, and reproductive systems depends on the constrictive capabilities of smooth muscle cells. Smooth muscle is distinguished from the striated muscles of the skeleton and heart by its structure and its functional capabilities.

Characteristics of smooth muscle

As the name implies, smooth muscle presents a uniform appearance that lacks the obvious striping characteristic of striated muscle. Vascular smooth muscle shortens 50 times slower than fast skeletal muscle but generates comparable force using 300 times less chemical energy in the process. These differences in the mechanical properties of smooth versus striated muscle relate to differences in the basic mechanism responsible for muscle shortening and force production. As in striated muscle, smooth muscle contraction results from the cyclic interaction of the contractile protein myosin (*i.e.*, the myosin cross bridge) with the contractile protein actin. The arrangement of these contractile proteins and the nature of their cyclic interaction account for the unique contractile capabilities of smooth muscle.

Structure and organization. Smooth muscle contains spindle shaped (Figure 23) cells 50 to 250 micrometres in length by five to 10 micrometres in diameter. These cells possess a single, central nucleus. Surrounding the nucleus and throughout most of the cytoplasm are the thick (myosin) and thin (actin) filaments. Tiny projections that originate from the myosin filament are believed to

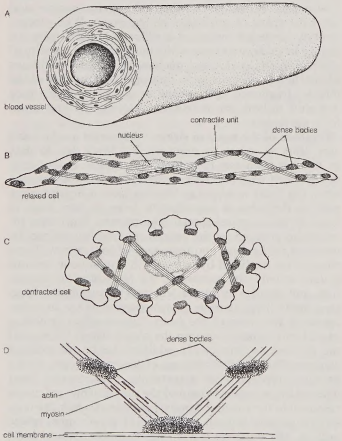

Figure 23: *The artery wall and the ultrastructure of the smooth muscle cells within it.*
(A) Smooth muscle cells are circumferentially oriented and interconnected within the wall by a dense connective tissue matrix. (B) A relaxed smooth muscle cell with a smooth membrane boundary and central nucleus. Contractile units traverse the cell interior. (C) A contracted smooth muscle cell with large membrane blebs formed as the contractile proteins generate force and pull at the dense amorphous plaques on the cell membrane. (D) Attachment sites (dense bodies) for the contractile proteins, actin filaments are located in the cytoplasm and on the membrane. Thick myosin filaments interdigitate with the thin actin filaments.

be cross bridges. The ratio of actin to myosin filaments (approximately 12 to 1) is twice that observed in striated muscle and thus may provide a greater opportunity for a cross bridge to attach and generate force in smooth muscle. An increased probability for attachment may, in part, account for the ability of smooth muscle to generate, with far less myosin, comparable or greater force than striated muscle.

Smooth muscle differs from striated muscle in lacking any apparent organization of the actin and myosin contractile filaments into the discrete contractile units called sarcomeres. Recent advances have shown that a sarcomere-like structure may nonetheless exist in smooth muscle. Such a sarcomere-like unit would be composed of the actin filaments that are anchored to dense, amorphous bodies in the cytoplasm as well as dense plaques on the cell membrane (Figure 23). These dense areas are composed of α-actinin, a protein, found in the Z lines of striated muscle, to which actin filaments are known to be attached. Thus, force generated by myosin cross bridges attached to actin is transmitted through actin filaments to dense bodies and then through neighbouring contractile units, which ultimately terminate on the cell membrane.

Changes with contraction

Relaxed smooth muscle cells possess a smooth cell membrane appearance, but upon contraction, large membrane blebs (or eruptions) form as a result of inwardly directed contractile forces that are applied at discrete points on the muscle membrane (Figure 23). These points are presumably the dense plaques on the cell membrane to which the actin filaments attach. As an isolated cell shortens it does so in a corkscrewlike manner. It has been hypothesized that, in order for a single cell to shorten in such a unique fashion, the contractile proteins in smooth muscle are helically oriented within the muscle cell. This helical arrangement agrees with earlier speculation that the contractile apparatus in smooth muscle may be arranged at slight angles relative to the long axis of the cell. Such an arrangement of contractile proteins could contribute to the slower shortening velocity and enhanced force-generating ability of smooth muscle.

The contractile proteins interact to generate a force that must be transmitted to the tissue in which the individual smooth muscle cells are embedded. Smooth muscle cells do not have the tendons present in striated muscles, which allow for transfer of muscular force to operate the skeleton. Smooth muscles, however, are generally embedded in a dense connective tissue matrix that connects the smooth muscle cells within the tissue into a larger functional unit (Figure 23).

Mitochondria

Other organelles of the cell interior are related to energy production and calcium storage. Mitochondria are located most frequently near the cell nucleus and at the periphery of the cell. As in striated muscles, these mitochondria are linked to ATP production. The sarcoplasmic reticulum is involved in the storage of intracellular calcium. As in striated muscle, this intracellular membrane system plays an important role in determining whether or not contraction occurs by regulating the concentration of intracellular calcium.

Initiation of contraction. Smooth muscle cells contract in response to neuronal or hormonal stimulation, either of which results in an increase in intracellular calcium as calcium enters through membrane channels or is released from intracellular storage sites. The elevated level of calcium in the cell cytoplasm results in force generation. The rise in the level of intracellular calcium, however, initiates contraction through a mechanism that differs substantially from that in striated muscle. In striated muscle, myosin cross bridges are prevented from attaching to actin by the presence of the troponin-tropomyosin system molecules on the actin filament (see above *Striated muscle*). In smooth muscle, although tropomyosin is present, troponin is not, which means that an entirely different regulatory scheme operates in smooth muscle. Regulation of the contractile system in smooth muscle is linked to the myosin filament; regulation in striated muscle is linked to the actin filament.

In order for the smooth-muscle myosin cross bridge to interact cyclically with actin, a small protein on the myosin

molecule, called the light chain, must be phosphorylated (receive a phosphate group). This phosphorylation is the result of a series of interdependent biochemical reactions that are initiated by the rise in intracellular calcium. For the cell to relax, the concentration of intracellular calcium falls, thus inactivating these biochemical processes associated with light chain phosphorylation. The phosphate molecule that was added in the previous steps, however, still must be removed from the light chain so that attachment of the cross bridge to actin is prevented. Phosphatases are enzymes in the muscle cell that cleave the phosphate group from the myosin light chain.

Release of chemical energy

Cross-bridge cycle and ATP breakdown. Smooth-muscle contraction requires the release of chemical energy stored in ATP molecules. The release of this chemical energy by the myosin cross bridge and the resultant mechanical work is commonly referred to as the cross-bridge cycle, which in smooth muscle is believed to be a multistep process similar to that in striated muscle. Therefore, the mechanical properties of smooth muscle, as of striated muscles, are intimately linked to this multistate cross-bridge cycle. For instance, there is a correlation between the rate at which the cross bridges cycle and the maximum shortening velocity of the muscle. Since the actomyosin ATPase cross-bridge cycle in smooth muscle is considerably slower than that in striated muscle, the slower shortening velocity in smooth muscle must be due, in part, to the reduced turnover rate of the cross bridge. The slower cycling rate could also account for the high economy of ATP utilization that characterizes smooth-muscle force production, since fewer cycles are required and less energy is consumed in the generation of force.

Mechanical properties. The relationship between smooth muscle's ability to shorten and to generate force is characterized by the force–velocity relationship. The form of this relationship is qualitatively similar to that in striated muscle; however, the smooth-muscle force–velocity relationship differs from that of striated muscle in having a slower maximum shortening velocity (V_{max}) and greater force per cross-sectional area of muscle (F_{max}). As mentioned above, the slower shortening velocity may relate to the slower cycling rate of the cross bridge as well as the orientation of the contractile proteins within the muscle cell.

Force-generating capabilities

The force-generating capabilities of smooth muscle are greater than those of striated muscle despite the fact that there is considerably less myosin in smooth muscle. Possible explanations for this relate to the arrangement of the contractile apparatus within the cell, which gives rise to more cross bridges effectively operating in conjunction with one another. Second, enhanced force production could be related to the greater amount of time that the cross bridge spends in the attached, high force-producing state (*i.e.,* duty cycle). Evidence for such an increase in the duty cycle does exist in smooth muscle.

When fully contracted, the amount of force that smooth muscle can generate depends on the muscle length. Therefore, as in striated muscle, an optimal length for force production exists, with force being reduced at both lesser and greater lengths (for an explanation of underlying mechanism, see above *Striated muscle*). The similarity in shape for both the force–velocity and length–tension relationships between smooth and striated muscle suggests that in smooth muscle both a cross-bridge mechanism and sliding of contractile filaments must occur.

Constant force

Smooth muscle cells often must generate constant force for prolonged periods of time. In order to do this without depleting the muscle's energy supply, smooth muscle appears to have adapted by altering the cross-bridge cycling rate during the time course of a single contraction. If shortening velocity is a reasonable indicator of cross-bridge cycling, then the observed reduction in shortening velocity with time of contraction suggests that the cross-bridge cycling rate must be slowing with contraction. At present it is not clear whether the cycling rate of the entire cross-bridge population slows with duration of contraction or whether a subset of slowly cycling cross bridges (*i.e.,* latch bridges) appears with a contraction time that hinders the action of the normally cycling bridges. Regardless of the mechanism, the modulation of cross-bridge cycling rate represents a highly economical means of generating force in a muscle that often exists in a tonic state of contraction.

Smooth muscle in disease states. Smooth muscle cells lining the artery walls have been implicated in cardiovascular diseases such as atherosclerosis and hypertension (high blood pressure). In hypertension an increase in the size of the individual cells (hypertrophy) and of their number (*i.e.,* hyperplasia) has been hypothesized. The increased quantity of smooth muscle in the artery wall could increase the constrictive ability of the artery or the artery wall thickness, either of which could constrict the lumen of the artery, thus reducing blood flow through the vessel. To compensate for this resistance to blood flow, the cardiovascular system responds by elevating blood pressure to assure that the various tissues of the body are adequately supplied with blood. A consequence of the need to raise blood pressure, however, is a greater workload for the heart, and thus individuals who are diagnosed with high blood pressure are at a higher risk of heart attack or stroke. Drugs that relax smooth muscle in an effort to lower blood pressure have been successful in reducing the risk of cardiovascular complications. (N.R.A./D.M.W.)

Diseases and disorders of muscle

Muscle diseases and disorders that result from direct abnormalities of the muscles are called primary muscle diseases; those that can be traced as symptoms or manifestations of disorders of nerves or other systems are not properly classified as primary muscle diseases. Because muscles and nerves (neurons) supplying muscle operate as a functional unit, disease of both systems results in muscular atrophy (wasting) and paralysis.

INDICATIONS OF MUSCLE DISEASE

Muscular atrophy and weakness are among the most common indications of muscular disease (see below *Muscle weakness*). Though the degree of weakness is not necessarily proportional to the amount of wasting, it usually is so if there is specific involvement of nerve or muscle. Persistent weakness exacerbated by exercise is the primary characteristic of myasthenia gravis.

Pain is ordinarily present in muscle disease because of defects in blood circulation or injury or inflammation of the muscle. Pain is rare, except as a result of abnormal posture or fatigue, in muscular dystrophy—a familial disease characterized by progressive wasting of the muscles. Cramps may occur with disease of the motor or sensory neurons; with certain biochemical disorders (*e.g.,* hypocalcemia, a condition in which the blood level of calcium is abnormally low); when the muscle tissues are affected by some form of poisoning; from disease of the blood vessels; and with exercise, particularly when cold.

Muscle enlargement—muscular hypertrophy—occurs naturally in athletes. Hypertrophy not associated with exercise occurs in two unusual forms of muscular dystrophy, known as myotonia congenita and hypertrophia musculorum vera. (The latter condition combines increased muscle size with strength; in the former, muscle cramping is an additional feature.) Pseudohypertrophy, muscular enlargement through deposition of fat rather than muscle fibre, occurs in other forms of muscular dystrophy, particularly the Duchenne type.

Tetany, tetanus, and fasciculation

Tetany is the occurrence of intermittent spasms, or involuntary contractions, of muscles, particularly of the arms and legs and the larynx, or voice box; it results from low levels of calcium in the blood and from alkalosis, an increased alkalinity of the blood and tissues. Tetanus, also called lockjaw, is a state of continued muscle spasm, particularly of the jaw muscles, caused by toxins produced by a particular bacillus, *Clostridium tetani.*

The twitching of muscle fibres controlled by a single motor nerve cell, a process called fasciculation, may occur in a normal person but may indicate that muscular atrophy is due to disease of motor nerve cells in the spinal cord. Fasciculation is seen most clearly in muscles close to the surface of the skin.

Glycogen is a storage form of carbohydrate, and its breakdown is a source of energy. Muscle weakness is found in a rare but important group of hereditary diseases, the so-called glycogen-storage diseases, in which various enzyme defects prevent the release of energy by the normal breakdown of glycogen in muscles. As a result, abnormal amounts of glycogen are stored in the muscles and other organs. The best-known type clinically affecting muscles is McArdle's disease, in which the muscles are unable to degrade glycogen to lactic acid on exertion because of the absence of the enzyme phosphorylase. Abnormal accumulations of glycogen are distributed within muscle cells. Features of the condition include pain, stiffness, and weakness in the muscles on exertion. McArdle's disease usually begins in childhood. No specific treatment is available, and persons affected are usually required to restrict exertion to tolerable limits. The condition does not appear to become steadily worse, but there are threats to continuing activity and to life when the muscle protein myoglobin is excreted in the urine. Other glycogen-storage diseases result from deficiency of the enzymes phosphofructokinase or acid maltase. With acid maltase deficiency both heart and voluntary muscles are affected, and death occurs within a year or so of birth as a rule.

McArdle's disease

MUSCLE WEAKNESS

Signs and symptoms. Weakness is a failure of the muscle to develop an expected force. Weakness may affect all muscles or only a few, and the pattern of muscle weakness is an indication of the type of muscle disease. Often associated with muscle weakness is the wasting of affected muscle groups. The many reasons why a muscle is not fully activated in weakness may include less than maximal voluntary effort; disease of the brain, spinal cord, or peripheral nerves that interferes with proper electrical stimulation of the muscle fibres; or a defect in the muscle itself. Only when all causes have been considered can weakness be attributed to failure of the contractile machinery (*i.e.,* the anatomy) of the muscle cell.

Clinical presentation

The effect of weakness in a particular muscle group depends on the normal functional role of the muscle and the degree to which force fails to develop. A weakness in muscles that are near the ends of the limbs usually results in a tendency to drop things if the upper limb is affected or in foot drop if the lower limbs are affected. The overall disability is not as great as weakness of more proximal (closer to the body) muscles controlling the pelvic or shoulder girdles, which hold large components of the total body mass against the force of gravity. Weakness of the proximal muscles that control the shoulder blade (or scapula), for example, results in "winging" (*i.e.,* when the sharp inner border protrudes backward) as the arms are held outstretched. If the weakness is severe, the arms cannot be raised at all.

Assessment. Muscle disease may be detected by assessing whether the muscle groups can withhold or overcome the efforts of the examiner to pull or push, or by observing the individual carrying out isolated voluntary movements against gravity, or more complex and integrated activities such as walking. The weakness of individual muscles or groups of muscles can be quantified by using a myometer, which measures force based on a hydraulic or electronic principle. The recording of contraction force repeatedly over a period of time is valuable in determining whether the weakness is improving or worsening.

Assessment of muscle weakness

The assessment of muscle weakness (and wasting) is directed toward discovering evidence of muscle inflammation or damage. These changes are discerned by blood tests or by measuring alterations of the electrical properties of contracting muscles. Another investigative tool is the muscle biopsy, which provides muscle specimens for pathological diagnosis and biochemical analysis. Muscle biopsies can be taken by a needle or by a surgical procedure.

Classification of muscle weakness. Muscle contraction results from a chain of events that begins with a nerve impulse traveling in the upper motor neuron from the cerebral cortex in the brain to the spinal cord. The nerve impulse then travels in the lower motor neuron from the spinal cord to the neuromuscular junction, where the neurotransmitter acetylcholine is released. Acetylcholine diffuses across the neuromuscular junction, stimulating acetylcholine receptors to depolarize the muscle membrane. The result is the contraction of the muscle fibre. Contraction depends on the integrity of each of these parts; disease or disorder in any part causes muscle weakness.

Upper motor neuron disease. Muscle weakness typical of upper motor neuron disease is seen in stroke (cerebrovascular accident), producing weakness of one side of the body. The arm is typically flexed, the leg is extended, and the limbs have increased tone. Some movement may be preserved, though the use of the hand is particularly limited. In comparison with muscle weakness due to disease of the lower motor neuron or muscle, in the upper motor neuron weakness the muscle bulk is usually well preserved. Other causes of upper motor neuron disorders include multiple sclerosis, tumours, and spinal cord injury.

Lower motor neuron disease. Degeneration of the lower neuron produces a flaccid muscle weakness. Muscle wasting is a prominent feature because the shrinkage and eventual death of neurons leads to denervation of the muscle. Diseases of the motor neurons lying in the spinal cord are termed motor neuron diseases. The most common is motor neuron disease itself, termed in the United States amyotrophic lateral sclerosis and generally known as Lou Gehrig's disease. Patients are generally between 50 and 70 years of age and have upper and lower motor neuron weakness. Paralysis progresses rapidly, and death often results within three years. The spinal muscular atrophies are a group of disorders affecting infants, juveniles, and young adults, often with an autosomal recessive mode of inheritance (*i.e.,* requiring the gene from both parents for expression). The infantile type is fatal within one year, but the older cases tend to be less severe. No cause is yet known for any of these diseases, and no cure is available.

Lou Gehrig's disease

Diseases of the peripheral nerves (peripheral neuropathies, or polyneuropathies) can produce symptoms and signs similar to the motor neuron diseases. Sensory disturbance due to involvement of the nerve fibres carrying sensory impulses is usually also involved. Symptoms usually begin in the hands and feet and progress toward the body. Peripheral neuropathies can cause degeneration of the axons, the core of the nerve fibres. The axons can regenerate but only at a rate of one to two millimetres per day. Thus, after injury to a nerve at the elbow, the hand will not recover for six to nine months. Toxins and damage to blood vessels tend to cause axonal types of neuropathy.

Peripheral neuropathy also can be caused by degeneration of the myelin sheaths, the insulation around the axons. These are termed demyelinating neuropathies. Symptoms are similar to neuropathies with axonal degeneration, but since the axons remain intact, the muscles rarely atrophy. Recovery from demyelinating neuropathies can be rapid. Diphtheria and the autoimmune diseases like Guillain-Barré syndrome cause demyelinating neuropathies. Other causes of peripheral neuropathy include diabetes mellitus, nerve trauma, inherited factors, and chronic renal failure.

Neuromuscular junction disorders. Diseases of the neuromuscular junction typically involve the generation of an end-plate potential that is too low to propagate an action potential in the muscle fibre. These diseases are associated with weakness and fatigability with exercise. Diseases of neuromuscular transmission may be acquired or inherited and may be the result of an autoimmune disorder such as myasthenia gravis (see below *Primary diseases and disorders*), a congenital disorder, or a toxin such as in botulism and some drug-induced disorders.

General causes

PRIMARY DISEASES AND DISORDERS

It appears that the maintenance of muscle mass and function depends on its use. For example, weight lifters and sprinters have muscle fibres with a greater capacity for glycolysis (and thus ATP production) and sudden force generation. Striated muscles can regenerate after damage and can adapt to the loads they carry. Thus, in a muscle biopsy from an individual with any of the muscular dystrophies, there is likely to be a mixture of the cellular changes associated with damage and those associated with regeneration and growth (hypertrophy).

Muscular activities in which the muscle resists an extending force (eccentric contractions) cause more damage to the muscle cells than contraction of the muscle at constant length (isometric contraction) or where shortening occurs (concentric contractions). The greater damage with eccentric contraction occurs despite the fact that the metabolic rate may be one-sixth of that of an equivalent concentric or isometric contraction.

Muscles that are immobilized, as by a plaster cast following fracture of a long bone, tend to waste rapidly through shrinkage of the muscle fibres. A consistent finding is that the oxidative capacity of the muscle is reduced. These changes are reversible with muscle-strengthening exercises. In animals with inherited muscle diseases, the progress of the disease is slowed by immobilizing the limb. Recent evidence in human muscular dystrophy, however, suggests that exercise can strengthen the muscle.

The muscular dystrophies. The muscular dystrophies are a group of hereditary disorders characterized by progressive muscular atrophy and weakness. In most varieties the muscles of the limb girdles—the pelvic and shoulder muscles—are involved.

Measurement of the activity of serum creatine kinase, analysis of a muscle biopsy, and recordings from an electromyograph frequently establish that the muscle weakness is due to primary degeneration of the muscles. Creatine kinase is an enzyme of muscle fibres that is released into the bloodstream when the fibres degenerate as in the muscular dystrophies. Muscle biopsies reveal the characteristic degeneration and necrosis of muscle fibres, as well as the phagocytic actions of wandering macrophages and the attempted regeneration of damaged fibres. Electromyography shows differences in the electrical patterns of normal muscle, myopathy, and chronic denervation, such as in the spinal muscular atrophies.

Duchenne's muscular dystrophy

In contrast to the several varieties of muscular dystrophy that are relatively benign, the Duchenne type, which predominately affects boys, is severe. It causes difficulty in walking at about the age of four years, loss of the ability to walk at about the age of 11, and death at about the age of 18 or later, usually because of respiratory failure. There is a paradoxical increase in the size of the calf muscles, giving rise to the term pseudohypertrophic muscular dystrophy (because the increase in size is the result of replacement with fat and fibrous tissue rather than growth of fibres, as in true hypertrophy). Duchenne's muscular dystrophy is an X-linked condition; a defect of a large gene on the X chromosome is responsible for the disease. Females do not manifest the disease but transmit the gene for the disease to half of their sons and half of their daughters (who themselves become carriers). Muscle degeneration appears to be due to lack of a large protein called dystrophin, which causes a disruption of the membrane covering the muscle fibre; the result is the entry of excess amounts of calcium ions into the cell and cell degeneration.

Other muscular dystrophies

Becker's muscular dystrophy is similar to the Duchenne type except that Becker's appears later in life and is more benign. It is due to different damage to the same gene on the X chromosome that causes Duchenne's muscular dystrophy.

Facioscapulohumeral muscular dystrophy starts in the face, the muscles around the shoulder blades, and the upper arms. It is more slowly progressive than Duchenne's muscular dystrophy, and most patients have a normal life span. The leg weakness frequently causes "drop foot" and a waddling gait. Facioscapulohumeral muscular dystrophy is inherited in an autosomal dominant fashion; thus, the individual will receive the gene from one parent and will pass the disease to approximately half the children.

Limb-girdle muscular dystrophy is similar to facioscapulohumeral muscular dystrophy, but the face is not involved. Where inheritance is observed, it is usually autosomal recessive; *i.e.,* both parents must donate the affected gene for expression of the disease.

There are a number of other muscular dystrophies, each characterized by an individual pattern of muscle weakness and inheritance. Ocular muscular dystrophy, or myopathy, predominantly affects muscles moving the eyes. Oculopharyngeal muscular dystrophy affects not only the eye muscles but also those of the throat and is usually dominant with onset in the later years of life. Distal myopathy particularly affects the muscles of the feet and hands.

Remedial devices and measures, including physical therapy, spinal supports, and splints for the limbs, may be useful. Prevention of obesity is considered important, especially in Duchenne's muscular dystrophy, and infections are promptly treated. The identification of carriers of the trait and genetic counseling represent the best hope of reducing the incidence of this group of diseases.

Myasthenia gravis. Myasthenia gravis is an acquired autoimmune disorder that involves a failure in the transmission of nerve impulses to the muscles and is characterized by persistent muscular weakness and a tendency of muscles to be easily fatigued. Individuals affected have weakness, particularly of the face, limbs, and neck. Symptoms include double vision, difficulty swallowing and breathing, and excessive muscle fatigue during exercise with partial recovery after rest.

Autoimmune antibodies (those produced against the body's own cells) cause the destruction of acetylcholine receptors of the neuromuscular junction. Removal of the thymus, treatment with high doses of corticosteroids (which depress the immune response), and blood exchange to remove the autoimmune antibodies are frequently effective in controlling this potentially fatal disease.

Toxic myopathies. Striated muscle may be damaged by a number of drugs and toxins. Some, such as intramuscular injection of bupivicaine, cause damage to the muscle fibres by disrupting the membrane and allowing calcium to enter and destroy the cell. Other drugs, such as chloroquine, emetine, and vincristine, seem to disrupt the internal biochemistry of the muscle fibre. Still others, such as corticosteroids, affect the muscle metabolism; this is particularly true of the fluoro-substituted corticosteroids, which cause increased catabolism and thereby produce proximal muscle weakness especially of the upper limbs. Finally, other drugs, such as hydralazine, produce an autoimmune lupuslike disorder and are associated with dermatomyositis or polymyositis.

There are rare individuals who suffer malignant hyperthermia, a potentially lethal attack of muscle rigidity and hyperthermia, when exposed to general anesthetic agents such as succinylcholine and halothane. During or after induction of the anesthesia, the patient develops rigidity and an increase in central body temperature. Death may occur in five to 15 minutes when the central temperature reaches above 110° F (43° C). There is a high death rate in such attacks; should the patient recover, there will be recurrences with future exposures to these drugs. The condition tends to run in families, and it may be inherited as an autosomal dominant trait. The cause is not completely known but apparently relates to an abnormality in the chemistry of calcium in the muscle fibre. Excess calcium is released into the sarcoplasm during exposure to the general anesthetic agents, stimulating the mitochondria to burn glycogen and thereby produce heat. The excess calcium also causes the muscle fibres to contract and become rigid. Drugs that prevent calcium release in the muscle appear to prevent the attack and are given at the first sign of attack. After the onset of the attack, the anesthetic agent should be removed and the patient cooled.

Inflammatory myopathies. Bacterial myositis, inflammation of muscle tissues as the result of infection with bacteria, is commonly localized and is the aftermath of injury. *Staphylococcus* and *Streptococcus* organisms are usually responsible. General indications of infection, such as fever and increased numbers of white blood cells, are accompanied by local signs of inflammation, such as reddening, swelling, and warmth. Abscess formation is rare, except in the tropics. In general, bacterial myositis responds to treatment with antibiotics and with minor surgery.

Common pathogens

Viral myositis may also occur. The best example of this is Bornholm disease, also called epidemic myalgia, devil's grip, and epidemic pleurodynia, caused by the Coxsackie virus. Affected persons recover completely after a brief period of intense muscular pain and fever.

In addition to bacteria and viruses, the muscles may be invaded by animal organisms, including protozoa and

helminths, or worms. Trichinosis is an infection with the roundworm *Trichinella spiralis*. It results from eating infested pork that has not been thoroughly cooked. Reproduction of the worm takes place in the intestines. Larvae migrate from the intestinal walls and bury themselves in muscle tissue. Fever, muscular pains, and sometimes weakness result from the invasion of the muscles. Most persons recover after about two months, but death can result from invasion of the heart muscle.

Auto-immune diseases

The autoimmune diseases of muscle, grouped together under the term polymyositis, frequently are associated with inflammation of the skin in a characteristic distribution. The eyelids, cheeks, knuckles, elbows, knees, and backs of the hands are frequently involved. The combination of polymyositis and the typical dermatitis is classified as dermatomyositis. Muscle weakness can be proximal or diffuse. Frequently swallowing is difficult and the neck is weak. The disease can develop acutely within a few days or chronically over years. The muscle biopsy shows infiltration of the striated muscle by white blood cells, mainly lymphocytes. These collect between the muscle fibres and around small blood vessels and appear to damage the muscle fibres. Vascular damage is a major feature, particularly in the childhood form of dermatomyositis.

The cause of the autoimmune reaction to the striated muscle is not known. The disease frequently occurs in association with other autoimmune diseases, such as rheumatoid arthritis and progressive systemic sclerosis, and it can be associated with carcinoma in a significant proportion of older patients, particularly those with dermatomyositis.

High-dose corticosteroid treatment, often combined with a cytotoxic immunosuppressant drug (*i.e.,* one that destroys the cells and suppresses the immune system), such as cyclophosphamide, frequently is successful in suppressing the disease and allowing destroyed muscles to regenerate.

Endocrine and metabolic myopathies. *Hormones.* Striated muscle is directly or indirectly affected in most disorders caused by the underproduction or overproduction of hormones. This is true because the rates of synthesis or breakdown of the proteins of muscle are affected. If the thyroid gland is overactive (thyrotoxicosis, hyperthyroidism), there is muscle wasting of both type 1 fibres (oxidative-rich fibres responsible for endurance) and type 2 fibres (glycogen-rich fibres responsible for rapid, sprint-type muscle contraction). If the thyroid exhibits underactivity (myxedema, hypothyroidism), there is a predominance of type 1 fibres and sometimes a decrease in type 2 fibre size. If the adrenal gland is overactive (Cushing's syndrome), there is selective atrophy of the type 2 fibres. This pattern is seen as well in prolonged treatment with corticosteroid drugs (such as prednisolone for asthma), which can result in profound wasting and weakness of proximal muscles.

Osteo-malacia

Vitamin D deficiency. A similar mechanism underlies the wasting and weakness associated with lack of vitamin D (osteomalacia) in which marked atrophy of type 2 fibres may be seen. The actions of vitamin D in muscle are not fully understood, but it appears that at least one of its metabolites, 25-hydroxycholecalciferol, may influence the resting energy state of the muscle and also protein turnover. Unlike the inherited diseases of muscle, endocrine causes of disease may be eminently treatable.

Mitochondrial myopathies. The mitochondria are the cellular structures in which biochemical processes produce energy (in the form of heat and work) from the oxidation of fuels such as glucose and fat. The first observation of a mitochondrial myopathy was in a patient with unregulated mitochondrial oxidative metabolism, resulting in excessive heat production. Since then a number of biochemical defects in mitochondria have been discovered. There is no single entity that can be diagnosed as a "mitochondrial myopathy." In those mitochondrial defects in which a defective oxidative metabolism exists, a common result is a tendency for the muscles to generate large amounts of lactic acid. This is a consequence of needing to provide energy from the nonoxidative breakdown of the glycogen stored in the muscle.

Glycogen storage diseases

Glycogenoses. In 1951 Brian McArdle recognized a disorder of muscle that gave cramplike pains yet was not associated with the normal production of lactic acid from exercise. The defect was identified later as an absence of phosphorylase, the enzyme involved in the first step in the cascade (the splitting off of the glucose-1-phosphate units from glycogen). Since blood-borne glucose could still be used to make glycogen, this disorder is classified among the 10 glycogen storage diseases (glycogenoses).

Lipid storage myopathies. Lipid storage myopathy is a potentially confusing term because the more severe forms of muscle disease (*e.g.,* muscular dystrophy) are often associated with the replacement of the lost muscle fibres with fat cells. In the lipid storage myopathies the fat, or triglyceride, is deposited as tiny droplets within the cytoplasm of the muscle fibre. Normal type 1 muscle fibres have a greater amount of lipid droplets than type 2 muscle fibres.

In the early 1970s two disorders of muscle fat metabolism were discovered to affect a component of the shuttle system transporting free fatty acids into mitochondria for subsequent oxidation. This shuttle requires the fatty acid (acyl) molecule to attach to the carrier molecule, carnitine, in the presence of the enzyme acylcarnitine transferase. The acylcarnitine that is formed crosses the outer and inner mitochondrial membranes and then is split in the presence of another form of the enzyme acyltransferase to give carnitine and the acyl molecule, which is then oxidized. A deficiency of carnitine results in the storage of fats in the cytoplasm. Deficiency of acylcarnitine transferase results in muscle damage on severe exertion. Recognition is important because the conditions are potentially treatable.

Symptoms of myotonia

Myotonic diseases. Myotonia is a difficulty in relaxing a muscle after contraction; it may manifest as difficulty in relaxing the hand after a handshake. Though slow relaxation may be due to delayed disengagement of the thick and thin filaments of myosin and actin, most cases of myotonia are due to continuing electrical activity of the sarcolemma. In this most common type of myotonia, a single nerve action potential causes multiple firing of the sarcolemma, thereby continuing muscular contraction. The cause of this problem lies in abnormal ion channels or ion pumps in the sarcolemma, although the exact cause is not known. In many forms of myotonia, cold exacerbates the problem. Weakness is a problem in the myotonic syndromes; it tends to be more pronounced after inactivity, with a rapid "warm up" on commencing exercise.

Myotonic dystrophy, or dystrophia myotonica of Steinert, is the most common of the myotonic disorders. It is an autosomal dominant disorder affecting many systems of the body in addition to muscle. There is premature balding, cataract formation, mental impairment, gonadal atrophy, endocrine deficiencies, gastrointestinal tract dysfunction, and muscle fibre degeneration. While the disease has manifested itself by the age of 25 years in most cases, some patients or family members may escape developing significant symptoms throughout their lives.

Myotonia congenita of Thomsen is also an autosomal dominant disorder, but it is not associated with any dystrophic features. The onset is at birth, usually with severe difficulty in relaxing the muscle after a forced contraction, such as a sneeze. Myotonia can occur in a number of other conditions including the periodic paralyses.

Drugs that suppress the extent of the myotonia, such as quinine, procainamide, and phenytoin, have had variable success on the weakness. No cure of these diseases is yet available.

THE PERIODIC PARALYSES

Patients with periodic paralysis suffer from recurrent attacks of muscle paralysis that may last from half an hour to 24 hours. Attacks particularly affect the legs and to a lesser extent the arms and trunk muscles. During an attack the muscles may be slightly swollen and tender. Attacks frequently occur with rest after vigorous exercise.

Types of periodic paralysis

There are two types of periodic paralysis. In hypokalemic periodic paralysis, the serum potassium falls during the attack, which also can be precipitated by anything that tends to lower the serum potassium. Hyperkalemic periodic paralysis, on the other hand, is associated with an increase in serum potassium. An attack may be precipitated by oral therapy with potassium.

Both periodic paralyses are autosomal dominant disorders. Though neither is likely to lead to fatal muscle weakness, the temporary incapacity and embarrassment are severe. In the attack, the muscle fibres lose their electrical potential (become depolarized) and thereby become incapable of excitation. The disease appears to be due to changes in the movements of ions through membranes of the skeletal muscle. Potassium appears to be one of the ions responsible for the condition. Abnormal ion channels or ion pumps in the membrane may be the cause. Treatment by drugs appropriately altering the serum potassium can be effective, and acetazolamide, which affects the acidity of the blood and cells, is often effective.

FATIGUE

Fatigue is a failure of the muscle to sustain force in a prolonged contraction or to reattain force in repeated contractions. The mechanisms underlying fatigue share several features with those underlying weakness: electrical excitation of the muscle cell; electromechanical coupling; and the major processes supplying energy for contraction, work, and heat production.

The action potential that is conducted along the length of the muscle cell has its origin in a depolarization of the postsynaptic membrane of the neuromuscular junction caused by the release of acetylcholine from the presynaptic nerve terminal. The synapse is thus potentially a key control point in the chain of command for muscular contraction. Complete failure of neuromuscular transmission occurs from poisoning with curare or botulinum toxin and results in complete paralysis. Incomplete or variable neuromuscular transmission is a feature of myasthenia gravis, the diagnosis of which can be confirmed by finding evidence of fatigue in response to electrical stimulation of the nerve supplying the muscle. This behaviour is a consequence of the immunologic damage to the postsynaptic membrane of the synapse by antibodies to the acetylcholine receptor.

Curare poisoning

Electrical stimulation of a muscle via its nerve is a means by which some of the mechanisms underlying human muscle fatigue can be analyzed. By stimulating the nerve at a range of frequencies and measuring the force of the contractions produced, it is possible to plot the frequency:force curve. Failure of force at high stimulation frequencies is seen with myasthenia gravis. In conditions in which normal muscle is cooled or lacks blood supply, there is also a high-frequency fatigue.

After severe exercise a form of fatigue may persist that is characterized by a lower force production at the lower stimulation frequencies with no decrease in the amplitude of the evoked action potential recorded from the muscle. This type of fatigue would be expected with the failure of excitation-contraction coupling, the inward spread of the action potential by the transverse tubular system, resulting in the release of intracellular calcium, which activates the actin-myosin interaction and subsequent contraction.

There is a relationship between the development of fatigue and the depletion of energy stores in exercising muscle. In prolonged exercise, such as marathon running, fatigue is associated with glycogen depletion due to oxidative glycolysis. Intense exercise that lasts only a few minutes is associated with the accumulation of lactate and an intracellular acidosis due to anaerobic (nonoxidative) glycolysis. In both types of exercise there is a reduction of phosphocreatine, although no appreciable depletion of ATP. In contrast, in patients with myopathies, more striking changes are seen with only low total work or power output. Fatigue in patients with McArdle's disease, in whom there is absent glycogenolysis, is not associated with the usual acidosis. Pronounced acidosis is a finding in patients with defective mitochondrial metabolism in whom there may be a slow resynthesis of phosphocreatine after exercise. (R.A.He./R.H.T.E./W.G.Br.)

BIBLIOGRAPHY

General features of muscles and muscle systems. Basic information at various levels of difficulty may be found in GEOFFREY H. BOURNE (ed.), *The Structure and Function of Muscle*, 2nd ed., 4 vol. (1972–73), a collection of important articles on most aspects and types of muscles; GRAHAM HOYLE, *Muscles and Their Neural Control* (1983), which includes a survey of the diverse kinds of muscle found in different animals; THOMAS A. MCMAHON, *Muscles, Reflexes, and Locomotion* (1984), a book that ranges from basic muscle mechanics to the mechanics of walking and running; R.B. STEIN, *Nerve and Muscle: Membranes, Cells and Systems* (1980), a comprehensive treatment of the biophysics of muscles; and "Design and Performance of Muscular Systems," *Journal of Experimental Biology*, 115:1–412 (1985), an entire volume devoted to the proceedings of an important conference.

Invertebrate muscle systems. R. MCNEILL ALEXANDER, *The Invertebrates* (1979), is a survey that emphasizes the mechanics of movement. E.R. TRUEMAN, *The Locomotion of Soft-Bodied Animals* (1975), is mainly about worms and mollusks.

Vertebrate muscle systems. Sources include ALFRED SHERWOOD ROMER and THOMAS S. PARSONS, *The Vertebrate Body*, 6th ed. (1986), a textbook of comparative anatomy that describes the embryonic development and evolution of the vertebrate muscular system; and WARREN F. WALKER, *Vertebrate Dissection*, 7th ed. (1986), a laboratory manual for comparative anatomy that gives a thorough description of the muscular systems of the dogfish, mud puppy, cat, and rabbit. MILTON HILDEBRAND, *Analysis of Vertebrate Structure*, 3rd ed. (1988); and ALFRED SHERWOOD ROMER, *The Vertebrate Story*, 4th ed. (1959, reprinted 1971), are reference texts on vertebrate muscle.

Human muscle systems. Information on the unique human musculature can be found in ERNST HUBER, *Evolution of Facial Musculature and Facial Expression* (1931, reprinted in *Evolution of Facial Expression*, 1972), detailed presentations of the evolution of two important groups of muscles; ARTHUR KEITH, "Man's Posture: Its Evolution and Disorders," *British Medical Journal*, 1:451–454, 499–502, 545–548, 587–590, 624–626, 669–672 (March 17–April 21, 1923), a classic summary of the adaptation of musculature to upright posture; and PAUL E. KLOPSTEG *et al.* (eds.), *Human Limbs and Their Substitutes* (1954, reprinted 1968), a comprehensive review of normal human limbs and their artificial replacements.

Muscle types. *Striated:* BERNARD KATZ, *Nerve, Muscle, and Synapse* (1966), is an excellent brief work. GERALD H. POLLACK, "The Cross-Bridge Theory," *Physiology Reviews*, 63(3):1049–1113 (July 1983), is a good summary of minority views suggesting alternatives to the cross-bridge theory. See also ERIC R. KANDEL and JAMES H. SCHWARTZ, *Principles of Neural Science*, 2nd ed. (1985).

Works on muscle contraction include J.R. BENDALL, *Muscles, Molecules and Movement: An Essay in the Contraction of Muscles* (1969), with numerous references to original papers; GRAHAM HOYLE, *Comparative Physiology of the Nervous Control of Muscular Contraction* (1957), a review of the literature for the general reader of biology; ANDREW HUXLEY, *Reflections on Muscle* (1980), rich in history and in identifying unsolved problems; and JOHN SQUIRE, *The Structural Basis of Muscular Contraction* (1981). Several useful journal articles are found in *Scientific American:* CAROLYN COHEN, "The Protein Switch of Muscle Contraction," 223(3):36–45 (November 1975); GRAHAM HOYLE, "How Is Muscle Turned On and Off?" 222(4):84–93 (April 1970); H.E. HUXLEY, "The Mechanism of Muscular Contraction," 213(6):18–27 (December 1965); KEITH R. PORTER and CLARA FRANZINI-ARMSTRONG, "The Sarcoplasmic Reticulum," 212(3):73–80 (March 1965); and DAVID S. SMITH, "The Flight Muscles of Insects," 212(6):76–88 (1965).

Cardiac: Diseases of the heart are discussed in NORMAN R. ALPERT (ed.), *Myocardial Hypertrophy and Failure* (1983); EUGENE BRAUNWALD, JOHN ROSS, JR., and EDMUND H. SONNENBLICK, *Mechanisms of Contraction of the Normal and Failing Heart*, 2nd ed. (1976), providing information on structure, metabolism of heart muscle, operation of the heart, and heart failure; and HARRY A. FOZZARD *et al.*, *The Heart and Cardiovascular System: Scientific Foundations*, 2 vol. (1986).

Smooth: Studies of smooth muscle include DAVID F. BOHR, ANDREW P. SOMLYO, and HARVEY V. SPARKS, JR. (eds.), *Vascular Smooth Muscle*, vol. 2 in *Handbook of Physiology: A Critical, Comprehensive Presentation of Physiological Knowledge and Concepts*, section 2, *The Cardiovascular System* (1980), and MARION J. SIEGMAN, ANDREW SOMLYO, and NEWMAN L. STEPHENS (eds.), *Regulation and Contraction of Smooth Muscle* (1987).

Muscle disease. A comprehensive modern review of the myopathies will be found in JOHN WALTON (ed.), *Disorders of Voluntary Muscle*, 5th ed. (1988); this work also contains chapters on the anatomy and physiology of muscle. MICHAEL H. BROOKE, *A Clinician's View of Neuromuscular Diseases*, 2nd ed. (1986), is a good, brief review of muscle disease. STIRLING CARPENTER and GEORGE KARPATI, *Pathology of Skeletal Muscle* (1984); and ANDREW G. ENGEL and BETTY Q. BANKER, *Myology: Basic and Clinical*, 2 vol. (1986), are extensive treatments.

Museums

A museum, in the traditional and commonly accepted meaning of the term, is an institution dedicated to preserving and interpreting the primary tangible evidence of humankind and the environment. In its preserving of this primary evidence, the museum differs markedly from the library, with which it has often been compared, for the items housed in a museum are mainly unique and constitute the raw material of study and research. In the museum the object, in many cases removed in time, place, and circumstance from its original context, communicates itself directly to the viewer in a way not possible through other media. It is this attribute that has seen the founding of museums for a variety of purposes: to serve as recreational facilities, scholarly venues, or educational resources; to contribute to the quality of life of the areas where they are situated; to attract tourism to a region; to promote civic pride or nationalistic endeavour; or even to transmit overtly ideological concepts. Given such a variety of purposes, museums reveal remarkable diversity in form, content, and even function. Yet, despite such diversity, they are bound by a common goal: the preservation and interpretation of some material aspect of society's cultural consciousness.

This article covers three major aspects of museums: their history, their types, and their operation. For coverage of related topics in the *Macropædia* and *Micropædia,* see the *Propædia,* section 10/61, and the *Index.*

The history of museums

ETYMOLOGY

From *mouseion* to *museum*

The word *museum* has classical origins. In its Greek form, *mouseion,* it meant "seat of the Muses" and designated a philosophical institution or a place of contemplation. Use of the Latin derivation, *museum,* appears to have been restricted in Roman times mainly to places of philosophical discussion. Thus the great Museum at Alexandria, founded by Ptolemy I Soter early in the 3rd century BC, with its college of scholars and its library, was more a prototype university than an institution to preserve and interpret material aspects of the heritage. The word *museum* was revived in 15th-century Europe to describe the collection of Lorenzo de' Medici in Florence, but the term conveyed the concept of comprehensiveness rather than denoting a building. By the 17th century *museum* was being used in Europe to describe collections of curiosities. Ole Worm's collection in Copenhagen (see Figure 1) was so called, and in England visitors to John Tradescant's collection in Lambeth (now a London borough) called the array there a museum; the catalog of this collection, published in 1656, was titled *Musaeum Tradescantianum.* The idea of an institution called a museum and established to preserve and display a collection to the public was well established in the 18th century. Indeed, Denis Diderot outlined a detailed scheme for a national museum for France in the ninth volume of his *Encyclopédie,* published in 1765.

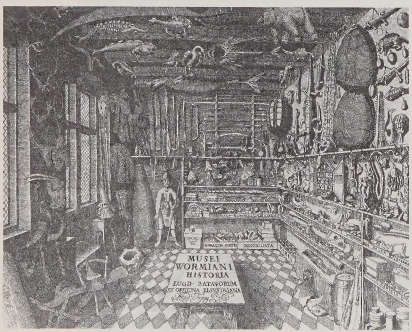

Figure 1: Ole Worm's cabinet of curiosities, a private collection that was eventually transferred to the Danish royal cabinet, Copenhagen. From an engraved frontispiece in the *Musei Wormiani Historia* (1655).
Library, The Academy of Natural Sciences of Philadelphia

Use of the word *museum* during the 19th and most of the 20th century denoted a building housing cultural material to which the public had access. Later, as museums continued to respond to the societies that created them, the emphasis on the building itself became less dominant. Open-air museums, comprising a series of buildings preserved as objects, and ecomuseums, involving the interpretation of all aspects of an outdoor environment, provide examples of this. In addition, so-called virtual museums exist in electronic form on the Internet. Although virtual museums provide interesting opportunities for and bring certain benefits to existing museums, they remain dependent upon the collection, preservation, and interpretation of material things by the real museum.

Museology and museography

Along with the identification of a clear role for museums in society, there gradually developed a body of theory the study of which is known as museology. For many reasons, the development of this theory was not rapid. Museum personnel were nearly always experienced and trained in a discipline related to a particular collection, and therefore they had little understanding of the museum as a whole, its operation, and its role in society. As a result, the practical aspects of museum work—for example, conservation and display—were achieved through borrowing from other disciplines and other techniques, whether or not they particularly met the requirements of the museum and its public.

Thus not only was the development of theory slow, but the theory's practical applications—known as museography—fell far short of expectations. Museums suffered from a conflict of purpose, with a resulting lack of clear identity. Further, the apprenticeship method of training for museum work gave little opportunity for the introduction of new ideas. This situation prevailed until other organizations began to coordinate, develop, and promote museums. In some cases museums came to be organized partly or totally as a government service; in others, professional associations were formed, while an added impetus arose where universities and colleges took on responsibilities for museum training and research.

The words derived from *museum* have a respectable, if confused, history. Emanuel Mendes da Costa, in his *Elements of Conchology,* published in 1776, referred to "museographists," and a *Zeitschrift für Museologie und Antiquitätenkunde* appeared in Dresden in 1881. But the terms *museology* and *museography* have been used indiscriminately in the literature, and there is a tendency, particularly in English-speaking countries, to use *museology* or *museum studies* to embrace both the theory and practice of museums.

THE PRECURSORS OF MUSEUMS

Evidence from antiquity and the classical age. The origins of the twin concepts of preservation and interpretation, which form the basis of the museum, lie in the human propensity to acquire and inquire. Collections of objects have been found in Paleolithic burials, while evidence of inquiry into the environment, and communication of the findings, can be seen in the cave and mobiliary art of the same period. A development toward the idea of the museum certainly occurred early in the 2nd millennium BC at Larsa, in Mesopotamia, where copies of old inscriptions were made for use in the schools. But the idea also involves the interpretation of original material—criteria that seem to have been met by objects discovered by Sir Leonard Woolley in the 6th-century-BC levels of the Babylonian city of Ur. Woolley's findings indicated that the Babylonian kings Nebuchadrezzar and Nabonidus certainly collected antiquities in their day. In addition, in a room next to the unearthed temple school there was found not only a collection of antiquities but also a tablet describing 21st-century-BC inscriptions. Woolley interpreted the tablet as a museum label. This discovery seems to suggest that Ennigaldi-Nanna, Nabonidus' daughter and a priestess who ran the school, had a small educational museum there.

The archaeological and historical records do not provide evidence that the museum as it is known today developed in such early times; nor does the word *museum* support this, despite its classical origin. Nevertheless, the collection of things that might have religious, magical, economic, aesthetic, or historical value or that simply might be curiosities was undertaken worldwide by groups as well as by individuals. In the Greek and Roman empires the votive offerings housed in temples, sometimes in specially built treasuries, are but one example: they included works of art and natural curiosities, as well as exotic items brought from far-flung parts of the empires, and they were normally open to the public, often upon payment of a small fee. Closer to the concept of a museum was the Greek *pinakotheke,* such as that established in the 5th century BC on the Acropolis at Athens, which housed paintings honouring the gods. Nor was there a lack of public interest in art at Rome. Indeed, art abounded in the public places of Rome, but there was no museum. The inaccessibility of the collection of more than one Roman emperor was the subject of public comment, and Agrippa, a deputy of Augustus, commented in the 1st century BC to the effect that paintings and statues should be available to the people.

The Greek *pinakotheke*

In Asia veneration of the past and of its personalities also led to the collection of objects. Collecting commenced at least as early as the Shang dynasty, which ruled China from approximately the mid-16th to the mid-11th century BC, and it was well developed by the Ch'in dynasty (3rd century BC)—as attested by the tomb of the Ch'in emperor Shih huang-ti, near Sian (Xian), which was guarded by an army of terra-cotta warriors and horses. Together with other grave goods, these objects are preserved on-site in the Museum of Ch'in Figures. The palace of Shih huang-ti is recorded as having many rare and valuable objects.

Successive Chinese emperors continued to promote the arts, manifest in fine works of painting, calligraphy, metalwork, jade, glass, and pottery. For example, the Han emperor Wu-ti (reigned 141/140–87/86 BC) established an academy that contained paintings and calligraphies from each of the Chinese provinces, and the last Han emperor, Hsien-ti (abdicated AD 220), established a gallery containing portraits of his ministers.

In Japan the Tōdai Temple, housing a colossal seated bronze statue of the Great Buddha (Daibutsu), was built in the 8th century at Nara. The temple's treasures still can be seen in the Shōsō-in repository there.

Medieval and Renaissance Europe. In medieval Europe collections were mainly the prerogative of princely houses and the church. Indeed, there was often a close link between the two, as in the case of the fine treasures of the emperor Charlemagne, which were divided among a number of religious houses early in the 9th century. Such treasures had economic importance and were used to finance wars and other state expenses. Other collections took the form of alleged relics of Christendom, in which there was a considerable trade. At this time Europe's maritime links with the rest of the world were largely through the northern Mediterranean ports of Lombardy and Tuscany, which, together with the ecclesiastical significance of Rome, brought considerable contact between the Italian peninsula and the Continent. There is evidence of the movement of antiquities, and of a developing trade in them, from the 12th century. Henry of Blois, bishop of Winchester, is reported to have bought ancient statues during a visit to Rome in 1151 and to have dispatched them to England, a journey of about one month's duration.

Trade in antiquities and relics

The movement of antiquities was not confined to those of Italy. Exotic material from other areas entering Italian ports soon found its way into royal collections, while the Venetian involvement in the Fourth Crusade early in the 13th century resulted in the transfer of the famous bronze horses from Constantinople to the San Marco Basilica in Venice.

The influences that led to the European Renaissance were already at work in Italy, and as a result the first great collections began to form. A reawakening of interest in Italy's classical heritage and the rise of new merchant and banking families at this northern Mediterranean gateway to the Continent produced impressive collections of antiquities, as well as considerable patronage of the arts. Outstanding among the collections was that formed by Cosimo de' Medici in Florence in the 15th century. The collection was developed by his descendants until it was bequeathed to the state in 1743, to be accessible "to the people of Tuscany and to all nations." In order to display some of the Medici paintings, the upper floor of the Uffizi Palace (designed to hold offices, or *uffizi*) was converted and opened to the public in 1582. Indeed, many of the palaces holding such collections were open to visitors and were listed in the tourist guides of the period.

Elsewhere in Europe, royal collections were developed. King Matthias I of Hungary maintained his paintings at Buda and kept Roman antiquities at Szombathely Castle during the 15th century. Maximilian I of Austria acquired a collection for his castle in Vienna. Samples of both scientific material and art were featured in the "green vaults" of the Dresden palace of Augustus of Saxony, while the archduke Ferdinand of Tirol housed a varied collection that included Benin ivories and Chinese paintings at Ambras Castle near Innsbruck. Other notable central European collections included those of the Holy Roman emperor Rudolf II at Prague and of Albert V, duke of Bavaria, who from 1563 to 1571 had buildings designed and erected to house his collections in Munich. The collection of the Polish king Sigismund II Augustus was housed at Wawel Castle, Kraków.

Royal patronage was crucial to the encouragement of the arts at this time. Rudolf II sponsored astrologers and alchemists as well as artists. Francis I of France invited famed French and Italian craftsmen and artists to rebuild

and embellish his château at Fontainebleau, and there he kept his outstanding collection of art. It was not until the 17th century that the first important royal collection was formed in England by Charles I, only to be much dispersed after his execution in 1649. Following the Restoration, Charles II also maintained a collection, but this was lost in a fire at Whitehall Palace in 1698. Early in the reign of Charles II, displays of arms and armour were being prepared at the Tower of London; clearly intended for the public benefit, these displays marked an important step in the development of a museum of the Royal Armouries.

Specialized personal collections. The developing interest in human as well as natural history in the 16th century led to the creation of specialized collections. In Italy alone more than 250 natural history collections are recorded in that century, including the fine herbarium of Luca Ghini at Padua and the more eclectic collection of Ulisse Aldrovandi at Bologna. Other notable natural history collections of the time elsewhere in Europe were those of Conrad Gesner, Félix Platter, and, a little later, the John Tradescants, father and son. Among the specialized historical collections were those of portraits of great men assembled by Paolo Giovio at Como, the archaeological collection of the Grimani family of Venice, and the fine collection of illuminated manuscripts gathered by Sir Robert Cotton in England. A number of the latter had been acquired from monasteries closed during the Reformation. In due time these various collections found their way into museums. So did the collections of Ferrante Imperato of Naples, Bernard Paludanus (Berant ten Broecke) of Amsterdam, and Ole Worm of Copenhagen.

Cabinet, Kammer, and *galleria*

A collection such as these was normally known as a *cabinet* in 16th-century England and France, while in German-speaking Europe the equivalents *Kammer* or *Kabinett* were used. Greater precision was sometimes applied, the terms *Kunstkammer* and *Rüstkammer,* for example, referring respectively to a collection of art and a collection of historical objects or armour. Natural specimens were to be found in a *Wunderkammer* or *Naturalienkabinett.* In England the term *gallery,* borrowed from Italian *galleria,* referred to a place where paintings and sculpture were exhibited. One Italian collection of natural specimens was called a *museo naturale.*

In 1565 Samuel van Quicheberg published a work on the nature of collections, advocating that they represent a systematic classification of all materials in the universe. His view reflects a spirit of system and rational inquiry that had begun to emerge in Europe. Collections of natural and artificial objects were to play an important part in this movement. This can be seen in antiquarian studies, in the work of Nicolas-Claude Fabri de Peiresc at Aix-en-Provence in France early in the 17th century, for example, or in the classification of the plant and animal kingdoms by Carolus Linnaeus a century later. For the less-specialized collector, works such as *Museographia,* by Casper F. Neickel (pseudonym of Kaspar Friedrich Jenequel), published at Leipzig in 1727, were generally available to aid in classification, care of a collection, and the identification of potential sources from which collections might be developed.

Another product of the age was the learned society, many of which were established to promote corporate discussion, experimentation, and collecting. Some commenced as early as the 16th century. Better-known societies, however, date from later years; examples are the Royal Society in London (1660) and the Academy of Sciences in Paris (1666). By the turn of the century, organizations covering other subject areas were being established, among them the Society of Antiquaries of London (1707), and learned societies were also appearing in provincial towns. This was the beginning of a movement that, through the collections formed and the promotion of their subjects, contributed much to the formation of museums.

TOWARD THE MODERN MUSEUM

Many of the collections formed during the Renaissance were symbols of social prestige and served as an important element in the traditions of the nobility and the ruling families, but over time a developing spirit of inquiry brought to collecting a different meaning and purpose as well as a much wider group of practitioners. These new collectors, concerned with enjoyment and study and the advancement of knowledge, while equally concerned with the continuity of their collections, had no such guarantee of succession. If this guarantee could not be found in the family unit, then the route of succession had to be found elsewhere, and the corporate unit provided greater security. Furthermore, if knowledge were to have lasting significance, it had to be transmitted in the public domain.

Ensuring the continuity of collections

The earliest recorded instance of a public body receiving a private collection occurs in the 16th century with the bequests of the brothers Domenico Cardinal Grimani and Antonio Grimani to the Venetian republic in 1523, to be supplemented in 1583 with a further bequest from the family. The motivation seems to have been both to promote scholarship and to grace the seat of government. At the time of the Reformation in Switzerland, material was transferred from ecclesiastical establishments to the authorities of Zürich and other municipalities, eventually forming important components of their museums. The city of Basel, concerned that the fine cabinet of Basilius Amerbach might be exported, purchased it in 1662 and nine years later arranged for its display in the university library. In 1694 the head abbot of Saint-Vincent-de-Besançon in France bequeathed his collection of paintings and medallions to the abbey to form a public collection. To some extent the emerging learned societies also were becoming repositories for such collections, in addition to developing their own. In the case of Ole Worm's collection, as in other cases, lack of interest among the owner's family after his death resulted in the transfer of the collection in 1655 to the royal cabinet in Copenhagen.

The first public museums. The first corporate body to receive a private collection, erect a building to house it, and make it publicly available was the University of Oxford. The gift was from Elias Ashmole; containing much of the Tradescant collection, it was made on the condition that a place be built to receive it. The resulting building, which eventually became known as the Ashmolean Museum, opened in 1683. (The Ashmolean later moved to another new building nearby, and its original building is now occupied by the Museum of the History of Science.)

The 18th century saw the flowering of the Enlightenment and the encyclopaedic spirit, as well as a growing taste for the exotic. These influences, encouraged by increasing world exploration, by trade centred on northwestern Europe, and by developing industrialization, are evident in the opening of two of Europe's outstanding museums, the British Museum, in London, in 1759 and the Louvre, in Paris, in 1793. The British Museum was formed as the result of the government's acceptance of responsibility to preserve and maintain three collections "not only for the inspection and entertainment of the learned and the curious, but for the general use and benefit of the public." These were housed at Montagu House, in Bloomsbury, specially purchased for this purpose. The collections had been made by Sir Robert Cotton, Robert Harley, 1st earl of Oxford, and Sir Hans Sloane. The Cotton and Harley collections were composed mainly of manuscripts. The Sloane collection, however, included his specimens of natural history from Jamaica and classical, ethnographic, numismatic, and art material, as well as the cabinet of William Courten, comprising some 100,000 items in all. Although public access to the British Museum was free of charge from the outset, for many years admission was by application for one of the limited number of tickets issued daily. Despite this, François de la Rochefoucauld, visiting from France in 1784, observed with approval that the museum was expressly "for the instruction and gratification of the public."

The British Museum

It was a matter of public concern in France that the royal collections were inaccessible to the populace, and eventually a selection of paintings was exhibited at the Luxembourg Palace in 1750 by Louis XV. Continuing pressure, including Diderot's proposal of a national museum, led to arrangements for more of the royal collection to be displayed for the public in the Grande Galerie of the Louvre palace. However, when the Grande Galerie was opened to

the public in 1793, it was by decree of the Revolutionary government rather than royal mandate, and it was called the Central Museum of the Arts. There were many difficulties, and the museum was not fully accessible until 1801. The collection at the Louvre grew rapidly, not least because the National Convention instructed Napoleon to appropriate works of art during his European campaigns; as a result many royal and noble collections were transported to Paris to be shown at what became known as the Musée Napoléon. The return to its owners of this looted material was required by the Congress of Vienna in 1815. Nevertheless the Napoleonic episode awakened a new interest in art and provided the impetus that made a number of collections available to the public.

The extensive collections of the Vatican also saw considerable reorganization during the 18th century. The Capitoline Museum was opened to the public in 1734, and the Palazzo dei Conservatori was converted to a picture gallery in 1749. The Pio-Clementino Museum, now part of the museum complex in Vatican City, opened in 1772 to house an extensive collection of antiquities. The Neoclassical architecture of this building set a standard that was emulated in a number of European countries for half a century.

The spread of the European model. Before the end of the 18th century the phenomenon of the museum had spread to other parts of the world. In 1773 in the United States the Charleston Library Society of South Carolina announced its intention of forming a museum. Its purpose was to promote the better understanding of agriculture and herbal medicine in the area. Another early institution, the Peale Museum, was opened in 1786 in Philadelphia by the painter Charles Willson Peale. The collections rapidly outgrew the space available in his home and were displayed for a time at Independence Hall. After a number of vicissitudes the collections were finally dispersed in the middle of the 19th century, but not before the fine Chinese collection had formed a major exhibition in London.

Early museums in America

European colonial influence was responsible for the appearance of museums elsewhere. In Jakarta, Indon., the collection of the Batavia Society of Arts and Science was begun in 1778, eventually to become the Central Museum of Indonesian Culture and finally part of the National Museum. The origins of the Indian Museum in Calcutta were similar, based on the collections of the Asiatic Society of Bengal, which commenced in 1784. In South America a number of national museums originated in the early 19th century: the Argentine Museum of Natural Sciences in Buenos Aires was founded in 1812; and Brazil's National Museum in Rio de Janeiro, which owes its origin to a selection of paintings presented by John VI, exiled king of Portugal, was opened to the public in 1818. Among others were the National Museum, Bogotá, Colom. (1824), and the national museums of natural history in Santiago, Chile (1830), and Montevideo, Uruguay (1837). In Canada the zoological collection of the Pictou Academy in Nova Scotia (founded in 1816) was probably opened to the public by 1822. In South Africa a museum based on the zoological collection of Andrew (later Sir Andrew) Smith was founded in Cape Town in 1825. It is likely that an amateur naturalist and diplomat, Alexander Macleay, was responsible for the initiatives that led to the opening in 1829 of what was to become the Australian Museum in Sydney.

New public collections in Europe. By this time a number of new collections were available to the public in Europe. Many of these resulted from royal and noble patronage, while others were created on the initiative of public authorities. The Prado Museum in Madrid dates from 1785, when Charles III commissioned the erection of a new building to serve as a museum of natural science. Construction was interrupted by the Napoleonic Wars, and when the building opened in 1819 it instead housed an art gallery to display part of the royal collection. In Prussia Frederick William III had a picture gallery built in Berlin to house some of his collection, and the gallery was opened to the public in 1830. This was the beginning of a remarkable complex that developed over the next century to house various portions of the national collection on a single site, now known as the Museuminsel. Another development in Germany was the erection of the Alte Pinakothek (1836) at Munich to display the painting collections of the dukes of Wittelsbach. This building was designed to exacting standards by Leo von Klenze, who was also responsible for the New Hermitage, one of the five buildings of the Hermitage museum in St. Petersburg, where in 1852 Nicholas I made available to the public the major collection of the Russian tsars. The Royal Museums in Brussels originated by royal warrant in 1835 in the interests of historical study and the arts. In the Netherlands a national art gallery was opened at the Huis ten Bosch in 1800; it was later moved to Amsterdam and eventually became the Rijksmuseum (State Museum). The National Gallery in London, founded on the personal collection of the merchant and philanthropist John Julius Angerstein, opened initially at Angerstein's house in 1824. In 1838 it moved to purpose-built premises on Trafalgar Square.

The National Gallery

Museums and national identity. Contributing to the establishment of museums in the early 19th century was a developing national consciousness, particularly among the peoples of central Europe. In 1807 the National Assembly of Hungary founded a national museum at Pest from collections given to the nation five years earlier by Count Ferenc Széchenyi. In Prague the natural history collections of the counts of Sternberg and other noble families were formed into a museum and opened in 1823 with the intention of promoting national identity. The Moravian Museum in Brno opened in 1817, and others followed at Zagreb and Ljubljana in 1821. At the centre of the Austro-Hungarian Empire, in Vienna, the imperial collections acted as the national museum; regional museums were formed at Graz, Innsbruck, and Salzburg during the period 1811–34. In Nürnberg the Germanic National Museum was directed by a proponent of a unified Germany, Hans von Aufsess, and by mid-century most of the German states had a museum. Farther north, in Poland, a national museum, although conceived in 1775, was not established until 1862, but Princess Izabella Czartoryska maintained a museum in the castle park at Puławy, near Warsaw, for eight years at the beginning of the 19th century, and two private collections were opened to the public at about the same time in Wilanów and Warsaw.

Increasing interest in antiquities led to the excavation of local archaeological sites and had an impact on museum development. In the years 1806–26, in Russian lands to the north of the Black Sea, four archaeological museums were opened, at Feodosiya, Kerch, Nikolayev, and Odessa (all now located in Ukraine). The Museum of Northern Antiquities was opened in Copenhagen in 1819 (it was there that its first director, Christian Jürgensen Thomsen, developed the three-part system of classifying prehistory into the Stone, Bronze, and Iron ages). This museum was merged with three others (of ethnography, antiquities, and numismatics) in 1892 to form the National Museum of Denmark. In France the Museum of National Antiquities opened at Saint-Germain-en-Laye late in the 18th century. It still acts as a national archaeological repository, as does the State Historical Museum in Stockholm, which houses material recovered as early as the 17th century. The national archaeological museum in Greece was started at Aegina in 1829. Certain European countries, however—the United Kingdom and Germany, for example—do not have well-developed national collections of antiquities, and as a result regional museums in those countries are the richer.

In Britain, social reforms to overcome problems resulting from industrialization contributed to the development of municipal museums. The support of museums by local authorities was seen as a means of providing both instruction and entertainment to the increasingly urbanized population and became the subject of special legislation in 1845. Museums were also viewed as a vehicle for promoting industrial design and scientific and technical achievement. Such promotion was the motivation behind the precursor of the Victoria and Albert Museum (for decorative arts) and the Science Museum, both in South Kensington, London; the founding collections were acquired from the Great Exhibition of 1851—the first of the

world's fairs. International exhibitions have contributed significantly to the formation of a number of museums since then, including the Technical Museum of Industry and Trade in Vienna and the Palace of Discovery in Paris.

The Smithsonian Institution

The Smithsonian Institution, in Washington, D.C., came into existence through the remarkable bequest of nearly one-half million dollars from James Smithson, an Englishman. He wished to see established in the United States an institution "for the increase and diffusion of knowledge among men." In 1846 the U.S. Congress accepted his bequest and passed legislation establishing the Smithsonian as an institution charged with representing "all objects of art and curious research . . . natural history, plants, [and] geological and mineralogical specimens" belonging to the United States. The U.S. National Museum opened in 1858 as part of the Smithsonian's scientific program and formed the first of its many museums, most of which stand along the Mall in Washington, D.C.

The first of the historic house museums to be developed by a local society (a type characteristic of the United States) was Hasbrouck House, at Newburgh, N.Y., which had served as the final headquarters of George Washington in the Revolutionary War. The purchase of the house by the State of New York in 1850 established another precedent, whereby public authorities provide and maintain museum buildings while a body of trustees assumes responsibility for the collections and staff. Two other well-known museums, both in New York City, provide examples of this system: the American Museum of Natural History, founded in 1869, and the Metropolitan Museum of Art, opened in 1870.

The middle of the 19th century saw the establishment of a number of other well-known museums. In Canada the collection of the National Museum commenced in 1843 in Montreal as part of the Geological Survey, while the precursor of the Royal Ontario Museum in Toronto, the Ontario Provincial Museum, was founded in 1855. In Australia the National Museum of Victoria was established at Melbourne in 1854; it was followed by the National Gallery of Victoria in 1861 and the Science Museum of Victoria in 1870. In Cairo the Egyptian Museum was established in 1858. These all followed the European model, and even in South America art collections tended to be predominately of European origin, to the neglect of indigenous works of art.

The first museum boom. It was during the second half of the 19th century that museums began to proliferate in Europe; civic pride and the free education movement were among the causes of this development. About 100 opened in Britain in the 15 years before 1887, while 50 museums were established in Germany in the five years from 1876 to 1880. This was also a period of innovation. The Liverpool Museums in England, for example, began circulating specimens to schools for educational purposes; panoramas and habitat groups were used to facilitate interpretation. As first gas lighting and then electric lighting became available, museums extended their hours into the evenings to provide service to those unable to visit during the day.

The museum boom in South America

The increase in the number of museums was not, however, a peculiarity of Europe or North America. In South America particularly, new museums were founded both in the capital cities and in the provinces. Some of these were provided by universities, as in the case of the Geological Museum in Lima, Peru (1891), or the Geographical and Geological Museum at São Paulo, Brazil (1895). Others were created by provincial bodies: the regional museums at Córdoba (1887) and Gualeguaychu (1898), both in Argentina, and at Ouro Prêto, Brazil (1876); the Hualpen Museum, Chile (1882); or the Municipal Museum and Library at Guayaquil, Ecuador (1862). New specialist national museums also appeared in certain countries, while at Tigre, in Argentina, a maritime museum was founded in 1892. Early in the following century, memorial museums were created, including those dedicated to Bartolomé Mitre, a former president of Argentina, in Buenos Aires (1906) and to Simón Bolívar in Caracas, Venez. (1911).

By this time the Indian Museum, in Calcutta, and the Central Museum of Indonesian Culture, Jakarta, were well-established institutions in Asia, but a number of new museums were appearing as well. In Japan a museum to encourage industry and the development of natural resources was opened in 1872; this provided the basis for the present-day Tokyo National Museum and National Science Museum. Although some learned-society museums existed in China in the late 19th century, the first museum in the strict sense of the word was the Nan-t'ung Museum in Kiangsu province, founded in 1905, to be followed within a decade by the Museum of the History of China in Peking (Beijing) and the Northern Territory Museum in Tientsin. The collections established in the Grand Palace at Bangkok in 1874 became, about 60 years later, the National Museum of Thailand. The National Museum of Ceylon (now Sri Lanka) opened to the public in 1877; the Sarawak Museum (now in Malaysia) opened in 1891; and the Peshāwar Museum, in Pakistan, opened in 1906.

In central and southern Africa, museums were founded early in the 20th century. Zimbabwe's national museums at Bulawayo and Harare (then known as Salisbury) were founded in 1901, the Uganda Museum originated in 1908 from collections assembled by the British District Commissioners, and the National Museum of Kenya in Nairobi was commenced by the East Africa and Uganda Natural History Society in 1909. Mozambique's first museum, the Dr. Alvaro de Castro Museum in Maputo, was founded in 1913. Meanwhile in North Africa the Egyptian Museum in Cairo had been relocated to its new building in 1902, and certain of the collections had been transferred to form two new institutions: the Museum of Islāmic Art (1903) and the Coptic Museum (1908). In South Africa there was steady museum development in a number of the provinces, for example in Grahamstown (1837), Port Elizabeth (1856), Bloemfontein (1877), Durban (1887), Pretoria (1893), and Pietermaritzburg (1903).

A period of reassessment. The first half of the 20th century saw the profound social consequences of two world wars, the Russian Revolution of 1917, and periods of economic recession. For museums in Europe this was a period of major reassessment. Governments, professional associations, and other organizations reviewed the role of museums in a changing society and made a number of suggestions to improve their service to the public. In some countries new approaches were developed; in others, museums continued to reflect their diverse ancestry, and some decades were to pass before resources generally became available for the implementation of major changes.

State control in Soviet Russia

Change was notably radical in Russia, where collections and museums were brought under state control following the Russian Revolution of 1917. Lenin's belief that culture was for the people and his efforts to preserve the country's cultural heritage led to a trebling of the number of museums in 20 years. Not only was much of the country's artistic, historic, and scientific heritage brought together in museums, but other types of museums emerged as well. Particular attention was given to amassing material related to Russia's three revolutions. The earliest museum to result from such collections opened in 1919 in the Winter Palace at Petrograd (St. Petersburg); after 1924 the Central Museum of the Revolution in Moscow became the focal point for these collections. Another type was the memorial museum housing the personal effects of well-known figures. These were often used as a means of communicating political propaganda—the Central Lenin Museum in Moscow, opened in 1936, serving this purpose.

In Germany a large number of regional museums were established after World War I to promote the history and important figures of the homeland, and they undoubtedly encouraged the nationalistic tendencies that led to the Nazi era.

In the main, however, museums were not well organized to meet changing social conditions. In Britain a diversity of providers—government at both national and local levels, universities, societies, companies, and individuals—did not encourage cohesive policymaking at a national level. In central Europe associations attempted to develop and run individual museums, but they were unable to provide the necessary resources. Outside Europe the influ-

ence of social change was less marked, and there was little evidence of museums being organized as a national force. In the United States museum development was influenced by a desire to establish a coherent past—a movement that was widely encouraged through private patronage.

In the industrialized world new types of museums appeared. Some nations made conscious attempts to preserve and display structures and customs of their more recent past. Examples, following Sweden's pioneering reerection of significant buildings, include the open-air museums at Arnhem in The Netherlands (the Open Air Museum, opened in 1912) and at Cardiff, Wales (the Welsh Folk Museum, opened in 1947). The preservation and restoration of buildings or entire settlements in situ also began; particularly well known is Colonial Williamsburg, founded in Virginia in 1926 (see Figure 5). A new type of science museum also emerged in which static displays of scientific instruments and equipment were replaced with demonstrations of the applications of science. London's Science Museum, founded in 1857, eventually was moved to specially built premises in 1919. Similarly the Deutsches Museum (German Museum) in Munich was transferred to new premises in 1925. Both established worldwide reputations for excellence in interpreting science and technology for the general public.

After World War II: new developments and new roles. The years immediately following World War II were a period of remarkable achievement for museums. This was reflected both in international and national policy and in the individual museums as they responded to a rapidly changing, better-educated society. Museums became an educational facility, a source of leisure activity, and a medium of communication. Their strength lay in the fact that they were repositories of the "real thing," which—unlike the surrounding world of plastics, reproduced images, and a deteriorating natural and human environment—could inspire and invoke a sense of wonder, reality, stability, and even nostalgia.

Postwar renovation and reconstruction

In Europe particularly there was a period of postwar reconstruction. Many art treasures had been removed to places of safety during the war, and they now had to be recovered and redisplayed; buildings also had to be refurbished. In some cases museums and their collections had been destroyed; in others collections had been looted (though in some cases restitution followed). Reconstruction provided opportunities for the realization of some of the ideas that had been advanced earlier in the century. A new approach emerged in which curators in the larger museums became members of a team comprising scientists as conservators, designers to assist in exhibition work, educators to develop facilities for both students and the public, information scientists to handle the scientific data inherent in collections, and even marketing managers to promote the museum and its work. There was a perceptible shift from serving the scholar, as befits an institution holding much of the primary evidence of the material world, to providing for a lay public as well. As a result of such innovations, museums found a new popularity and attracted an increasing number of visitors. Many of the visitors were tourists, and governments, particularly in certain European countries, soon acknowledged the museums' contribution to the economy.

Statistics from the United States give an indication of the increase in the number of museums and in museum visiting. Of 8,200 museums reported for 1988, 75 percent had been founded since 1950 and 40 percent since 1970. In the 1970s nearly 350 million visits per year were made to American museums; in 1988 the recorded figure was 566 million. Elsewhere the Russian state museums alone were known to receive about 140 million visits annually, while some of the oldest established museums in Europe—such as the British Museum, the Louvre, and the Hermitage—each regularly attracted more than 3 million visits a year. Some science and technology museums were even more popular.

Despite such growth, there has remained a great disparity in museum provision. More than two-thirds of the world's museums are still located in the industrialized countries, with a ratio of one museum to fewer than 50,000 inhabitants in Europe and the United States. In India or Nigeria, on the other hand, the ratio is approximately one museum for every 1.5 million inhabitants.

Among other factors that have contributed to the development of museums since the mid-20th century is an increased awareness of the environment and the need to preserve it. Many sites of scientific significance have been preserved and interpreted, sometimes under the aegis of a national park service, and historic sites and buildings have been restored, the latter sometimes being used as museums. This has led to the development of historic and natural landscapes as museums, such as the renovation of Mystic Seaport in Connecticut as a maritime museum, the use of Ironbridge Gorge as a museum to interpret the cradle of the Industrial Revolution in England, and the restoration of the walled medieval cities at Suzdal and Vladimir in Russia. In Australia the heyday of the gold rush has been re-created in the form of the Sovereign Hill Historical Park, at the gold-mining town of Ballarat. Gorée, a small island off the Senegal coast that served as a major entrepôt for the Atlantic slave trade, has been restored as a historic site with a number of supporting museums (see Figure 7).

The ecomuseum

A related development has been the ecomuseum, such as the Ecomuseum of the Urban Community at Le Creusot–Montceau-les-Mines in France. Here a bold experiment involves the community as a whole, rather than specialists, in interpreting the human and natural environment, thereby generating a better understanding among its inhabitants of the reasons for cultural, social, and environmental change. Some of these projects have involved the acquisition and preservation of massive artifacts, but perhaps no undertaking has been as spectacular as the recovery from the seabed of ships such as the *Vasa,* the Sung-dynasty ship from Ch'üan-chou, the *Mary Rose,* or the Hanseatic cog from Bremerhaven; all these vessels are now preserved in museums in Sweden, China, England, and Germany, respectively.

Contemporary museum development has been much influenced by changing policies in public sector finance. In many countries the contribution of public funds to museums has remained static or has fallen, so that museums' governing bodies and directors have had to seek funding from alternative sources. This not only has affected the way museums are organized but also has accentuated the need for marketing and fund-raising expertise. Thus, with Russian state museums having acquired greater budgetary autonomy since the collapse of the Soviet Union, the Hermitage in St. Petersburg has drawn on international expertise and financing to conduct major renewal work. In the United Kingdom the National Museum of Arms and Armour raised substantial funding from the private sector to build its new Royal Armouries Museum in Leeds; in addition it established a public company to operate the museum after it opened in 1996.

Another reflection of the changed financial situation has been the introduction of admission charges. In 1984 none of the British national museums charged an entry fee, but 10 years later almost half were doing so. The number of American museums charging fees for admission increased over a similar period from 32 percent to 55 percent.

Despite constraints in public funding, governments have not been inactive. In 1982, for instance, Australia opened its National Gallery of Art in Canberra. Also in Australia the National Gallery of Victoria has been developed as part of Melbourne's arts complex, while Sydney's Powerhouse Museum (1988), provides a major attraction in that city. In Paris the Pompidou Centre (1977) combines a gallery of modern art and special exhibition galleries with other cultural activities, while the "Grand Louvre" project has included the opening of the pyramid (1989) and the renovation of the Richelieu, Denon, and Sully wings—all considerably enlarging the capacity of the Louvre. The Museum of London, amalgamating the collections of two previous museums, was opened in 1976 to tell the story of the capital and its immediate environs. In 1964 the National Museum of Anthropology, just one of a fine complex of museums in Mexico City, opened a magnificent new building to display the country's archaeological

richness (see Figure 4). Additions to the Smithsonian's museums in Washington, D.C., have included the National Air and Space Museum (1976; see Figure 3) and the Hirshhorn Museum and Sculpture Garden (1974). A spectacular development from an architectural point of view is the Canadian Museum of Civilization at Hull, Quebec, which opened in 1989. Other new museum buildings have included the Vasa Museum in Stockholm (1990), the Olympic Museum in Lausanne, Switz. (1993), and the Holocaust Memorial Museum in Washington, D.C. (1993).

Many buildings of historical significance have been adapted to house museums. Among these is the Orsay Museum (see Figure 2), formerly a major railroad station in Paris, which was reopened in 1986 as a national museum of the 19th century, and the Tate Gallery of the North at Liverpool (1988), an art museum housed in a warehouse in the Albert Dock, by the River Mersey.

Figure 2: The main gallery of the Orsay Museum, Paris. Formerly the Gare d'Orsay, a major railroad station, the building was reopened in 1986 as a French national museum of the 19th century.

Nor have developments been restricted to the industrialized countries. A desire to preserve their local history has led many Caribbean islands to establish small museums.

Museums in the Third World

Several African states also have given high priority to the provision of museums. Museums have been established in the principal cities of Nigeria by its National Museums and Monuments Commission to assist in developing cultural identity and promoting national unity. The Jos Museum, one of the earliest of these, also administers a museum of traditional buildings, while others have developed workshops where traditional crafts can be demonstrated. Crafts are also a feature of the National Museum in Niamey, Niger, and products of these workshops are exported to Europe and North America.

Types of museums

For purposes of description and discussion, it is often convenient to group museums according to type. However, with their diverse origins, varying philosophies, and differing roles in society, museums do not lend themselves to rigid classification. Certain museums provide for a specialist audience—for example, children, societies, universities, or schools. Some have particular responsibilities for a defined geographic area, such as a city or region. Others may offer unusual perspectives, resulting in alternative interpretations of artistic, historical, or scientific collections. (This last can occur at museums where the primary ethos is nationalistic, religious, or political.)

Sometimes museums are classified according to the source of their funding (*e.g.*, state, municipal, private), particularly in statistical work. Classifying by source of funding, however, fails to indicate the true character of the museums' collections. For example, institutions funded by the national government—national museums—may hold outstanding international collections, as do the British Museum, the Hermitage, and the Louvre; may hold specialized collections, as do a number of the national museums of antiquities on the European continent; or may have an essentially local character, as does the Smithsonian Institution's Anacostia Neighborhood Museum in Washington, D.C.

An analysis of museums based on the nature of their collections, although it fails to indicate disparities of scale and quality, does have the merit of distinguishing between general and specialized museums. In addition, by emphasizing collections, this method focuses on the very raison d'être of museums. In this section, museums are classified into five basic types—general, natural history and natural science, science and technology, history, and art. The basic characteristics of each type are described in turn.

GENERAL MUSEUMS

General museums hold collections in more than one subject and are therefore sometimes known as multidisciplinary or interdisciplinary museums. Many were founded in the 18th, 19th, or early 20th century. Most originated in earlier private collections and reflected the encyclopaedic spirit of the times. Certain general museums reflect the influence of cultural contact made through trade. Some museums hold a number of important specialized collections that would qualify them to be grouped in more than one category of specialization. This is true particularly of many of the large general museums, which may have collections in one or more fields equal to if not exceeding both the quantity and quality of material exhibited in a specialized museum. Some national museums display general collections within their main building; indeed, many commenced in this fashion, but the necessity of finding additional space later caused a division of the collections and encouraged the growth of specialized museums.

Regional and local general museums

Most common among general museums are those which serve a region or a locality. Many of these owe their foundation to civic pride and a desire to promote knowledge of the area. They are widespread in eastern and western Europe and are found as well in India, Australia, New Zealand, and North and South America. Their prime responsibility is to reflect the natural and human history, traditions, and creative spirit of the area. In many cases the community thus served is culturally homogeneous; where it is not, the museum may develop specific programs to foster mutual understanding among the diverse peoples. In cities that have a sizable immigrant population, such as, for example, Bradford or Leicester in England, the regional museum has engaged actively in such work. Sometimes special exhibitions prepared by the national museum or other agencies provide opportunities at regional museums for the community to appreciate the wider aspects of the national or even international heritage.

The general museum, particularly at the regional or local level, faces severe problems because of the high cost of employing the large numbers of specialists necessary to care for the variety of collections involved, particularly if a strong research program is maintained. In some museums research has diversified as curators, particularly in archaeology, history, and the natural sciences, have become involved in recording the environment of an area or in preparing data banks in order to advise planners and developers who are considering projects to be conducted on sites of scientific or historical interest. Other general

museums have maintained their more traditional roles but have concentrated their efforts on public services, as at the Kanazawa Bunko Museum, Yokohama, Japan, where a multidisciplinary approach is apparent in its exhibitions.

Certain museums provide for a particular audience, often acquiring general collections to suit the purpose. One of these is the children's museum (also frequented by adults), well-known examples of which are the Brooklyn Children's Museum, New York City; the Children's Museum, Boston; the National Children's Museum of New Delhi; and the Mont Riant Children's Museum of Algiers.

NATURAL HISTORY AND NATURAL SCIENCE MUSEUMS

Museums of natural history and natural science are concerned with the natural world; their collections may contain specimens of birds, mammals, insects, plants, rocks, minerals, and fossils. These museums have their origins in the cabinets of curiosities built up by prominent individuals in Europe during the Renaissance and Enlightenment. Specimens from the natural world were also included (albeit as part of an encyclopaedic collection) in some of the earliest museums: the Ashmolean Museum at Oxford, Eng., the British Museum in London, and the National Museum of Natural History in Paris. With the development of the natural sciences in the 19th century, museums exhibiting objects from the natural world flourished and their number multiplied. In the United States and Latin America their collections often included objects of physical and social anthropology as well as the natural sciences.

Expanding roles of natural science museums

More recently, natural science museums have responded to new trends of nature conservation and broader environmental matters. Some have established programs for recording biological data for the area they serve, to facilitate environmental planning (often in conjunction with local planning authorities), and to provide information to assist in the interpretation of ecological displays.

Major museums such as the Natural History Museum in London, the Smithsonian Institution's National Museum of Natural History in Washington, D.C., and the American Museum of Natural History in New York City hold enormous comparative collections from the natural world, including the type specimens from which species have been named. Such museums are international centres of taxonomic work and sustain considerable research programs.

SCIENCE AND TECHNOLOGY MUSEUMS

Museums of science and technology are concerned with the development and application of scientific ideas and instrumentation. Like museums of natural science and natural history, science museums have their origins in the Enlightenment. Some of them developed from the collections of learned societies, others from private collections such as the Teylers Museum at Haarlem, Neth., in the 18th century. A later development in science museums involved the applications of science, so that museums began to preserve the material evidence of technological as well as scientific endeavour. Some science and technology museums now concentrate on demonstrating science and its applications; in these museums the preservation of process is emphasized over the preservation of objects.

Demonstration models

Science museums are particularly popular with children as well as adults and often provide opportunities for their visitors to participate through demonstration models and interactive displays. Well-known examples of these are at the Deutsches Museum in Munich, the Science Museum in London, and (of a more specialized nature) the National Air and Space Museum in Washington, D.C. (shown in Figure 3). Other specialized institutions include transport museums, such as the National Railway Museum in York, Eng., or the Swiss Transport Museum on the shores of Lake Lucerne. Of more recent establishment are industrial museums, which often include a large technical component.

Museums devoted to modern science, such as the Palace of Discovery in Paris, also provide demonstrations of scientific theory. In India, where museums of science and technology are seen as having an important role in education, the National Council for Science Museums has established a network of such museums across the country.

Figure 3: The Air Transportation gallery at the National Air and Space Museum, Washington, D.C.
© Richard T. Nowitz

Performing a similar function are science centres where science is demonstrated but where there is not normally a responsibility for collecting and conserving historical apparatus. A pioneer in this field is the Ontario Science Centre in Toronto.

Some science and technology museums, such as the very popular Museum of Science and Industry in Chicago or the Technological Museum in Mexico City, are of a more technical nature. These museums are often sponsored directly or indirectly by industries, which occasionally found their own museums in order to preserve their heritage and promote their work.

HISTORY MUSEUMS

The term history museum is often used for a wide variety of museums where collections are amassed and, in most cases, are presented to give a chronological perspective. Because of the encompassing nature of history, museums of this type may well hold so many objects of art and science that they would more properly be called general museums (see above).

Museums dealing with specialized aspects of history may be found at the national, provincial, or local level, while museums of general history are rare at the national level. One example of the latter is the National Museum of History in Chapultepec Castle, Mexico City. Other national museums of history can be found particularly among newer states, where they have been used as a means of arousing national consciousness and providing historical perspective. At the local and regional level there are many examples, of which the Museum of London and the city museums of Amsterdam, Dresden, Luxembourg, New York City, Stockholm, and Warsaw are but a few. In many cases, if artifacts are not available or are inappropriate, curators use reconstructions, models, and graphics, sometimes with multimedia techniques, to maintain chronological continuity and to increase the opportunity for interpretation within their essentially didactic approach.

While history museums may include archaeological material, there is nevertheless a distinctive type that specializes in it: the antiquities museum. Collections of material of the ancient world can be found in national museums in a number of cities—for example, Amman, Jordan; Athens; Cairo; Copenhagen; Edinburgh; Madrid; and Mexico City (see Figure 4). The antiquities museum is particularly common in Europe and Asia. Specialized archaeology museums also are found in areas of rich antiquity or as on-site museums. The archaeology museum is concerned mainly with historical evidence recovered from the ground and in many cases provides information on a period for which the written record can make little or no contribution.

The ethnography museum

Another specialized form of the history museum collects and exhibits material from an ethnographic viewpoint. As the term suggests, emphasis is placed on culture rather than chronology in the presentation of the collections. The ethnography museum is common among newer nation-states of Africa and Oceania, where it is seen as a

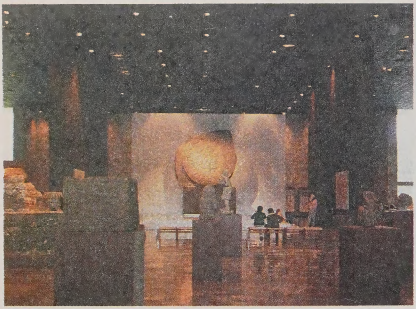

Figure 4: An Aztec calendar stone as the centrepiece of a gallery of archaeological artifacts, National Museum of Anthropology, Mexico City.
© SuperStock

means of contributing to national unity among different cultural groups. Among the industrialized nations, and particularly in countries that have been involved in colonization, the ethnography museum is a museum of the cultures of other peoples. Many of these institutions have been established in the capital cities, which at the height of colonization were the nation's window on a world otherwise distant and unknown. Thus were founded the Musée de l'Homme (Museum of Man), Paris; the extensive ethnographic collections of the British Museum, London; and the Tropenmuseum (Museum of the Royal Tropical Institute), Amsterdam. Specialized ethnography museums are also to be found in provincial cities. Normally these have arisen through personal associations, as with the Pitt Rivers Museum in Oxford, or because of trade connections, as with the Overseas Museum in Bremen or the National Museums and Galleries on Merseyside, Liverpool. The last two examples result from proximity to a major international port.

Many other forms of the cultural history museum exist. Particularly prolific are museums concerned with preserving urban and rural traditions; these have rapidly increased in number with the pace of technological progress. Indeed, some history museums are involved in documenting various material aspects of contemporary life and in the selective collection of artifacts. Work of this type was pioneered in Sweden, where in 1873 Artur Hazilius developed the first museum of traditional life at the Nordic Museum, Stockholm. This was followed 18 years later by the first open-air museum, at Skansen. Museums of both types soon appeared in other countries. Today the National Museum of Popular Arts and Traditions in Paris exemplifies a national approach within a museum building. Outdoor museums preserving traditional architecture, sometimes in situ, and often demonstrating the activities associated with them, are to be found in many parts of the world: the National Museum of Niamey, Niger, or the Museum of Traditional Architecture in Jos, Nigeria; the Village Museum of Bucharest, Rom.; Upper Canada Village, Morrisburg, Ont.; Colonial Williamsburg, Va., U.S. (see Figure 5); or the Novgorod State Museum Preserve in Russia.

Figure 5: A museum interpreter demonstrating the 18th-century art of wig making at the King's Arms Barber Shop, Colonial Williamsburg, Va., U.S.
© Richard T. Nowitz

Another form of history museum is the portrait gallery, in which pictures are collected and displayed less for aesthetic reasons than for the purpose of communicating the images of actual persons. Although the idea of a portrait gallery is of some antiquity—a large collection of portraits of the kings of France and their statesmen was exhibited in Paul Ardier's gallery at the Château de Beauregard near Blois in the 1620s, for example—the national portrait gallery as a public institution is a later development. In a similar vein, paintings and prints of people, as well as places and events, often constitute an important element in other types of history museums.

ART MUSEUMS

The art museum (called art gallery in some places) is concerned primarily with the object as a means of unaided communication with its visitors. Aesthetic value is therefore a major consideration in accepting items for the collection. Traditionally these collections have comprised paintings, sculpture, and the decorative arts. A number of art museums have included the industrial arts since the 19th century, when they were introduced, particularly to encourage good industrial design. The collection of so-called primitive art had a profound influence on certain forms of 20th-century art, but it can be argued that aesthetics have subordinated function and association to such an extent that objects often are presented in a totally alien context. In some countries this criticism applies to archaeological material as well.

The display of works of art presents the curator with certain problems. Works of art are exhibited to convey a visual message. While other disciplines tend to adopt didactic methods of display, the art curator is concerned particularly with unimpeded presentation of a given work. The ambience of the work is enhanced by highlighting its form and colour with proper lighting and background. At one time artificial light was preferred for paintings, both to create an effect and to prevent exposure to harmful elements in natural light, but it sometimes provides an unnecessarily theatrical presentation or creates an artificiality that can inhibit the visitor's appreciation and enjoyment of the work. Much greater use is now made of indirect natural light or—as at the Tate Gallery, London, for example—a controlled mixture of daylight and simulated daylight. Some art museums have returned to the earlier custom of hanging paintings in a tiered arrangement in order to exhibit more of their works.

The display of works of art

The search for context has led to the design of period settings in which to present certain art objects, to the development of furnished period-house museums, and to the preservation of country houses and other appropriate properties, together with their contents, in situ. In a specialized context, the restoration of the Moscow Kremlin, particularly the Great Palace and the churches with their fine murals and icons, provides an example of this approach. Some of the churches are open to the public as museums.

In many cases modern art is displayed in a separate institution. The role of such museums is to confront the public with art in the process of development, and there is a considerable experimental component in their exhibits. This is particularly so at the Pompidou Centre in Paris, the Stedelijk Museum in Amsterdam, or the museums of modern art in Stockholm and New York City, where other contemporary art forms besides painting also are presented. Because of the experimental nature of modern

art and the high cost involved in purchases, temporary exhibitions normally play a major role in such museums and in some cases are their principal activity. Contemporary sculpture is often exhibited outdoors, as at the Hirshhorn Museum and Sculpture Garden in Washington, D.C., the Open-Air Museum in Hakone, Japan, or the Billy Rose Art Garden in Jerusalem.

The operation of museums

ADMINISTRATION

There is no consistent pattern for the general administration of museums throughout the world. In part, the lack of such a pattern reflects the diversity of museums' collections, but it also reflects an ambivalence in the understanding of the role of museums in society—*i.e.,* whether museums are guardians and interpreters of the cultural heritage, repositories for the study of primary evidence relating to human and natural history, social instruments in community development, or facilities for leisure and recreation.

Private and public administration

On the most general level, museums may be either privately or publicly administered. Since 1970 there has been a marked increase in the number of private-sector museums, yet even some of these have corporate standing under general legislation and receive public moneys. In addition, private patronage also has become important for public museums, which often find themselves competing with private museums for additional funding from individual and corporate sources. In the public sector, national museums may be overseen by such diverse ministries as education, tourism, defense, environment, national heritage, culture, and leisure. The situation can be even more complicated at the local level.

The level of state control varies from country to country. In France, for instance, the state has traditionally exercised greater control over museums. A number of the national museums in Paris operate under a semiautonomous administrative council, with an executive chairman who has a dual responsibility for policy and executive matters. In addition, there are a number of national museums located outside Paris, and some technical control over the country's municipal museums is exercised by the central administration. In the United Kingdom, on the other hand, public museums have traditionally enjoyed greater autonomy. Britain's national museums—located mainly in the capital cities of London, Edinburgh, Cardiff, and Belfast—receive funds from the national government, but each museum has been established by its own specific legislation, which empowers a board of trustees (nominally independent of the government) to administer and raise funds and to guide the museum's policies. British municipal museums, however, are provided under general legislation, and representatives from local government form the management committees by law. The British model can be found in other European and English-speaking countries. In the United States only the dependent museums of the Smithsonian Institution and the National Park Service have national status and are financed by the federal government.

MANAGEMENT

Most museums operate under some form of governing body. This body defines the general policy of the museum and provides and controls the necessary resources to deliver it. The appointment of the director and perhaps of other staff members usually is among its responsibilities. The director of a museum governed by this type of body is responsible for the formulation and implementation of policy and for the day-to-day running of the institution and generally provides the link between the governing body, the staff, and the museum's clientele.

The operation of a museum involves a wide variety of skills. These involve specialists in subjects relevant to museum collections (normally designated curators or keepers), information scientists involved in the documentation of collections and related scientific information (sometimes known as registrars), and conservators concerned with the scientific examination and treatment of collections to prevent deterioration. Another group is involved more actively with the public functioning of the museum. These include specialists in education, communication, and interpretation, designers, the security staff, and marketing and public relations personnel as well as administrative, maintenance, and other support workers. Such diversity can lead to complex staff structures. Many of the larger, older established museums with encyclopaedic collections have a large number of senior specialized personnel. In museums where the emphasis is on providing services for the general public and the collections are less wide-ranging, there are likely to be fewer curatorial and more service personnel. Nevertheless, museums are labour-intensive, and the extent to which new technologies can alleviate the need for labour is limited. In all types of museums, operation is based on teamwork, and this has important implications for the management structures adopted as well as for the training of museum staffs.

Staff structures

It was not until about 1965 that university faculties or departments of museology—museum studies, as it is more commonly known in English-speaking countries—were created with a specific emphasis on the theory and practice of museums, as opposed to an emphasis on the subjects represented in their collections. In certain countries, notably Japan and some Latin-American nations, curators are required by law to have graduated in museology before they can practice. Such courses, where available, normally provide some training in museum management. Although some museum studies are taught at the undergraduate level, postgraduate training is the generally recognized requirement.

FUNDING

Public and private sources. Until the mid-1970s, public funds constituted the major income source for public museums and in many cases contributed a considerable percentage of the income of those operated privately. With increasing restrictions on expenditure of public moneys, however, funding from multiple sources has become far more commonplace. In both developed and developing countries this can be crucial to the formation and continued maintenance of a museum service.

The main source of funds for museums in the public sector remains the local or national government. This can result in a lack of flexibility in the use of such moneys, because the funds usually are subject to government policies that have little bearing on the particular requirements of museums. In addition, these museums are required to compete for funds against such traditional public expenditures as education, social services, defense, and law and order, and in consequence museums often are given low priority.

Private benefactors

Many museums were founded through private benefaction, and a few have endowments that help to support their routine operation. Others may have received bequests, many of which are designated to be used only for the purchase of objects. Such sources, although they may seem appropriate when secured, can suffer from changes in economic circumstances and may have attached to them conditions that are incompatible with requirements of the modern museum.

Today museums are becoming increasingly involved in fund-raising, in seeking commercial sponsorship, and in their own trading activities. Fund-raising may be undertaken by the museum, by a commissioned organization, or by a support body such as the many "friends of the museum" organizations now in existence. Fund-raising and sponsorship are normally directed toward a specific project or development.

Entrance fees. Many museums charge entrance fees to help finance operations—even in some countries, such as the United Kingdom, that previously had a strong tradition of free entry to museums. Some museums charge admission fees only for major exhibitions. Others have introduced a system of voluntary donations by visitors on entry to supplement their income, but the results of this approach generally have been disappointing.

Commercial activities. Commercial activities have become a significant feature of many museums. These may

take the form of restaurants or shops that provide a service to visitors as well as income to the museum. Some museums have separate trading companies that act as publishers or engage in mail-order business, the profits from which are directed to the museum for general purposes. In this way the museum retains its charitable status, is not exposed to the direct dangers that would follow commercial failure, and also circumnavigates any requirements that direct income be returned to the public purse.

MUSEUM COOPERATION

The first organized cooperation among museums at the international level arose through the League of Nations' Committee of Intellectual Cooperation. In 1922 the Committee established an International Museums Office, which initiated a number of studies and publications until it went out of existence in 1946. In that year the International Council of Museums (ICOM) was created, and today this nongovernmental organization provides a world forum for museum professionals through regular meetings and through continuous communication over the Internet. In some countries where there are no separate associations for museum personnel, the national committees of ICOM fill the role of professional association. ICOM is also the recognized adviser on museum matters to the Social and Economic Council of the United Nations as well as the United Nations Educational, Scientific, and Cultural Organization (UNESCO).

The International Council of Museums

Since its inception in 1946, UNESCO has been responsible for a growing body of legislation to protect the world's cultural heritage, has been active in promoting the return and restitution of cultural property to its country of origin, has initiated campaigns to ensure the protection of major world heritage sites, and has provided financial assistance for the renovation of older museums and the establishment of new ones, particularly in developing countries. Some of its member states were responsible for the creation in 1956 of the International Centre for the Study of the Preservation and Restoration of Cultural Property (ICCROM).

COLLECTION

Acquisition policies. The history of museums and their precursors indicates the influence that the existence of a collection has had on the founding of museums and therefore on the nature of their original holdings. Relatively few museums have been established with the goal of making a collection; instead, most have been created to receive an existing collection. With the existing collection as its base, the museum has proceeded to collect to fill gaps or to extend its activity into other, usually related, fields. For this reason many museums have heterogeneous collections, at best accumulated under an "encyclopaedic" philosophy (which has rarely been successful unless major resources were available to achieve it) and at worst continuing a "cabinet of curiosities" approach (which may amuse and entertain the clientele but has little scientific validity). Often the collections made depended on the expertise or whim of the curator and were sure to change when that curator was succeeded by someone with different interests. This method has produced some outstanding special collections, but these have resulted from circumstance rather than long-term planning.

Explicit collection policies are now more common. Indeed, where national codes of practice exist, a strong recommendation is normally to be found on the need for a clear statement of collecting activity. This has arisen for a number of reasons. Not only should a public institution's policies be available for scrutiny, but the cost of maintaining collections of ever-increasing size must be justified, a factor highlighted at times of economic pressure. Further, although a museum may have arisen from circumstance, an assessment of its available resources, the clientele it attracts or intends to attract, and the role it can serve in society generally must be matched against its primary resource, its collections.

Legality. Every museum is responsible for ensuring the legality of its acquisitions. Laws regulating collection vary from country to country, but, whether or not a state has enacted its own legislation or ratified relevant international conventions, museum staff are expected to conform to generally recognized professional codes of ethics. Most regulation of collecting activity embodies principles established in the 1954 Convention for the Protection of Cultural Property in the Event of Armed Conflict and the 1970 Convention on the Means of Prohibiting and Preventing the Illicit Import, Export, and Transfer of Ownership of Cultural Property, both approved by member states of UNESCO. However, a number of countries involved in international trade found it difficult to ratify the 1970 convention, and certain difficulties arose over the definition of cultural property. The 1995 Unidroit Convention on Stolen or Illegally Exported Cultural Objects was intended to resolve these issues. Similar conventions exist on the regional level as well.

International conventions

Given the number and variety of legal regulations and professional codes, it is unlikely that a museum with clearly stated academic objectives will acquire illicit material. Indeed, methods of collection reflect the fact that a museum is concerned not only with collections per se but also with the information inherent in or associated with them. Where applicable, direct acquisition through fieldwork is much preferred. This involves collecting material through archaeological excavation, ethnological expeditions, or natural science fieldwork, and the collecting either is undertaken by the staff of the museum or is sponsored by it. Indirect acquisition is handled through purchases, gifts, bequests, and loans of objects.

Protection of cultural property. Conventions such as those cited above reflect the fact that the collecting activities of the industrialized world are markedly different from those available to the developing nations. In some instances the significant cultural property of entire nations has been dispersed to private collections and museums in different parts of the world, leaving the developing museums to rely on casts and replicas to convey the area's cultural achievements. The international community has had only limited success in encouraging the return, through exchange or loan, of such material to its country of origin.

The true significance of cultural property, collectively the universal heritage of humankind, places on museums a considerable responsibility. The acceptance of objects or collections into their care implies a permanence not associated with the acceptance of other types of property. Some museum legislation acknowledges this, declaring such collections inalienable. The disposal of museum collections in part or in full therefore normally only occurs in cases where items no longer serve a useful scholarly or interpretative purpose. The case for deaccessioning, as it is known in North America, can only otherwise have any validity where it is done to correct the imbalances of earlier indiscriminate collecting, and in that case the material concerned should first be made available to other suitable museums before disposal.

CONSERVATION

A museum's prime responsibility must be to maintain its collections and to do everything possible to delay the natural laws of deterioration. The acquisition of an item almost certainly brings it into a new and potentially alien environment. Material that has been recovered from the ground through archaeological excavation may need immediate treatment to stabilize it. Many of the materials from which objects are made are inherently unstable and undergo chemical or structural change as they age. A new or shifting environment can accelerate these changes, and temperature, light, humidity, and human and other biological factors all need to be controlled. In addition, conservation involves the treatment and, where feasible and acceptable, the restoration of objects as nearly as possible to their former condition.

Most large museums have their own laboratories where preservation and restoration work is carried out (see Figure 6), and some take on projects for other museums as well. In some cases, as at the British Museum, a separate department of scientific research supports the museum's academic and conservation work, providing advanced scientific equipment for the analysis, dating, and identi-

fication of materials. Some museums are served by independent conservation laboratories, an example of which is the Canadian Conservation Institute, in Ottawa, which uses a fleet of mobile laboratories to attend to museum collections in many parts of the country.

DOCUMENTATION

Documentation is a significant function of any museum, whether it holds only a few hundred objects or many millions of items. Quite apart from the need for records to maintain adequate control of its collections, a museum's documentation system provides an indispensable record of the information associated with the objects for research. The documentation system also may include records to facilitate the museum's interpretative and other work.

The form of a museum's documentation system may vary considerably, but to meet these requirements it should provide the fullest possible information about each item and its history. There are no generally accepted classification schemes for museum objects, although certain subjects have developed schemes with numeric or alphanumeric notations to facilitate the ordering and retrieval of information. For the natural sciences, taxonomic names are normally used.

Computerized documentation system

A number of museums have developed computerized documentation systems, some on-line but others relying on machine-generated indexes, periodically updated, to meet most of their information requirements. The advantages of computerized documentation are being exploited in a number of ways—for instance, in exchanging data between museums to facilitate study and research or in making collection information available for public use in the museum gallery or over the Internet.

RESEARCH

Because they hold the primary material evidence for a number of subjects concerned with an understanding of humans and their environment, museums clearly have an important role in research. The museum's research program is related to its objectives as an institution. A program may be concerned directly with the public services provided, in preparing exhibitions, catalogs, and other publications; or with promoting a better understanding of the discipline or region that it serves. In large museums, and in university museums in particular, pure and applied research may be of national or international significance and may be associated with fieldwork or study visits. Active research and publication on a given topic, apart from contributing to the academic standing of the institution, may attract further collections relevant to the topic.

Many museums provide facilities, apart from those used by casual visitors, for researchers to study collections and associated documentation. Such facilities may include study rooms with a supporting library and equipment to assist in the examination of collections. Certain museums have accommodations for visiting foreign scholars; this feature is particularly helpful at site museums that are difficult to reach.

EXHIBITION

Many museums have abandoned the traditional view of exhibition, by which storage and display are ends in themselves, in favour of an approach that enhances the setting of the object or collection. To this end museums use the expertise of a number of specialists—designers, educators, sociologists, and interpreters as well as curators—to improve communication through objects. The result has been a remarkable transformation in the presentation of museum displays. Far greater use is made of colour and light (within the bounds prescribed by conservation requirements), in the way material is interpreted through a variety of mediums (sound, video, interaction between visitor and exhibit, virtual reality, as well as more traditional methods), and in the provision of a more relaxing environment in which to enjoy the exhibits. A result of museums' increased awareness of the needs of their visitors has been a considerable increase in museum attendance.

As the museum's cultural role has developed, so its exhibition work has diversified. Large international exhibitions have been organized by cooperating nations and have been shown in the major museums of the participating countries. Exhibitions organized for national circulation are also increasingly common. Museums concerned with a particular region have arranged topical exhibitions to tour the area, and, in places without suitable premises for display or in sparsely populated areas, exhibitions have toured in specially adapted buses or trains. Some countries have developed multipurpose cultural centres, and collaboration with museums has resulted in exhibition programs successfully reaching a wide audience.

Interest in the historic and natural environment globally has involved museums in the preservation and interpretation of sites, monuments, and landscapes (as in the Slave House museum at Gorée Island, Senegal; see Figure 7). Here the conflict inherent in imposing an interpretive medium into a natural or historical context has to be resolved. In its simplest form, interpretation may be conveyed through nature or history trails in which information is provided in written or recorded form. With a historic property there are also opportunities to reenact events associated with the property, such as period battle scenes and banquets, to demonstrate industrial or craft techniques, or to use theatre and son et lumière performances to interpret the site.

EDUCATIONAL SERVICES

The contribution that museums can make to education is widely acknowledged. The majority of their clientele learn by looking at exhibitions and displays. There has been, however, a long association with schools, and many museums provide services specifically designed to meet schools' needs. Services include facilities for use both in the museum and at the school, many of which are administered by separate departments of museum education employing teachers for the purpose.

Facilities for education

Special rooms equipped for teaching and for handling specimens are provided in many museums. By allowing the study and handling of objects from its collections, the museum can give substance and form to the bare facts of art, history, and science. Some museums build special collections for this purpose. Teaching may be undertaken by the museum's educational staff or, more often, by the schoolteacher, who will have been advised and instructed by the staff. For advanced studies, particularly in subjects

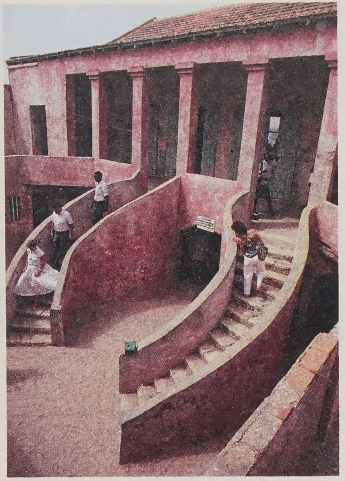

Figure 7: Visitors tour the Slave House, a historic site restored as a museum, Gorée Island, Senegal.
© Christine Burton/Robert Harding Picture Library

like archaeology and geology, the availability of museum collections can be indispensable.

Although opinion differs as to the value of school loan collections, many museums do provide small exhibit cases or kits that may be borrowed by the school for a limited period for classroom teaching. Unlike libraries, museums are not able to provide extensive loan services (which would conflict with their prime purpose), but, for rural schools unable to visit the museum, such a facility, albeit limited, meets a need. In some areas museums include the larger community schools within their traveling exhibition schedules.

As a better-educated adult population with increased leisure time seeks purposeful outlets, museums are well placed to provide activities. Many museums have adult programs such as lectures, courses, demonstrations, and field excursions, some of which are planned as family events.

BIBLIOGRAPHY. Until recently the information relating to museums has been much dispersed, but detailed studies are now being published in book form. The following list identifies some of the literature available.

Directories of museums providing worldwide coverage include BETTINA BARTZ, HELMUT OPITZ, and ELISABETH RICHTER (eds.), *Museums of the World,* 4th rev. and enlarged ed. (1992); and KENNETH HUDSON and ANN NICHOLLS, *The Directory of Museums & Living Displays,* 3rd ed. (1985), including zoos, aquaria, botanical gardens, and living history farms. SUSAN PETERS *et al.* (eds.), *Directory of Museums in Africa* (1990), in English and French; INTERNATIONAL COUNCIL OF MUSEUMS, *Directory of Museums in the Arab Countries, 1995* (1995), also in English and French, and *Directory of Museums of the Asia-Pacific Countries,* vol. 1 (1993), covering Australia, New Zealand, and the Pacific Islands, provide lists for these regions. A number of national museum directories are published, including *Museums Yearbook,* published by the Museums Association and covering museums in the United Kingdom; and *The Official Museum Directory* (annual), published by the American Association of Museums for museums of art, history, and science. The International Council of Museums (ICOM) also publishes several directories of specialized museums.

The most comprehensive bibliographic listing is *International Museological Bibliography* (annual), maintained by the ICOM, and is also available on CD-ROM. A number of other bibliographies are published, such as SIMON J. KNELL (compiler and ed.), *A Bibliography of Museum Studies,* 11th ed. (1994); MICHAEL STEVEN SHAPIRO and LOUIS WARD KEMP (eds.), *The Museum: A Reference Guide* (1990); and PETER WOODHEAD and GEOFFREY STANSFIELD, *Keyguide to Information Sources in Museum Studies,* 2nd ed. (1994). *Art and Archaeology Technical Abstracts* (semiannual) provides abstracts on museum techniques within these fields. ISTVÁN ÉRI and BÉLA VÉGH (eds.), *Dictionary of Museology* (1986), lists museum terms in 20 languages.

General periodicals include *Museum International* (quarterly); *I C O M News* (quarterly); *Curator* (quarterly); *Museum Management and Curatorship* (quarterly); *Museums Journal* (quarterly); *Museum News* (bimonthly); and *Museum Practice* (3/yr.).

Works concerning the history of museums and collecting include EDWARD P. ALEXANDER, *Museums in Motion: An Introduction to the History and Functions of Museums* (1979), and *Museum Masters: Their Museums and Their Influence* (1983), tracing the origins of 12 important 18th-, 19th-, and 20th-century museums; GERMAIN BAZIN, *The Museum Age,* trans. from French (1967); PAULA FINDLEN, *Possessing Nature: Museums, Collecting, and Scientific Culture in Early Modern Italy* (1994), on natural history collecting before 1700; KENNETH HUDSON, *Museums of Influence* (1987), reviewing worldwide museum development over the past 200 years through the histories of 37 pioneer museums; OLIVER IMPEY and ARTHUR MACGREGOR (eds.), *The Origins of Museums: The Cabinets of Curiosities in Sixteenth and Seventeenth Century Europe* (1985); SUSAN SHEETS-PYENSON, *Cathedrals of Science: The Development of Colonial Natural History Museums During the Late Nineteenth Century* (1988); and NIELS VON HOLST, *Creators, Collectors, and Connoisseurs: The Anatomy of Artistic Taste from Antiquity to the Present Day* (1967; originally published in German, 1960). Ongoing research is published in *Journal of the History of Collections* (semiannual).

General works about museums and their operation include TIMOTHY AMBROSE and CRISPIN PAINE, *Museum Basics* (1993); JOHN M.A. THOMPSON *et al.* (eds.), *Manual of Curatorship: A Guide to Museum Practice,* 2nd ed. (1992); and GARY EDSON and DAVID DEAN, *The Handbook for Museums* (1994). Professional training is covered in GARY EDSON, *International Directory of Museum Training* (1995); JANE R. GLASER and ARTEMIS A. ZENETOU, *Museums: A Place to Work: Planning Museum Careers* (1996); and STEPHEN E. WEIL, *A Cabinet of Curiosities: Inquiries into Museums and Their Prospects* (1995), and *Rethinking the Museum and Other Meditations* (1990), on museum administration and techniques. Examples of national position statements may be found in AMERICAN ASSOCIATION OF MUSEUMS, *Museums for a New Century* (1984), and *Museums Count* (1994); and GREAT BRITAIN, MUSEUMS AND GALLERIES COMMISSION, *Museums Matter* (1992).

Museum operations in various types of museums are considered in SUSAN PEARCE (ed.), *Art in Museums* (1995); STELLA V.F. BUTLER, *Science and Technology Museums* (1992); PETER DAVIS, *Museums and the Natural Environment: The Role of Natural History Museums in Biological Conservation* (1996); GAYNOR KAVANAGH, *History Curatorship* (1990); and SUSAN M. PEARCE, *Archaeological Curatorship* (1990). Works on specific aspects of museum operation include JOSEP MA. MONTANER, *New Museums,* trans. from Spanish (1990), an architectural view of recent museums; GAIL DEXTER LORD and BARRY LORD, *The Manual of Museum Planning* (1991); H.J. PLENDERLEITH and A.E.A. WERNER, *The Conservation of Antiquities and Works of Art: Treatment, Repair, and Restoration,* 2nd ed. (1971); GARRY THOMSON, *The Museum Environment,* 2nd ed. (1986, reissued 1994); DAVID LISTON (ed.), *Museum Security and Protection* (1993); D. ANDREW ROBERTS, *Planning the Documentation of Museum Collections* (1985); and DOROTHY H. DUDLEY *et al., Museum Registration Methods,* 3rd ed., rev. (1979).

Interpretive functions of museums are treated in R.S. MILES *et al.* (compilers), *The Design of Educational Exhibits,* 2nd ed. (1988); MICHAEL BELCHER, *Exhibitions in Museums* (1991); GILES VELARDE, *Designing Exhibitions* (1989); EILEAN HOOPER-GREENHILL, *Museum and Gallery Education* (1991); EILEAN HOOPER-GREENHILL (ed.), *The Educational Role of the Museum* (1994); ROGER MILES and LAURO ZAVALA (eds.), *Towards the Museum of the Future: New European Perspectives* (1994); SUE RUNYARD, *The Museum Marketing Handbook* (1994); and G. DONALD ADAMS, *Museum Public Relations* (1983).

The legal arrangements concerning museums are closely related to those of the preservation of cultural property, and the following are helpful: LYNDEL V. PROTT and P.J. O'KEEFE, *Law and the Cultural Heritage* (1984–); *The Protection of Movable Cultural Property* (1984–), collected legislative texts for many countries published by UNESCO; STEPHEN E. WEIL, *Beauty and the Beasts: On Museums, Art, the Law, and the Market* (1983); and MARIE C. MALARO, *A Legal Primer on Managing Museum Collections* (1985), and *Museum Governance: Mission, Ethics, Policy* (1994). (G.D.L.)

The Art of Music

The word music comes from the Greek *mousike* by way of the Latin adaptation *musica.* The Greek word is itself derived from *mousa,* "muse," and hence was applied to all branches of art over which the Muses were supposed to preside. In the instruction of the young, *mousike* was roughly equivalent to what in modern times would be called a liberal education, as opposed to *gymnastike,* which was concerned with the development of the body (the modern "gymnastics"). This conception survived in the Roman world, so that *ars musica* could mean either music or poetry; but it did not prevent "music" from being used in the specific sense now given to it. The use of a comprehensive term of this kind implied particularly a close connection between music and poetry that has survived to the present day. It is characteristic that St. Augustine's treatise *De musica,* in the form in which it has come down, is concerned almost entirely with metrics.

This article is divided into four main sections. Music's nature and significance includes the philosophical and theoretical basis and is followed by the elements of musical sound. Composition is discussed in sections on rhythm, scale, mode, harmony, and counterpoint as well as those on notation, the history of compositional technique, and instrumentation. Modern recording covers types of mechanical and electronic reproduction and their effects on composition, criticism, and music appreciation.

The article is divided into the following sections:

The nature and significance of music 493
- Historical conceptions 493
  - The non-Western world
  - Ancient Greek ideas
  - Music in Christianity
  - 17th- and 18th-century Western conceptions

The nature and significance of music

HISTORICAL CONCEPTIONS

Music is everywhere to be heard. But what *is* music? Commentators have spoken of "the relationship of music to the human senses and intellect," thus affirming a world of human discourse as the necessary setting for the art. A definition of music itself will take longer. As Aristotle said, "It is not easy to determine the nature of music or why anyone should have a knowledge of it."

Early in the 20th century, it was regarded as a commonplace that a musical tone was characterized by the regularity of its vibrations; this uniformity gave it a fixed pitch and distinguished its sounds from "noise." Although the view may be supported by traditional music, it would be an unacceptable yardstick in the latter half of the 20th

century, when "noise" itself may be treated as an element in composition, to say nothing of the random sounds incorporated (without prior knowledge of what they will be) by modern composers, such as the American John Cage, and others in works having aleatory (chance) or impromptu features. Tone, moreover, is only one component in music, others being rhythm, timbre (tone colour), and texture. Electronic machinery has enabled some composers to create works in which the traditional role of the interpreter is abolished and to record, directly on tape, sounds that were formerly beyond human ability to produce, if not to imagine.

The non-Western world. From historical accounts, it is clear that the power to move men has always been attributed to music; its ecstatic possibilities have been recognized in all cultures and have usually been admitted in practice under particular conditions, sometimes stringent ones. In the civilization of India, music was put into the service of religion from earliest times; Vedic hymns stand at the beginning of the record. As the art developed over many centuries into a music of profound melodic and rhythmic intricacy, the discipline of a religious text or the guideline of a story determined the structure. Even today the narrator is central in most performances of Indian music, and the virtuosity of a skillful singer rivals that of the instrumentalists. There is very little concept of vocal or instrumental idiom in the Western sense. The vertical dimension of chord structure—that is, the effects created by sounding tones simultaneously—has never been developed in South Asian music; the divisions of an octave (intervals) are more numerous than in Western music, and melodic complexity in Oriental music goes far beyond that of Western practice. Moreover, an element of improvisation is retained that is vital to the success of a performance. The spontaneous imitation carried on between an instrumentalist and narrator, against the insistent rhythmic subtleties of the drums, can be a source of the greatest excitement, which in large measure is because of the faithful adherence to the rigid rules that govern the rendition of ragas—the ancient melodic patterns of Indian music.

Indian music in religion

Chinese music, like the music of India, has traditionally been an adjunct to ceremony or narrative. Confucius (551–479 BC) assigned an important place to music in the service of a well-ordered moral universe. He saw music and government as reflecting one another and believed that only the superior man who can understand music is equipped to govern. Music, he thought, reveals character through the six emotions that it can portray: sorrow, satisfaction, joy, anger, piety, love. According to Confucius, great music is in harmony with the universe, restoring order to the physical world through that harmony. Music, as a true mirror of character, makes pretense or deception impossible.

Confucius and music in China

Ancient Greek ideas. Although music was important in the life of ancient Greece, it is not now known how that music actually sounded. Only a few notated fragments have survived, and no key exists for restoring even these. The Greeks were given to theoretical speculation about music; they had a system of notation, and they "practiced music," as Socrates himself, in a vision, had been enjoined to do. But the Greek term from which the word music is derived was a generic one, referring to any art or science practiced under the aegis of the Muses. Music, therefore, as distinct from gymnastics, was all encompassing. (Much speculation, however, was clearly directed toward that more restricted meaning with which we are familiar.) Music was virtually a department of mathematics for the philosopher Pythagoras (*c.* 550 BC), who was the first musical numerologist and who laid the foundations for acoustics. In acoustics, the Greeks discovered the correspondence between the pitch of a note and the length of a string. But they did not progress to a calculation of pitch on the basis of vibrations, though an attempt was made to connect sounds with underlying motions.

Plato (428–348/347 BC), like Confucius, looked on music as a department of ethics. And like Confucius he was anxious to regulate the use of particular modes (*i.e.*, arrangements of notes, like scales) because of their supposed effects on men. Plato was a stern musical disciplinarian; he saw a correspondence between the character of a man and the music that represented him. Straightforward simplicity was best. In the *Laws*, Plato declared that rhythmic and melodic complexities were to be avoided because they led to depression and disorder. Music echoes divine harmony; rhythm and melody imitate the movements of heavenly bodies, thus delineating the music of the spheres and reflecting the moral order of the universe. Earthly music, however, is suspect; Plato distrusted its emotional power. Music must therefore be of the right sort; the sensuous qualities of certain modes are dangerous, and a strong censorship must be imposed. Music and gymnastics in the correct balance would constitute the desirable curriculum in education. Plato admitted and valued music in its ethically approved forms; his concern was primarily with the effects of music, and he therefore regarded it as a psychosociological phenomenon.

Yet Plato, in treating earthly music as a shadow of the Ideal, saw a symbolic significance in the art. Aristotle carried forward the concept of the art as imitation, but music could express the universal as well. His idea that works of art could contain a measure of truth in themselves—an idea voiced more explicitly by Plotinus in the third century AD—gave added strength to the symbolic view. Aristotle, following Plato, thought that music has power to mold human character, but he would admit all the modes, recognizing happiness and pleasure as values to both the individual and the state. He advocated a rich musical diet. Aristotle made a distinction between those who have only theoretical knowledge and those who produce music, maintaining that persons who do not perform cannot be good judges of the performances of others.

Aristotle's view

Aristoxenus, a pupil of Aristotle, gave considerable credit to the human listener, his importance and his powers of perception. He denigrated the dominance of mathematical and acoustical considerations. For Aristoxenus, music was emotional and fulfilled a functional role, for which both the hearing and the intellect of the listener were essential. Individual tones were to be understood in their relations to one another and in the context of larger formal units. The Epicureans and Stoics adopted a more naturalistic view of music and its function, which they accepted as an adjunct to the good life. They gave more emphasis to sensation than did Plato, but they nevertheless placed music in the service of moderation and virtue. A dissenting 3rd-century voice was that of Empiricus, who said that music was an art of tones and rhythms only that meant nothing outside itself.

The Platonic influence in musical thought was to be dominant for at least a millennium. Following that period of unquestioned philosophic allegiance, there were times of rededication to Greek concepts, accompanied by reverent and insistent homage (*e.g.*, the group of late 16th-century Florentines, known as the Camerata, who were instrumental in the development of opera). Such returns to simplicity, directness, and the primacy of the word have been made periodically, out of loyalty to Platonic imperatives, however much these "neo" practices may have differed from those of the Greeks themselves.

In the 20th century, the effects of Greek thought are still strongly evident in the belief that music influences the ethical life; in the idea that music can be explained in terms of some component such as number (that may itself be only a reflection of another, higher source); in the view that music has specific effects and functions that can be appropriately labelled; and in the recurrent observation that music is connected with human emotion. In every historical period there have been defectors from one or more of these views, and there are, of course, differences of emphasis.

Music in Christianity. Much of the Platonic–Aristotelian teaching, as restated by the Roman philosopher Boethius (*c.* 480–524), was well suited to the needs of the church; the conservative aspects of that philosophy, with its fear of innovation, were conducive to the maintenance of order. The role of music as accessory to words is nowhere more clearly illustrated than in the history of Christianity, where the primacy of the text has always

been emphasized and sometimes, as in Roman Catholic doctrine, made an article of faith. In the varieties of plainchant, melody was used for textual illumination; the configurations of sound took their cue from the words. St. Augustine (AD 354–430), who was attracted by music and valued its utility to religion, was fearful of its sensuous element and anxious that the melody never take precedence over the words. These had been Plato's concerns also. Still echoing the Greeks, Augustine, whose beliefs were reiterated by St. Thomas Aquinas (*c.* 1225–74), held the basis of music to be mathematical; music reflects celestial movement and order.

Martin Luther (1483–1546) was a musical liberal and reformer. But the uses he envisioned for music, despite his innovations, were in the mainstream of tradition; Luther insisted that music must be simple, direct, accessible, an aid to piety. His assignment of particular qualities to a given mode is reminiscent of Plato and Confucius. John Calvin (1509–64) took a more cautious and fearful view of music than did Luther, warning against voluptuous, effeminate, or disorderly music and insisting upon the supremacy of the text.

Music as mathematics

17th- and 18th-century Western conceptions. In reviewing the accounts of music that have characterized musical and intellectual history, it is clear that the Pythagoreans are reborn from age to age. The German astronomer Johannes Kepler (1571–1630) perpetuated, in effect, the idea of the harmony of the spheres, attempting to relate music to planetary movement. Renê Descartes (1596–1650), too, saw the basis of music as mathematical. He was a faithful Platonist in his prescription of temperate rhythms and simple melodies so that music would not produce imaginative, exciting, and hence immoral, effects. For another philosopher–mathematician, the German Gottfried von Leibniz (1646–1716), music reflected a universal rhythm and mirrored a reality that was fundamentally mathematical, to be experienced in the mind as a subconscious apprehension of numerical relationships.

Immanuel Kant (1724–1804) ranked music as lowest in his hierarchy of the arts. What he distrusted most about music was its wordlessness; he considered it useful for enjoyment but negligible in the service of culture. Allied with poetry, however, it may acquire conceptual value. Georg Wilhelm Friedrich Hegel (1770–1831) also extolled the discursive faculties, saying that art, though it expresses the divine, must yield to philosophy. He acknowledged the peculiar power of music to express many nuances of the emotions. Like Kant, Hegel preferred vocal music to instrumental, deprecating wordless music as subjective and indefinite. The essence of music he held to be rhythm, which finds its counterpart in man's innermost self. What is original in Hegel's view is his claim that music, unlike the other arts, has no independent existence in space, is not "objective" in that sense; the fundamental rhythm of music (again an aspect of number) is experienced within the hearer.

Subjectivism in Hegel

After the 18th century, speculations upon the intrinsic nature of music became more numerous and profound. The elements necessary for a more comprehensive theory of its function and meaning became discernible. But philosophers whose views have been summarized thus far were not speaking as philosophers of music. Music interested them in terms extrinsic to itself, in its observable effects; in its connections with dance, religious ritual, or festive rites; because of its alliance with words; or for some other extramusical consideration. The only common denominator to be found, aside from the recognition of different types of music, is the acknowledgment of its connection with the emotional life; and here, to be sure, is that problematic power of the art to move men. Various extramusical preoccupations are today the raison d'être of "contextualist" explanations of music, which are concerned with its relation to the human environment. The history of music itself is largely an account of its adjunctive function in rituals and ceremonies of all kinds—religious, military, courtly—and in musical theatre. The protean character of music that enables it to form such easy alliances with literature and drama (as in folk song, art song, opera, "background" music) and with the dance (tribal, ethnic, "social," ballet) appears to confirm the wide range and influence that the Greeks assigned to it.

MODERN THEORIES OF MUSICAL MEANING

Musical theorists

Before the 19th century, musicians themselves seldom were theorists, if theorist is defined as one who explicates meaning. Musical theory, when it was something other than the exposition of a prevalent or emerging style, was likely to be a technical manual guiding vocal or instrumental performance, a set of directions for meeting current exigencies in church or theatre practice, or a missive advocating reforms. Prolific masters, such as Johann Sebastian Bach, produced not learned treatises but monuments of art.

The 19th century saw the emergence of composer–critics (Carl Maria von Weber, Robert Schumann, Hector Berlioz, Franz Liszt), versatile artists with literary proclivities who were not, to be sure, propounding comprehensive theories or systems of thought. Richard Wagner, an active theorizer, presaged a new species, the composer–author. But he did little to advance musical theory. He proposed a unity of music and drama (*Gesamtkunstwerk*)—a reflection of the "programmatic" preoccupations of 19th-century composers—but its multiplicity of musical and extramusical elements only added to the confusion of musical thought. The distinctly musical character of Wagner's genius, clearly discernible in *The Ring,* is in no way explained by his discursive credos. Igor Stravinsky, Arnold Schoenberg, and other composer–authors of the 20th century were to be somewhat more successful in elucidating their techniques and aims.

The concept of dynamism. Present-day ideas of music as a symbolism owe much to two German philosophers, Arthur Schopenhauer (1788–1860) and Friedrich Nietzsche (1844–1900), who brought to the theory of music a new concept, articulated by each in different ways and in divergent terms but faithful to the same principle—dynamism. Both saw in music an art that is not "spatialized" (hence not "objective") in the way that other arts are by the very conditions of their manifestation. Music is closer to the inner dynamism of process; there are fewer technical (and no concrete) impediments to immediate apprehension, for an entire dimension of the empirical world has been bypassed.

Schopenhauer looked upon Platonic Ideas as objectifying will, but music is

> by no means like the other arts, the copy of the Ideas, but the *copy of the will itself.* This is why the effect of music is so much more powerful and penetrating than that of the other arts, for they speak only of shadows, but it speaks of the thing itself.

In contrast to Kant he accords a special efficacy to music:

> The effect of music is stronger, quicker, more necessary and infallible. Men have practiced music in all ages without being able to account for this; content to understand it directly, they renounce all claim to an abstract conception of this direct understanding itself.

Schopenhauer acknowledged a connection between human feeling and music, which "restores to us all the emotions of our inmost nature, but entirely without reality and far removed from their pain." Music, which he is presenting an as analogue of the emotional life, is a copy or symbol of the will.

Nietzsche posed an Apollonian–Dionysian dichotomy, the former representing form and rationality and the latter drunkenness and ecstasy. For Nietzsche, music was the Dionysian art *par excellence.* In *The Birth of Tragedy from the Spirit of Music,* Nietzsche anticipated the 20th-century discovery that symbol making (whether in dreams, myth, or art) is a necessary and to some extent even automatic human activity. The rich suggestiveness and prescience of his insights embraced the concept of the "symbolical analogue"—the artistic function of ordering and heightening the ingredients of the actual world—and the polarities of experience symbolized in the Apollonian–Dionysian conflict itself, which Igor Stravinsky also explored. Nietzsche gave short shrift to mathematical aspects of music, and like Schopenhauer he deprecated blatantly programmatic music that abounds in obvious imitations of natural

sounds. Discerning a power in music to create myths, he looked upon mere "tone painting" as the antithesis of its essential character.

Efforts of theorists to account for the universal appeal of music and to explain its effects have, since the 19th century, been various, contradictory, and highly controversial. In pointing out the chief points of view that have emerged, it must be emphasized that there are no completely isolated categories, and there is usually considerable overlapping; a single spokesman, the 19th-century English psychologist Edmund Gurney, for example, may incorporate formalist, symbolist, expressionist, and psychological elements, in varying proportions, to explain the phenomenon of music. Although some disagreements are more apparent than real because of the inherent problems of terminology and definition, diametrically opposing views are also held and tenaciously defended.

Referentialists and Nonreferentialists. Among those who seek and propound theories of musical meaning, the most persistent disagreement is between the referentialists (or "heteronomists"), who hold that music can and does refer to meanings outside itself, and the nonreferentialists (who are sometimes called formalists or absolutists), who maintain that the art is autonomous and "means itself." The Austrian critic Eduard Hanslick, in his *The Beautiful in Music* (German edition published 1854), was a strong proponent of music as an art of intrinsic principles and ideas; yet even Hanslick, ardent formalist though he was, struggled with the problem of emotion in music. Hanslick's views have been classified as a modified heteronomous theory.

One looks in vain for an extremist of either persuasion, referentialist or nonreferentialist. Igor Stravinsky first achieved fame as a composer of ballet music, and his works throughout his career were rich in extramusical associations. It would be a comfortable simplification to ally referentialism with "program" music and nonreferentialism with "absolute" music. But the problem cannot be resolved by such a choice, if only, first of all, because extramusical referents can vary in complexity from a mere descriptive title to the convolutions of the Wagnerian leitmotiv, in which a particular musical phrase is consistently associated with a particular person, place, or thing. The referentialist does not require an explicit program (which may, when present, be altogether too meagre by his canons), and the nonreferentialist does not necessarily denigrate program music, though he makes a point of distinguishing between the extramusical program and the musical meaning. The contemporary U.S. theorist Leonard Meyer, in his *Emotion and Meaning in Music* (1956), speaks of "designative" and "embodied" meanings; he recognizes both kinds in music but appears to give equal weight to the extrinsic and intrinsic.

If there is intrinsic, or embodied, meaning, one may well ask what meaning is embodied and how it is to be apprehended. An extreme formalist would say that the acoustic pattern itself and nothing more is the sense of music; Hanslick, indeed, said this, though he did not hold consistently to the view. But most nonreferentialists regard music as, in one way or another, emotionally meaningful or expressive. Referentialists, too, find expressive content in music, though this emotional content may be extramusical (even if not explicit) in origin, according to the American theorists John Hospers in *Meaning and Truth in the Arts* (1946) and Donald Ferguson in *Music as Metaphor* (1960). Meyer has made the observation that while most referentialists are expressionists, not all expressionists are referentialists. He makes the useful distinction between absolute expressionists and referential expressionists and identifies his own position as "formalist–absolute expressionist." In acknowledging that music can and does express referential (designative) meanings as well as nonreferential ones, Meyer exhibits an eclectic and certainly permissive view. But he has been criticized for failing to make clear the *modus operandi* of this referential meaning in music.

Intuition and intellect. Most theorists agree that music is an auditory phenomenon and that hearing is the beginning of understanding. Beyond this there is little agreement. There is bad blood especially between proponents of intuition, like Benedetto Croce, and champions of intellectual cognition, like Hospers. Gurney was constrained to postulate a special musical faculty that need not reside exclusively either in the mind or the heart. The main problem for theorists arises from the inveterate tendency to dichotomize thought and feeling. Henri Bergson (1859–1941) broke with this tradition when he spoke for "an intellectual act of intuition." Recently, a reawakened philosophic and artistic concern for the concept of organic unity has revealed strong affinities among such disparate works as Gurney's *The Power of Sound* (1880); the U.S. philosopher Susanne K. Langer's *Philosophy in a New Key* (1942) and her later works; John Dewey's classic *Art as Experience* (1934); and the U.S. composer Roger Sessions' *The Musical Experience* (1950).

It is apparent that music is connected in some way with the emotional life of man, but the "how" continues to be elusive. Sessions (echoing Aristotle) states the problem fairly:

> No one denies that music arouses emotions, nor do most people deny that the values of music are both qualitatively and quantitatively connected with the emotions it arouses. Yet it is not easy to say just what this connection is.

The language analogy

It was long fashionable to speak of the "language" of music, or of music as the "language of the emotions," but since a precise semantics is wanting in music, the analogy breaks down. Two or more listeners may derive very different "meanings" from the same piece of music, and since written and spoken language cannot render these musical "meanings," whatever they may be, in consistent and commonly recognizable terms, verbal explication often seems to raise more questions than it settles. Philosophic analysts who hold that all meaning is capable of rendition in language therefore pronounce music—unless it can be saved by the referentialists—without meaning, confronting the thoughtful listener, thereby, with a proposition that seems clearly to contradict (and trivialize) his own experience. The difficulty, of course, is a semantic one and explains why some theorists substitute such terms as import, significance, pattern, or gestalt for meaning. Recognizing an incompatibility between the modalities of nonverbal arts and their treatment by discursive thought, it is hardly surprising that musical aestheticians have been few.

Symbolist contributions. Significant contributions to musical theory have been made in the 20th century by several investigators who may be classified as symbolists, though most of them exhibit formalist, expressionist, and psychological elements as well. The most influential (and controversial) work has been done by Langer. Her most adamant critics (such as John Hospers) have objected to her use of the term symbol that must, in their lexica, stand for something definite; she takes pains to ascribe this more limited usage to the term signal. The more general use of the term symbol that she endorses has a long history, notably in such 19th-century figures as Goethe, Carlyle, and the French Symbolist poets. Langer is accused of having somewhat weakened her argument through a vacillating terminology, and she has described the musical symbol as "unconsummated" because of its ambiguity. But the validity of her theory does not depend upon the term symbol; her thought, indeed, has much in common with that of Edmund Gurney, who does not employ the term and whose "ideal motion," if substituted for symbol, would remove most of her critics' objections. Her use of symbol is nevertheless defensible; she construes art as a "symbolic analogue of emotive life," rendering the "forms of sentient being" into intelligible configurations. She is a naturalist; she sees art as organic in origin, and she echoes the view, long held among symbolists, that artistic form and content compose an indissoluble unity that each art manifests according to its peculiar conditions. The symbolism of music is therefore tonal (or, at its broadest, auditory) in character and can be realized only in time; in psychological experience, time assumes an ideal guise. (Painting and sculpture, in their distinctive modalities, embody ideal space.) Langer embraces all the arts in her purview. The U.S. musical theorist Gordon

Epperson's *The Musical Symbol* (1967) is an application of her concepts, with modifications, intensively to music.

Contextualist theories. In moving from symbolic to contextualist explanations of music, it is well to note that a source of great confusion, in the former, is the fact that tone painting (with explicit signals that yield, when the code is understood, designative meanings) is widely regarded as musical symbolism. An example of such tone painting is Bach's introduction of musical notes, corresponding to the letters of his own name, as a theme in the unfinished final fugue of the *Art of the Fugue.* And surely it may be argued that this qualifies on one level. But the contention that there is an intrinsic symbolism in the musical meaning itself is a claim that referentialists are generally unwilling to honour. Yet many theorists, whose concern is with the sociological or psychological effects of music, are not so much opposed to the idea of inner or profound meaning as indifferent to such meaning per se. Even an absolutist, however, is unable to examine music in isolation from its human environment. Meyer deliberately eschews logical and philosophical problems of music and makes "no attempt to decide whether music is a language or whether musical stimuli are signs or symbols." (He does not defend the inference that such concerns are irrelevant to meaning.) Musical meaning and communication, he maintains, cannot exist in the absence of the cultural context. The statement is hardly open to dispute; a theorist is classified according to his proximity to the referential or nonreferential pole. If a referentialist emphasizes explicit aims and associations of a particular work (as in varieties of *Gebrauchsmusik*, or "utility" music, written for specific social or educational purposes), the formalist can maintain that there is also an intrinsic, or embodied, meaning to which he attaches the greater aesthetic value.

Among contextualists, however, a simple referential view is the exception rather than the rule. Any theorist who examines musical perception is making a study of a complex human activity. He is dealing with the psychology of music, in which certain elements—*e.g.,* music, listener, mode of apprehension, cultural context—are indispensable and in which characteristic processes recur. Specialists will emphasize one element or another: formalists the music itself, sociologists the listener and his milieu, psychologists the how of perception. Though psychology could survey the whole field, in practice psychologists, according to their persuasions, investigate the perception of measurable acoustic phenomena, the physical-mental effects of musical sound, or—more rarely—the functional role of music in human experience; and pragmatists and analysts alike may leave something out of account. But it remains for the comprehensive theorist, probably one who, like Langer, is equipped to discern relationships among many departments of thought, to construct a valid hierarchical structure of musical meaning in all its ramifications.

Psychological approaches

Deryck Cooke, the British musicologist and the author of *The Language of Music* (1959), who may be classified as a referential expressionist, has offered a sophisticated argument for the notion of music as language. Concepts, however, may not be rendered by this language, only feelings. Cooke reaffirms the possibility, long disputed by many theorists, that such feelings may be recognized, identified, and even classified. But he confines his investigation to the last few hundred years of the Western tradition.

Information theory. The French theorist Abraham Moles's *Information Theory and Esthetic Perception* (1966) brings the new science of information theory to bear on musical perception, emphasizing that the concept of form is the essential thing; the "sonic message," whose dimensions vary from one composition to another, is a whole. Information theory thus proves to be a novel ally for organicists. The message, which is subjected to "atomistic" study of its components, is (thanks to recording) concrete; there is a temporal sonic material, a *materia musica.* Moles gives reinforcement to the aesthetic theory of distance:

> The esthetic procedure of isolating sonic objects is analogous to the sculptor's or decorator's isolating a marble work against a black velvet draping: This procedure directs attention to it, alone and not as one element among many in a complex framework.

Information theory, which Leonard Meyer also discusses, begins its investigations without the help of traditional theory, which it finds to be untenable for its procedures. Musical messages discerned through information theory are not referential, yet Moles chooses to term the measurable elements in the sonic repertoire symbols: "each definable temporal stage represents a 'symbol' analogous to a phoneme in language." According to Moles, music must, as an art, obey rules; the role of aesthetics is to enumerate universally valid rules, not to perpetuate the arbitrary or merely traditional. He foresees experimentation with a much richer repertoire of sounds, transcending musical instruments and drawing on whatever sources—certainly electronic ones—are available for realizing the "most general orchestra." A host of composers have set out to fulfill this desideratum. In order to increase the compass of possible sounds, various electronic synthesizers were constructed. In electronically synthesized music, the medium itself is indistinguishable from its message.

The quest for some distillation of musical meaning may be foredoomed to failure. Meanings, intrinsic and extrinsic, abound; meanings of all kinds, moreover, are revealed in and through the social setting. Church, theatre, and broadcasting affect music in characteristic ways. The modern concert is a device whereby formal, autonomous meanings are emphasized; further, the scope and available repertoire of the concert have been enormously increased through recordings, for any suitably equipped room may become, at the turn of a switch, a recital hall.

Considerations related to performance practice. Listening to music for its own sake, apart from ritual or storytelling, is a recent historical development. There have always been impromptu song and dance; and performances of music in home, church, and theatrical productions have a long history. But there was no public opera house until 1637 when the first one opened in Venice; the first public concerts for which admission was charged appeared in London in 1672. During the next 50 years there were beginnings in Germany and France also, but the modern concert was not a significant feature of musical life until the late 18th century.

Of the forms that have characterized distinct periods of musical history, it is sufficient to remark here that the chief Renaissance forms—mass, motet, the polyphonic chanson, and madrigal—were allied to texts that strongly influenced their structure. Instrumental music was for the most part in the service of the voice, though instrumental church compositions, dances, and chansons arranged for organ were not uncommon. A strong alliance between voices and instruments has continued into the present, with musical theatre, the art song, and religious music. Instrumental music as a separate genre emerged in the 16th century, gaining considerable momentum in the 17th through a variety of idiomatic pieces. Increased attention to technical fluency was accompanied by greater complexity and sophistication in the instruments themselves. In response to stylistic demands for greater resonance and power, the modern forms of the violin appeared in the late 16th century, only gradually supplanting the earlier viols. The harpsichord did not finally yield to the pianoforte until the 18th century. The once-prevalent idea that early stringed and keyboard instruments were primitive precursors of their modern counterparts has been effectually demolished by research in medieval and Renaissance music and by dedicated performers, who seek to restore the sounds and spirit of those eras.

The development of opera, oratorio, and the cantata gave a prominence to vocal music throughout the Baroque era (*c.* 1600–1750) that made it equal in importance to instrumental music, with which these forms were closely allied. But instrumental chamber and independent orchestral ensembles, as they exist today, also had their beginnings during this period. A highly significant development of the late 18th century was the definitive appearance of the modern sonata (whether in the form of the solo and duo sonata, piano trio, string quartet, concerto, or symphony) with the Viennese classicists Haydn and Mozart and, later, Beethoven.

Since a vocal text is likely to be confused with intrinsic

musical meaning, or at least to divert attention from a preoccupation with it, it is not surprising that modern aesthetic theory followed on the emergence of an autonomous instrumental music requiring greater concentration on the sound itself, its colour and intensity, and the intelligibility (in terms of tonal organization alone) of a composition. Moreover, the very concept of listening as an attentive (and sometimes rigorous), serious, and necessary activity of the music lover gained acceptance only slowly, following the inauguration of public concerts, and is still vigorously resisted. The expectation that the art should provide enjoyment without effort is, indeed, widespread and accounts for much of the opposition to new and demanding idioms. But even for the well-disciplined and eager listener there is the problem of quantity: he must cope as best he can with what Langer has called "the madhouse of too much art." If more effort is required, more discrimination is also needed. In music education, articulate voices ask that teaching be centred more upon qualitative aspects of the art ("aesthetic education"), less upon music making as an activity. This concern for musical value appears to reflect a more intensive search for meaning, which is not likely to be the exclusive property of a particular style or era; nor is it to be sought in an indiscriminate acceptance or rejection of novelty per se. A pronounced pedagogical interest developed in such contemporary popular music as "rock," "soul," and similar folk idioms with great numbers of followers, especially among the young, whose gigantic festivals generated feelings of religious exaltation. The texts of the songs are highly emotional and often deal with "protest" themes; accompaniments are provided by guitars, keyboard and percussion instruments, and are electronically amplified. Music educators became attracted by the intrinsic structural values of this music, especially its distinctive rhythmic and modal characteristics, its texts, and the qualitative levels that may be distinguished. A music so vital and widespread, moreover, was deemed by many to be worth studying in school. The "rock" movement became a musical-sociological phenomenon of large proportions.

Music and world view. Again, music proves its protean susceptibilities in the service of disparate world views. Among humanist psychologists (such as the Americans Gordon Allport and Abraham Maslow) music may be one among other means toward self-fulfillment, integration, self-actualization; for aesthetic Existentialists (such as the philosopher Jean-Paul Sartre) it is yet another crucial department of choice and freedom; for spiritual Existentialists (such as the philosophers Karl Jaspers and Martin Buber) it transmits transcendent overtones. For expressionists (such as the composers Schoenberg, Ernst Krenek, and René Leibowitz) music carries austere, and sometimes doctrinaire, moral imperatives. Theodor Adorno, a composer–philosopher and pupil of Alban Berg, writes powerfully of these and speaks for an awareness of dazzling lucidity, but the tone, notwithstanding his humour, is one of obligation. Only the expressionists, among those mentioned here, are committed primarily to music, though Adorno, in particular, considers music and musicians always in interaction with their environments. The aesthetic concept of play is virtually absent, except among such humanists as Maslow. With Sartre, no less a humanist, the tone is one of responsibility. Many educators long held the explicit aim (at least in part because of a misinterpretation of John Dewey) of presenting the content of a discipline as "fun"; the present concern for aesthetic education, an area of great interest to Dewey himself, eschews this trivial view. But play, in the aesthetic sense, follows rules, as information theory has demonstrated; even "controlled aleatory" composition observes some limits. And the play may be very serious indeed, as in the important 20th-century atonal style known as "12-tone technique," practiced by the Viennese expressionists and their successors.

Tonality and meaning. The most troublesome problem not only for the untutored listener but also for the professional musician has been, in much contemporary work, the loss of explicit tonality; and this accounts for the tardy popular response to Schoenberg and his school: the vocabulary is esoteric. Nineteenth-century compositions did, indeed, stretch the tonal system to its outer limits; but it is now clear that Wagner and Richard Strauss, and even the early Schoenberg, had not broken from it. As for Debussy, his use of "exoticisms" was filigree upon a secure tonal base. So were such practices as the juxtaposition of keys by Stravinsky. This is not to say that the tonality of the Western world, fecund though it has been, is superior or more natural than other systems. Ethnomusicology and comparative musicology have proved this to be a parochial view, though there are still those who champion harmonic practices based on the physical laws governing overtones—as Western tonality is—as the only "natural" source of development. It should not be irrelevant, however, to inquire if any folk music has been discovered that exhibits atonal characteristics.

Tonality in Western music, though a significant aspect, cannot be considered the crux of musical meaning. The tone rows that are used in the 12-tone compositions of Schoenberg, like major–minor tonality in earlier music, are a technical substratum and must be no more explicit in the finished work than the chemical makeup of pigments in the "Mona Lisa." The devices selected may affect the comprehensibility or accessibility of the work, but they are not, per se, the determinants of its worth or quality. Similarly with musical colour, or timbre; the 19th century produced a great profusion of compositions, particularly in the orchestral repertoire (*e.g.*, works by Liszt and Berlioz) that exploited the unique sonorities of instruments; control of volume was, in itself, a rich source of colour. Works with literary or other extramusical associations were excellent vehicles for sonorous effects, but colour, like tonality, must be evaluated in musical context. Langer, among present-day aestheticians, regards words themselves as musical, rather than discursive, ingredients; they are "assimilated" by the song. (G.E./Ed.)

CRITICISM

Musical criticism, properly considered, is a branch of philosophy—more exactly, of aesthetics. It is chiefly concerned with making value judgments, either about composition or about performance, or both. This section reviews the history and fundamental issues of music criticism.

Unfortunately, it is difficult to show that a value judgment can stand for anything that is even remotely true about music, as opposed to standing for something that is merely a personal whim on the part of the critic, since there is, as yet, no such thing as an organized body of knowledge called "musical criticism." The entire history of musical criticism can be summed up as a vain struggle to forge itself into a suitable tool for coming to grips with the art of music.

Historical development. The criticism of music first gained serious hold in the 17th and 18th centuries. Among the first writer-musicians to make systematic contributions to criticism were Jean-Jacques Rousseau in France, Johann Mattheson in Germany, and Charles Avison and Charles Burney in England. Their work coincided with the emergence of periodicals and newspapers all over Europe. The first journal devoted entirely to music criticism was *Critica Musica*, founded by Johann Mattheson in 1722. Mattheson had a number of successors, notably the Leipzig composer Johann Adolph Scheibe, who brought out his weekly *Der critische Musicus* between the years 1737 and 1740 and whose chief claim to notoriety was his scurrilous attack on Bach. Generally speaking, the criticism of the time was characterized by an obsessive interest in the rules of music, and it tended to judge practice in the light of theory—a fatal philosophy. Mattheson, for instance, castigated Bach for ignoring certain rules of word setting in his cantatas.

Mattheson's contribution to musical criticism

At the turn of the century, the age of academicism dissolved into the age of description. Schumann, Liszt, and Berlioz, the leaders of the Romantic era, frequently saw in music the embodiment of some poetic or literary idea. They composed program symphonies, symphonic poems, and lesser pieces bearing such titles as "novellette," "ballade," and "romance." Their literary outlook naturally influenced criticism, the more so as they themselves frequently wrote it. In his pamphlet *On John Field's Noc-*

turnes (1859), Liszt wrote, in the purple prose of the time, of their "balmy freshness, seeming to exhale copious perfumes; soothing as the slow, measured rocking of a boat or the swinging of a hammock, amid whose smoothly placid oscillations we seem to hear the dying murmur of melting caresses." Most of the Romantics were guilty of this type of descriptive criticism. Its weakness is that, unless the music is already known, the criticism is meaningless; and once the music is known, the criticism is redundant, since the music itself says it all far more effectively.

Schumann and Hanslick

The most influential critic of the age was Schumann. In 1834 he founded the periodical *Neue Zeitschrift für Musik* ("New Journal for Music") and remained its editor in chief for 10 years. Its pages are full of the most perceptive insights into music and music makers. The first major article Schumann wrote was a laudatory essay on the young Chopin, "Hats off, gentlemen, a genius" (1834), and the last, called "New Paths" (1853), introduced to the world the young Brahms.

During the second half of the 19th century, the critical scene was dominated by the Viennese critic Eduard Hanslick, who is rightly regarded as the father of modern musical criticism. He was a prolific writer, and his book *Vom Musikalisch-Schönen* (1854: *The Beautiful in Music*) is a milestone in the history of criticism. It took an anti-Romantic stand, stressing the autonomy of music and its basic independence of the other arts, and it encouraged a more analytical, less descriptive approach toward criticism. The book was continually reprinted until 1895, appearing in many languages.

Inspired by Hanslick's example, critics in the 20th century rejected the age of description for the age of analysis. Scientific materialism created a climate of rationalism from which music did not remain immune. Critics spoke of "structure," "thematicism," "tonality"—a far cry from Liszt's "dying murmur of melting caresses." A group of musician–thinkers arose who questioned the very basis of musical aesthetics. They included Hugo Riemann, Heinrich Schenker, Sir Henry Hadow, Sir Donald Tovey, Ernest Newman, and, above all, Arnold Schoenberg, whose theoretical writings show him to be one of the most radical thinkers of the age. Criticism itself was criticized, its basic weakness clearly diagnosed. The search was on to discover the criteria for the evaluation of music. This quest—made ever more urgent by the rapidly changing language of music in the late 20th century—has dominated the work of serious critics ever since.

Criticism always seems to founder on the same small handful of basic problems. These problems are essentially philosophical. They appear to be insoluble. They are aggravated not only by the esoteric nature of music but also by the psychological mystery surrounding the very act of criticism. Are there any "standards" in criticism? If so, can they be defined? Are they objective or subjective? If the latter, can they possibly be true? These questions are fundamental. They disclose the full range of the philosophy of criticism.

The practice of criticism. Musical criticism has a primary aim: the evaluation of music. How does the critic set about this difficult task? The scientific school of criticism holds that he apply certain standards to the work in question. His evaluation is the result of testing music against his critical yardsticks and observing how far short it falls. According to this view, a value judgment is like a prize to be won by careful, objective, intelligent effort. This is an attractive notion, particularly among critics. It fosters the view that the critic is in a position of authority, and that he possesses the means to arbitrate over the creative artist. Unfortunately for criticism, there is nothing to suggest that this is anything but an illusion.

The intuitive nature of value judgments

If one reflects on the way in which one listens to music, a basic fact is apparent. Music's value is inherent; it resides in the work of art itself. A value judgment is something that comes across as part of musical communication. Paradoxically, a value judgment appears to be necessary before the critical process can start. The consequences of this observation are far-reaching. Rather than critics with standards, there appear to be only works with standards, which critics observe. It is not necessary to prove that Mozart's *Jupiter Symphony* is a masterpiece in order to be certain that it *is* a masterpiece. Its mastery is self-evident. Critics did not bestow value on Mozart; they perceived it in him.

Music as an autonomous communication. Music is autonomous. It refers to nothing outside itself. This sets it apart from the other arts, which rely upon the outside world for their images. A hat, a man, or an apple tree may all turn up in a painting, a sculpture, or a play. Indeed, they may be part of the very language of visual art and therefore essential to its understanding. Music has no such aids toward comprehension. It is completely lacking in conceptual crutches. It develops according to its own laws. It is a purely musical truth that is comprehended on a purely musical level. The purity of musical communication is what the German philosopher Arthur Schopenhauer was admiring when he said that all of art aspires toward the condition of music.

The inexplicability of musical experience

The totally musical nature of musical experience raises a difficulty for the critic. Such experience is virtually impossible for him to describe. Consequently, the critic can hardly be called "the man in the middle," a role frequently assigned to him. Music is not like a foreign language that requires an expert to translate it for a lay audience. It is a universal tongue. It either speaks to each listener directly, or it does not speak to him at all. If it speaks, the critic's words are already redundant. If it does not speak, a problem exists that his words cannot solve.

Two important consequences flow from these views. They are among the axioms of criticism. First: since music is autonomous, all knowledge about it must spring from experience of it; practice, in short, precedes theory. Second: because of the purely private and personal nature of musical communication, a work's mastery can only be demonstrated to those listeners who already know about it, who have already experienced it—and they hardly require the demonstration. To those listeners who have not experienced it, a work's mastery is not demonstrable. If it were demonstrable, it goes without saying that critical differences would cease to exist: there would be nothing to prevent those who had experienced it from converting those who had not. Yet critical differences remain.

Objectivity versus subjectivity. A difficulty confronting all critics concerns the subjectivity of their observations. Since music is perceived subjectively, so the argument runs, does this not reduce criticism to mere personal opinion? And if this is so, what makes one critic's opinions any truer than another's? This objection can be disposed of, first, on the broadest philosophical level. Since all things perceivable are perceived subjectively, the charge of subjectivity must either be levelled against every other human endeavour, or it must be withdrawn from criticism. Second, and more to the point, what would be said of a performer who proclaimed to all the world his objectivity, his noninvolvement with music? As for the composer, he would be thought strange indeed if he managed to avoid subjective entanglement with his creations. Why is it considered virtuous for performers and composers to enjoy an inner participation with music and not critics? Quite clearly, there is a contradiction here.

The crucial question facing every critic is how to demonstrate the truth of his reaction. Yet all critics cannot be right; many are diametrically opposed to one another. It is no wonder that musical criticism has been described as stuck at the litmus paper stage: critics take a dip into music, and one sees what colour they turn. Plainly, criticism remains indistinguishable from mere speculation until the critic develops the means of confirming the truth of his views. If he wishes to develop such means, it is to the theory of criticism that he must turn.

A definition of criticism

Meanwhile, a definition of musical criticism emerges: Criticism is the rationalization of intuitive musical understanding.

Issues in the theory of criticism. If the practice of criticism, as has been noted, can be reduced to one thing—expressing value judgments—the theory of criticism is essentially one thing, too—explaining them. It is not enough for critics to assert that one work is a masterpiece, another a mediocrity. An attempt must be made to explain why,

and this may lead to a central discovery. A masterpiece is not a matter of chance, nor is a mediocrity. Both are symptomatic of deep, far-reaching principles.

Unity. When Rudolph Reti, the Viennese critic, was a young man studying music at the Vienna Conservatory, he once stood up in the middle of a composition class and put the following question to his professor: "Why can't we take the themes of one work and substitute the themes of another?" Reti did not receive a very convincing reply and was therefore stimulated to think about the problem for himself. Forty years later, he worked out an answer in his book *The Thematic Process in Music* (1951). Briefly, it was that masterpieces diversify a unity. They grow from an all-embracing idea. Their contrasting themes hang together because each of them represents a different aspect of a single basic thought. This observation was not new. Schoenberg had made it years earlier. So, too, had Heinrich Schenker, who used it as the basis for a major theory of aesthetics in his monumental *Das Meisterwerk in der Musik*, 3 vol. (1926–29; "The Masterpiece in Music"). Reti sharpened the concept. He made the critics think again about what, precisely, they mean when they talk about the integrity of a musical structure.

Diversity in unity

Reti's thesis can be vividly demonstrated by taking an existing masterpiece and substituting random themes from another. Even if such themes preserve a semblance of continuity (matching the key, metre, and mood of the themes they displace), they lose the deep sense of unity communicated by the original.

Not all musicians accept this theory. They argue that many composers, notably Bach, have put together works by borrowing materials from other sources. They fail to realize, however, that the act of borrowing is so highly selective that it, too, must be regarded as part of the creative process. The question then becomes: Why was that particular theme or movement borrowed?

Medium. Another question is why a composition expresses itself through its particular medium? Why that medium rather than another?

If a masterpiece is transferred from the instrumental medium for which it was conceived to some other, alien medium, it undergoes a curious distortion. Such distortion offers the clearest proof that a musical law is operating in the original: an identity of the idea with its medium. A master's inner inspiration adapts to his outer terms of reference. Individual instruments lay down individual limitations. If a composer ignores this fact, he can never be certain that his creative aims will ever coincide with the musical results.

Collision of idea and medium

Occasionally, a great composer deliberately engineers a collision between the idea and the medium for a special musical purpose. The fugue in Beethoven's *Hammerklavier Sonata*, for example, is one of the most physically awkward works to play in the entire piano repertoire. It has been composed against, rather than for, the instrument. Some bars are strictly unplayable, and Beethoven knew it; they contribute to the sense of struggle that is an essential part of musical communication, which is present even in the greatest performance. The orchestration of this fugue by the Austrian composer and conductor Felix Weingartner does a major service to musical aesthetics by providing an alternative musical experience of the same work; but by rendering the difficult easy, his orchestral version robs the music of its basic characteristics. It is a splendid illustration of the way in which, in Beethoven's original, a creative aim has been identified with a physical limitation.

Thematic chronology. A further question is why the chronology of the themes of a masterpiece cannot be changed. Why does one thematic chronology sound good, another bad? If the movements of a great sonata or a symphony are switched around, the result will be musically inferior. If the themes of one movement are mixed with those from the same work's companion movements, the result may even be an artistic disaster.

An illuminating exercise in criticism is to "reconstruct" a masterpiece so that its thematic running order is altered; that is, to transfer the first movement's second subject to the position occupied by the finale's second subject, and vice versa. Any musician can carry out this simple experiment for himself. Nothing is better calculated to reveal to him the presence of a creative principle of contrast distribution in the original. Given the thousands of different directions in which the material of a work could be unfolded, a master chooses the "right" one, the one that maintains structural tension—and, hence, musical interest. The themes of a masterpiece cannot assume one another's functions. They are born to fulfill specific roles. They develop out of each other because they create a musical need for each other.

The creative principle of contrast distribution

Economy. Composers through the ages have hinted at a law of economy toward which all great music strives. Brahms, in a characteristic piece of understatement, once said of composing that "the essential thing is that every note should be in its place." Beethoven expressed the same truth another way. Once, after he had heard the "Funeral March" from the opera *Achille* by the Italian composer Ferdinand Paer, he observed: "I must compose that!" To "fix" the idea, to define it, to pin it down—both composers felt that this was of the essence. Notes are redundant that do not stand for precisely those musical thoughts they are supposed to express. To have more notes, or less, than are actually required to communicate musical meaning must render such meaning correspondingly obscure. This law may be divided into three subsidiary principles.

First is the principle of identity between the idea and its utterance. There is a concrete musical difference between what a composer intends (the idea) and what he actually says (the utterance). Some musicians contend that the distinction is merely theoretical, that in practice it cannot be made. Fortunately, composers have left ample evidence to the contrary. Consider the act of revision. Revision is an acknowledgment by the composer himself that what he actually wrote was not, on reflection, what he actually meant. Revision is self-criticism. The very word implies that a composer has a re-vision of the work, that he returns to the utterance and modifies it in order to be truer to the idea. Revision can sometimes result in criticism on a grand, creative level. Composers occasionally revise the work of other composers with such effective results that the original composition may be eclipsed by the new version, the "criticism," often succeeding where the original work failed. Bach's arrangement (in A minor) for four harpsichords of Vivaldi's *Violin Concerto in B Minor,* for example, is more than an adaptation from one medium to another. It is an act of musical criticism *par excellence.* Vivaldi created the idea. But it was left to Bach to give it complete utterance.

Revision as self-criticism

Second is the relation of form and content. Why does music unfold a particular structure? Why that kind of structure rather than another? The textbooks on form remain silent. Yet this is a profound question. It is surely of paramount interest to know why music unrolls in one direction rather than another. Inspired music appears to carry within itself its own blueprint, according to which it propels itself across precise distances and in precise directions. If it is prematurely halted, diverted, or too long continued—all hallmarks of creative immaturity—it loses the sense of punctuality, the feeling of arriving "on time," the knowledge of being in the right place at the right moment, which characterizes each stage of an emerging structure masterfully handled.

The importance of structure

Some musicians have observed that the distinction between form and content is a false one. They rightly argue that no one hears one without the other, that the one is an organic result of the other. Therefore, why not abolish the distinction? They are right in regard to good forms, forms that arise inevitably from the musical material, in which case there is indeed no distinction to abolish. But bad forms, those that are not true to their content, produce a symptomatic division between the inner direction the music was born to follow and the outer direction it was made to follow.

The third subsidiary principle is audibility. The objective of all compositions is to make a total aural impact. There have been some famous miscalculations, intrinsically inaudible passages, which even the most illustrious performance could not render audible. A striking case of inaudibility occurs toward the end of Grieg's *Piano Con-*

certo in A Minor, in which the "big tune" of the finale returns in full orchestral splendour and obliterates the part of the solo pianist. In the concert hall, it is an extraordinary sight to see the soloist racing up and down the keyboard, fortissimo, without producing any sound. The observation is beyond all question and may be checked every time the work is played in public.

In 1937 Schoenberg completed an orchestration of Brahms's *Piano Quartet in G Minor*, Opus 25. As a young man, he had regularly participated in performances of the quartet. Time and again, he was bothered by its intermittent inaudibility: the piano tended to swamp the strings. Schoenberg's orchestration, as he himself claimed, attempted to put matters right. It remains an exercise in musical audibility—one master helping another to communicate. It constitutes an act of criticism on the highest creative level.

Other principles could be formulated to show that a theory of criticism is also a theory of composition. A search for these principles is really a search for the ultimate justification of the feelings of value inspired by great music.

Criticism and performance. Since music does not exist until it is brought to life by the player, two basic requirements are demanded of the critic: a knowledge of the work and a knowledge of the instrument. Many critics talk loosely about "the work" and "the performance" as though they were separate aspects of musical experience. They are, in fact, different aspects of a total musical experience, and it can be misleading to split them. Much bad criticism results from trying to do so. The Polish-American pianist Leopold Godowsky used to survey his audience before commencing his recitals in an endeavour to discover how many "detectives" there were in the house. Being such a superb pianist, he attracted all those critics exclusively interested in keyboard gymnastics. On the other hand, those interested exclusively in the composition may be equally biassed. In this age of authenticity, when the urtext is the thing, many a promising career has been blighted through what, in the profession, is called a "departure from the text." It is not always appreciated that at least a part of the total musical experience is created by the performer, who has a twofold artistic duty: first, to the fundamental character of the work he interprets; and, second, to his own artistic conscience, which tells him how the work should unfold. The two are not necessarily mutually exclusive.

The performer's duty

The criticism of performance is the most public, and publicized, aspect of a critic's function. It is also the least important. Unfortunately, what particular critics think of particular artists accounts for most contemporary music criticism. This is due rather to arbitrary factors than to the critic's sense of priority. Most newspapers insist that a musical event be reported the following day. The critic, consequently, is forced to telephone his review to his newspaper immediately after the concert, limiting himself to a strictly prescribed number of words. Under these conditions, it is not surprising that most criticism consists of predictable accounts of what was played, who played it, and how it was played. Nevertheless, performing artists are obliged to rely on these critical notices if they are to secure further work, even though neither critics nor artists like it. The box-office economics of performance are so delicate that bad publicity, or no publicity, can wreck artists and management alike.

(A.W./Ed.)

PERFORMANCE

Musical performance is that step in the musical process during which musical ideas are realized and transmitted to a listener. In Western music, performance is most commonly viewed as an interpretive art, though it is not always merely that. A performer to some degree determines aspects of any music he plays. Issues of tempo, phrasing, dynamics, and, in some types of music, pitches and instrumentation are subject to a performer's discretion. In this section, the various aspects and traditions of musical performance in Western and non-Western civilization are treated and their development traced.

Because the pleasure people derive from sounds has always been closely related to the pleasure they derive from making the sounds themselves, it is difficult to conceive of the origin of music as separate from an act of musical performance. Models for the establishment of rhythm may be found in heartbeat and breathing, and in the inflections of speech and cries of grief, pleasure, and desire are found the source of what became song.

The earliest visual manifestations of musical performance are found in rock paintings and excavated objects. While the interrelationship of music and ritual is clear, there is evidence that music was performed for dancing, in various work activities, and primitive games as well. Flutelike instruments of many sizes, made from bones and wood, and elaborate percussion instruments figure prominently in all primitive cultures, in which these instruments often were assigned symbolic significance associated with forces of the supernatural.

Singing is most probably the oldest musical activity. Even in the most primitive cultures the singer has had a special, defined position. In primitive singing there are three classes of sound: the first is called logogenic, in which words form the basis for the wavering musical incantation; the second, called pathogenic, consists of harsh, forceful, percussive, nonverbal sounds emitted to express strong feeling; in the third category, called melogenic, the sounds of the two previous categories combine to form a contour of pitches that pursue a course seemingly dictated by the weight of tensions inherent in the sequence of pitches and hence melodic in effect.

Primitive societies evolved several means to relieve the monotony of one person's singing. A principle device is called antiphony, which involved two groups that sang in alternation or a leader who sang and was answered by a group of singers. In the latter may be seen the origin of responsorial singing, which continues today and which may be the point of origin for several types of musical phrase structures. Polyphony was also anticipated in primitive musical performance. It appeared through haphazard rather than intentional manifestations, such as the singing of the same melody with the parts starting on different pitches or at different times.

Primitive antiphony

This section deals primarily with Western musical performance and its history but also deals briefly with non-Western traditions.

Aspects of Western musical performance. *The performer as interpreter.* Music as an interpretive art is a relatively recent phenomenon. In primitive societies, music plays a ritual role based on an oral tradition, and each performer in a sense interprets the tradition, but, more importantly, he renews it and transforms it through his own performance.

The development of the performer's role as interpreter coincided with the development of musical notation. Because composers for so many centuries were in a position to supervise the performances of their music, certain aspects of performance were not notated. Notation has grown increasingly complex as the dissemination of printed music has become more widespread. Ultimately, the degree of judgment a performer may exercise is determined by the period in which the music was composed. For music of certain periods, even though their notational systems are incomplete and give few indications of how the music should sound beyond pitch and rhythm, musical scholarship has amassed much information concerning proper instrumentation, ornamentation, improvisation, and other traditional performing practices that determine to a large degree the sound and stylistic character of the music. A performer as interpreter operates within a range of limitations imposed upon him by his understanding of the printed page, whatever knowledge may be available concerning the tradition that surrounds the music he is playing, and the extent to which his personal tastes coincide with this information. Certain aspects of the musical taste of the past sometimes cease to be expressive and gradually disappear from usage. Just as often, with the passage of time, performers tend to reassess the literature of previous ages and find renewed interest in practices that an earlier generation may have set aside. In any case, the performer as interpreter speaks to and with the tastes of his own

time. And his task, no different from that of the performer in primitive music, is to renew, to refine, and to enrich the materials and traditions he inherits.

Mediums of performance. The mediums for musical performance are extraordinarily various. Western technology has had a tremendous impact on the development of musical instruments and has thereby greatly expanded the means whereby music is made. Performance may be vocal, instrumental, or electronic. Vocal performance is the oldest and the primary influence for the development of all subsequent musical gestures and materials. Instrumental music began with the development of percussion instruments and crude horns; stringed instruments came later. Electronic music is a 20th-century development involving the reproduction of traditional performance mediums through electronic means, at the same time that it is also evolving composition and performance of its own. At first it reproduced natural sounds by electronic means; later, composers and technicians began to invent electronic sounds and to discover new sound relationships.

Vocal, instrumental, and electronic performance

In all musical mediums the solo performance is the most spectacular. The power of music to compel attention and to stir emotions lends to the solo performer an especially fascinating aura. This is the domain of the virtuoso, that musical performing phenomenon of prodigious technical mastery, invention, and charisma. Most solo literature includes another instrument or group of instruments, and the literature varies from one medium to another according to the expressive range and technical capabilities of the solo instrument.

The largest solo literature for a single instrument is for keyboard instruments. Vocal solo literature is very important and extensive, and the stringed instruments also have a distinguished solo repertoire. The wind, brass, and percussion solo literature is more restricted.

In vocal and instrumental chamber ensemble performance, the performing groups are divided into duets, trios, quartets, quintets, sextets, septets, and octets, which exist for every medium and combination. Of particular importance is a string quartet consisting of two violins, viola, and violoncello. Dating from the 18th century, this instrumental ensemble is analogous to the vocal ensemble consisting of soprano, alto, tenor, and bass.

Beginning of symphonic music

Symphonic music dates from the 17th century. With the rise of the middle class and its aspirations for culture, music as an art required performing situations that would accommodate more people. Larger halls required ensembles acoustically suited to the expanded performing areas. The primary result of this development was the symphony orchestra with its multiple stringed, wind, brass, and percussion instruments.

Ensemble performance places a special responsibility on the concentration of the performer, who must attend not only to his own playing but also to that of all the others in the ensemble. All aspects of the performance depend on this mutual awareness. The leader of most small ensembles is one of the performers, the first violinist, a keyboard player, or one of the singers who indicates tempi, entrances, and musical character and supervises rehearsals. As ensembles grew in size and complexity and their problems of coordination increased, the leader set aside his instrument and devoted his efforts to the beating of time and the communication through clear hand signals of his indications for entrances, tempo changes, dynamic accents, and the shaping of phrases. This leader is called a conductor. The conductor often occupies a position analogous to that of a soloist in the attention of an audience, though the conductor himself makes no musical sound. As they are chiefly responsible for the music orchestras play, both in terms of choice and execution, conductors have had considerable impact on the development of music.

Opera, the marriage of music and drama, is the most complex performance situation. It entails much more than a single performer or group of performers, their instruments, and a hall in which to play. Text, decor, costumes, histrionic projection, preparation time, as well as singers, instrumentalists, and a bevy of extramusical technicians, must all be brought together and coordinated into the final production.

Artistic temperament. Many forces interact in developing those traits that distinguish various performing traditions and individual performers. Personality and temperament fundamentally affect the manner in which a performer works, as does his cultural milieu. There are performers who use music as a vehicle for display and others for whom performance is only a means to illuminate the music. Nor does performance necessarily mean public performance. For some people musical performance is essentially private, requiring no confirmation in the form of audience approval. The musical pleasure of such people rests solely on performing, either alone or with other musicians. Much chamber music is played under these private circumstances, and much music has been written for such situations. This used to be the primary realm of the musical amateur, that skilled but nonprofessional music lover whose ranks are diminishing in the era of the phonograph.

The type of performing situation at the opposite end of the spectrum is one directed to securing audience attention and affection. The need for audience approval has led to innovations as well as some decadence in its impact on the musical scene: innovation, if the performer is led to discover imaginative and fresh means of attracting public acclaim; decadence, if the devices for audience attraction become cheap and thinly spectacular, when the performer may distract the audience from more deserving work and debase its taste.

Intuition versus intellect

Intuition and intellect figure prominently in the temperament of a musical performer. Intuition is the capacity to do the musically "right" thing without instruction or special consideration of the alternatives. Intellect is the means whereby a musician enlarges the range of his instincts through the pursuit of new information, reflection, and analysis of the musical material at hand. Each element informs and completes the other.

Many musicians depend heavily on intuition in solving performance problems. Their solutions are often imaginative and fresh and their performances exciting. Others pursue a methodical path as they examine minutely relevant musical details. They analyze thoroughly the scores they perform, comparing manuscript facsimiles and various printed editions, and attempt to discover new musical relationships, new ways of delineating these relationships in performance, and, in short, new ideas as to how the music might best be played and how it should sound. Art, poetry, biography, cultural history, and any material relating to the period of the piece of music being studied for performance may be sources of musical insight for the performer.

National characteristics. At various times in history, national origin has been considered an important delineating characteristic in musical performance. This is partly the result of certain consistent emphases and features in the music written by composers of different nationalities. The Italians' interest in the voice has evolved a special singing (bel canto) quality in their music, which has carried over into their music for instruments (the stringed instruments especially), and into the general texture of Italian music, which has always given melody special prominence.

The English have had a highly developed and sophisticated musical performance tradition. Amateur improvisation figured importantly in its early history. While this has perhaps tended toward a conservative musical atmosphere, it has also produced a high standard for performance. The French have maintained a strong sense of national identity in their performing arts. In music their concerns for orderly design, delicate expressiveness, simplicity, naturalness, and beauty of sound extend back for centuries. Articulate philosophical and structural considerations have played important roles in developing nationalistic traits in the German tradition of musical performance.

The rich folklorist traditions of Spain, Hungary, and Russia have influenced rhythm, melody, and sonority in Western musical performing traditions. The Russian schools of string and piano technique have greatly advanced the performance resources of these instruments in the past 100 years. The United States, younger and more heterogeneous, has had a shorter musical history but an

abundance of great symphony orchestras and solo artists, who are in demand because of their precise execution, versatility, and breadth of repertoire.

Historical stylistic developments. In antiquity the Sumerians, Egyptians, Greeks, and Romans evolved the first aesthetic theories and musical systems relevant to the music of the modern Western world. Unfortunately, few actual musical examples survive because of primitive notational practices and the gradual erosion of oral traditions. What is known is derived from the writings of the period and iconography—depictions of performing musicians, instruments, and musical events in sculpture and in wall and vase paintings.

In the Middle Ages traditions of musical performance were kept alive by the church and in the music sung and played by wandering minstrels.

In the Renaissance, polyphony (combining several simultaneous voice parts) and the early precursors of modern tonality (organization of music around a focal tone) were developed. The smooth flow of Renaissance liturgical counterpoint (polyphony) and the perky rhythms of secular Renaissance dance music remain as models of taste and musical technique even into the 20th century.

Developments in the Baroque

The performer emerged as a central figure in the focus of musical attention and purpose during the Baroque period. The heightening of the role of the individual performing artist and the invention of increasingly dramatic gestures to demonstrate performers' skills combined with a steady refinement in the construction of musical instruments. The reduction of musical materials to two modes (scale and melody patterns), in this case the major and minor scales, and the initial efforts to compose with large musical forms (opera, oratorio, sonata, and concerto) took place in this period. It is notable that in the Baroque era the equal-temperament system for tuning the strings or pipes of keyboard instruments evolved—a development that has had profound effect on the nature of musical language.

In the Rococo or Classical period that followed, the elaborate contrapuntal texture of Baroque music gave way to music of subtle dynamic differentiation, often based on simple folk materials (rhythms and melodies). The relationships between tonal materials and large musical forms achieved their highest state in the sonata and in opera.

The Romantic age was a period of refinement and intensification of Rococo principles with heavy literary overtones. It was the true age of the star virtuoso; that is, the age in which the role, person, and effect of the virtuoso was most dramatized and glamourized. The symphony orchestra in this period achieved its maximum development. Italian opera under Verdi found its noblest expression and German opera with Wagner expanded into the *Gesamtkunstwerk* ("complete art work").

Modern music dates from an era beginning roughly around World War I. Concert life has remained more or less what the 19th century established; the virtuoso conductor and performer dominate the musical establishment. More chamber, symphony, and opera programs are performed in more parts of the world than ever before, but musical progress has ceased to occur in established organizations and is found instead in the combo: jazz, rock, improvisational, experimental, live electronic, and multimedia groups that have sprung up in the 20th century.

The development of Western musical performance. *Antiquity.* The civilizations of antiquity expanded the role assigned to music in primitive cultures. The Sumerians established the foundations for the tradition of liturgical music. Some of the prayers that they sang have survived. From various artifacts of this civilization something is known about Sumerian musical instruments and some of the situations in which music was played. Such instruments as the lyre, harp, sistra, pipes, timbrels, and various drums figured importantly. Particular instruments were identified as accompaniment with specific types of religious poetry, and indeed the development of different poetic genres seems to have been considerably influenced by the nature of these instruments. While its primary purpose was religious, music also had something of a secular role in Sumerian culture and was played in processions, at banquets, and during primitive sporting events. Music as a profession first developed in Sumerian culture. Both men and women participated as singers and instrumentalists and held priestlike positions with specific functions and ranks of authority.

The musical culture of ancient Egypt, which apparently emerged from the same primitive sources as Sumer, resembles that earlier culture in many aspects: the close relationship between music and religion, the presence of a musical profession, some secular musical activity, and similar musical instruments. Of special interest in Egyptian music is the development of chironomy, the use of hand signals to indicate to instrumentalists what they should play. The singer in this manner guided instrumentalists through melodies with which the singer was seemingly more familiar than the players.

In these ancient cultures there was no notational system or codified theory of musical practice. Different musical traditions were exchanged in the process of trade, migration, military conquest, and intermarriage to form that common body of practices that is the basis of Western music.

Importance of Greek music

Of the early civilizations, Greece provided the musical culture of greatest significance for the development of Western music. The system of scales and modes, as well as a large part of the general philosophy concerning the nature and effect of musical sounds, has been inherited from the Greeks. It was also the Greeks who developed the theory of ethos, which defines the character of psychological and emotional response to different musical stimuli. Building on the ancient religions and magical accoutrements of music, the Greeks assigned specific mental and emotional states to specific pitch arrangements and instrumental combinations. Music infused with this motivating power stood at the centre of the social order.

Though a major part of Western musical terminology, basic music theory and philosophy, basic notational practices, and the foundations of acoustical physics derive from the ancient Greeks, very little of their music has survived. The great ethical significance of music in Greek society caused performing mastery to be an essential aspect of education. Everyone was taught to sing and to play instruments. For a major part of the period all music was a setting of words with instrumental accompaniment, for the most part doubling the voice at the interval of octaves, fourths, or fifths. It was only in the later part of the period, after the age of Pericles (late 5th century BC), that instruments began to play independently of singers.

Music, in the later stages of the Hellenic period, became an increasingly important part of public spectacles. As musical performance became increasingly secularized and became the property of the masses, the upper classes withdrew to esoteric considerations of the art and reflections on its past. It was perhaps at this point that music was divided into two fairly artificial categories: the contemplation of music's nature and history and practical musical performance.

Assuming the artistic mantle of ancient Greece, the Romans disseminated Greek music throughout the known world. The essential role of music in the Roman Empire remained unchanged. Rome's principal contribution consisted in serving as a catalyst for the mixing of Hebraic and Hellenic traditions of musical performance, which, preserved by the Christian Church for a thousand years, emerged again in the Renaissance into the first flowering of modern musical practices in the West.

Although not in the mainstream of Western musical performance, Islāmic (North African and Near Eastern) classical music closely approaches the orchestral tradition of European music in one respect: large choruses and orchestras—consisting of tambourines, pot drums, recorder-flutes, *'ūds* (plucked lutes), bowed lutes, and dulcimers—are assembled to perform "suites" consisting of a series of instrumental solos and orchestral selections interspersed with unison choral songs or solo recitatives based on classical poetry. But while these suites are perfectly suited to performance in formal concert halls, they may also be heard in much less regulated settings, such as cafés. Here the listener is free either to concentrate intellectually on the progress and development of the musical ideas or to

"Oriental" side of Islâmic musical performance

converse and eat, relaxing in the beauty of the general musical design. The more "oriental" side of Islâmic musical performance is more improvisatory, either in solo performance on a recorder-flute, fiddle, *'iúd,* or dulcimer or by any of these in combination with the voice—the instrumentalist then elaborating on the singer's improvisation. Here, too, the relationship of audience to performer is much less formal than in the performance of European music.

The Middle Ages. The tradition of sung prayers and psalms extends into the shadows of early civilization. Such sacred singing was often accompanied by instruments, and its rhythmic character was marked. In the synagogue, however, the sung prayers were often unaccompanied. Ritual dance was excluded from the synagogue as the rhythmic character of sacred music surrendered its more sensual aspects. Even in the prayers themselves, rhythmic verse gave way to prose. The exclusion of women, the elevation of unison singing, and the exclusion of instruments served to establish a clear differentiation between musical performance in the synagogue and that of the street.

The musical performance tradition of the Christian Church grew out of the liturgical tradition of Judaism. The melodic formulas for the singing of psalms and the sung recitation of other scriptural passages are clearly based on Hebraic models.

Music in the Roman Catholic liturgy was performed mainly for the mass. Originally, the music was performed by the priest and the congregation, until, in time, there emerged from the congregation a special group of singers, called the choir, who assumed the musical role of answering and contrasting the solo singing of the priest. Women participated actively in musical performances in the ancient Christian Church until 578, when older Hebraic practices excluding them were restored. From that time until the 20th century, Roman Catholic Church choirs were composed solely of men and boys.

First codification of church music

The first codification of early church music was reputedly made by Pope Gregory I during his reign (590–604). Gregory's collection was selected from chants already in use. His codification assigned these chants to particular services in the liturgical calendar. In general it reinforced the simple, spiritual, aesthetic quality of liturgical music. The music in this collection serves as a model of melodic design even in the 20th century and is regarded as one of the monuments of Western musical literature. This school of unison liturgical singing is called plainchant, plainsong, or Gregorian chant. Specific details concerning the manner in which chant was performed have been lost. There are speculations that the quality of sound the singers employed was somewhat thinner and more nasal than that used by contemporary singers. The authentic rhythmic style of chant cannot be ascertained. There is a theory, however, that the basic rhythmic units had the same durational value and were grouped in irregularly alternating groups of twos and threes. Pitch levels and tempos apparently varied somewhat according to the occasion. There are preserved manuscript notations reminding singers to be careful and modest in their work, indicating that temptations of inattention and excessive vocal display existed for even the earliest liturgical musicians.

While modern musical traditions in the West are based to a large extent on the principles of antiquity preserved in the notated music of the early church, a secular musical practice did exist; but because of the pervasive influence of the church, the dividing line between sacred and secular aspects was thin throughout a good part of the medieval period.

Several types of later secular song have survived. The musical notations are for the most part inadequate to give an accurate impression of the music, but it is known that it retained the essential monophonic character of liturgical music. One curious type of secular song, conductus, originated in the church itself. This song did not use traditional liturgical melodies or texts but was composed to be sung in the liturgical dramas or for processions. For this reason it dealt occasionally with subjects not religious in character. The goliard songs dating from the 11th century are among the oldest examples of secular music. They were the often bawdy Latin songs of itinerant theological students who roamed rather disreputably from school to school in the period preceding the founding of the great university centres in the 13th century.

Several other groups of medieval performers developed literary and musical genres based on vernacular texts: the jongleurs, a group of travelling entertainers in western Europe who sang, did tricks, and danced to earn their living; the troubadours in the south of France and the trouvères in the north; and the minnesingers, a class of artist-knights who wrote and sang love songs tinged with religious fervour.

Instruments, such as the *vielle,* harp, psaltery, flute, shawm, bagpipe, and drums were all used during the Middle Ages to accompany dances and singing. Trumpets and horns were used by nobility, and organs, both portative (movable) and positive (stationary), appeared in the larger churches. In general, little is known of secular instrumental music before the 13th century. It is doubtful that it had a role of any importance apart from accompaniment. Yet the possibility of accompanied liturgical music has not been eliminated by modern scholars.

Medieval polyphony

The medieval musical development with the furthest-reaching consequences for musical performance was that of polyphony, a development directly related, as indicated above, to the experience of performing liturgical chant. For performers and performance, perhaps the most important developments in the wake of polyphony were refinements of rhythmic notation necessary to keep independent melodic lines synchronous. At first the obvious visual method of vertical alignment was used; later, as upper voices became more elaborate in comparison with the (chant-derived) lower ones, and writing in score thus wasted space, more symbolic methods of notating rhythm developed, most importantly in and around the new cathedral of Notre-Dame in Paris.

In the 14th century, partly because of the declining political strength of the church, the setting for new developments in music shifted from the sacred field to the secular, from the church to the court. This shift led in turn to a new emphasis on instrumental music and performance. Already the lower voices began to be performed on instruments—both because their long notes made them difficult to sing and because their texts (of only a few syllables) became senseless outside their original liturgical positions. Now, as secular princes became increasingly important patrons of composers and performers—a situation that would continue well into the 18th century—secular and instrumental music flourished. The polyphonic music of the church merged with the poetic art of the troubadours, and the two most important composers of the age were the blind Florentine organist Francesco Landini and the French poet Guillaume de Machaut, canon of Reims.

Most of the music of these composers seems to have been intended for combined vocal-instrumental performance, although this is seldom expressly indicated in the manuscripts. Medieval composers probably had no rigid expectations about performance media. Until the 17th century, and even through the 19th in the case of domestic performance, choice of instruments was likely to be dependent as much on available performers as on anything else. Many sources do, however, indicate that medieval musicians tended to separate instruments into two groups, loud and soft (*haut* and *bas,* or, very generally, wind and string), and to prefer contrasting sonorities within those groups for maximum differentiation of the individual parts. Outdoor or ceremonial music would be performed with loud instruments (shawm, bombard, trombone, organ); room music, with soft ones (lute, viol, recorder, harp). Paintings and manuscript illuminations of the period show that much secular performance included both a wide variety of bells, drums, and other percussion instruments and instruments with drones—bagpipes, fiddles, double recorders, hurdy-gurdies. The parts for these instruments are never found in the musical sources and must be reconstructed for modern performance.

The notation of medieval music often is misleading for the modern performer. Accidentals (sharps and flats, called then musica ficta) were often omitted as being understood.

Notation of medieval music

Further, it seems likely that variation, embellishment, and improvisation were very important elements of medieval performance. It is known that sections of some 15th-century two-part vocal music were enhanced by an extempore third part, in a technique called fauxbourdon; the notation of the 15th-century *basse danse* consisted of only a single line of unmeasured long notes, evidently used by the performing group of three instrumentalists for improvisation, much as a modern jazz combo's chart.

The Renaissance. The very concept of improvisation as a mere subcategory within performance practice could arise only after the invention of music printing, which had at first little discernible effect on performance. Extemporized ornamentation of polyphonic music continued and increased during the 16th century in instrumental, vocal, and combined performance, both secular and sacred. Later in the century, liturgical music again became less extravagant in the wake of the Council of Trent (1545–63), which ordered that masses be sung "clearly and at the right speed" and that singing "be constituted not to give empty pleasure to the ear, but in such a way that the words may be clearly understood by all." Music printing was at first too expensive to alter seriously the social structure of musical performance; the traditions of ostentation and exclusiveness embodied in music written by Guillaume Dufay for the early 15th-century Burgundian court were continued in the magnificent musical establishments of the Italian Renaissance princes and popes. Detailed records exist of the elaborate musical festivities arranged for weddings and baptisms of the powerful Florentine family, the Medici. Printing increased the dissemination as well as the survival of these works; but, like the earlier Burgundian chanson and unlike the contemporary Parisian chanson, which was cast in a more popular mould, they were nonetheless primarily intended for a select group of discriminating performers.

Printing, both of music and of books, does document the ever increasing development and sophistication of instrumental music during the 16th century. Printed descriptions of instruments date from the 16th century. Their discussions of tuning and technique supplied the needs of professional and nonprofessional musicians alike. There was a growing tendency to construct instruments in families (whole consorts of homogeneous timbre, high, middle, and low), a tendency perhaps related to recent expansion at both ends of the musical scale: with more space available, contrapuntal parts no longer crossed so frequently and no longer needed the differentiation provided by the markedly contrasting timbres of the medieval "broken consort."

The 17th and 18th centuries. After printing, the next significant influence on music performance was the gradual emergence of the audience, for the relationship between participants in the musical experience—between performer and listener—became polarized. The first evidence for this shift was the rise of the professional vocal virtuoso about the last quarter of the 16th century, and this development soon had a profound influence on musical style. Italian composer-singers, such as Giulio Caccini and Jacopo Peri, reacted quickly to their audiences' desire for more expressive and passionate vocalism, and the music they wrote for themselves eventually was imitated and refined by other composers, such as the Italian Claudio Monteverdi, whose nine successive books of madrigals document the changes in style from music composed for four to six essentially equal voices to music in which the interest lay primarily at the extremes of the texture. The technical underpinning for this new monodic style was the basso continuo, or thorough bass, played by one or more polyphonic solo instruments "realizing" a "figured bass": that is to say, improvising chords above a single line of music provided with numbers and other symbols to indicate the other notes of the chords. In the 17th century a wide variety of continuo instruments was used, including lute, theorbo, harp, harpsichord, and organ. By the 18th century the practice was more standardized: the bass line would be realized on a keyboard instrument and reinforced by a monophonic bass instrument, such as a lute, viola da gamba, violoncello, or bassoon. The continuo player not only completed the harmony but could also control rhythm and tempo to suit the particular conditions of a performance.

Rise of the vocal virtuoso

The development of monody was itself a necessary precondition for that most expensive of all performance institutions, opera. Beginning in Florence at the very end of the 16th century, opera soon spread over Italy: through Rome, where its initially pastoral nature matured into full-blown spectacle, to Venice, where the first public opera theatre opened in 1637. There, although audiences were still aristocratic, opera was dependent upon the sale of admissions rather than royal patronage, and musical performance began to find an entirely new method of economic support.

In the realm of purely instrumental music, the new economy of performance was slower to emerge, but there were many other new developments. By far the most popular Renaissance instrument had been the versatile lute; it served all levels from the merchant's daughter learning the simplest dance melody to the virtuoso. In the 17th century the lute began to yield to keyboard instruments, but the intimate music of the French *clavecinistes* (harpsichordists) was still a clear outgrowth of the precious and evanescent performance style of the lutenist Denis Gaultier (1597/1603–1672). Later, keyboard ornamentation began to be codified in tables of agrément-symbols published with each new collection of music. In Italy composers also were attempting to provide performers with more explicit directions. Contemporary keyboard fingering systems, which used the thumb much less than modern ones, also served contemporary preference for subtlety and unevenness of rhythm. As the century progressed and national styles drew further apart, there evolved a specifically French tradition of *inégalité:* performing certain evenly written notes unequally, with alternately longer and shorter values.

Predominance of keyboard instruments

A more lasting French development was the first instance of instrumental music consistently performed by more than one player to a part. In 1656, Jean-Baptiste Lully made his orchestra, the Petits Violons ("Little Violins"), abandon the old tradition of free embellishment and drilled them in a disciplined and rhythmically pointed precision that was widely imitated. Simultaneously, the violin and its family, because of their passionate brilliance and versatility, replaced viols as the standard ensemble instruments—especially quickly in Italy, where performance was less sophisticated, less mannered, and less restrained than in France.

In the 18th century, national performance styles tended again to merge, except in the case of opera. French opera, which had reached its first height under Lully and had counted among its star performers Louis XIV himself, continued to emphasize ballet and correct declamation more than pure vocalism. In other areas, standardization and codification were the trend. The place of improvised embellishment and variation was further circumscribed, limited in general to such recognized spots as repeated sections in binary and da capo forms, slow movements of sonatas and concertos, and cadences. Instrumental tutors by famous performers were important and widespread.

Foundation of public concerts

The foundation of public concerts increased, and orchestras all over Europe followed the pattern set by the famous ensemble maintained by the Elector of the Palatine at Mannheim, with its standard size (about 25) and new style of performance with dramatic dynamic effects and orchestral devices (*e.g.,* crescendos, tremolos, grand pauses). The Mannheim composers also hastened the decline of the improvised thorough bass by writing out harmonic filler parts for the violas; conducting from the keyboard nevertheless remained standard practice into the 19th century. Meanwhile, entrepreneurial speculation was finally supplanting aristocratic patronage as the economic base for concert activity. Haydn, who had already spent one full career in Austria, in the service of the House of Esterházy, in 1791 began another and more lucrative one in association with the concert manager Johann Peter Salomon—conducting his London symphonies from the piano.

The 19th century. The heyday of the concert artist began before Haydn's first journey to London, and it still shows few signs of ending. It reached its zenith and was the

primary factor in all music performance in the 19th century. Mozart and Beethoven were famous concert pianists before they were famous composers, and succeeding generations saw a large number of piano virtuosos travelling over Europe and, later, North and South America. Some were composers of works for themselves; others were more important as interpreters of other composers' works. The tradition of the star singer was of course much older, and it continued; one new development was that of the claquer, paid by the star for his applause. The independent conductor, as distinct from the first violinist or the continuo player, emerged from the body of the orchestra during the first half of the 19th century, and his development toward the lionized figures of the 20th century was swift. Parallel with this rise came the establishment of many of today's major orchestras: New York Philharmonic (1842), Vienna Philharmonic (1842), Boston Symphony (1881), Berlin Philharmonic (1882), Amsterdam Concertgebouw (1883), Chicago Symphony (1891), and London Symphony (1904).

Establishment of major orchestras

The result of the enormous widening of concert activity and of the increasingly international reputations of performers was an even further standardization of performance practice. Eighteenth-century concern with appropriateness and taste in embellishment yielded to emphasis on clarity and evenness of touch, purity of intonation, and accuracy of execution. As composers' scores became increasingly precise, the performers' interpretative decisions were increasingly limited to matters of technique, tempo, rhythmic and dynamic nuance and personality—a subjectivism justified by the cult of Romantic genius prevalent in 19th-century artistic life. Real improvisation in music would not re-emerge until the 20th century—in jazz. The addition of such mechanical aids and improvements as chin rests and end pins to stringed instruments (which permitted a wider and more constant vibrato without tiring); valves and extra keys to brass and woodwind instruments (making scales more even and intonation more secure); and double-escapement action, iron frames, and cross-stringing to the piano (which facilitated crisper and surer attack and made both tone and tuning last longer) all had profound influence not only on performance techniques but also on the very sound of the instruments. The most successful new instrumental and vocal teaching methods emphasized virtuosity, brilliance, evenness, and wide range, reflecting a desire to make music more effective for large audiences.

Technical advances in instruments

The rise of the concert artist was seconded by the appearance of the professional music critic, whose influence on performance has been, and is, difficult to assess. At first critics tended to be primarily practicing musicians; later this was less the case. A more tangible residue of 19th-century music performance and one that illustrates how little its basic social structures have changed since then is the large number of concert halls and opera theatres that were built and are still used today.

One final development, the import of which would not be fully realized until the present century, was that of historicism: the active revival of old music. This incipient recognition of the validity of other styles of composition and performance is dated conventionally from the German composer Felix Mendelssohn's 1829 performance of parts of Bach's *St. Matthew Passion,* but it was preceded in a sense by the Concerts of Antient Music (1776–1848) in London. The stated policy of this musical group was not to perform music less than 20 years old (but they often updated the compositions with added brass parts). The revival of interest in the music of Palestrina and Bach, while at first expressed only in terms of 19th-century Romanticism, would pave the way for 20th-century advances and retrenchments in both style and performance.

The 20th century. The major performing institutions of the 19th century have continued into the 20th century with only minimum structural change, except for a rather belated movement toward unionization of personnel; this development has of course improved the performers' lot greatly, while increasing the costs of performance. Unquestionably, the major new influence on 20th-century music performance has been electronics. Broadcasting and recording have widened even further the potential audience for concert artists, at the same time as they have tended to decrease the physical necessity for large new public performance arenas. Electronic instruments have appeared, both amplified versions of older ones (guitar, piano, and even some woodwinds) and instruments with fundamentally electronic means of tone production (electronic pianos and organs, the theremin and Ondes Martenot, and sound synthesizers). Other new compositional and performance possibilities have also developed; for example, film, tape, stereophonism, and computers. Even before the phonograph (invented *c.* 1875) had begun to be regarded as more than a toy, serious research into the authentic performance of older music had produced an awareness of possibilities that pointed the way out of the seeming dead end of late Romantic gigantism and subjectivism. From the very beginning of the century, the chamber concerts given by Arnold Dolmetsch and his family, on reconstructions of old gambas and recorders, attracted attention to small ensembles and different sonorities and encouraged the activities of other artists.

Appearance of electronic instruments

The true end of the Romantic era and the beginning of the modern era can be dated from the second decade of the 20th century, the time of the composition of two masterpieces that more than any others mark the departure from 19th-century performance ideas: the German composer Arnold Schoenberg's *Pierrot Lunaire* (1912) and the Russian composer Igor Stravinsky's *Histoire du soldat* (*The Soldier's Tale,* 1918). These are chamber works, but their instrumental makeup is a unique mixture of instruments that do not necessarily blend and that seem further to repudiate the orchestra as a performing medium. *Pierrot* is a series of songs which repudiate the 19th-century lied: the voice does not sing but produces a kind of pitched speech (*Sprechstimme*). *Histoire* repudiates both orchestra and opera as previously understood: it is specifically (and inexpensively) designed for performance on a portable stage by three dancers, a narrator, and seven instrumentalists. For these works a new kind of performer is required, and these works in turn have helped to train the new performer—who might be called the group-virtuoso. Teams or groups of such performers have sprung up everywhere. Often they are centred on a living composer or the university where he teaches, where they function as partners to his composition, realizing the work rather than interpreting it. The performer is very much involved in the creative act, the product of which reflects his particular skills and personality, and the dynamics of the working situation.

In the second half of the 20th century the established performance situation moved from the formal, ritualized event of the past to a more informal and spontaneous type of gathering. The interaction of various media has led to new art forms and circumstances. Many artists attempt to create performance situations that actively involve as participants all those in attendance. The roles of composer, performer, and listener are consolidated in a single participant, who in interaction with others arrives at an art work, which all have invented, realized and perceived, and which can never take place again. On the other hand, the growing use of technology intensifies the problem of evaluating the meaning and effect of electronically produced and assembled performances that, in their totality, never took place at all and possibly never could.

Increasing spontaneity of performance situations

The electronic media continue to improve so that anyone may be able to select chamber, concert, opera, and other new types of performance from anywhere in the world, experiencing them through nearly lifelike reproduction facilities. Vast numbers of people may study performance skills via two-way transmission with great artists. The number of actual public performing events may decrease as private musical performance increases. Already there is the phenomenon of the widespread dissemination of great performers' recordings, which has forced the standards of quality for a live performance to almost inhuman heights and has increased interest in the performance of older as well as contemporary music.

Non-Western musical performance traditions. *South Asia.* Although the classical South Asian or Indian musician usually performs in a concert situation quite analogous to that of a typical Western artist, his audience

responds to him quite differently: he is not judged on how faithfully he reproduces the music the composer imagined but on how well he creates his own music within certain wide bounds set by the composer and by the general practice of Indian music. Since Indian musical performance is based on improvisation, Indian musical pedagogy is therefore a more personal procedure, in which an aspiring musician will "apprentice" himself to a guru, with whom he thereafter identifies himself; in the West this kind of organization is reflected in the rise of the group-virtuoso discussed above. Similarly, Western development away from large performing groups such as the full orchestra reflects—or at least parallels—the more intimate character of Indian music, the basic texture of which usually involves a quite small group of performers: one player to provide rhythm on a drum such as the double-headed, pitched tabla; one to provide a basic drone, often on the lute-like tamboura; and a central performer on the sitar (technically also a plucked lute but one with melodic capability, unlike the tamboura). The players often engage in a kind of competition not unlike that of Western jazz groups. If there is singing, the style of performance is low and soft, in contrast to that of Indonesian classical vocalism.

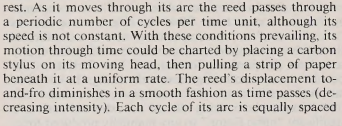
Intimate character of Indian music

Southeast Asia. The gamelan is at the center of the art-music tradition of Indonesia. It may range in size from a few to over 75 instruments. The basic melodic instrument is the *saron* (bronze xylophone), accompanied by various gongs, a kind of violin, a recorder-flute and/or a zither; the group is led by a drummer. As in medieval Western music, there are two kinds of gamelan playing, one emphasizing the bronze instruments (comparable to medieval *haut*, or loud, consorts) and the other the wind and stringed instruments (*bas*, or soft, groups). A similar differentiation exists in Indochinese music in the contrast between the percussion-dominated *pi phat* band of Thailand and the string-dominated *mahori* bands of Thailand and Cambodia. Gamelan playing, particularly of the softer type, often accompanies solo and unison choral singing of classical poetry (music is connected with most of Indonesian literature). Southeast Asian vocal performance—like that of a great deal of non-Western art music—is characterized by tense, high, often nasal voice production; this is one of many alternatives being explored by the more experimental 20th-century Western composers and performers.

China and Japan. The most extensively developed and most important Chinese and Japanese traditions of musical performance are closely tied to theatrical styles and traditions. Perhaps the most spectacular of non-Western performance traditions is Chinese opera, in which singers, acrobats, costumes, scenery, and instruments are combined in the creation of a highly varied work of art. Peking opera uses two basic kinds of instrumentation: for military scenes a battery of drums, gongs, and cymbals with a kind of oboe playing the melody; for the more frequent domestic scenes a wider variety based on a drum (*pan ku*) with a peculiarly sharp, cracking sound for keeping time, and a number of two-stringed, bowed lutes played with the bow passing between the strings. Plucked lutes and flutes also appear at times. All of the melody instruments play heterophonically with the singers, whose vocal style, as in the West, is highly artificial. Heroines are usually portrayed (sometimes by female impersonators) in a high, thin voice; heroes use a raucous, rasping tone quite foreign to traditionally oriented Western ears—but, again, not unlike some of the vocal techniques required by 20th-century Western avant-garde composers.

A performance tradition peculiarly Japanese is the emphasis on the visual aspects of making music: custom directs that *gagaku* (court orchestra) instruments must be played as gracefully as possible. (L.Fo./J.Th./B.A.C.)

Musical sound



That some sounds are intrinsically musical, while others are not, is an oversimplification. From the tinkle of a bell to the slam of a door, any sound is a potential ingredient for the kinds of sound organization called music. The choices of sounds for music making have been severely limited in all places and periods by a diversity of physical, aesthetic, and cultural considerations. This section will analyze those involved in Western musical traditions.

General characteristics. The fundamental distinction usually made has been between tone and noise, a distinction best clarified by referring to the physical characteristics of sound. Tone differs from noise mainly in that it possesses features that enable it to be regarded as autonomous. Noises are most readily identified, not by their character but by their sources; *e.g.*, the noise of the dripping faucet, the grating chalk, or the squeaking gate. Although tones too are commonly linked with their sources (violin tone, flute tone, etc.), they more readily achieve autonomy because they possess controlled pitch, loudness, timbre, and duration, attributes that make them amenable to musical organization. Instruments that yield musical sounds, or tones, are those that produce periodic vibrations. Their periodicity is their controllable (*i.e.*, musical) basis.

The strings of the violin, the lips of the trumpet player, the reed of a saxophone, and the wooden slabs of a xylophone are all, in their unique ways, producers of periodic vibrations. The pitch, or high-low aspect, created by each of these vibrating bodies is most directly a product of vibrational frequency. Timbre (tone colour) is a product of the total complement of simultaneous motions enacted by any medium during its vibration. Loudness is a product of the intensity of that motion. Duration is the length of time that a tone persists.

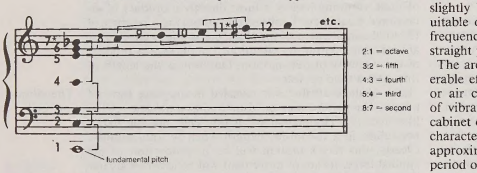
The vibrating reed

Each of these attributes is revealed in the wave form of a tone. The pattern may be visualized as an elastic reed—like that of a clarinet—fixed at one end, moving like a pendulum in a to-and-fro pattern when set into motion. Clearly, this reed's motion will be in proportion to the applied force. Its arc of movement will be lesser or greater depending upon the degree of pressure used to set it into motion. Once moving, it will oscillate until friction and its own inertia cause it to return to its original state of rest. As it moves through its arc the reed passes through a periodic number of cycles per time unit, although its speed is not constant. With these conditions prevailing, its motion through time could be charted by placing a carbon stylus on its moving head, then pulling a strip of paper beneath it at a uniform rate. The reed's displacement to-and-fro diminishes in a smooth fashion as time passes (decreasing intensity). Each cycle of its arc is equally spaced

Visual representation of a reed's vibration.

(uniform frequency). Each period of the motion forms the same arc pattern (uniform wave content). If this vibratory motion were audible, it could be described as follows: it grows weaker from the beginning (diminishing loudness) until it becomes inaudible; it remains at a stable level of highness (steady pitch); and it is of unvarying tonal quality (uniform timbre). If the reed were a part of a clarinet and the player continued blowing it with unvaried pressure, loudness, pitch, and timbre would appear as constants.

TONE



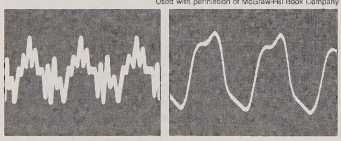
Most musical tones differ from the demonstration tone (above) in that they consist of more than a single wave form. Any material undergoing vibratory motion imposes its own characteristic oscillations on the fundamental vibration. The reed probably would vibrate in parts as well as a whole, thus creating partial wave forms in addition to the fundamental wave form. These partials are not fortuitous. They bear harmonic relationships to the fundamental motion that are expressible as frequency ratios of 1:2, 3:4, etc. This means that the reed (or string or

air column as well) is vibrating in halves and thirds and fourths as well as a whole. Another way of expressing this is that half the body is vibrating at a frequency twice as great as the whole; a third is vibrating at a frequency three times greater; etc.

Overtone series

These numerical relationships also are expressible by pitch relationships as the harmonic, or overtone, series, which is merely a representation of numerical ratios in terms of pitch equivalents. Depending upon its shape and substance, a vibrating mass performs motions that are the equivalents of these partial vibrations, whether it be the mass of a string, reed, woodblock, or air column. This means that most tones are composites: they consist of partial vibrations of the vibrating body as well as the vibrations of the whole mass. Although one can develop the acuity required to hear some of these overtones within a musical tone, the ear normally ignores them as separate parts, recognizing only a more or less rich tone quality within the fundamental pitch.

Although pure tones, or tones lacking other than a fundamental frequency, sometimes occur in music, most musical tones are composites. A typical violin tone is



* Actual pitch slightly lower than standard notation shows.

Overtone series.

relatively rich in overtones while a flute tone sometimes approaches a pure tone. What the listener recognizes as "a violin tone" or "a trumpet tone" also is a product of the noise content that accompanies the articulation of any sound on the particular instrument. The friction of the bow as it is set into motion across the string, the eddies of air pressure within a horn's mouthpiece, or the hammer's impact on a piano string all add an extra dimension, a significant "noise factor," to any manually produced tone. After articulation, however, it is the presence or absence of overtones and their relative intensities that determine the timbre of any tone. The violin and flute tones are distinguishable because their articulatory "noises" are quite different and their overtone contents are dissimilar, even when they produce the same pitch.

Electronic sound

Musical tones of determined harmonic content can be produced by electronic vacuum tubes or transistors as well as by traditional manual instruments. Some electronic organs, for example, use single vacuum tubes whose frequency output can be varied through control of an adjustable transformer. Through ingenious mixing circuits a compound tone consisting of any predetermined overtone content can be produced, thereby imitating the sound of any traditional instrument. Composers of electronic music have utilized this capability to synthesize tones quite different from any available on traditional instruments, as well as tones similar to natural sounds. Electronic computers are capable of complete imitation of such sounds; the tone is broken down into its component parts, then synthesized through an auditory output circuit.

MOVEMENT

Once an audible oscillation is produced by a vibrating body, it moves away from its source as a spherical pressure wave. Its rate of passage through any medium is determined by the medium's density and elasticity; the denser the medium, the slower the transmission; the greater the elasticity, the faster. In air at around 60° F, sound moves at approximately 1,120 feet per second, the rate increasing by 1.1 feet per second per degree of rise in temperature.

Sound waves move as a succession of compressions through the air. The wavelength is determined by frequency; the higher the pitch, the shorter the wavelength. A pitch of 263 cycles per second (middle C of the piano) is borne as a wavelength of around 4.3 feet (speed of sound ÷ frequency = wavelength).

By the time a wave has moved some distance, it has changed in some of its characteristics. The journey has robbed it of intensity, which is inversely proportional to the square of the distance. Its timbre has been altered slightly by objects within its path that disrupted an equitable distribution of frequencies, particularly the high-frequency waves, which, unlike the low, move in relatively straight paths from their sources.

Resonance

The area within which a sound occurs can have considerable effect upon what is heard. Just as a string or reed or air column has a natural resonance period (or rate of vibration), any enclosure—whether an audio speaker cabinet or the nave of a cathedral—imposes its resonance characteristics on a sound wave within it. Any tone that approximates in frequency the characteristic resonance period of an enclosure will be reinforced through the sympathetic response, or natural resonance, of the air within the enclosure. This means that tones of frequencies differing from the resonance of the enclosure will be less intense than those that agree, thereby creating an inequity of sound intensities.

Fortunately, most rooms where music is performed are large enough (wall lengths greater than about 30 feet) so that their natural resonance periods are too slow to fall within the range of pitches of the lowest musical tones (usually no lower than 27 cycles per second, although some organs have pipes that extend to 15 cycles per second). Smaller rooms can produce disturbing sympathetic resonance unless obstructions or absorbent materials are added to minimize that effect. (Bathroom singers revel in this phenomenon because the band of resonance sometimes lies close enough to the pitches of the male voice to support it, making it appear richer and more powerful.)

Reverberation period

In addition to resonance, any enclosure possesses a reverberation period, a unit of time measured from the instant a sound fills the enclosure (steady state) until that sound has decayed to one-millionth of its initial intensity. Anyone who has spoken or clapped his hands inside a large, empty room has experienced prolonged reverberation. There are two reasons for such protracted reverberation: first, the space between the surfaces of the enclosure is so great that reflected sound waves travel extended distances before decaying; and, second, the absence of highly absorbent materials precludes appreciable loss of intensity of the wave during its movement.

The reverberation period is a crucial factor in rooms where sounds must be heard with considerable fidelity. If the period is too long in a room where speech must be understood, spoken syllables will blend into each other and the words will be mumbled confusion. If, on the other hand, the reverberation period is too brief in a room where human "presence" and music each contribute to the acoustics, only a "cold" and "dull" feeling will persist, because no reverberative support of the prevailing sounds can be provided by the enclosure itself. (See also ENGINEERING: *Acoustical engineering*.)

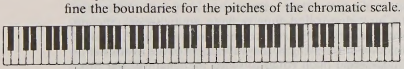
Although all sound waves, regardless of their pitch, travel at the same rate of speed through a particular medium, low tones mushroom out in a broad trajectory while high tones move in straight paths. For this reason listeners in any room should be within a direct path of sound

propagation. Seats far to the side at the front of an auditorium offer occupants a potentially distorted version of sound from its source. Thus the high-frequency speakers (tweeters) in good audio reproduction systems are angled toward the sides of the room, ensuring wider coverage for high-frequency components of all sounds.

Sites of musical performance in the open demand quite different acoustical arrangements, of course, since sound reflection from ceilings and walls cannot occur and reverberation cannot provide the desirable support that would be available within a room. A reflective shell placed behind the sound source can provide a boost in transmission of sounds toward listeners. Such a reflector must be designed so that relatively uniform wave propagation will reach all locations where listening will occur. The shell form serves that purpose admirably since its curved shape avoids the right angles that might set up continuous reflections, or echoing. Furthermore, sound waves are reflected more uniformly over a wide area than with any other shape, diffusing them equally over the path of propagations. (The needs here are similar to those of the photographer who wishes to flood a scene uniformly with flat light rather than focus with a spotlight on a small area.)

PITCH AND TIMBRE

Just as various denominations of coins combine to form the larger units of a monetary system, so musical tones combine to form larger units of musical experience. Although pitch, loudness, duration, and timbre act as fourfold coordinates in the structuring of these units, pitch has been favoured as the dominating attribute by most Western theorists. The history of music theory has to a great degree consisted of a commentary on the ways pitches are combined to make musical patterns, leaving loudness and timbre more as the "understood" parameters of the musical palette.



Music terminology, for example, recognizes loudnesses in music in terms of an eight-level continuum of nuances from "extremely soft" (ppp, or pianississimo) to "extremely loud" (fff or fortississimo). (The musical dominance of Italy from the late 16th to the 18th century—when these Italian terms first were applied—explains their retention today.)

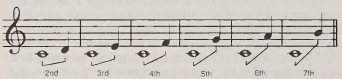
The timbres of music enjoy an even less explicit and formalized ranking; other than the vague classifications "shrill," "mellow," "full," and so on, there is no standard taxonomy of tone quality. Musicians for the most part are content to denote a particular timbre by the name of the instrument that produced it.

Divisions of the pitch spectrum

Pitch is another matter. A highly developed musical culture demands a precise standardization of pitch, and Western theory has been occupied with this task from as early as Aristoxenus (4th century BC). Especially since the Renaissance, when instruments emerged as the principal vehicles of the musical impulse, problems of pitch location (tuning) and representation (notation) have challenged the practicing musician. When at least two instrumentalists sit down to play a duet, there must be some agreement about pitch, or only frustration will result. Although the standardization of the pitch name *a'* (within the middle of the piano keyboard) at 440 cycles per second has been adopted by most of the professional music world, there was a day—even during the mid-18th century of Bach—when pitch uniformity was unknown.

Man's perception of pitch is confined within a span of roughly 15 to 18,000 cycles per second. This upper limit varies with the age and ear structure of the individual, the upper limit normally attenuating with advancing age. The pitch spectrum is divided into octaves, a name derived from the scale theories of earlier times when only eight (Latin *octo*) notes within this breadth were codified. Today the octave is considered in Western music to define the boundaries for the pitches of the chromatic scale.

Piano keyboard.



The piano keyboard is a useful visual representation of this 12-unit division of the octave. Beginning on any key, there are 12 different keys (and thus 12 different pitches), counting the beginning key, before a key occupying the same position in the pattern recurs.

One must keep in mind that the chromatic scale, within the various octave registers of man's hearing, is merely a conventional standard of pitch tuning. Performers like singers, trombone and string players, who can alter the pitches they produce, frequently make use of pitches that do not correspond precisely to this set of norms. The music of many non-Western cultures also utilizes distinct divisions of the octave. Furthermore, some contemporary music makes use of pitch placements that divide the octave into units smaller than the half-step. This music, called microtonal, has not become standard fare in Western cultures, in spite of its advocates (Alois Hába, Julian Carillo, Karlheinz Stockhausen) and even its special instruments that provide a means for consistent performance.

Western music history is dotted with systems formulated for the precise tuning of pitches within the octave. From a modern viewpoint all suffer from one of two mutually exclusive faults: either they lack relationships (intervals) of uniform size, or they are incapable of providing chords that are acceptable to the ear. Pythagorean tuning provides uniformity but not the chords. Just tuning, based on the simpler ratios of the overtone series, provides the chords but suffers from inequality of intervals. Meantone tuning provides equal intervals but gives rise to several objectionable chords, even in simple music. All three of these systems fail to provide the pitch wherewithal for the 12 musical keys found in the standard repertoire (see below *Tuning and temperament*).

The compromise tuning system most widely accepted since the mid-19th century is called "equal temperament." Based on the division of the octave into 12 equal half-steps, or semitones, this method provides precisely equal intervals and a full set of chords that, although not as euphonious as those of the overtone series, are not offensive to the listener.

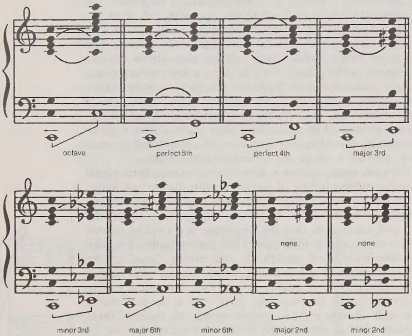
The semitone is the smallest acknowledged interval of the Western pitch system. The sizes of all remaining intervals can be calculated by determining how many semitones each contains. The names of these intervals are derived from musical notation through a simple counting of lines

Generic names of pitch intervals.

and spaces of the staff. Just as the overtone content of a single tone determines timbre, the relationship of the constituent pitches of an interval determines its quality, or sonance. There is a long history of speculations in this area, but the subjectivity of the data indicates that little verifiable fact can be sorted from it.

Consonance and dissonance

Until the 20th century, music theorists were prone to concoct tables that showed an "objective" classification of intervals into the two opposing camps of consonant and dissonant. But only the person who utters these terms can know with assurance what he means by them, although many attempts have been made to link consonant with pleasant, smooth, stable, beautiful and dissonant with unpleasant, grating, unstable, and ugly. These adjectives may be reasonably meaningful in musical contexts, but difficulty arises if one attempts to pin a singular evaluation on a particular interval per se.



Theorists have noted that the character of an interval is altered considerably by the sounds that surround it. Thus the naked interval that sounds "grating," "unstable," and lacking in fusion might within a particular context create an altogether different effect, and vice versa.

Recognition of the power of context in shaping a response to the individual pitch interval has led some music theorists to think more in terms of a continuum of sonance that extends from more consonant to more disso-

nant, tearing down the artificial fence once presumed to separate the two in experience.

Helmholtz theory

The explanation of consonance and dissonance offered by Hermann von Helmholtz in *On the Sensations of Tone* (1863) is perhaps as helpful as any. An initial theory was based on the notion that dissonance is a product of beats, which result from simultaneous tones or their upper

Common overtones (incomplete series, excluding the seventh) at various pitch intervals.

overtones of slightly differing frequencies. Another explanation, offered later by Helmholtz, held that two tones are consonant if they have one or more overtones (excluding the seventh and ninth) in common.

Music in which a high degree of dissonance occurs has rekindled interest in this old problem of psychoacoustics. The German composer Paul Hindemith (1895–1963) provided one explanation of harmonic tension and relaxation that depends upon the intervals found within chords. According to his view a chord is more dissonant than another if it contains a greater number of intervals that, as separate entities, are dissonant. Although Hindemith's reasonings and conclusions have not been widely accepted, the absence of any more convincing explanation and classification often leads musicians to use his ideas implicitly.

Although the complete pitch spectrum can be tuned in a way that provides 12 pitches per octave (as the chromatic scale), pitch organization in music usually is discussed in terms of less inclusive kinds of scale patterns. The most important scales in traditional Western theory are seventone (heptatonic), which, like the chromatic, operate within the octave. These scales are different from one another only in the intervals formed by their constituent pitches. The major scale, for instance, consists of seven pitches arranged in the intervallic order: tone–tone–semitone–tone–tone–tone–semitone.

Called major because of the large (or major) third that separates the first and third pitches, this scale differs from the minor scale mainly in that the latter contains a small (or minor) third in this location. Since three variants of the minor scale are recognized in the music of the Western repertoire, it is important to note that they share this small interval between their first and third pitches.

Scales and modes

Major and minor scales formed the primary pitch ingredients of music written between 1650 and 1900, although this is a sweeping generalization for which exceptions are not rare. Other scales, called modes, possess greater representational power for music of earlier times and for much of the repertoire of Western folk music. These too are heptatonic patterns, their uniqueness produced solely by the differing pitch relationships formed by their members. Each of the modes can most easily be reproduced by playing successive white keys at the piano.

The modes and the major and minor scales best represent the pitch structure of Western music, though they do not utilize the total complement of 12 chromatic pitches per octave. They are abstractions that are meaningful for tonal music; *i.e.*, music in which a particular pitch acts as a focal point of perception, establishing a sense of repose or tonality to which the remaining six pitches relate. Major and minor scale tonality was basic to Western music until it began to disintegrate in the art music of the late 19th century. It was replaced in part by the methods of Arnold Schoenberg (1874–1951), which used all 12 notes as basic material. Since that revolution of the early 1920s, the raw pitch materials of Western music have frequently been drawn from the complete chromatic potential. By contrast, the music of several Eastern cultures, a number of children's songs, and occasional Western folk songs incorporate pitch materials best classified as *pentatonic* (a five-pitch scale).

SOUND PRODUCTION OF MUSICAL INSTRUMENTS

Classification of musical instruments

Excluding electronic tone synthesizers, which employ vacuum tubes or transistors to produce tones, musical instruments can be classified within three groups: (1) chordophones, or strings; (2) aerophones, or winds; and (3) idiophones and membranophones, nearly all of which are percussion instruments. Each category is further divisible into groups according to the way the vibrating medium is set into motion.

Chordophones. Three means of eliciting sounds determine three categories within the family of chordophones. They are bowing, plucking, and striking. Most common of the first category are the violin, viola, violoncello, and double bass of the orchestra, all of which use a horsehair bow for setting their strings into motion. Essentially a resonant box bearing strings of four different fundamental frequencies, members of this group have not changed appreciably in construction since the 17th century, except for the 20th-century advent of the electrified bass, which is in fact a close cousin of the amplified guitar.

Violins and the larger members of its group are sounded by plucking (pizzicato) on occasion, which provides a brittle tone of extremely brief duration. The harp is the best known orchestral instrument whose tone depends upon the noise components added by plucking. Other plucked instruments are the guitar, banjo, mandolin, ukelele, zither, lyre, lute, and the harpsichord. The latter differs from the piano in that its strings are actuated by the plucking action of a tiny plectrum.

The piano is most notable of the struck stringed instruments, employing a hammer mechanism linked with the keyboard for producing its wide range of sounds. Other instruments of this group are the clavichord and the dulcimer.

For all chordophones pitch is proportional to string tension and inversely proportional to length, thickness, and density. Since string length is the most readily altered of these factors, all chordophones provide a means for altering the resonating length of strings (as with the violin and guitar) or a set of many string lengths and masses (as with the piano and harp) for producing a variety of pitches.

Aerophones. This category covers everything from the piccolo to the pipe organ and is best understood by consistent reference to the nature of the air column employed in the various types of instruments, as well as the way this air column is set into motion.

Brass instruments consist of a long tube whose cross section is proportionately small. Coupled with a mouthpiece that, in response to vibrations of the performer's lips, helps to create eddies of air pressure that set an enclosed air column into motion, these instruments produce a range of pitches corresponding to the overtone series. The bugle is a primitive kind of brass instrument in that it is limited to only one overtone series, while the modern trumpet, cornet, French horn, trombone, tuba, flügelhorn, and various kinds of euphoniums utilize valves or a slide to lengthen the air column and thus provide up to seven different overtone series. Pitch on these instruments is primarily a function of tube length, the wavelength of the instrument's fundamental pitch equal to twice the length of the tube, plus a so-called end correction that accommodates variations of bore. Timbre is a product of mouthpiece shape,

bore (whether cylindrical or conical), and material, aside from the important role performed by the player himself in obtaining desired overtones.

Woodwinds prior to the 20th century were made for the most part of wood. Today the flutes and clarinets are classified in this group only because of this heritage, while the saxophones, always built of metal, share only the reed mouthpiece and similar fingering technique with the clarinet. All are, nonetheless, called woodwinds, and they consist of an air column set into motion by one of two means: (1) through high pressure eddies produced by the wind of the performer blown directly into the instrument (as with a recorder or whistle) or over it (as with the flute and piccolo), or (2) by means of a vibrating reed that is set into motion by air pressure from the performer. The clarinets and saxophones utilize a single reed fixed at one end, while the oboe, English horn, and bassoon use two thin reeds that are connected laterally and vibrate jointly. For all of these instruments, either keys or the fingers of the performer directly open holes, with the effect of shortening the enclosed air column of the instrument and thereby producing higher fundamental pitches. Through overblowing and various fingering procedures, the overtone series provides the wealth of pitches available on these instruments.

Free reed instruments utilize a single, freely vibrating reed, different in nature from that of a woodwind. The category includes the accordion, harmonica, and harmonium and their relatives. In these instruments the reed vibrates, causing periodic vibrations in the air; but the reed's size, rather than the air enclosed by the instrument, determines the pitch.

Pipe organs are of the aerophone (wind) category, too, although their keyboard mechanism and literature link them closely with the piano and harpsichord. Like a grand synthesis of woodwinds and brasses, organs produce their tones by means of tuned air columns that are formed with pipes of varied length, cross section, and shape (called flue pipes) or by means of a vibrating brass reed actuated by forced air (called reed pipes). Flue pipes range in length from under an inch to 32 feet.

Idiophones and membranophones. Idiophones are instruments whose bodies vibrate to produce sound. The class contains most of the pitched percussion instruments. These include instruments made of wood or other organic material, such as xylophones. They also include pitched percussion instruments that are struck or plucked and are made of metal or other inorganic material (triangle, glockenspiel, vibraphone, celesta, tubular bell, gong, steel drum, cymbal, glass harmonica, etc.). Idiophones without pitch consist of such instruments as the percussion board, castanets, and rattles, all of which are made of wood or other organic material and are struck, scraped, rubbed, brushed, or shaken.

Membranophones produce sound by a vibrating membrane. The group consists most notably of the timpani, or kettledrums, which can be tuned by increasing or decreasing the tension of the membranes that form the heads of the enclosed cavities. Other membranophones consist of drums without fixed pitch, such as side drums, bongos, and various non-Western types of fixed and indefinite pitch. Tone quality and character are the result of the player's skill in controlling intensity and overtone character of the sound.

(W.E.T.)

TUNING AND TEMPERAMENT

Musical sound largely depends on the organization of pitch, the high or low quality of sound; and the determination of acceptable pitch plays a large part in both the theory and practice of music. The adjustment of one sound source—such as a voice, a string, or a column of air enclosed in a wind instrument—to produce a desired pitch in relation to a given pitch is called tuning. Two concepts fundamental to the theory of tuning are those of frequency ratio and of consonance and dissonance. A given musical pitch is determined by the frequency of vibration of the sound wave that produces it, as $a' = 440$ cycles per second. An interval, or distance between two pitches, can thus be mathematically described as the ratio of the frequency of the first pitch to the frequency of the second. Various frequency ratios can be reduced to the same basic relationship; for example, 440:220 and 30:15 and 750:375 can all be reduced to the ratio 2:1.

Consonance and dissonance

When two tones are sounded together the subjective reaction may be anything from one of perfect consonance to one of extreme dissonance. Dissonance is produced by beats (interference between pulsations of sound waves), and it is found that maximum dissonance occurs when the rate of beats between the two tones is about 33 per second. Consonance results from the absence of beats, which occurs only when the ratio between the frequencies of the two tones is numerically simple. When the two tones are tuned to the same pitch, they are said to be in unison (ratio 1:1) and their consonance is absolute. Next in order of consonance comes the octave (2:1), the interval between c and c′ (encompassing eight notes of the piano keyboard); another highly consonant interval is the fifth (3:2, as from c to g). When a unison, octave, or fifth is slightly mistuned, the resulting combination is markedly dissonant and is judged "out of tune." The slight mistunings that occur in systems of tempered tuning are necessary for reasons that will be discussed later in this article.

The problems of tuning. So long as music consists of melody without harmony, consonance plays little part in the determination of successive pitches in a scale. Many primitive scales are sung, not played, and are variable in the exact pitches of their notes. When instruments are made, it is often necessary to determine precise pitches. The tendency is either to make the steps in the scale sound equal in size or to place them in simple arithmetic relationship to one another. The fundamental unit is the octave, which has the unique property that its two notes are felt in some indefinable way to be the same, though in pitch level they are recognizably different. For this reason, high and low voices naturally sing the same tune an octave apart. In nearly all musical cultures the octave is subdivided into a number of steps, each a simple fraction of an octave. In the diatonic, or seven-note scale, for example, which is the basis of Western music and is represented by the white notes on the piano keyboard, there are five steps of one-sixth of an octave and two of one-twelfth. In contrast to these uncomplicated fractions, the frequency ratios of these intervals are actually the irrational numbers: $\sqrt[6]{2}$:1 and $\sqrt[12]{2}$:1. As has been noted, consonance is related to simple frequency ratios such as 2:1. Consequently, the arithmetic subdivision of the octave can never produce perfectly consonant intervals. This unavoidable fact underlies many of the problems in the history of tuning. Insignificant when notes are heard melodically, it becomes highly important when notes of different pitch are heard simultaneously. The complex development of harmony has been the most striking peculiarity of Western music, and it has brought with it a host of tuning problems.

Conflict of scale and consonance

Apart from the octave, which presents no problem, there are really only three distinct intervals in the diatonic scale the consonance of which is important. These are the fifth (3:2, as C–G), the major third (5:4, as C–E), and the major sixth (5:3, as C–A). The other three consonant intervals are the fourth (4:3, as C–F), the minor sixth (8:5, as C–Ab), and the minor third (6:5, as C–Eb). The intervals of this second group are not truly distinct, for they can be derived from the first three by inversion—*i.e.*, by transposing the lower note of the interval up an octave. Thus, inverting the fifth c–g yields the fourth g–c′. Inverting the major third c–e yields the minor sixth e–c′, and inverting the major sixth c–a yields the minor third a–c′. Because of the phenomenon of inversion, if the fifths in a scale are in tune, the fourths also will be in tune. For each of these six intervals the tuning expressed by the above simple frequency ratios sounds "right"; if modified slightly in either direction it sounds seriously out of tune. The same cannot be said of other intervals of the diatonic scale. The major and minor seventh (as c–b and d–c′) and the diminished fifth (as b–f′), with their inversions, sound dissonant in any case; they have no one tuning that is clearly more acceptable than another. Hence the harmonic merits of any tuning system depend on the way fifths, major thirds, and

Inversion of intervals

semitones

*The sizes of successive steps in the diatonic and chromatic scales are shown for each of the four systems, in cents. Black notes of the chromatic scale are indicated by bold lines.

major sixths are tuned. In the diatonic scale (indefinitely extended through several octaves) there are six perfect fifths (F–C, C–G, G–D, D–A, A–E, E–B), three major thirds (F–A, C–E, G–B), and four major sixths (F–D, C–A, G–E, D–B). It is impossible to tune the seven notes of the scale so that each of these 13 intervals is maximally consonant. This is the second inescapable obstacle to perfection in the tuning of the diatonic scale.

The Pythagorean system

Classic tuning systems. Of the two ancient Greek systems that were used chiefly in the Middle Ages, one, Pythagorean tuning, makes all the fifths perfectly consonant. As a result, all the major thirds and major sixths are sharp (too wide) by 22 cents (a cent is 1/1200 of an octave) or by the ratio of 81:80. This amount is called a comma of Didymus, and it makes intervals severely dissonant when their notes are sounded simultaneously. Within the gamut, the pitch range in use during the Middle Ages, a major third or sixth mistuned by a comma beats between 6 and 32 times a second. Melodically, the Pythagorean system is satisfactory. (Table 1 compares whole tone and semitone sizes in the four main tuning systems.) Pythagorean tuning makes all five whole tones (the larger steps in the diatonic scale) equal at 9:8 (204 cents), and the two semitones (the smaller steps) equal at 256:243 (90 cents). The semitones are considerably less than half the whole tones in size, but this is not particularly objectionable in a melody.

Just intonation

Ptolemaic tuning, often misleadingly named just intonation, sacrifices one of the fifths (D–A), which is altered to 40:27 from the simpler ratio 3:2, making it flat (too narrow) by a comma. The advantage of this system is that all the major thirds are true, or "in tune," as are all the major sixths except F–D, which is tuned to the ratio 27:16, as in the Pythagorean tuning (instead of to 5:3). The triad D–F–A is quite unusable, although the other triads used are perfectly in tune. (A triad is a chord built of two thirds.) For melody the system has the drawback of employing two different sizes of whole tones: C–D, F–G, and A–B are major tones (9:8, or 204 cents), and D–E and G–A are minor tones (10:9, or 182 cents). The difference is noticeable without being great enough to suggest that they are two purposely distinct intervals. To sing the first phrase of "Three Blind Mice" with the middle note perceptibly too high can hardly have seemed satisfactory at any period.

Although just intonation occupied the attention of many theorists, its disadvantages are so great that it is doubtful whether the system was ever strictly applied to harmonized music. Some kind of temperament may have been practiced empirically long before it was described in writing. The addition over several centuries of the five chromatic notes (the black notes of the piano), giving the full chromatic scale, certainly does nothing to improve either the Pythagorean or the Ptolemaic tuning (see Table 2, which shows the deviation of the four main tuning systems from the ideal tuning of the principal intervals). To either system the use of the chromatic notes adds more true fifths but also more untrue thirds and sixths. The advantages of just intonation over Pythagorean tuning are experienced only

*The tuning of each of the three basic intervals is analyzed for each system. Deviations from the "true" intervals are given in cents. 100 cents = 1 equal-tempered semitone. The sizes of the "true" intervals are as follows: perfect fifth, 702 cents; major third, 386 cents; major sixth, 884 cents.

in chords made up of white notes. With the development of harmony and the increased use of chromatic notes, both tuning systems became increasingly unsatisfactory.

Temperament. The first mention of temperament is found in 1496 in the treatise *Practica musica* by the Italian theorist Franchino Gafori, who stated that organists flatten fifths by a small, indefinite amount. This practice tends to spread out the mistuning of the fifth D–A over several fifths, so that all are tolerable although none is perfect. This principle was systematized as mean-tone temperament, first described in 1523. Under this scheme, all the major thirds of the scale are made perfect (*i.e.*, are tuned in the simple ratio 5:4); it results in an imperfection in the tuning of fifths that is spread out evenly over the entire cycle. Specifically, the interval of two octaves and a major third is tuned perfectly and divided into four fifths (C–G–d–a–e′), each of which has the ratio $\sqrt[4]{5}$:1 (compared to 3:2 for a perfectly tuned fifth). The fifths are flat by a quarter of a comma, which is much less dissonant than a comma: it gives a beat rate of 0.9 to 4 per second for fifths that fall within the compass of the medieval gamut. All major sixths are sharp by the same amount. Melodically, the scale resulting from mean-tone temperament is superior to the Ptolemaic (just intonation) scale, for all the whole tones are equal in size, being exactly half a true major third, or 193 cents. This is the source of the system's name: the mean, or average, whole tone. The semitones of the diatonic scale are relatively large, at 117 cents.

Mean-tone temperament

Mean-tone temperament, which was specifically designed for keyboard instruments, was an acceptable compromise so long as the black notes used in a composition did not extend beyond E♭ and G♯. As soon as D♯ was needed as well as E♭, the system collapsed. The keyboard provided only one key for E♭ and D♯. This key was tuned as E♭ and with no reference to the G♯ below it. The enharmonic fifth G♯–E♭ (in which E♭ is treated as equal to D♯) is nearly two commas out of tune in the mean-tone system. Worse even than the mistuned fifth of just intonation, it was often given the name "the wolf." Organs were occasionally built with split black keys so that E♭ and D♯ could be differently tuned and also A♭ and G♯. This expedient slightly extended the range of usable harmonies, but a more drastic remedy was soon needed. By spreading out the mistuning of the "wolf" fifth among its neighbours, in the same way that their predecessors had spread out the mistuning of the fifth D–A, musicians of the 17th century moved imperceptibly away from mean-tone temperament, in which the fifths are tuned unequally, toward the system of equal temperament, in which all fifths are equally flat.

Equal-tempered tuning

In equal temperament, all intervals are made up of semitone units, each of which is set exactly at a 12th of an octave, or 100 cents. A fifth is built of seven semitones; in relation to a pure fifth, it is 2 cents flat. A major third is four semitones and is 14 cents sharp; a major sixth is nine semitones and is 16 cents sharp. Because in equal temperament the intervals are identical in all parts of the chromatic scale, the system is the only one that can accommodate the expanded range of harmonies of 19th- and 20th-century music. Melodically, it fulfills the ideal of equal steps. The price for these great advantages is the total disappearance of perfectly tuned intervals, save only the octave. For the piano and the harpsichord this is scarcely a drawback: the characteristic tone of these instruments is, in any case, rich in dissonant components. Indeed, it has been found that piano tuners systematically set octaves and even unison strings out of tune. But on the organ, with its purer and more sustained tone, the disadvantages of equal temperament are considered by many to outweigh its blessings. In England such musicians as the organist and composer Samuel Sebastian Wesley continued to oppose it even as late as the mid-19th century.

On fretted instruments—such as lutes, guitars, and viols—the frets extend across the fingerboard, producing at any one point divisions of equal lengths on strings of different pitch. Unless equal temperament is used, the positioning of the frets results in mistuned octaves and unisons when the same note is played on different strings. For this reason equal temperament was applied at least as early as the 16th century in the construction of fretted instruments.

It has often been stated that singers and players on instruments of undetermined tuning, such as violins and trombones, naturally use just intonation when performing together. Experimental evidence does not support this theory. In such circumstances musicians tend either to play in equal temperament, or, if anything, to distort intervals away from perfect consonance. Most probably this is the result of generations of conditioning. Moreover, it has been found that few musicians can distinguish melodically between just intonation and equal temperament and that those who can do so prefer the latter.

Tuning and musical history. It is seldom realized what an important effect tuning practices have had on the development of harmony and tonality. From the 10th to the 13th century thirds and sixths—now considered consonant—were treated as dissonances simply because, according to then-current tuning methods, they *were* dissonances. In Pythagorean tuning, only the bare fifth and octave could provide a tolerable point of repose in music accompanied by the organ. Although just intonation permitted some harmony based on triads, the use of sharpened leading notes (the last note of the scale, leading upward into the first), which by the 16th century had caused the older system of modes to disintegrate, was made acceptable only by the use of some kind of temperament. At a later date it was the existence of lutes tuned in equal temperament that made possible the more extreme experiments in chromaticism of composers such as Luca Marenzio and Don Carlo Gesualdo. The formation of a unified orchestra was probably delayed by the simultaneous practice of two incompatible tuning systems—mean-tone for keyboard instruments, equal temperament for lutes and viols. The decline of viols and their replacement by the violin family may have been hastened by the inability of viols to play with the organ. The modern orchestra began with the Vingt-quatre Violons du Roi (Twenty-four Violins of the King) of Louis XIV, and most later Baroque music is based on a keyboard instrument with from one to 30 members of the violin family playing in mean-tone temperament. The cycle of six related keys, established in the operas of Alessandro Scarlatti and the sonatas of Arcangelo Corelli and followed closely in most of the music of J.S. Bach and George Frideric Handel, is probably a direct outcome of mean-tone temperament. Within the limits of mean-tone temperament, the six keys exhaust the chromatic compass available. On the other hand, "wolf" chords may have been deliberately introduced by Domenico Scarlatti, François Couperin, and other composers to give an added piquancy to certain harpsichord passages. Many harpsichord players, including Bach, would retune a few notes of their instruments to prepare to play a piece in a new key, shifting the "wolf" fifth to part of the scale where it would do no harm. But in organ works such temporary retuning was hardly possible. Bach's organ tuning must have been as close to equal temperament as modern instruments are, although it is known that he was opposed to a strictly mathematical equality of intervals. By his title *Well-Tempered Clavier* he probably meant a kind of modified mean-tone temperament.

Enharmonic modulation, in which one note (say B♭) is treated as identical to another (say A♯) that actually has the same pitch only in equal temperament, was an exceptional device in Baroque music. But as orchestras became free of keyboard instruments and as keyboard instruments increasingly adopted equal temperament, it became a normal stock-in-trade, allowing the use of a series of key changes in one direction that eventually returns to the original key. Thus, it is not unusual for Mozart to complete the cycle of 12 keys in the course of a movement. Equal temperament permitted 19th-century composers to use the 12 notes of the chromatic scale with the utmost freedom. It also fixed those 12 notes so immutably in the Western musical consciousness that the revolutionary developments of 20th-century music, far from undermining them, have tended to perpetuate them.

Enharmonic modulation

(N.T.)

Elements of musical composition

At its most fundamental level the act of composition involves the ordering of pitched sounds in musical time and space. Pitch relationships are referred to as intervals; their specific occurrence in musical time is determined by rhythm, a concept that embraces all durational aspects of music. Rhythm in turn may or may not be regulated by metre. In metrically organized rhythm, recurring patterns of accented and unaccented "beats" furnish a durational substructure that necessarily affects all the other elements of composition, including the nature of melody, harmony, and texture. Metrical rhythm is nearly always present in dance music because its patterning is largely analogous to that of bodily motions and step figurations. But logogenic, or word-determined, music also often employs metrical patterns, corresponding as a rule to those of the poetic text. The first large corpus of logogenic compositions transmitted through the ages is that of medieval plainchant, consisting of monophonic settings (limited to a single melodic line) of liturgical texts for the entire year, based on a system of eight church modes, diatonic scales abstracted from the melodic motives utilized by medieval singers. Modality—whether referring to a melodic or a rhythmic framework—furnishes compositional frames of reference in a wide variety of essentially monophonic musical styles, especially in Asia. Asian influences upon early European music cannot be ruled out, whether by way of ancient Judaea, Greece, Byzantium, or the medieval Arab invasions. But unlike their Asian counterparts, Europeans at first limited modality to melody, through pitch arrangements. The rhythmic properties of plainchant have largely remained a matter of conjecture, for no systematic discussion of plainchant rhythm survives, and the notation used was noncommittal with respect to rhythm. By the same token, plainchant no doubt owed much of its amazing vitality to the absence of an all-encompassing notation, which made possible the flexibility of performance and regional variation inherent in a partly written, partly oral tradition.

Music like medieval plainchant, in which the lengths of individual tones tend to be rather uniform, is often referred to as nonrhythmic or rhythmless. Such careless terminology denies the very essence of music as a temporal art, which implies by definition the omnipresence of rhythm as "order in musical time." Actually, the relative presence or lack of rhythmic differentiation in the duration of tones can act as a decisive stylistic determinant. Thus the rhythmic equanimity of the monophonic plainchant, at least in the interpretation set forth by the 19th-century Benedictine monks of Solesmes, France, and recognized as authoritative by the Roman Catholic Church, effectively symbolizes an atmosphere of faith and inner peace. By contrast, the strictly metrical organization of rhythm in most 18th-century music reflects the thinking of an age of reason, favouring mathematically definable, hence "natural," structures in its music.

The smallest melodic-rhythmic unit (minimally two separately perceived sounds) is the motive. Pitched sounds are, however, not of the essence: drum motives are so effective rhythmically precisely because they lack pitch definition. By and large, rhythmic motives are used to endow pitch relationships with identifiable durational characteristics. And consequently rhythmic identity often serves to establish motive connections between different intervals. A famous case in point is the opening short–short–short–long motif of Beethoven's *Symphony No. 5 in C Minor*, Opus 67, which serves as an effective element of structural cohesion in this large-scale work.

Types of melody owe their aesthetic associations in many instances to their motivic peculiarities. In Western music motivic contrast has been identified with emotional conflict since at least the mid-16th century, when composers of madrigals (Italian polyphonic secular songs) began to set dramatic texts. The opening of Mozart's *Symphony No. 35 in D Major*, K 385 (the *Haffner Symphony*), offers an excellent example. Analogous in its motivic structure to a section of the first act of Mozart's opera *Don Giovanni*, the opening of the symphony engenders emotional contrasts similar to those inherent in the opera's dramatic action when Donna Anna, under the double impact of attempted rape and her father's violent death at the Don's hands, impulsively rejects Don Ottavio's sympathy until, realizing that she has no one else to rely on for help, she reverses herself and induces him to swear revenge. Conversely, melodic lyricism correlates with a high degree of motive affinity.

This section will examine the process of musical composition in the Western tradition from its basic elements to its history as an art.

RHYTHM

In its most general sense rhythm (Greek *rhythmos*, derived from *rhein*, "to flow") is an ordered alternation of contrasting elements. The notion of rhythm occurs in music and in other arts (*e.g.*, poetry, painting, sculpture, and architecture) as well as in nature (*e.g.*, biological rhythms).

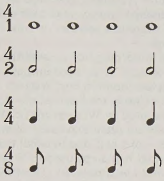
Attempts to define rhythm in music have produced much disagreement, partly because rhythm has often been identified with one or more of its constituent, but not wholly separate, elements, such as accent, metre, and tempo. As in the closely related subjects of verse and metre, opinions differ widely, at least among poets and linguists, on the nature and movement of rhythm. Theories requiring "periodicity" as the *sine qua non* of rhythm are opposed by theories that include in it even nonrecurrent configurations of movement, as in prose or plainchant.

Elements of rhythm. Unlike a painting or a piece of sculpture, which are compositions in space, a musical work is a composition dependent upon time. Rhythm is music's pattern in time. Whatever other elements a given piece of music may have (*e.g.*, patterns in pitch or timbre), rhythm is the one indispensable element of all music. Rhythm can exist without melody, as in the drumbeats of primitive music, but melody cannot exist without rhythm. In music that has both harmony and melody, the rhythmic structure cannot be separated from them. Plato's observation that rhythm is "an order of movement" provides a convenient analytical starting point.

Beat. The unit division of musical time is called a beat. Just as one is aware of the body's steady pulse, or heartbeat, so in composing, performing, or listening to music one is aware of a periodic succession of beats.

Tempo. The pace of the fundamental beat is called tempo (Italian "time"). The expressions slow tempo and quick tempo suggest the existence of a tempo that is neither slow nor fast. his "moderate" tempo is often assumed to be that of a natural walking pace (76 to 80 paces per minute) or of a heartbeat (72 per minute). The tempo of a piece of music indicated by a composer is, however, neither absolute nor final. In performance it is likely to vary according to the performer's interpretative ideas or to such considerations as the size and reverberation of the hall, the size of the ensemble, and, to a lesser extent, the sonority of the instruments. A change within such limits does not affect the rhythmic structure of a work.

Rubato. The tempo of a work is never inflexibly mathematical. It is impossible to adhere in a musical manner to the metronomic beat for any length of time. In a loosely knit passage a tautening of tempo may be required; in a crowded passage a slackening may be needed. Such modifications of tempo, known as *tempo rubato*—*i.e.*, "robbed time"—are part of the music's character. Rubato needs the framework of an inflexible beat from which it can depart and to which it must return.



Time. The mind apparently seeks some organizing principle in the perception of music, and if a grouping of sounds is not objectively present it imposes one of its own. Experiments show that the mind instinctively groups regular and identical sounds into twos and threes, stressing every second or third beat, and thus creates from an otherwise monotonous series a succession of strong and weak beats.

In music such grouping is achieved by actual stress; *i.e.*, by periodically making one note stronger than the others. When the stress occurs at regular intervals, the beats fall into natural time measures. Although in European music the concept of time measures reaches back to a remote

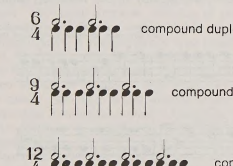
age, only since the 15th century have they been indicated by means of bar lines. Thus, the terms measure and bar are often used interchangeably.

Time signatures

The time measure is indicated at the opening of a piece by a time signature; *e.g.*, $\frac{2}{4}$, $\frac{4}{4}$, $\frac{3}{4}$, $\frac{9}{8}$. The length of each beat in a measure may be a time unit of short or long duration:

The signature $\frac{4}{1}$ (above) means that the whole note (1) is the unit in each measure, and there are four (4) of them to each measure. In the second illustration, $\frac{4}{2}$, the half note (2) is the unit of measurement, with four of them (4) to each measure, etc.

The two basic types of time measure have either two or three beats and admit of many different notations.



"Four time," or "common time," is really a species of duple time allied to "two time," as it can hardly be thought of without a subsidiary stress at the half measure; *i.e.*, on the third beat; thus:

Duple, triple, and quadruple time measures—*i.e.*, those in which there are two, three, and four beats to a measure—are known as simple time. The division of each of the component beats into three produces compound time:

More complex times, such as the quintuple, $\frac{5}{4}$, usually fall into groups of 3 + 2, as in "Mars" from Gustav Holst's suite *The Planets* and in the second movement of Tchaikovsky's *Sixth Symphony.* Rimsky-Korsakov, in *Sadko,* and Stravinsky, in *Le Sacre du printemps,* use 11 as a unit. Ravel's piano trio opens with a signature of $\frac{5}{8}$ with the internal organization 3 + 2 + 3. Folk song and folk dance, particularly from eastern Europe, influenced the use of asymmetrical time measures, as in the "Bulgarian Rhythm" pieces in $\frac{7}{8}$ and $\frac{5}{8}$ in Bartók's *Mikrokosmos.*

Prosody applied to music

Metre. The combinations of long (—) and short (∪) syllables are known in prosody as feet. The system of notating the musical equivalents of feet derives from the application of prosody to music. The foundations for European music were laid in ancient Greece, where classical music and poetry were regarded as parts of a single art. These principles were adopted by the Romans and were transmitted, by way of Latin poetry, to medieval Europe. The feet of classical poetry and their equivalents in music are shown in Table 3. And in late antiquity St. Augustine (354–430), in *De musica,* added more.

Table 3: Classical Poetic Metre

	metrical foot	poetic syllables	musical notation	groups of beats	equivalent time signatures
duple	dactyl	— ∪ ∪		2 + 2	$\frac{2}{4}$
	anapest	∪ ∪ —		2 + 2	$\frac{2}{4}$
triple	trochee	— ∪		2 + 1	$\frac{3}{8}$
	iamb	∪ —		1 + 2	$\frac{3}{8}$

Rhythmic metre. Until the 12th century, church music was virtually limited to unadorned plainchant. The early composers found that polyphony required a rhythmical organization to keep the parts together; so rhythmic metre was adopted (see Table 4). Compared with a hypothetical flow of beats equal in stress, metre adds significance to what was merely a forward flow in time—though the continuation of a metrical pattern may itself become monotonous. Thus, metre, though "rhythmic" by comparison with pulse, is not the whole of rhythm. The 13th-century musicians often varied the rhythmic modes by combining several of them simultaneously in different parts of polyphonic composition.

Table 4: Classification of Rhythmic Metre

poetry	metrical foot	musical notation
— ∪	trochee	
∪ —	iamb	
— ∪ ∪	dactyl	
∪ ∪ —	anapest	
— —	spondee	
∪ ∪ ∪	tribrach	

Polyphonic metre. Theoretically, metre appears to be without stress accent, and certainly much polyphonic music of a later period, such as the masses of Palestrina, has an almost stressless flow. Yet these works reveal a subtle rhythmical organization. At a later period metre and time measure cannot be wholly separated. In their "purest" forms they may be extremes, but in music predominantly of one type, the other element is rarely wholly absent, though on an instrument such as the organ, actual dynamic stress is impossible. After all, metres like the spondee, 𝅗𝅥 𝅗𝅥, and the dispondee, 𝅗𝅥. 𝅘𝅥𝅘𝅥, need an accent on the first beat to keep their identity. Notwithstanding the opposite tendencies of metrical organization and stress accent, however, some metre is obviously subject to stress, so that metre and time measure become very closely linked, as in the scherzo of Beethoven's *Ninth Symphony,* where a measure has a strong first beat and at the same time follows a metre.

Organic rhythm. In broad terms, the time framework of music is composed of tempo, time measure, metre, and period; and its rhythmical life hangs on rubato, musical motif (which may already include cross accent), and metrical variation, as well as on asymmetry and balance of phrase. Whereas the former are more or less measured and rational, the latter are organically inspired and numerically irrational—the very life of the music.

Rational and irrational features

Prose rhythms and plainsong. Rhythm is, therefore, not any one of these rational or formal features, nor is it composed solely of a combination of these factors. Yet rhythm requires the background of a rational framework in order that it may be fully perceived, but this framework need not embrace all the rational factors described above.

Thus plainchant, as it is known in modern times, makes no use at all of measure or of regular metre but is

supremely rhythmical in conception; its "free" rhythms are felt. Whereas so much music has for its framework a regular repetition of underlying accent, whether stress or durational, the framework of plainchant is irregular. Its rhythm belongs to the Latin tongue and springs from the correct accentuation of the text and the dynamic quality inherent in the word grouping.

Rhythm, melody, and harmony. Thus far, music's structure in time has been examined separately from its structure in tone, but no such separation is really possible. Melody and rhythm are intimately connected. Moreover, various styles of music tend to standardize their melodic cadences and, with them, their time divisions (*e.g.*, Mozart's melodic rhythm is much more regular than Prokofiev's).

In music employing harmony, the rhythmic structure is inseparable from harmonic considerations. The time pattern controlling the change of harmonies is called harmonic rhythm. In 17th- and 18th-century music, harmony tends to limit rhythmic subtleties and flexibility of the melodic elements (as well as determining the basic type of melody) in regard to stress accents. It is, therefore, no accident that the polyphonic music of Indonesia and Southeast Asia, like much European music, exhibits certain four-square melodic tendencies. By contrast, the music of India and the Perso-Arab world employs a melody instrument or voice performing in a given metre offset by a drum playing cross rhythms or (in the Arab world) a quite different metre; with no harmony (except a drone) to impede its flow, the rhythm can reach a structure of great subtlety and complexity.

Diversity from conceptual differences

Rhythm, structure, and style. In European music the great variety of styles derives its relation to melody from different concepts of rhythm. They include the strict rhythmic modes of the 13th century; the free oratorical speech-rhythms of the Renaissance; the almost stressless flow of Renaissance polyphony; the strong body rhythms of the Baroque; the freedom of the late Romantics; and the primitivistic rhythms of the 20th century with composite and ever changing time signatures.

Thus, study of musical history shows a varying attitude toward rhythm, sometimes closer to strict rule, sometimes to "freedom," as the temper of the times and the relative influence of poetry, dance, and folk music decree. Plato's definition of rhythm as "an order of movement" might, therefore, be expanded. As a determining factor in the vitality of music, rhythm may be described as "an inspired, organic order of movement," communicating intelligibly to the senses. From the analytical viewpoint, it operates in the rational framework described, which it varies in terms of rubato, motif, etc. Ultimately, rhythm is the organic process of music in time; it is music's direction in time. The quality of rhythm is the quality of life; however vitally the composer conceives his music, he must depend upon the performer to recreate it rhythmically. (P.C.-H.)

SCALE

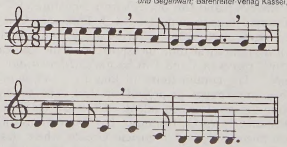
A theoretical description of pitch relationships that exist in music is called a musical scale. The specific selection of different tones in any piece of music generally reveals a pattern of relationships among its pitches that can be expressed as a series of fixed distances (intervals) from one pitch to another within the span of an octave. The interval relationships among pitches of a scale are its essential feature, and a particular pattern of intervals defines every scale. Other aspects of pitch usage in music, such as range (distance from the highest pitch used to the lowest), emphasis placed on certain pitches, or the simultaneous (harmonic) and successive (melodic) occurrence of tones, do not alter the identity of the scale, although they may be essential in describing its function.

Although the number of different scales that can be formulated is theoretically nearly infinite, particular scales tend to become conventionalized within any given culture or musical tradition. The scale of a single piece of music may therefore be characteristic of the tone system of a whole culture. In general, the simplest scales can be found in very old music and in the music of nonliterate cultures, while the most complex scales occur in the world's most advanced cultures.

Scale and melody. Scales have proven to be important in the analysis of folk music and the music of nonliterate cultures, but scholars have been obliged to deduce the scales through a study of the actual music, since the creators of the music were not cognizant of scales as theoretical concepts. By contrast, music of the most highly developed cultures (variously described as classical music, art music, cultivated music, and high-culture music) is created in full awareness of rules or conventions pertaining to scale usage.

Non-explicit scales

In view of the wide range of possibilities, a surprisingly small number of scale types predominate throughout the world. The intervals found in non-Western music often approximate rather closely the basic whole-step and half-step intervals that are used in Western music. Variations from Western intervals are often expressed as measurements in cents (100 cents = one half step in equal temperament, the pattern of 12 equal half steps used in Western music; see above *Tuning and temperament*). The task of identifying scales in non-Western music is complicated further by the occasional appearance of highly variable intervals or by singing techniques that produce sounds whose pitches cannot be specified accurately through conventional notation, like the "tumbling strains" (falling melodies) described by musicologist Curt Sachs in the singing of Aboriginal Australians.



Although music performed only on one pitch does exist, the study of scales properly begins with the occurrence of at least two different pitches. Scales consisting of only one or two intervals (*i.e.*, two or three pitches) can be found throughout the world in monophonic music (that consisting of a single unharmonized melodic line), though they are perhaps most numerous in Ceylon, eastern Siberia, California Indian cultures, and in regions near the Ural Mountains. Such scales commonly display a narrow range in which the pitches are separated by a half step, a whole step, or a minor third (one and one-half steps, as, C–Eb). Larger skips in two- and three-note scales do occur but are less frequent. Some simple scales have probably acquired additional pitches through a tendency to fill in large skips with intervening pitches. Another process by which scales may have expanded is the transposition within a single melody of one characteristic melodic motive (identifiable fragment) to a different pitch level, thus creating additional scale degrees, as in the melody of the Makurap Indians shown below.

From F. Blume (ed.), *Die Musik in Geschichte und Gegenwart*; Bärenreiter-Verlag Kassel, Basel

Occasionally, primitive melodies apparently generated by motivic transposition also contain evidence of emphasis on particular pitches. As an example, the skips in the following Osage Indian melody are arranged so that the pitches G and C are consistently reiterated.

From F. Blume (ed.), *Die Musik in Geschichte und Gegenwart*; Bärenreiter-Verlag Kassel, Basel

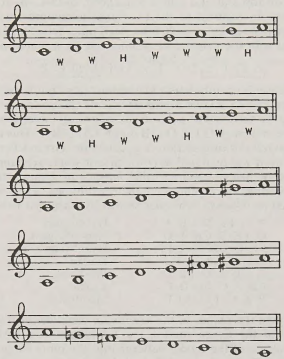
The melodic "weight" given to those two pitches could not have been achieved by the simple transposition of motives. Further, weighted scales may also give prominence to certain pitches by using them as range limits or by placing a particular pitch at the ends of sections or the end of a piece.

Explicit scale systems

Scales function somewhat differently in the art-music traditions of highly sophisticated cultures, since they are not only a means of description and analysis but are also pre-existent assumptions for the composer or performer. Within those cultures, knowledge of the characteristics and requirements of various scales is often perpetuated by written treatises on music theory as well as by oral communication from generation to generation. The existence of professional composers and performers also encourages continuity in musical knowledge, even though some cultures, like those of the Western world, advocate continuous change in musical practices within acceptable limits. Through gradual evolutionary processes, the nature of scales and their functions may change radically over a period of several centuries.

Highly developed, complex systems governing the use of scales exist in a variety of cultures, principally in the Far East, India, Iran, the Muslim world, and the West. The differences in musical styles among those cultures are indeed great, yet there are some similarities in the manner in which scales function in each instance. Each culture has a number of basic scales (interval patterns), called *grāma* in India, *dastgah* in Iran, *maqām* in Muslim cultures. Generally, a basic scale is used to produce a number of different modes, or bases for melodic construction, in which the intervallic structure of the scale remains intact while primary and secondary melodic importance is attached to different pitch degrees (see below, *Mode*). This hierarchy in which modes are generated by basic scale types consequently produces a greater number of modes than there are basic scales. The terms *maqām* and *dastgah* also are used to refer to such modes; the corresponding Indian term is *jāti*. In some art-music traditions the modes serve as the basis for an even larger number of specific melody types, which may again be elaborated further by improvisation in performance. In India the basic melodies are called *rāgas*; in Iran they are *gusheh*. Although Western art music has a system of scales and modes, the melody types are not used as systematically or as consciously as they are in some of the non-Western traditions.

Common scale types. Pentatonic (five-note) scales are used more widely than any other scale formation. In fact, Western art music is one of the few traditions in which pentatonic scales do not predominate. Their frequency is especially notable in the Far East and in European folk music. The most common varieties of pentatonic scales use major seconds and minor thirds, with no half steps (anhemitonic). A representative type could be spelled C–D–E–G–A, for example. The pentatonic scale is so pervasive that melodies exhibiting tetratonic (four-note) scales often appear to be pentatonic with one pitch omitted. Hexatonic (six-note) scales appear rather rarely in folk music and nonliterate cultures. Examples that are known often seem to be fragments of the seven-note Western diatonic scale.



Heptatonic scales are especially prominent in the world's art-music traditions. The tone systems of India, Iran, and the West are entirely heptatonic, and seven-note scales are also present in the art music of some cultures that do not use such scales exclusively (*e.g.*, the *ritsu* scale in Japan and the *pelog* scale in Java).

The diatonic scale

With some exceptions in both the distant and the recent past, Western art music has been based largely on one heptatonic scale, known as the diatonic scale. The origins of this scale can be traced to ancient Greece, and it has been formulated to some extent according to acoustical principles. Since the octave in Western music is normally divided into 12 equal half steps, the characteristic intervals of the diatonic scale can be constructed upon any one of the 12 pitches. Such transpositions of the scale are known as keys.

Before the 17th century, as many as 12 different mode permutations of the diatonic scale were in common use (see below *Mode*), but only two modes—now called major and minor—have been in general use during most of the past 300 years. The diatonic scale itself consists of five whole steps (W) and two half steps (H), with the half steps dividing the whole steps into groups of two or three. The major scale uses the sequence W–W–H–W–W–W–H, as shown in the first of the following examples, while the intervals in the minor scale are W–H–W–W–H–W–W, as in the second.

In actual music the minor scale is usually altered in one of two ways to create greater emphasis on particular pitches. In the harmonic minor scale (the third example shown) the seventh note is raised one half step, and in the melodic minor scale (the fourth example) both the sixth and seventh notes are raised by one half step in ascending patterns while they are left unaltered in descending patterns (the fifth example).

Chromatic, whole-tone, and microtonal scales

In the 19th and 20th centuries, composers have made increasing use of pitches lying outside the diatonic scale, and that tendency has stimulated a variety of novel scale systems, developed as alternatives to the diatonic scale. Principles for composition within the chromatic scale (consisting of all of the 12 half steps within the octave) were first articulated by the Austrian-born composer Arnold Schoenberg early in the 20th century. Other scales have also been employed on an experimental basis. The whole-tone scale (comprising six whole steps) was used prominently by the French composer Claude Debussy and others, especially in France and England. Microtonal scales requiring intervals smaller than the conventional half step have also appeared sporadically in the 20th century. Among microtonal structures the most important, perhaps, have been scales calling for quarter tones (equal to half the distance of a half step).

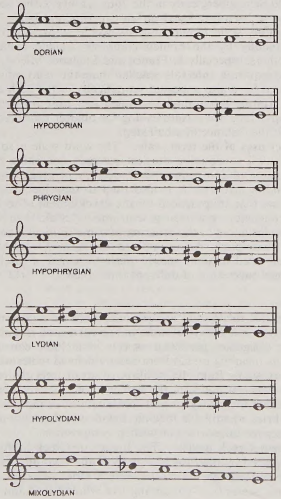
Other uses of the term scale. The word scale is sometimes used to describe musical passages consisting of a succession of consecutive scale degrees in ascending or descending patterns. It is also used to describe scalelike exercises that are practiced for the development of technical proficiency on a musical instrument. "Scale" can refer in rare instances to the ordering of some musical element other than pitch. An example is the term *Klangfarbenmelodie* used in some recent music to denote a carefully arranged succession of different tone colours. (J.C.Gr.)

MODE

In musical theory and analysis, the word mode has been employed in a variety of more or less correlated meanings. Mode designates particular aspects of melodic construction; its meaning ranges from strictly defined scales whose identity stems from the position of given intervals (distances between notes) in the sequence of tones to broadly delineated melody types and constellations of motivic figures (brief, identifiable melodic fragments) that may serve as bases for improvised or written compositions.

Ancient Greek modes. The modes of Greek antiquity were placed by theorists in orderly fashion within a larger context. Although the modes were a series of seven-note diatonic scales (*i.e.*, containing five whole tones and two

semitones), the nucleus of the tone system was the tetrachord—a group of four consecutive notes (as, from C to F on the piano) comprising the interval of a fourth. Except in late antiquity, the notes were always arranged in a descending order, the basic tetrachord consisting of two whole tones and one semitone: E–D–C–B. Two such tetrachords, separated from one another by a whole tone, formed the so-called Greek Dorian mode: E–D–C–B A–G–F–E. The Dorian mode was taken as a basis for the construction of the larger system. Its single-octave range was extended by the addition of a third tetrachord, A–G–F–E, on top and of a fourth tetrachord, E–D–C–B, at the bottom. In contrast to the two inner tetrachords, which were separated by a whole tone, each outer tetrachord was linked with the neighbouring inner one by a shared note:



A G F E D C B A G F E D C B .

Because the combination of the four tetrachords yielded a range of two octaves minus one whole tone, a low A was added by theorists to achieve the following diatonic two-octave system: A G F E D C B A G F E D C B A. This two-octave row, or disdiapason, was called the Greater Perfect System. It was analyzed as consisting of seven overlapping scales, or octave species, called *harmoniai*, characterized by the different positions of their semitones. They were termed as follows (semitones shown by unspaced letters):

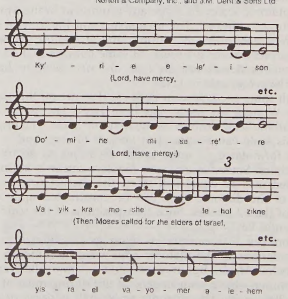
The Greater Perfect System

A G FE D CB A	Hypodorian
G FE D CB A G	Hypophrygian
FE D CB A G F	Hypolydian
E D CB A G FE	Dorian
D CB A G FE D	Phrygian
CB A G FE D C	Lydian
B A G FE D CB	Mixolydian

Although the names of the *harmoniai* were identical with those of the Greek modes, the *harmoniai* were instead projections of the modal patterns into the more extensive Greater Perfect System. The modes proper were termed *tonoi*, their essence being their interval pattern. On the kithara or *lyra* (the two basic plucked stringed instruments of ancient Greece) the *tonoi* were produced either by the basic tuning or by the raising or lowering of one or more of the strings by a semitone. Thus, the seven *tonoi* would sound within the octave E–E as follows (black notes indicate changes from the Dorian tuning):

Greek theory distinguished three different genera of tetrachords, producing an additional variety of modes. The previously described tetrachord (two descending whole tones plus one semitone) was called diatonic. There were also chromatic and enharmonic genera. The two tones bounding the tetrachord were fixed and always formed a perfect fourth; the two inner tones were movable. The chromatic tetrachord consisted of a minor third (encompassing 1½ whole tones) plus two semitones, the enharmonic tetrachord of a major third (encompassing two whole tones) plus two approximate quarter tones:

Also prominent in Greek music was the concept of ethos, which ascribed certain ethical characteristics to the different modes. The Dorian mode was preferred because of its strong and virile character; the Phrygian mode was ecstatic and emotional, the Lydian mode intimate and lascivious. In *The Republic* Plato stressed the educational values of the Dorian mode and warned against the softening influence of the Lydian ode.



In early Greek antiquity a system of modal categories developed, referred to as *nomoi* (singular, *nomos*, "law"). The *nomoi* represented modes in that they were characterized by distinctive melodic formulas suited to different song types. The performers were free to improvise within the boundaries of these modal formulas.

Jewish and Eastern Christian chant. Ancient Hebrew music followed well-established modal patterns. According to Abraham Zevi Idelsohn, a musicologist whose comparative research conducted during the early decades of the 20th century established modern understanding of the Hebrew modes,

> A mode . . . is composed of a number of motives (*i.e.*, short music figures or groups of tones) within a certain scale. The motives have different functions. There are beginning and concluding motives, and motives of conjunctive and disjunctive [*i.e.*, convergent and divergent] character. The composer operates with the material of these traditional folk motives within a certain mode for his creations. His composition is nothing but his arrangement and combination of this limited number of motives. His "freedom" of creation consists further in embellishments and in modulations from one mode to the other.

The modal Hebrew music strongly influenced early Christian chant. This correlation can be illustrated by comparing a plainchant Kyrie, in the third mode, with a Babylonian Jewish melody for a phrase from Exodus:

Reprinted from *Music in the Middle Ages* by Gustave Reese. Copyright 1940 by W.W. Norton & Company, Inc. Copyright renewed 1968 by Gustave Reese. By permission of W.W. Norton & Company, Inc., and J.M. Dent & Sons Ltd.

Syria played an important part in developing early Christian chant by integrating both Hellenistic and Hebrew

elements. The Syrians devised a musical system called *oktōēchos,* a term suggesting a classification into eight *ēchoi.* The Syrian *ēchoi* are modes, although there is no consensus on whether they represented modes in a specifically technical sense, comparable to the Greek *tonoi,* or melodic formulas, comparable to the Greek *nomoi.*

Byzantine chant molded the features of early Christianity with Hellenic and Oriental traits, including the Syrian *oktōēchos,* and achieved a brilliant and distinctive style that served as a prototype for the chant of the Greek Orthodox Church. The eight *ēchoi* of the Byzantine *oktōēchos* were divided into four authentic and four plagal (derived) forms. The most common classification of the Byzantine modes was in terms of typical initial and final notes of melodies in a given mode, with the characteristic distinctions as follows (the orderly progression of notes in each series should be observed).

	Ēchos	Initial Note	Terminal Note
Authentic	I	a′	a′ or d′
	II	b′ or g′	e′ or b′
	III	c″ or a′	f′ or c″
	IV	d″ or g′	g′ or d″
Plagal	I	d′ or g′	d′
	II	e′ or g′	e′
	III	f′ or a′	f′
	IV	g′, a′, or c″	g′

The above classification reflects only two of various characteristics (not all completely clarified by modern scholars) that gave the modes their identity.

Even before the foundation of the Byzantine Empire, Armenia adopted Christianity as a state religion (AD 303). Although the early Armenian chant did not survive, the arrangement of the hymns of the Armenian Church in the comprehensive collection, known as the *Sharakan,* indicates that Armenian chant used an *oktōēchos* classification the modal characteristics of which seem to have been defined by melodic formulas rather than by scalar distinctions.

Another variety of the *oktoëchos* occurs in Russian Church chant. Although a concept of eight *ēchoi* points to the Byzantine system, the Russian *ēchoi* show a different structure. The melodic motives characteristic of the *ēchoi* are called *popievki;* but similar *popievki* could be employed in more than one *ēchos.* The use of some *popievki* is limited to the beginning, the middle, or the end of a chant. Occasionally, two *popievki* are merged into a compound *popievka.*

Plainchant. Plainchant, or plainsong, is also known as Gregorian chant and forms the core of the musical repertoire of the Roman Catholic Church. It consists of about 3,000 melodies collected and organized during the reigns of several 6th- and 7th-century popes. Most instrumental in codifying these chants was Pope Gregory I.

Melodically, Gregorian chants are based on eight different modes, often called church modes. Seven of them were given names identical with those used in the musical theory of ancient Greece: Dorian, Hypodorian, Phrygian, Hypophrygian, Lydian, Hypolydian, and Mixolydian, while the name of the eighth mode, Hypomixolydian, was adapted from the Greek. Each mode comprises a diatonic scale with the compass of one octave. The modes are classified by their *finalis,* the usual final note of a melody in that mode. Each of the four notes of the tetrachord D–E–F–G serves as the *finalis* of an "authentic" mode (see chart below).

Structure of Gregorian modes

An authentic mode consists of a pentachord (a succession of five diatonic notes) followed by a conjunct tetrachord, for example:

D E F G | A B C D |.

But the tetrachord may be added below rather than above the pentachord, thus generating a "plagal" mode:

| A B C | D E F G A |.

In either case the *finalis* falls on the lowest note of its pentachord. Each authentic mode has a correlated plagal mode, which is identified by the prefix *Hypo.* In the following chart of the eight church modes, the *finalis* is marked by a capital letter:

1. Dorian			D	e	f	g	a	b	c	d
2. Hypodorian	a	b	c	D	e	f	g	a		
3. Phrygian			E	f	g	a	b	c	d	e
4. Hypophrygian	b	c	d	E	f	g	a	b		
5. Lydian			F	g	a	b	c	d	e	f
6. Hypolydian	c	d	e	F	g	a	b	c		
7. Mixolydian			G	a	b	c	d	e	f	g
8. Hypomixolydian	d	e	f	G	a	b	c	d		

The tones of the Hypomixolydian mode are identical with those of the Dorian, but the two modes differ in the location of their *finalis.* The character of the church modes was further determined by a number of distinctive melodic formulas, and sometimes a particular ethos was attributed to the different modes.

Contrary to the Byzantine classification, which lists first the four authentic and then the four plagal modes, the Roman classification alternates the authentic and plagal modes, so modes with the same *finalis* follow each other. This principle underlies the medieval fourfold system of the so-called *maneriae* (Latin: "manners"), a division of the modes into four pairs. The first pair, or *protus maneria,* includes the Dorian and Hypodorian modes; the second, or *deuterus,* the Phrygian and Hypophrygian; the third, or *tritus,* the Lydian and Hypolydian; and the fourth, or *tetrardus,* the Mixolydian and Hypomixolydian.

Although Greek names were sometimes applied to the church modes and the principle of diatonic octave scales is found in both systems, certain significant discrepancies seem to belie any direct historical connection. Most conspicuous is the different meaning attributed to the names of the Greek octave species and of the church modes. Comparing the two systems provides a plausible explanation: medieval theorists apparently assumed wrongly that the Greek octave species were named in ascending rather than descending order. The Greek octave species Dorian (E–E), Phrygian (D–D), Lydian (C–C), and Mixolydian (B–B) thus appeared in the church modes as Dorian (D–D), Phrygian (E–E), Lydian (F–F), and Mixolydian (G–G).

Gradual emergence of major and minor tonality

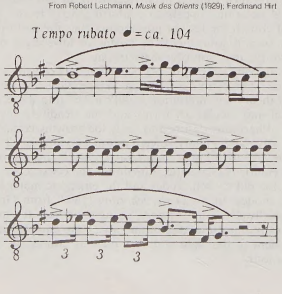
The strict consistency of the system of church modes was gradually weakened by the appearance of B♭ in addition to B♮, although the two notes never occurred in succession. The main reason for the use of a tone not included in the basic scale pattern was that medieval musicians sought to avoid the tritone F–B. The tritone (so called because it includes three whole tones) was considered an undesirable interval sharply contrasting with the perfect fourth F–B♭. The substitution of B♭ for B♮ changed the character of a mode. For example, the Lydian mode with a flattened B was identical with the modern major mode, specifically, with the F–major scale (F G A B♭ C D E F); and the Dorian mode with a flattened B generated a minor mode corresponding to the natural D minor scale (D E F G A B♭ C D).

Nevertheless, for centuries medieval theorists considered these alterations as special forms of the Lydian or Dorian mode rather than as new modes. The reluctance to acknowledge the existence of additional modes is reflected in the so-called musica ficta. According to this practice, musical notation appears to conform strictly to the system of church modes but presupposes that the performer makes certain adjustments by raising or lowering a note through the insertion of a sharp or flat.

Two different developments occurring between the 12th and the 16th centuries resulted in a radical change in modal theory: an infiltration of folk music into the ecclesiastical and secular art forms and the steadily evolving fabric of harmony destined to unify the growing complexity of polyphonic (many-voiced) musical texture. Finally, a theorist, Heinrich Loris, commonly known by his assumed name Henricus Glareanus, sanctioned the coexistence between the old church modes and the emerging major and minor modes. In his *Dodecachordon* (1547; from Greek *dōdeka,* "twelve," and *chordē,* "string"), perhaps the most significant musical treatise of the time, Glareanus enlarged the system of the eight church modes by adding the following four:

9. Aeolian			A	b	c	d	e	f	g	a
10. Hypoaeolian	e	f	g	A	b	c	d	e		
11. Ionian				C	d	e	f	g	a	b	c
12. Hypoionian	g	a	b	C	d	e	f	g		

The Ionian and Hypoionian modes correspond to the major mode, the Aeolian and Hypoaeolian modes to the "natural" minor mode. The 12 modes of the *Dodecachordon* comprise authentic and plagal structures with tonal centres on the notes C, D, E, F, G, and A, without recourse to sharpened or flatted tones. Glareanus mentions another two modes: the Locrian and the Hypolocrian, having B as their tonal centre. But because in these two modes B and the fifth degree above it, F, form a "false" (*i.e.*, diminished, or flattened) fifth (another form of the forbidden tritone), Glareanus states that for practical purposes only 12 modes are available.



The growing complexity of polyphonic music caused the distinction between authentic and plagal modes to become more and more irrelevant, and, as a result, the number of modes was virtually reduced to only six. The further development of art music in the Western Hemisphere is characterized by the gradual abandonment of the old ecclesiastical modes in favour of the dual major-minor system that dominated 18th- and 19th-century harmony. This system is often termed tonal, in contradistinction to that of the church modes; in fact, some 20th-century works reviving the patterns of the old church modes, as well as folksongs that occasionally use them, are often termed modal. Nevertheless, major and minor scale patterns have all essential characteristics of modes and should therefore be evaluated as such.

Non-Western modes and melody types. Modal concepts permeate all manifestations of Oriental art music. They represent a synthesis of well-established systems both of scalar construction and of a variety of melodic formulas and motivic configurations. The amalgamation of these elements yields specific melody types that are imbued with ethical, emotional, and cosmological connotations and form the basis of musical creation. Whereas the Western composer strives for originality and individual expression, his Eastern counterpart submits to the limitations of existing melody types, seeking to excel in an exploitation of their potentials.

The *rāga* and the *maqām*

The most elaborate modal concepts are those of the Indian *rāga* and of the Arabian-Persian *maqām*. They correspond to the Javanese *patet*, the Jewish *nigun*, and the aforementioned Greek *nomos*. The Oriental musician first exposes the characteristic features of a particular melody type in a free, improvisatory prelude leading to the more formalized section of the composition. These improvised introductions developed into a specific art form, called in India *ālāpa* ("conversation"), in Java *bebooka* ("guide"), in Iran *mukhtaṣarī* ("summary"), in Egypt and Turkey *taqsīm* ("dissection, analysis"), and in northwestern Africa *istaḥbar* ("information"). The following example (recorded by G. Schünemann, transcribed by R. Lachmann)—the first of four phrases constituting an introduction to a Tunisian art song composed in the *maqām raṣd ad-dīl*—illustrates this aspect of modal exposure.

From Robert Lachmann, *Musik des Orients* (1929); Ferdinand Hirt

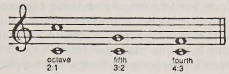
Rāgas and *maqāmāt* embrace a wide variety of emotional content. They can be courageous, amorous, melancholy, cheerful, soothing, or ecstatic and are capable of conveying these qualities to the listener. Some melody types are supposed to influence illnesses, calm storms, tame wild animals, and increase the fertility of the soil. Others have pernicious power; for example, a certain *maqām* attracts evil spirits, while a certain *rāga* may cause fire. According to an ancient legend, a singer who performed such a *rāga* under the reign of Emperor Akbar (1556–1605) was reduced to ashes, although as a precaution he had submerged his body in the Ganges River. Cosmological connotations have caused melody types to be assigned to different parts of the day; for example, a mid-morning *rāga* may not be performed during the evening. The Westernized younger generation, however, tends to disregard these traditional restrictions.

The music of many tribal societies shows well-organized scalar and modal patterns, but they have not been explicitly formulated and systematized by the peoples involved. A comparative analysis reveals that, in spite of a great structural diversity, scalar and modal correlations exist not only among culturally unrelated tribal societies but also among tribal, Western folk, and Eastern art music. Modal systems and their unconscious counterparts thus may be said to have contributed substantially to the structure of a vast amount of the world's music.

(M.Ko.)

HARMONY

In music, harmony can be broadly defined as the sound of two or more notes heard simultaneously. In practice, this broad definition can also include some instances of notes sounded one after the other. If the consecutively sounded notes call to mind the notes of a familiar chord (a group of notes sounded together), the ear creates its own simultaneity in the same way that the eye perceives movement in a motion picture. In such cases the ear perceives the harmony that would result if the notes had sounded together. In a narrower sense, harmony refers to the extensively developed system of chords and the rules that allow or forbid relations between chords that characterizes Western music.



Musical sound may be regarded as having both horizontal and vertical components. The horizontal aspects are those that proceed during time such as melody, counterpoint (or the interweaving of simultaneous melodies), and rhythm. The vertical aspect comprises the sum total of what is happening at any given moment: the result either of notes that sound against each other in counterpoint, or, as in the case of a melody and accompaniment, of the underpinning of chords that the composer gives the principal notes of the melody. In this analogy, harmony is primarily a vertical phenomenon. It also has a horizontal aspect, however, since the composer not only creates a harmonic sound at any given moment but also joins these sounds in a succession of harmonies that gives the music its distinctive personality.

Non-harmonic music

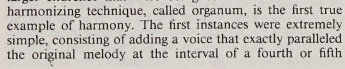
Melody and rhythm can exist without harmony. By far the greatest part of the world's music is nonharmonic. Many highly sophisticated musical styles, such as those of India and China, consist basically of unharmonized melodic lines and their rhythmic organization. In only a few instances of folk and primitive music are simple chords specifically cultivated. Harmony in the Western sense is a comparatively recent invention having a rather limited geographic spread. It arose less than a millennium ago in the music of western Europe and is embraced today only in those musical cultures that trace their origins to that area.

The concept of harmony and harmonic relationships is not an arbitrary creation. It is based on certain relationships among musical tones that the human ear accepts almost reflexively and that are also expressible through elementary scientific investigation. These relationships were first demonstrated by the Greek philosopher Pythagoras in the 6th century BC. In one of his most famous experiments, a stretched string was divided by simple arithmetical ratios (1:2, 2:3, 3:4, . . .) and plucked. By this means he demon-

strated that the intervals, or distances between tones, that the string sounded before and after it was divided are the most fundamental intervals the ear perceives. These intervals, which occur in the music of nearly all cultures, either in melody or in harmony, are the octave, the fifth, and the fourth. (An octave, as from C to the C above it, encompasses eight white notes on a piano keyboard, or a comparable mixture of white and black notes. A fifth, as from C to G, encompasses five white notes; a fourth, as from C to F, four white notes.) In Pythagoras' experiment, for example, a string sounding C when cut in half sounds C, or the note an octave above it. In other words, a string divided in the ratio 1:2 yields the octave (c) of its fundamental note (C). Likewise the ratio 2:3 (or two-thirds of its length) yields the fifth, and the ratio 3:4, the fourth. These notes—the fundamental and the notes a fourth, fifth, and

octave above it—form the primary musical intervals, the cornerstones on which Western harmony is built.

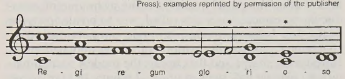
The roots of harmony. The organized system of Western harmony as practiced from *c.* 1650 to *c.* 1900 evolved from earlier musical practices: from the polyphony—music in several voices, or parts—of the late Middle Ages and the Renaissance and, ultimately, from the strictly melodic music of the Middle Ages that gave rise to polyphony. The organization of medieval music, in turn, derives from the medieval theorists' fragmented knowledge of ancient Greek music.



Although the music of ancient Greece consisted entirely of melodies sung in unison or, in the case of voices of unequal range, at the octave, the term harmony occurs frequently in the writings on music at the time. Leading theorists such as Aristoxenus (fl. 4th century BC) provide a clear picture of a musical style consisting of a wide choice of "harmonies," and Plato and Aristotle discuss the ethical and moral value of one "harmony" over another.

Greek scales

In Greek music a "harmony" was the succession of tones within an octave—in modern usage, a scale. The Greek system embraced seven "harmonies," or scale types, distinguished from one another by their particular order of succession of tones and semitones (*i.e.,* whole steps and half steps). These "harmonies" were later erroneously called modes, a broader term involving the characteristic contours of a melody, as well as the scale it used (see above *Mode*).



Harmony before the common practice period. By the 9th century the practice arose in many churches of performing portions of plainchant melodies with an added, harmonizing voice—possibly as a means of greater emphasis, or of reinforcing the sound to carry through the larger churches that were being built at the time. This harmonizing technique, called organum, is the first true example of harmony. The first instances were extremely simple, consisting of adding a voice that exactly paralleled the original melody at the interval of a fourth or fifth

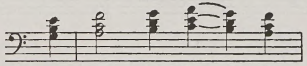
From the booklet edited by Gerald Abraham accompanying *The History of Music in Sound* (booklet published by Oxford University Press); examples reprinted with permission of the publisher

(parallel organum). Within a short time the new technique was explored in far greater diversity. Added harmonic lines took on melodic independence, often moving in opposite, or contrary, motion to the given melody. This style was called free organum. In such cases it was impossible to maintain at all times the accepted harmonies of fourth, fifth, and octave. These intervals were considered consonances—*i.e.,* intervals that because of their clear sonority, implied repose, or resolution of tension. In free organum they were used at the principal points of articulation: the beginnings and ends of phrases and at key words in the text. In between occurred other intervals that were relatively dissonant; *i.e.,* they implied less repose and more tension. In the following example of free organum, dissonances are marked by asterisks. Free organum is an early example of harmonic motion from repose to tension to repose, basic to Western harmony. The emphasis on con-

From the booklet edited by Gerald Abraham accompanying *The History of Music in Sound* (booklet published by Oxford University Press); examples reprinted by permission of the publisher

sonances at the end of compositions set the final points of arrival in strong relief and reinforced the idea of the cadence, or the finality of the keynote of a mode (on which pieces normally ended).

Until the late 14th century the attitude toward consonance, especially among continental composers, adhered largely to the Pythagorean ideal, which accepted as consonances only intervals expressible in the simplest numerical ratios—fourths, fifths, and octaves. But in England the interval of the third (as from C to E) had been in common use for some time, although it is not expressible as such a simple ratio. A kind of English organum known as gymel, in which the voices move parallel to each other at the interval of a third, existed in the late 12th century; and in the famous *Sumer is icumen in* canon of the 13th century, a remarkably elaborate piece for the time, the harmonic style is almost entirely centred on thirds. The sixth (as from E to C), an interval closely related to the third, was also common in English music. These two intervals sounded much sweeter than did the hollow-sounding fourths, fifths, and octaves.



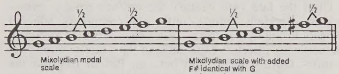
Rise of the intervals of the third and the sixth

By the early 15th century, in part because of the visits of the illustrious English composer John Dunstable to the courts of northern France, the third and sixth became accepted in European music as consonant intervals (prior to this time they were considered mildly dissonant). The result was an enrichment of the harmony in musical compositions.

This was a time, too, of a developing awareness of tonality, the concept of developing a composition with a definite keynote used as a point of departure at the beginning and as a point of arrival at the final cadence.

At this time there also began the tendency by composers to think of harmony as a "vertical" phenomenon, to regard the sound of notes heard simultaneously as a definite entity. Although the basic style of composition was primarily linear—*i.e.,* concerned with counterpoint—the chords that emerged from the coincidences of notes in contrapuntal lines took on a personality of their own. One phenomenon that bears out this development is fauxbourdon (French: "false bass"), or, in England, faburden. The following example illustrates English faburden of about 1300. This was a musical style in which three voices move

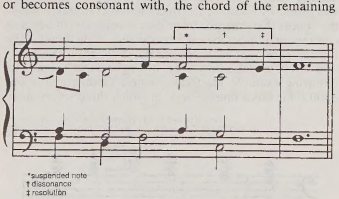
From the booklet edited by Gerald Abraham accompanying *The History of Music in Sound* (booklet published by Oxford University Press); examples reprinted with permission of the publisher



parallel to each other; the middle voice consisted of a succession of notes in parallel organum a fourth below the top voice; the lowest voice paralleled the sequence a third below the middle voice, producing a chord such as G–B–E, known as a $\frac{6}{3}$, or first inversion, chord. This was originally an English development adopted in the 15th century by continental composers seeking to enrich their harmonies. It combined the continental fondness for "pure" intervals such as the fourth (here, B–E) with the English taste for parallel thirds (here, G–B) and sixths (here, G–E).

A final phenomenon in early 15th-century harmonic

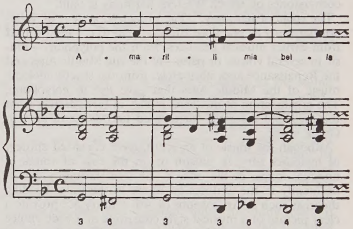
The weakening of the modes



practice clearly foreshadowed the end of the ancient modal system in favour of the major and minor modes of the later common practice period. The old modes were used by composers of the time, and they persisted to some extent until the end of the 16th century. But their purity became undermined by a growing tendency to introduce additional notes outside the mode. This was achieved by writing either a flat or sharp sign into the manuscript, or by leaving the performer to understand that he was expected to improvise accordingly. The effect of this musica ficta (Latin: "invented music"), as the technique of introducing nonmodal notes was called, was to break down the distinction between modes. A mode owes its distinctive character to its specific pattern of whole and half steps. Introducing sharps and flats upsets the mode's normal pattern by placing half steps at unusual points. In many cases the resulting change made one mode resemble another. For example, adding an F♯ to the medieval Mixolydian mode (from G to G on the white keys of the piano) made that mode's intervals identical with those of the Ionian

mode (from C to C on the white keys), which in turn is identical with the modern major scale. Likewise, adding a B♭ to the Dorian mode (from D to D) made its intervals equivalent to those of the Aeolian (A to A) mode, which is identical with one form of the modern minor scale. As this practice became increasingly prevalent, the major and minor modes gradually became predominant over the medieval church modes. The process is especially observable in the music of the late Renaissance.

New uses of dissonance



At the same time there emerged a more sophisticated attitude toward dissonance, favouring its use for expressive purposes. By the time of the Flemish Josquin des Prez, the leading composer of the Renaissance, contrapuntal music had assumed a more resonant texture through the use of four-, five-, and six-part writing instead of the older three-part scoring. The increased number of voices led to further enrichment of the harmony. A typical Josquin device using harmony for expressive purposes was the suspension, a type of dissonant harmony that resolved to a consonance. Suspensions arose from the chords occurring in contrapuntal music. In a suspension one note of a chord is sustained while the other voices change to a new chord. In the new chord the sustained, or "suspended," note is dissonant. One or two beats later the suspended voice changes pitch so that it resolves into, or becomes consonant with, the chord of the remaining

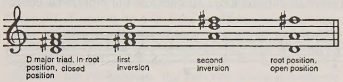
voices. The following illustration from Jean d'Okeghem's *Missa prolationum* shows a suspension at the cadence. The suspension, which became a standard musical device, creates tension because the expected harmony is delayed until the suspended voice resolves. Its use as the next to last chord of a cadence, or stopping point, was favoured by composers as a way to enhance, through dissonance resolving to consonance, the sense of completeness of the final chord. The use of suspensions indicates a growing awareness of chords as entities, rather than coincidences, that have expressive potential and of the concept that harmony moves through individual chords toward a goal. This concept was developed in the harmony of the common practice period.

At the end of the 16th century there was an upheaval in musical style. Contrapuntal writing was frequently abandoned, and composers sought out a style that placed greater emphasis on an expressive melodic line accompanied, or supported, by harmonies. This style, called monody, brought about no marked changes in the harmonic language (the particular chords used), although such composers as the Italian Claudio Monteverdi did experiment with a heightened use of dissonance toward expressive ends. The major change at this time was in the conception of harmony. The bass line became the generating force upon which harmonies were built. It was often written out with figures below it to represent the harmonies to be built upon it. From this single line—plus figures, known variously as figured bass, basso continuo, or thorough bass—the accompanying instrumentalists were expected to improvise, or "realize," a full harmonic underpinning for the melody of the topmost voice or voices. In the example below, from the continuo madrigal *Amarilli* by Giulio Caccini, the second line shows the harmonies supplied by the keyboard player. There was, thus, a polarization between

From W.J. Starr and G.F. Devine, Music Scores Omnibus, Part 1 (© 1964). Prentice-Hall, Inc.

the melodic and bass lines, with everything in the middle regarded as harmonic filling-in. This contrasts markedly with the older concept, in which all voices were regarded as of equal importance, with the harmony resulting from the interweaving of all parts.

Classical Western harmony. The approach to harmony according to which chords are purposely built up from their bass note marked the beginning of the common practice period of Western harmony. The transition began around 1600 and was nearly complete by 1650. Certain new concepts became important. These had their roots in the harmonic practices of the late Middle Ages and Renaissance and in the medieval modal system. They include the concepts of key, of functional harmony, and of modulation.



A key is a group of related notes belonging to either a major or minor scale, plus the chords that are formed from those notes, and the hierarchy of relationships among those chords. In a key the tonic, or keynote, such as C in the key of C—and thus the chord built on the keynote—is a focal point toward which all chords and notes in the key gravitate. This is a further development of the idea of a harmonic goal that appeared in the music of the late Renaissance and that ultimately developed from the medieval idea that modes have characteristic final notes.

In the new system keys further assumed relationships to one another. The larger organizational system embracing keys, key relationships, chord relationships, and harmonic goals was called tonality, or the major-minor system of tonality, because the keys were built on major and minor scales. In the tonal system, given chords assumed specific functions in moving toward or away from harmonic goals, and the system assigning goals to all chords was called functional harmony. The main goal was the keynote, or tonic, of the principal, or tonic, key. Modulation, or change of key, became an important factor in composition

because it allowed the composer to exploit the listener's ability to sense the relations between keys.

Rameau's theories of chords

The approach to harmony that emerged about 1650 (the bass-note approach) was soon formalized in one of the most important musical treatises of the common practice period, *Traité de l'harmonie* (1722), by the French composer Jean-Philippe Rameau. The crux of Rameau's theory is the argument that all harmony is based on the "root" or fundamental note of a chord; for example, D. Other notes are placed a third (as D–F or D–F♯) and a fifth (as D–A) above the root. A chord formed in this way is a triad (as D–F–A or D–F♯–A), the basic chord type of the common practice period. The third and fifth above the triad can be placed within the same octave as the root (close position) or can be spread out over several octaves (open position) in compound intervals such as an octave plus a third or two octaves plus a fifth. A triad can exist in its basic, or root position, with the root as the lowest, or bass, note (as D–F♯–A). It can also exist in inversions or rearrangements of its notes placing the third or fifth in the bass, as F♯–A–D (first inversion) and A–D–F♯′ (second inversion). Theorists after Rameau observed that inverted

chords are less stable than chords in root position; at the end of a composition, for example, they do not have sufficient finality. Although Rameau's monumental work contains certain elements that later practices tended to disprove, his writing remains the basis for the study of common-practice harmony.

By Rameau's time no vestige remained of the ancient modal system, which was replaced by 12 major and 12 minor keys beginning on each of the 12 notes of the piano keyboard (C, C♯, D, . . . A♯, B). The invention in the late 17th century of equal temperament (see above *Tuning and temperament*) made it possible to play keyboard and other instrumental music in all 24 keys of the chromatic system, the system embracing all possible notes of the 24 scales. Such a work as J.S. Bach's *Well-Tempered Clavier* was, among many things, a set of exercises to acquaint keyboard players with this newfound freedom. Equal temperament also made it possible for a composer to modulate freely from one key to another to obtain contrast in works of an extended nature. Modulation was no new invention, but it now became of prime importance.

In normal, or functional, harmony, the succession of chords is analyzed by the distance, or interval, between their roots. The most common movement from chord to chord is through "strong" intervals: fourths (as C to F), fifths (as C to G), and seconds (as C to D). A movement from one chord to another having this root relation is strong because the two chords have the fewest notes in common and therefore contrast more with each other. Movement by "weak" intervals—thirds (as C to E) and sixths (as C to the A above it)—is weaker, or less pronounced, because the two chords in this case usually share two out of their three notes; for example, C–E–G and E–G–B, or C–E–G and A–C–E. Similarly, modulation from one key to another in the course of a piece was most characteristically from one key to another whose keynote is a strong interval apart from that of the first key, as from C to G. Usually the modulation was to the key built on the fifth note, or dominant, of the original scale. A work in C major, for example, tended to move toward the area of G. In works in a minor key, the modulation might be to the dominant minor key (A minor to E minor, for example); or it might be to the relative major key (the key that shares the same scale notes as the minor scale but arranging them in major scale order rather than minor scale order [A minor and C major, for example]). In the second case the contrast of major and minor mode appeared to compensate for the weak modulation (A and C are a third apart).

By the early 18th century these modulatory principles were well established and were made use of in musical form. In the keyboard sonatas of Domenico Scarlatti, for example, or the instrumental dance movements in Bach's partitas, the opening key is well established at the beginning of the piece. There then begins a movement to a new key, normally the dominant key. This is characteristically achieved by an emphasis on chords common to both keys (known as "pivots"), plus a strong musical statement in the new key leading to a cadence in that key. After the modulation there is a process of return to the initial key. During this process the harmonic motion tends to be more rapid, passing quickly through many chords and often including momentary diversions into many new keys, thus lending greater impact to the eventual return to the original key. Such a composition is said to be in "binary form." In binary form compositions in a minor key, there occasionally occurred an exception to the rule of return to the home key. The composer could at his option return to the tonic major, the major key built on the same keynote, or tonic, as the original minor key—A major from A minor, for example. But even in this case the harmonic goal toward the tonic note (A in this case) remained the same.

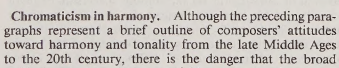
Harmony and modulation in the 18th century

This basic modulatory scheme from tonic key to dominant key back to tonic key formed the basis of the large-scale musical forms that developed during the 18th century and persisted well into the 19th. The sonata forms of Mozart and Haydn, with their exposition, development, and recapitulation, adhere closely to this plan, often greatly expanded. Here the movement from the tonic to the dominant key or to the relative major key made up the exposition; the rapid harmonic movement en route back to the tonic made up the development; and the return to the tonic key—usually reinforced by a return of the initial thematic (melodic) material—signalled the start of the recapitulation. An optional final coda, or concluding section, further strengthened the sense of the tonal journey's having come to an end. In the large, multi-movement works from this period, there was usually a further contrast achieved by having one of the inner movements in another key, but the final movement almost invariably was once again in the same key as the first movement.

Romantic changes in classical harmony

This clear and logical system of organization seemed highly consistent with an age that took its cues from the clarity and balance of ancient classical architecture. It was not so consistent, however, with the ideals of the ensuing era of Romanticism. Already in the mature works of Beethoven, there is the beginnings of a breaking-down of the classic modulatory scheme; the opening movement of the *Waldstein Sonata,* Opus 53 (completed, 1804), for example, is built on a modulation from the tonic, C major, to the sharply contrasting key of E major, instead of the expected key of G. Much of the individual harmonic language of Franz Schubert is based on his purposeful disavowal of modulation via the smooth succession of pivot chords and his fondness, instead, for dropping suddenly into unrelated, and therefore unexpected, keys, as C major to E flat major in the opening movement of the *String Quintet in C Major,* Opus 163 (1828); C major to E minor in the opening movement of the *Symphony No. 9 in C Major* (1828), known as the *Great Symphony.*

Throughout the 19th century there was also a great increase in the use of chromatic tones—tones not belonging to the scale of a given key and that formed "foreign," sometimes dissonant, harmonies with the notes of that key. In addition to the triad, the typical chord of functional harmony, other more complex chords were used, the harmonic functions of which were extremely ambiguous to the listener. As a result the sense of clearly established tonality created by traditional harmonies began to vanish from the musical language—doubtless in line with composers' greater obsession with music and all arts as something mysterious and personalized.



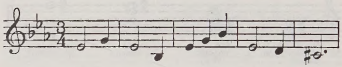
By the time of the German composer Richard Wagner, the sense of tonality as the unifying musical force showed definite signs of disintegration. For one thing, Wagner's idea of the "endless melody" led him in his late works to abjure almost completely, except at the end of acts, the full cadence that establishes tonality. A seeming approach to a cadence in *Tristan und Isolde* or the *Ring des Nibe-*

lungen tetralogy is more often than not thwarted by a quick and unprepared switch to a sharply contrasting key and a continuation of the music in that new area. For another, Wagner's passion for complex chords subject to more than one functional interpretation made the tonality of even short passages difficult to assess.

Although Wagner's specific harmonic concepts were not universally accepted, during his time or afterward, the blurring of the tonal sense by one means or another became prevalent throughout Western music by the last decades of the 19th century. Even in the works of the Italian Giuseppe Verdi, whose music was regarded as the opposite pole from Wagnerian techniques, this abandonment of clear tonal outlines may be noted: the sudden changes to unrelated keys, the piling up of dissonances that leave the sense of key obscured for minutes at a time, the emergence in his late works of a continuous melodic style that avoided regular, key-defining cadences. In France the blurring of clear outlines characteristic of Impressionist painters found its musical counterpart in the music of Claude Debussy, who employed such devices as the scale consisting entirely of whole tones as a means of sidestepping the tonal feeling created by traditional scales. In the music of later French composers, especially the members of the post-World War I group known as "Les Six," a common practice was polytonality, or the sounding of two tonalities simultaneously, each defined with relative clarity but neither dominating the other. Similar polytonal methods also occur in the works of the Hungarian-born Béla Bartók and the Russian émigré Igor Stravinsky.

The Wagnerian influence continued most directly, via the music of Gustav Mahler, into the serial techniques developed in the 1920s by Arnold Schoenberg and his Viennese school. In Schoenberg's serialism the 12 notes of the chromatic scale are arranged into an arbitrary series, or 12-tone row, that becomes the basis for the melodies, counterpoint, and harmonies of the composition. Of these 12 notes no single note is allowed to predominate. This is in complete contrast to the predominance of the tonic, or keynote, in the music of the late Renaissance and the common practice period. Serialism thus completely and systematically obliterated traditional harmonic organization. With no single note serving as a musical goal, tonality—at least as it was known from the 15th century—ceased to be a unifying musical force. Other elements, including serialization of rhythms and tone colours as well as of notes, came to prevail.

Schoenberg's 12-tone row



twelve-tone row and chord formed from first four notes of this row

Chromaticism in harmony. Although the preceding paragraphs represent a brief outline of composers' attitudes toward harmony and tonality from the late Middle Ages to the 20th century, there is the danger that the broad outlines may be taken as a rigid statement of standard practices by composers at any period in musical history. Actually, although these outlines remained the general framework in which composers worked, they frequently diverged from it to some extent, particularly in their use of chromatic notes (notes outside the scale of the basic key of the composition) and chromatic chords (chords containing chromatic notes).

The capacity of chromatic tones to add harmonic colour, expressiveness, and interest was apparent to composers from the beginnings of standard harmonic practice. J.S. Bach, for example, in a striking passage at the end of the "Crucifixus" of the *Mass in B Minor,* lent poignance to the verbal description of the burial of Christ by the musical device of a sudden modulation from B minor to a sharply contrasting new key, G major, that contained notes chromatic to the basic key. Mozart, too, derived much of the drive of his harmonic style from a constant use of chromaticism. A characteristic device of Mozart, for example, is his frequent use of secondary dominants to intensify harmonic movement. A secondary dominant is a chord related to the dominant; specifically, it is the dominant of the dominant. If the key is C, the dominant is G and the secondary dominant is D. Secondary dominant chords by their nature contain a note that is chromatic to the basic key. In Mozart's music a harmonic progression from tonic chord (I) to dominant chord (V) will often pass through the dominant of the dominant (V-of-V): from I to V-of-V to V. By using the secondary dominant, he expanded the harmonic range of the composition by introducing chromaticism. In his later works Mozart also came to rely more and more on the dissonant value of suspensions to create harmonic interest. The slow introduction of his *String Quartet in C Major,* K 465 (the *Dissonance Quartet;* 1785), consists of a string of long-delayed suspensions so that the harmonic definition at any given instant is as blurred as anything in Wagner.

Although the harmonic style of the common practice period remained a basic framework, the history of music from Mozart's time to the present shows a constant increase in harmonic density, or the amount of chromaticism and frequent chord changes present. The opening bars of Beethoven's *Eroica Symphony* demonstrate the power of chromaticism to enhance the emotional effect.

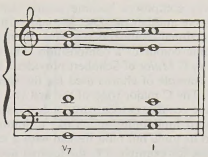
Increased use of chromaticism

The first eight notes of the theme are resolutely normal in their outline, the triad of E flat major, the tonic chord of the movement. But the ensuing two notes lead violently away from this harmonic stability, with the 10th note a totally unrelated C sharp. This sudden shift completely upsets the harmonic structure and gives unmistakable notice that a long, complex movement will be necessary to right the imbalance. Not until the coda of the movement is this opening theme allowed to follow the expected harmonic outline dictated by the style of the times.

Throughout the 19th century, composers remained rooted in the basic concept of tonality while at the same time doing everything in their power to complicate or obscure the tonal sense for the listener. Even in the 20th century, the large, varied, and important group of composers who are called conservative—among them, Samuel Barber, Aaron Copland, Sir William Walton, Dmitri Shostakovitch, Gian Carlo Menotti, Benjamin Britten—adhered to the concept of tonality only as a challenge. Tonality in their works exists, in the sense that there are extended stable areas that give the impression of being in some definable key. But the intense chromaticism of 20th-century composition, be it conservative or radical, makes it nearly impossible for the listener to grasp the unity of a work in terms of its adherence to a clear tonal plan. Unity is achieved, rather, by melodic means, the organization of rhythms, or even of tone colour. For all practical purposes, the function of tonality as the prime unifying force in musical structures, known from the 15th through the 19th century, is a thing of the past.

Dissonance in harmony. The very foundation of harmonic music has been the interplay of consonance and dissonance. Consonance can be defined as the normal range of tone combinations accepted by theorists and composers of any given time as implying repose; dissonance, therefore, refers to any sounds outside that range. From the 19th century on, as writers increasingly explored the exact effect of music on the emotions, these two terms took on the aspect of value judgments. There is a tendency to confuse consonance with concord, or sweet sound, dissonance with discord, or clashing sound. This has led to a certain amount of confusion.

Dissonance is in fact the prime element in the harmony that creates movement, and this has been recognized by composers from the dawn of the harmonic millennium. When the human ear recognizes a certain harmony as unstable within the context of a composition, it demands that this instability be rectified by the resolution to a stable harmony. Dissonance, therefore, has never been forbidden in music, for without it music would be hopelessly static.



What has been clearly defined in each era has been, rather, the treatment of dissonance, the approach toward it and away from it in a smooth and logical manner so that the musical flow is of a continual tension and relaxation.

The regulation of dissonance. The notion of which specific chords and intervals constitute consonance and dissonance has altered violently from the beginning of harmony. In the earliest harmonic writing, the parallel organum of the 9th century, the accepted intervals were the perfect consonances, or those of the simplest harmonic ratios: the fourth, the fifth, and the octave. As contrapuntal movement among voices became freer, certain other combinations necessarily occurred: thirds and sixths and, in some cases, seconds (as C–D) and sevenths (as C–B). These combinations were regarded as dissonances and were to be confined to weak beats of the musical metre; they were to be resolved, for the most part, by stepwise movement downward to the adjacent consonance. Another interval that the musicians of the modal era took great pains to avoid was the augmented fourth (the tritone, or "devil in music"), an interval containing three whole steps, as between F and B—the whole steps F–G, G–A, and A–B. This interval was considered intolerably dissonant. Primarily to avoid the forbidden, unstable harmonic relationship of the tritone, the use of accidentals (sharps, flats, natural signs) entered music and introduced chromatic tones into a mode.

Chords with a pull to cadence

By the time of Rameau, the concept of the dissonance had altered markedly. The basis of the harmony had changed, as noted above, from the perfect intervals (unison, fourth, fifth, octave) to the triad, or chord such as C–E–G, built of thirds above a root, or bass note. The tonic, or keynote, triad became the point of departure and of arrival for an entire composition and also for melodic phrases and larger sections within that composition. The harmonic movement to the cadence, a prime means of establishing points of articulation, became by the mid-18th century a more or less standard progression of harmonies subject to variation according to the composer's own powers of imagination. Preceding the tonic chord in these cadences, and pushing toward it, was the chord built on the dominant, or fifth note of the scale. This convention developed because of the nature of the dominant chord. In a dominant chord, the note a third above the root (as B in the chord G–B–D—considering the G chord the dominant and the basic key C) is the seventh note of the scale (C, D, E . . . B). This note has a strong leading tendency toward the tonic, or keynote (here, C), because it is only a half step away from the tonic, and is thus called the leading note. Because the leading note is a member of the dominant chord, this chord also has a strong pull toward the tonic chord.

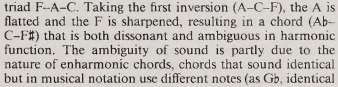
By Rameau's time it was also a common practice to enhance the pull of the dominant chord to the cadence by adding to it the note a seventh above the root of the chord (as F, in the chord G–B–D–F), that note being the fourth note of the scale (C, D, E, F). Such a chord, a dominant seventh chord (V_7) contains two leading notes: the seventh of the scale, here B, with its strong pull toward the tonic, and the fourth of the scale, here F, which has a strong pull toward another of the notes of the tonic chord (in this case toward E in the chord C–E–G), being a half step away from that note. In this way two notes of the dominant seventh chord pulled strongly toward two notes of the tonic chord. Another reason for the strong pull of the seventh chord toward the tonic is that that chord contains a tritone (in this case B–F). Although the tritone was less intolerable by that time than it was to medieval ears, it was still considered a particularly strong dissonance that demanded resolution. This resolution occurred when the dominant seventh chord moved to the tonic chord. In the example below a dominant seventh chord (V_7) moves to a tonic chord (I) in the key of C major. Arrows show the resolution of the tritone dissonance. The dominant seventh chord thus became one of the basic chords in functional harmony. In addition, because it contained two dissonances (a seventh, as G–F in the chord G–B–D–F, and a tritone, as B–F in the same chord), it was the first instance of incorporating dissonance into a

system built on the basically consonant triad. Throughout the common practice period dissonances were continually added to the basic harmonic language, so that the range of harmony and use of dissonance in late 19th-century music had expanded considerably beyond that of the early 17th century.

Music using the system of functional harmony has a flow of harmonic movement through contrasting chords and through passages from consonant to dissonant to consonant chords. If the change of chords is frequent in relation to the musical rhythm, there is said to be a rapid harmonic rhythm. Similarly, a leisurely pace of chord change is a slow harmonic rhythm. The slow or fast harmonic rhythm of a composition helps define its musical character, and by varying the harmonic rhythm within a piece a composer can create contrast, thereby defining sections of musical form.

Modulation and dissonance in the common practice period

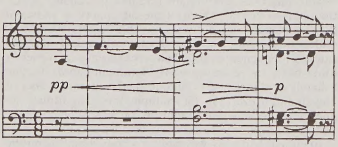
Modulation. Modulation, or change of key, was, like dissonance, increasingly explored during the common practice period. In the sonata forms that emerged as the primary musical forms of the mid-18th century, modulation from the tonic to other keys as a means of obtaining contrast became of prime importance. This musical esthetic involved not only the necessity of modulation itself but also drew much of its strength from the varying rate of modulation. Thus, the exposition, or first section, of the "normal" sonata form involves a modulation from the tonic to a nearby related key—usually the dominant, or in works in a minor key, the relative major. The development, or second section, on the other hand, depended on a rapid series of modulations, the purpose being to cast the return to the tonic in as strong a dramatic light as possible by having the stability of the tonic contrast with the instability of rapid modulation that preceded it.



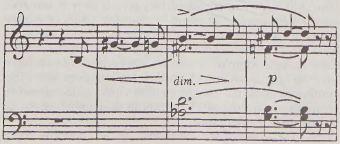
The process of modulation to many keys involved the addition of dissonant, often chromatic, notes to the basic harmonic outline of a composition. A common way of preparing for the appearance of the dominant key area in a sonata exposition was for the composer to overshoot his mark, moving temporarily to the dominant of the dominant, thereby using chromatic chords. Thus, in the transition from tonic key (C major) to dominant key (G major) in the first movement of *Symphony No. 1 in C Major,* Opus 21 (1800), of Beethoven, there is considerable emphasis on the chords of D, both major and minor, establishing D as a dominant leading to a cadence on G, the point of arrival. Much of the dissonance in music of the late classic composers is traceable to this use of secondary dominants. The tendency to move quickly through extended sequences (musical patterns repeated at higher or lower pitch) based on secondary dominant chords became a highly sophisticated technique in the mature works of Haydn and Mozart (as, for example, the extraordinary sequence in the slow movement of Haydn's *Symphony No. 104 in D Major,* the *London Symphony*).

Functional harmony was based on chords built from the diatonic (seven-note) major and minor scales; chromatic notes and chords were integrated into the functional system. Although composers of this period proved remarkably adventurous in straying beyond the limits of purely diatonic harmony, their use of dissonance and chromatism was at all times both rational and functional. Chords, even though complex, normally resolved sooner or later into the chords toward which they tended, even when the composer, as in the Haydn passage cited, added unstable elements to the chord of resolution and therefore occasioned further resolution.

Use of dissonance for harmonic colour. By the early



19th century, composers became aware that harmony could also serve another purpose: it could exist outside of a purely functional context as a means of enhancing the pure harmonic colour of a composition. The opening of the *Quintet in C Major* of Schubert provides a simple and quite early example of chords used for the sheer effect of their sound. The C major triad of the first two bars seems to swell in the ensuing two bars into a diminished seventh chord, a chord functioning much like a dominant chord in its pull to its tonic but built instead with a leading note as its root, as, for example, F♯, the leading note of G, on which is built a chord such as F♯–A–C–Eb. (The top and bottom notes of such a chord, here F♯–Eb, encompass the interval of a diminished seventh, giving the chord its name.) In Schubert's quintet the particular diminished seventh chord used would normally resolve to a chord on G. Instead it simply subsides back to the C major triad of the preceding bars, so that there occurs no real harmonic movement in the opening six bars.



Nineteenth-century harmonic usage, therefore, tended to expand not only the chordal vocabulary itself but also the function of chords. In the former respect there was an increase in the use of chords the particular type of dissonance of which lent them an unstable and a functionally ambiguous quality; for example, a chord that became of prime importance as a means of thickening the harmonic sound and of blurring the exact tonality of a musical passage was the augmented sixth chord. This is an altered chord, or one built by taking a chord normally occurring in its key and chromatically altering it. In this case, two of its notes are changed by a half step. Specifically, an augmented sixth chord is built on the first inversion of a triad, as, for example, A–C–F, the first inversion of the triad F–A–C. Taking the first inversion (A–C–F), the A is flatted and the F is sharpened, resulting in a chord (A♭–C–F♯) that is both dissonant and ambiguous in harmonic function. The ambiguity of sound is partly due to the nature of enharmonic chords, chords that sound identical but in musical notation use different notes (as G♭ identical in sound with F♯). Thus the chord A♭–C–F♯ may move smoothly to a chord built on G, but the identical sounding chord A♭–C–G♭ will progress to a vastly different chord,

on D♭. Composers can thus use such ambiguous chords to achieve unusual or expressive harmonies that blur the listener's expectations and therefore his ability to perceive key and tonality.

The opening of Wagner's music drama *Tristan und Isolde*, famous for its ambiguous sense of tonality, is an augmented sixth chord that resolves by way of a second

dissonance to the dominant seventh chord of the key of A. This sequence is repeated at a higher pitch, here resolving to the dominant seventh chord of the key of C. Although this passage can be explained in terms of normal harmonic analysis, it was in itself strikingly abnormal for its time. The passage occurs at the beginning of the composition, the point where a composer normally would be expected to establish his basic tonality. In addition, there is considerable doubt as to the exact nature of the resolution. The dominant seventh chord (here the chord of resolution) is itself dissonant, although less so than the augmented sixth chord. The tonality of the passage is obscured, for it is impossible to tell whether the passage is in A minor or A major. Since the notes of the scale that would give this information to the listener are missing from the passage, it is clear that Wagner does not want the listener to be sure. He wants the passage, rather, to stand for the substance of the opera itself: unrequited passion is equal to unresolved harmonies.

Dissonance and emotion in Wagner's music

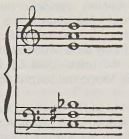
Other composers, too, sought out harmonic as well as melodic and rhythmic means to underscore the content of passion, restlessness, mystery, or tragedy in their scores. The unstable, ambiguous chord of the diminished seventh accompanies the appearances of the evil Samiel and his seven supernatural bullets in the opera *Der Freischütz (The Freeshooter)* by Carl Maria von Weber. Long strings of this chord, moving rapidly up and down the scale for purely colouristic purposes, also appear in climactic passages of the tone poem *Les Préludes*, by Franz Liszt, expressing the struggle of the soul against supernatural forces. The highly embroidered piano style of Frédéric Chopin, touched, in passing, on showers of dissonant, often chromatic tones—again used not for any exploitation of their functional value but as a spray of colour used as an overlay for a basically diatonic (nonchromatic) style, well-hidden underneath and recognizable only at the cadence.

Until the genuinely revolutionary *Tristan und Isolde* of 1865, the increase in the amount of chromaticism in the musical language of the Romantic composers was largely an enhancement of expressive detail. The diatonic (nonchromatic) basis of 18th-century functional harmony was in the main respected, as was the orderly process of modulation as a means for giving structure to large musical forms. With *Tristan*, and even more markedly with Wagner's music drama *Parsifal*, one can discern the beginnings of a gradual but unmistakable dissolution of the diatonic system on which traditional harmony was based. The analysis of *Tristan's* harmony by Rameau's principles, although possible, is simply unimportant. What matters more is the constant flow of chromaticism, of Wagner's wide variety of means—altered chords, chains of secondary dominants, and resolutions to chords that themselves prove unstable—for blurring any sense of functional harmony. Doubtless impelled by the dramatic substance of this music drama, he succeeded in evading the cadence, or coming to rest, that traditionally defined harmonic direction.

The impact of this step became apparent in the directions taken by harmony by the end of the 19th century. After Wagner, dissonance, particularly dissonance caused by chromaticism, largely ceased to function as it had in traditional harmony, and composers created their own individual, often experimental, usage of dissonance. No composer, whether he accepted *Tristan* as a masterpiece or dismissed it as madness, was left untouched by its implications.

Dissonance after Wagner. In France, where musical culture stood in some ways the direct antithesis to Wagnerism, Claude Debussy evolved his own style that succeeded, as Wagner's had, in beclouding the harmonic basis of a work either altogether or for extended periods. Debussy was influenced by a number of sources: the Impressionist painters, who were involved with the renunciation of clear perspectives and outlines in favour of the play of light across surfaces and the effect of images only half seen; exotic music, particularly that of Indonesia; and folk music, especially the modal scales of Russia. All of these led him to a partial abandonment of functional tonality. Among the devices he used toward this end is a scale composed

Debussy's sources



entirely of whole tones (as C–D–E–F♯–G♯–A♯–C). Such a scale lacks the distribution of whole and half steps that define the character of the major and minor scales of the common practice period. Chords built from the whole tone scale are by normal harmonic analysis unstable: all possible triads are augmented (the top note is altered by being sharpened; for example, C–E–G♯ instead of C–E–G) and as a result are dissonant. The perfect fourth and fifth, the ancient cornerstones of harmony, do not exist. Because the chords to which dissonances traditionally resolve are impossible with this scale, a work built upon it—*e.g.,* "Voiles" ("Sails"), from the first book of preludes for piano—can be said to exist without harmonic resolution and, therefore, without traditional tonality. Other Debussian devices include the regarding of the seventh chord (*e.g.,* dominant seventh, diminished seventh) as a self-sufficient harmony instead of as a dissonance that must resolve; sequences of sevenths moving parallel to each other giving the effect, in his music, of lines of harmony plus a dissonant descant (a countermelody in the highest part, or voice) blurring any real sense of traditional harmonic movement. This use of self-sufficient seventh chords was also much exploited by Maurice Ravel and came, through his great appeal, into a great deal of the popular music of western Europe and America from the 1920s onward.

Chord structures of Stravinsky

Again, as with Wagner, Debussy's methods cast their shadow over composers both influenced by and hostile to his musical style. Igor Stravinsky, who was a little of both, first mirrored some of Debussy's harmonic usage in *Le Sacre du printemps* (*The Rite of Spring;* 1913). In *Le Sacre,* chords appear, as they often do in Debussy, purely for their colouristic value, related to each other only by virtue of the rhythmic insistence in the music's patterns. Much of Stravinsky's harmonic style, however, is actually derived from much simpler elements than Debussy's. His complex chord structures often break apart to reveal two unrelated and dissonant diatonic chords sounded simultaneously. In the works of his Neoclassical period, Stravinsky reverts to a clear harmonic language reminiscent, at least as regards individual chords, of the 18th century; but in harmonic movement from chord to chord there is a noticeable difference from earlier styles. Stravinsky, even in this clear compositional style that occupied him in the 1920s and into the 1930s, tends to use these classical harmonies in isolation, for the chords move freely one to the other without their classical function.

Polytonality. Similar in a sense to Stravinsky's pandiatonicism, or use of diatonic chords without the limitations of classical harmonic function, is the tendency toward polytonality in the works of the post-World War I group of French composers known as "Les Six." These composers, notably Darius Milhaud, worked for a time with simple, diatonic chords piled upon each other in a way that suggested a clash between simultaneous tonal areas, almost a kind of counterpoint of tonalities—again leading to the dissolution of any sense of a single, central key area. Some traces of polytonality also occur in the early works of Bartók, who was much taken with French influences early in his career. But Bartók did not pursue this device to any great extent later on. He turned instead to an exploration of the folk styles of eastern Europe—Hungarian and Romanian, predominantly. His music, though harmonically dense and complex, remained rooted in tonality, with an admixture of harmonies gleaned from the modal scales of folk music.

Certain other composers, similarly obsessed with the desire to expand the harmonic vocabulary but loath to abandon the tonal system entirely, experimented with some success with synthetic scales of their own devising and with chords built of intervals other than the third. The Russian mystic Aleksandr Scriabin and the German Paul Hindemith both worked extensively with chords built out of fourths (as C–F–B♭). Scriabin employed these sounds primarily in a quasi-Impressionist way, using their unusual sounds as sonorous self-sufficient units. His "mystic" chord, shown below, formed the entire basis for many of his later works. Hindemith, whose orientation was toward the Neoclassical, dealt with these chords by devising his own system of harmonic function, creating a quite successful reincarnation of the dissonance–consonance tensions of earlier composers.

The direct influence of Wagner's methods, however, was felt within the German–Austrian orbit. The restless, unresolved chromaticism of *Tristan* was directly reflected in the late works of Gustav Mahler. In such a work as the long, slow movement that ends Mahler's *Ninth Symphony,* one feels the *Tristan* influence quite directly: the long, lyric lines move freely through a systematic evasion of cadences and through a widening range of tonalities, often reaching tonal regions far removed from the starting point. Yet Mahler, too, remained a tonal composer, as did Richard Strauss, whose overlays of dissonance in such works as *Elektra* are easily separable from a basically tonal harmonic movement.

Schoenberg's relationship to Wagner

Early scores by the Viennese composer Arnold Schoenberg—such as the string sextet *Verklärte Nacht* (*Transfigured Night;* 1899), the *Chamber Symphony in E Major,* Opus 9 (1906), and the first two string quartets—are direct outgrowths of *Tristan*'s chromaticism, masking but not obliterating the tonal basis. But by 1912 Schoenberg began actively to question tonality as a musical inevitability and to accept the broader implications of Wagner's style. From then on the pileup of dissonance in Schoenberg's music became so pronounced as to make the concept of dissonance itself meaningless. In such a seminal work as the chamber cantata *Pierrot Lunaire* (1912), tonality has been put aside. In this work it is no longer possible to discuss consonance and dissonance, for these concepts relate to the structure of a composition according to the harmonic principles of tonality.

Schoenberg's far-reaching musical philosophies, which were epitomized in his invention of the technique of serialism, have had a potent impact on the music of the decades following his own writing. They have also been resisted by large numbers of composers who are conveniently, if not always accurately, described as conservative. The conflict between tonality and atonality (*i.e.,* nontonality) has provided a dynamic dualism for musical styles ever since.
