Radar. *Operation.* Radio waves with wavelengths in the centimetre range can be beamed by a reflector, like light in an automobile head lamp, to make up a radar system. The narrowness of the beam depends on the shortness of the waves and on the width of the reflector. For ships and aircraft, radio waves of a very few centimetres in length are commonly used because longer waves would require reflectors too big to be mobile. Ground radars can have much bigger reflectors, and wavelengths of 10 centimetres or more are common. A radar antenna mounted on a ship is tall and narrow to produce a beam that is narrow in the horizontal plane and wide in the vertical plane. Narrowness in the vertical plane could cause the radio waves to miss the target when the ship rolls. As the radar antenna rotates, the transmitter sends out a series of very short pulses every degree or so. When the pulse strikes an object, it is reflected back to the radar aerial and thence passed to the radar receiver. The pulse is displayed on a cathode-ray tube. Electronic lines are drawn from the centre outward, each starting as the pulse starts from the transmitter. When an echo returns, the image on the tube brightens. Thus a spot of light appears on the cathode-ray tube at a distance from the centre proportional to the time the pulse takes to go out and back and in a direction the same as that in which the pulse was transmitted. Hence, on the cathode-ray tube a faint ray of light rotates around the screen like a searchlight, following the rotation of the antenna, and paints in the positions of any reflecting objects as if they were on a map. The face of the cathode-ray tube is coated with a persistent phosphor—that is, one that continues to glow for several seconds after it is excited—thus allowing the viewer time to study and analyze the image.

Antenna shapes and sizes

The strength of the return signals will vary depending on the reflectivity of the surface of the reflecting object and on its distance. There will be little reflection from water unless it is very rough. From cliffs, ships at sea, and buildings, there will be strong reflections from the vertical surfaces. From the ground, there will be only scattered reflections, generally stronger in wooded country. Nevertheless, because the shortest radar waves are so much longer than light waves, the picture painted by radar shows little detail and requires careful interpretation.

Applications. The main use of radar is in avoiding collision. Using radar, the navigator of a ship can see other vessels irrespective of light conditions. It is therefore safe for a craft to proceed—though slowly—even in thick fog, whereas without radar it would be necessary to heave to or anchor. Since the radar picture is imperfect, collision avoidance requires great skill in interpretation. In particular, it is not easy to see the direction in which other vessels are traveling, and the navigator has to make particularly bold alterations of course to make certain that other navigators do not misinterpret them.

Use of radar to avoid collision

With radar, air traffic controllers can watch the progress of aircraft in a large area. As each one approaches and lands, one radar follows it in the vertical plane and another in the horizontal plane. If necessary, the aircraft can be "talked down" (told exactly how to land) by the radar operator on the ground.

Special systems. For military purposes, infrared waves may be used; these are midway in frequency between radio and light waves. An infrared detector can distinguish between objects of different temperatures and can identify a ship on the water or a man hidden in undergrowth. Infrared radiation needs only a very small transmitter or receiver and therefore has been used to guide small missiles launched from aircraft to strike at enemy planes. The detectors, however, are distracted by other sources of infrared radiation, including the Sun and the engines of friendly aircraft.

Use of infrared waves

Lasers can also be adapted to produce radar-like devices of extreme precision. In addition, there is increased interest in simple television cameras; when equipped with light intensifiers, they can "see" in almost total darkness. Finally, for underwater detection of either submarines or shoals of fish, sonar systems have been developed.

Automation. The computer has already been mentioned in connection with point and area navigation systems, the use of satellites, and the mixing of various aids with inertial navigators. Automation is needed because craft speeds are increasing to meet demands for quick delivery of passengers and cargo and to lower operating costs. A jet aircraft with a crew of fewer than 10 can carry more passengers across the Atlantic than an ocean liner with a crew of hundreds, because its greater speed enables it to make many more trips a year.

Automation can also reduce crew sizes by taking over tasks that machines can do more reliably and more consistently. On the other hand, because engineers must design machines years before they are used, they cannot foresee some situations that arise. The first landing of astronauts on the Moon involved events not anticipated by the designers of the landing module. Had a human crew not been in the spacecraft, it would have crashed. Therefore the human navigator will doubtless be required in many types of craft well into the foreseeable future. Although the machine can manipulate, it cannot manage except insofar as it is programmed.

The navigator, although increasingly a manager of systems, is required to undertake certain manipulative tasks because there is no substitute for human judgment in dealing with unexpected situations. (E.W.A.)

Nebula

Nebula (Latin: "mist") is a term formerly used in astronomy to denote any object situated beyond the solar system that is seen as a bright or dark area, in contrast to the pointlike images of stars. This definition, adopted at a time when very distant objects could not be resolved into great detail, unfortunately includes two unrelated classes of objects: the extragalactic nebulae, now called galaxies, which are enormous collections of stars and gas; and the galactic nebulae, which are composed of the interstellar medium (the gas between the stars, with its accompanying small solid particles) within a single galaxy. Today the term nebula generally refers exclusively to the interstellar medium.

In a spiral galaxy the interstellar medium makes up 3 to 5 percent of the galaxy's mass, but within a spiral arm its mass fraction increases to about 20 percent. About 1 percent of the mass of the interstellar medium is in the form of "dust"—small, solid particles that are efficient in absorbing and scattering radiation. Much of the rest of the mass within a galaxy is concentrated in visible stars, but there are strong indications from the rotation of galaxies about their centres that there is also some form of dark matter accounting for a substantial fraction of the mass in the outer regions. This material might consist of dim stars or compact objects such as neutron stars or black holes.

The most conspicuous property of interstellar gas is its clumpy distribution on all size scales observed, from the size of the entire Milky Way Galaxy (about 10^{20} metres, or hundreds of thousands of light-years) down to the distance from the Earth to the Sun (less than 10^{11} metres, or a few light-minutes). The large-scale variations are seen by direct observation; the smallest are observed by fluctuations in the intensity of radio waves, similar to the "twinkling" of starlight caused by unsteadiness in the Earth's atmosphere. Various regions exhibit an enormous range of densities and temperatures. Within the Galaxy's spiral arms about half of the mass of the interstellar medium is concentrated in molecular clouds, in which hydrogen occurs in molecular form (H_2) and temperatures are as low as 10 kelvins. These clouds are inconspicuous optically and are detected principally by their carbon monoxide (CO) emissions in the millimetre wavelength range. Their densities in the regions studied by carbon monoxide emissions are typically 1,000 H_2 molecules per cubic centimetre. At the other extreme is the gas between the clouds with a temperature of 10 million kelvins and a density of only 0.001 H^+ ion per cubic centimetre. Such gas is produced by supernovas, the violent explosions of unstable stars.

This article surveys the basic varieties of galactic nebulae distinguished by astronomers and their chemical composition and physical properties. For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 131 and 132, and the *Index*.

CLASSES OF NEBULAE

All nebulae observed in the Galaxy are forms of interstellar matter—namely, the gas between the stars that is almost always accompanied by solid grains of cosmic dust. Their appearance differs widely, depending not only on the temperature and density of the material observed but also on how the material is spatially situated with respect to the observer. Their chemical composition, however, is fairly uniform; it corresponds to the composition of the universe in general in that approximately 90 percent of the constituent atoms are hydrogen and nearly all of the rest are helium, with oxygen, carbon, neon, nitrogen, and the other elements together making up about two atoms per thousand. Based on appearance, nebulae can be divided into two broad classes: dark nebulae and bright nebulae. Dark nebulae appear as irregularly shaped black patches in the sky and blot out the light of the stars lying beyond them. Bright nebulae appear as faintly luminous, glowing surfaces; they either emit their own light or reflect the light of nearby stars.

Two major classes

Dark nebulae are very dense and cold molecular clouds; they contain about half of all interstellar material. Typical densities range from hundreds to millions (or more) of hydrogen molecules per cubic centimetre. These clouds are the sites where new stars are formed through the gravitational collapse of some of their parts. Most of the remaining gas is in the diffuse interstellar medium, relatively inconspicuous because of its very low density (about 0.1 hydrogen atom per cubic centimetre) but detectable by its radio emission of the 21-centimetre line of neutral hydrogen.

Bright nebulae are comparatively dense clouds of gas within the diffuse interstellar medium. They have several subclasses: (1) reflection nebulae, (2) diffuse nebulae, (3) planetary nebulae, (4) supernova remnants, and (5) diffuse ionized gas.

Reflection nebulae reflect the light of a nearby star from their constituent dust grains. The gas of reflection nebulae is cold, and such objects would be seen as dark nebulae if it were not for the nearby light source.

Diffuse nebulae are clouds of hydrogen ionized (separated into positive H^+ ions and free electrons) by a neighbouring hot star. The star must be of stellar type O or B, the most massive and hottest of normal stars in the Galaxy, in order to produce enough of the radiation required to ionize the hydrogen.

Planetary nebulae are composed of the outer parts of stars that are dying but are not massive enough to become supernovas—namely, red giant stars. That is to say, a red giant has shed its outer envelope in a less violent event than a supernova explosion and has become an intensely hot star surrounded by a shell of material that is expanding at a speed of tens of kilometres per second. Planetary nebulae typically appear as rather round objects of relatively high surface brightness. Their name is derived from their superficial resemblance to planets—*i.e.*, their regular appearance when viewed telescopically as compared to the chaotic forms of other types of nebula.

Supernova remnants are the clouds of gas expanding at speeds of hundreds or even thousands of kilometres per second from comparatively recent explosions of massive stars. If a supernova remnant is younger than a few thou-

sand years, it may be assumed that the gas in the nebula was mostly ejected by the exploded star. Otherwise, the nebula would consist chiefly of interstellar gas that has been swept up by the expanding remnant of older objects.

Diffuse ionized gas

Diffuse ionized gas, so pervasive among the nebular clouds, has been recently recognized as a major component of the Galaxy. It is observed by faint emissions of H^+, N^+, and S^+ (positive hydrogen, nitrogen, and sulfur ions) detectable in all directions, collectively requiring far more power than the much more spectacular diffuse nebulae, planetary nebulae, or supernova remnants that occupy a tiny fraction of the volume. The origin of the diffuse ionized gas is still somewhat controversial (see below *Diffuse ionized gas*).

HISTORICAL SURVEY OF THE STUDY OF NEBULAE

Pre-20th-century observations of nebulae. In 1610, two years after the invention of the telescope, the Orion Nebula (see Plate 2), which looks like a star to the naked eye, was discovered by the French scholar and naturalist Nicolas-Claude Fabri de Peiresc. In 1656 Christiaan Huygens, the Dutch scholar and scientist, using his own greatly superior instruments, was the first to describe the bright inner region of the nebula and to determine that its inner star is not single but a compact quadruple system.

Early 18th-century observational astronomers gave high priority to comet seeking. A by-product of their search was the discovery of many bright nebulae. Several catalogs of special objects were compiled by comet researchers; by far the best known is that of the Frenchman Charles Messier who in 1781 compiled a catalog of 103 nebulous, or extended, objects in order to prevent their confusion with comets. Most are clusters of stars, 35 are galaxies, and 11 are nebulae. Even today many of these objects are commonly referred to by their Messier catalog number: M20, for instance, is the great Trifid Nebula, in the constellation Sagittarius.

The work of the Herschels. By far the greatest observers of the early and middle 19th century were the English astronomers William Herschel and his son John. Between 1786 and 1802 William Herschel, aided by his sister Caroline, compiled three catalogs totaling about 2,500 clusters, nebulae, and galaxies. John Herschel later added to the catalogs 1,700 other nebulous objects in the southern sky visible from the Cape Observatory in South Africa but not from London and 500 more objects in the northern sky visible from England.

The origin of NGC and IC numbers

The catalogs of the Herschels formed the basis for the great *New General Catalogue* (NGC) of J.L. Dreyer, published in 1888. It contains the location and a brief description of 7,840 nebulae, galaxies, and clusters. In 1895 and 1908 it was supplemented by two *Index Catalogues* (IC) of 5,386 additional objects. The list still included galaxies as well as true nebulae, for they were often at this time still indistinguishable. Most of the brighter galaxies are still identified by their NGC or IC numbers according to their listing in the *New General Catalogue* or *Index Catalogues*.

Advances brought by photography and spectroscopy. The advent of photography, which allows the recording of faint details invisible to the naked eye and provides a permanent record of the observation for study of fine details at leisure, caused a revolution in the understanding of nebulae. In 1880 the first photograph of the Orion Nebula was made, but really good ones were not obtained until 1883. These early photographs showed a wealth of detail extending out to distances unsuspected by visual observers.

Much can be learned about the physical nature of an astronomical object by studying its spectrum—*i.e.,* the resolution of its light into different wavelengths (or colours). Study of the spectrum of an object provides a decisive test as to whether it is composed of unresolved stars (as are galaxies) or glowing gas. Stars radiate at almost all wavelengths, with perhaps dark absorption lines superimposed, while hot, transparent gas clouds radiate only emission lines at certain wavelengths characteristic of their constituent gases. In 1864 observation of the spectrum of the Orion Nebula showed bright emission lines of glowing gases, with conspicuous hydrogen lines and some green lines even brighter. By contrast, the spectrum of galaxies was found to be stellar, so that a distinction between galaxies and nebulae—that nebulae are gaseous and galaxies are stellar—was appreciated at this time, although the true sizes and distances of galaxies were not demonstrated until the 20th century.

20th-century discoveries. The 20th century has witnessed enormous advances in observational techniques as well as scientific understanding of the physical processes that operate in interstellar matter.

Advances in instrumentation

In 1930 a German optical worker, Bernhard Schmidt, invented an extremely fast wide-angled camera ideal for photographing faint, extended nebulae. In addition, photographic plates became progressively more sensitive to an ever-widening range of colours. Since about 1960, however, photography has been almost completely replaced for research purposes by photoelectric devices. Most images are now recorded with so-called charge-coupled devices (or CCDs) that act as arrays of tiny photoelectric cells, each recording the light from a small patch of sky. Modern CCDs consist of square arrays of up to 4,000 cells on each side, or 16 million independent photocells, capable of observing the sky simultaneously. CCDs possess three advantages over photography: (1) their sensitivity to light is up to 100 times greater; (2) the range of light levels that they can record in one exposure is much greater, so that information about both the bright and faint parts of the same nebula can be obtained in a single exposure; and (3) they (or similar arrays) can record light ranging from 0.1 micrometre in the vacuum ultraviolet (accessible only from satellites orbiting above the Earth's atmosphere) to more than 1.2 micrometres in the infrared.

The most important recent development for the study of nebulae has been the use of spacecraft, which allows the observation of radiation normally absorbed by the Earth's atmosphere: X rays (which have very short wavelengths), far-ultraviolet radiation (with wavelengths shorter than about 0.3 micrometre, below which atmospheric ozone is strongly absorbing), and infrared (from about 3 micrometres to 1 millimetre) strongly absorbed by atmospheric water vapour and carbon dioxide. X rays and ultraviolet radiation reveal the physical conditions in the hottest regions in space (extending to some 100 million kelvins in shocked supernova gas). Infrared radiation reveals the conditions within dark, cold clouds, into which starlight cannot penetrate because of absorbing dust layers.

Principal means of studying nebulae

The primary means of studying nebulae is not by images but by spectra, by means of prisms (in the earlier part of the century), diffraction gratings, or crystals in the case of X rays. A particularly useful instrument is the echelle spectrograph, in which one coarsely ruled grating spreads the electromagnetic radiation in one direction, while another finely ruled grating disperses it in the perpendicular direction. This device, often used both in spacecraft and on the ground, allows astronomers to record simultaneously a wide range of wavelengths with very high spectral resolution (*i.e.,* to distinguish slightly differing wavelengths). For even higher spectral resolution astronomers employ Fabry-Pérot interferometers. Spectra provide powerful diagnostics of the physical conditions within nebulae. Images and spectra provided by Earth-orbiting satellites, especially the Hubble Space Telescope, have yielded data of unprecedented quality.

Ground-based observations also have played a major role in recent advances in scientific understanding of nebulae. The emission of gas in the radio and submillimetre ranges of wavelengths provides crucial information regarding the physical conditions and molecular composition of gas. Large radio telescope arrays, in which several individual telescopes function collectively as a single enormous instrument, give spatial resolutions in the radio regime vastly better than any yet achieved by optical means.

CHEMICAL COMPOSITION AND PHYSICAL PROPERTIES OF NEBULAE

Many characteristics of nebulae are determined by the physical state of their constituent hydrogen, by far the most abundant element. For historical reasons, nebulae in which hydrogen is mainly ionized (H^+) are called H II regions; those in which hydrogen is mainly neutral are

designated H I regions; and those in which the gas is in molecular form (H_2) are referred to as molecular clouds. The distinction is important because neutral hydrogen atoms are extremely efficient at absorbing ionizing radiation, with an energy per photon of at least 13.6 electron volts or, equivalently, a wavelength of 0.0912 micrometre or less. If the hydrogen is mainly neutral, no ionizing radiation can penetrate except for photons with energies in the X-ray range and above, or thousands of electron volts or more, in which case the hydrogen becomes somewhat transparent. For photon energies less than 13.6 volts, the radiation within an H I region has a spectrum similar to that of a fairly hot star (*i.e.*, about 15,000 K), since hot stars produce much more radiation than do cooler ones. However, the absorption by neutral hydrogen abruptly reduces the radiation field to almost zero for energies above 13.6 volts. This dearth of hydrogen-ionizing radiation within the H I region implies that no ions requiring more energy than hydrogen can be produced, and the ionic species of all elements are limited to the lower stages of ionization. Within H II regions, with almost all of the hydrogen ionized and thereby rendered nonabsorbing, photons of all energies propagate, and ions requiring energetic radiation for their production (*e.g.*, O^{++}) occur.

Ultraviolet photons of more than 11.2 volts can dissociate molecular hydrogen (H_2) into two H atoms. In H I regions there are enough of these photons to prevent the amount of H_2 from becoming large, but the destruction of H_2 as fast as it forms takes its toll on the number of photons of suitable energies. Furthermore, interstellar dust is a fairly efficient absorber of photons throughout the optical and ultraviolet range. In some regions of space the number of photons with energies higher than 11.2 volts is reduced to the level where H_2 cannot be destroyed as fast as it is produced on grain surfaces. In this case, H_2 becomes the dominant form of hydrogen present. The gas is then part of a molecular cloud. The role of interstellar dust in this process is crucial because H_2 cannot be formed efficiently in the gas phase.

Absorption of stellar radiation by interstellar dust

Interstellar dust. Only about 0.7 percent of the mass of the interstellar medium is in the form of solid grains, but these grains have a profound effect on the physical conditions within the gas. Their main effect is to absorb stellar radiation; for photons unable to ionize hydrogen and for wavelengths outside of absorption lines or bands, the dust grains are much more opaque than the gas. The dust absorption increases with photon energy, so that long-wavelength radiation (radio and far-infrared) can penetrate dust freely, near-infrared rather well, and ultraviolet relatively poorly. Dark, cold clouds, within which all star formation takes place, owe their existence to dust. Besides absorbing starlight, the dust acts to heat the gas under some conditions (by ejecting electrons produced by the photoelectric effect, following the absorption of a stellar photon) and to cool the gas under other conditions (because the dust can radiate energy more efficiently than the gas, and so in general is colder). The optical appearance of most nebulae is significantly modified by the obscurating effects of the dust.

The chemical composition of the gas phase of the interstellar medium alone, without regard to the solid dust, can be determined from the strength of narrow absorption lines in the spectra of background stars that are produced by the gas. Comparison of the composition of the gas with cosmic (solar) abundances shows that almost all of the iron, magnesium, and silicon, much of the carbon, and only some of the oxygen and nitrogen are contained in the dust. The absorption and scattering properties of the dust reveal that the solid grains are composed partially of silicaceous material similar to terrestrial rocks, though of an amorphous rather than crystalline variety; the grains also have a carbonaceous component. The carbon dust probably occurs in at least two forms: (1) graphitic grains, produced by the temporary heating of very small amorphous carbon particles after the absorption of a single photon of ultraviolet light, and (2) individual freely floating hydrocarbon molecules, with a range varying from 70 to several hundred carbon atoms and some hydrogen atoms that dangle from the outer edges of the molecule or are trapped in the middle of it. It is merely convention that these molecules are referred to as dust, since the smallest may be only somewhat larger than the largest molecules observed with a radio telescope. Both of the dust components are needed to explain spectroscopic features arising from the dust. In addition, there are probably mantles of hydrocarbon on the surfaces of the grains. The size of the grains ranges from perhaps as small as 0.0003 micrometre for the tiniest hydrocarbon molecules to a substantial fraction of a micrometre; there are many more small grains than large ones.

The dust cannot be formed directly from purely gaseous material at the low densities found even in comparatively dense interstellar clouds, which would be considered an excellent laboratory vacuum. For a solid to condense, the gas density must be high enough to allow a few atoms to collide and stick together long enough to radiate away their energy to cool and form a solid. Grains are known to form in the outer atmospheres of cool supergiant stars where the gas density is comparatively high (perhaps 10^9 times what it is in such nebulae). The grains are then blown out of the atmosphere by radiation pressure (the mechanical force of the light they absorb and scatter). Calculations indicate that refracting materials, such as the constituents of the grains proposed above, should condense in this way.

There is clear indication that the dust is heavily modified within the interstellar medium by interactions with itself and with the interstellar gas. The absorption and scattering properties of dust show that there are many more smaller grains in the diffuse interstellar medium than in dense clouds; apparently in the dense medium the small grains have coagulated into larger ones, thereby lowering the ability of the dust to absorb radiation with short wavelengths (namely, ultraviolet, near 0.1 micrometre). The gas-phase abundances of some elements, such as iron, magnesium, and nickel, also are much lower in the dense regions than in the diffuse gas, although even in the diffuse gas most of these elements are missing from the gas and are therefore condensed into dust. These systematic interactions of gas and dust show that dust grains collide with gas atoms much more rapidly than one would expect if the dust and gas simply drifted together. There must be disturbances, probably magnetic in nature, that keep the dust and gas moving with respect to each other.

Dark nebulae. The dark nebulae are clumps or clouds that become opaque because of their internal dust grains. The form of such dark clouds is very irregular: they have no clearly defined outer boundaries and sometimes take on convoluted serpentine shapes. The largest dark nebulae are visible to the naked eye, appearing as dark patches against the brighter background of the Milky Way. An example is the Coalsack in the southern sky.

Giant molecular clouds

The hydrogen of these opaque dark clouds exists in the form of H_2 molecules. The largest nebulae of this type, the so-called giant molecular clouds, are more than a million times as massive as the Sun. They contain much of the mass of the interstellar medium, are some 150 light-years across, and have an average density of 100 to 300 molecules per cubic centimetre and an internal temperature of only 7 to 15 K. Molecular clouds consist mainly of gas and dust but contain many stars as well. The cloud cores are completely hidden from view and would be undetectable except for the microwave emissions from their constituent molecules. This radiation is not absorbed by dust and readily escapes the cloud. The material within the clouds is clumped together in all sizes, with some clouds ranging down to the masses of individual stars. The density within the clumps may reach up to 10^5 H_2 per cubic centimetre or more. Small clumps may extend about one light-year across. The clouds have an internal magnetic field that provides support against their own gravity (see below).

As one penetrates into the interior of a molecular cloud, the chemistry and physical conditions become quite different from those of the surrounding low-density interstellar medium. In the outer parts of the dark cloud, the hydrogen is neutral. Deeper within it, as dust blocks out an increasing amount of stellar ultraviolet radiation, the cloud becomes darker and colder. As the centre is approached,

the predominant form of carbon changes successively from C^+ (on the outside) to neutral C to finally the molecule carbon monoxide (CO), which is so stable that it remains the major form of carbon in the gas phase in the darkest regions. At great depths within the cloud other molecules can be seen from their microwave transitions, and more than 70 chemical species have been identified within the constituent gas. Owing to the comparatively low densities and low temperatures, the chemistry is very exotic, as judged by terrestrial experiments; some rather unstable species can exist in space because there is not enough energy to convert them to more stable forms. An example is the near equality of the abundances of the interstellar molecule HNC (hydroisocyanic acid) and its isomer HCN (hydrocyanic acid); in ordinary terrestrial conditions there is plenty of energy to allow the nitrogen and carbon atoms in HNC to exchange positions and produce HCN, by far the preferred species for equilibrium chemistry. In the cold clouds, however, not enough energy exists for the exchange to occur. There is less than one-thousandth as much starlight within a cloud as in the interstellar space outside the cloud, and the heating of the material in the cloud is provided primarily by cosmic rays. Cooling within the cloud occurs chiefly by transitions between low-lying levels of the carbon monoxide molecule.

Recent observations of the emission lines from C^+, C^0, and CO show that the edges of the dark nebulae are very convoluted spatially, with stellar ultraviolet radiation able to penetrate surprisingly far throughout the cloud despite the absorption of the dust. Stellar radiation can apparently enter the cloud through channels where the dust (and gas) density is lower than average. The clumpiness of the interstellar material has profound effects on its properties.

Star formation

In the inner regions of dark nebulae important events take place: the formation of stars. The discussion that follows will be slightly oversimplified by the assumption that a nebula has very little net rotation. Since the density in a star is immensely greater than that in a nebula, star formation must occur through condensation. The force of gravity in the nebula constantly pulls it together, working against the disruptive collisions of any one nebula or cloud with its neighbours and against the pressure provided by an internal magnetic field. But, even if gravity can hold the cloud together against other forces, the cloud cannot collapse unless it can cool; gravitational energy is released in a contraction and would heat the gas cloud, thus increasing the outward pressure and preventing further collapse. The dust grains are efficient emitters of infrared radiation, which escapes, removing the energy from the nebula. A cloud, therefore, contracts under its own gravity, radiating away half of the gravitational energy of the contraction, the other half going into heating the gas. As it contracts, the density and gravitational binding increase until finally the cloud's gravity so dominates the internal pressure that the material rushes inward in almost a free fall.

While the entire cloud has been collapsing, it does not have a smooth density distribution but rather consists of a chaotic jumble of smaller clouds. These cloudlets pull themselves together by their own gravity into "protostars," each of which is destined to be an individual stellar system. Most of these protostars are smaller than one solar mass, but a very few may be several (up to about 100) times as massive as the Sun. These few massive stars have a profound influence in the evolution of the nebula.

Each protostar collapses very quickly; its gas falls inward in free fall. A protostar can collapse from a size equal to the outer diameter of the solar system to about 30 times the Sun's size (the size of Mercury's orbit) in about six months. After it reaches that size, the material becomes so hot it has become a star—that is, an opaque body radiating energy only from its surface. Around it is a whirling ring of cold, dusty material, which will also break up into even smaller fragments, the "protoplanets." It is now believed that planetary systems are made out of this dusty chaos.

Origin of planetary systems

Such newly formed stars continue to contract, becoming hotter but less luminous in the process, until they start to produce heat by converting hydrogen into helium rather than by contracting. If massive enough, a star ionizes the nebular material, producing a bright nebula around it.

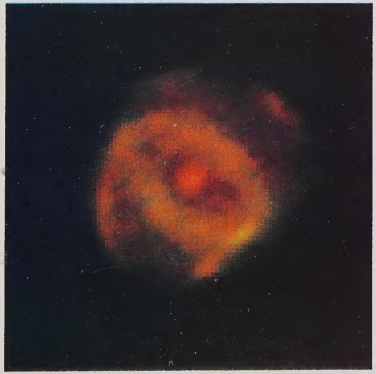
These ideas are given encouraging confirmation by observations of dark nebulae in very long wavelength infrared radiation. Some of the brightest infrared sources are associated with such dark dust clouds; a good example is the class of T Tauri variables, named for their prototype star in the constellation Taurus. The T Tauri stars are known for a variety of reasons to be extremely young. The variables are always found in or near dark nebulae; they often are also powerful sources of infrared radiation, corresponding to warm clouds of dust heated by the T Tauri star to a few hundred kelvins. There are some strong infrared sources (especially in the constellation of Orion) that have no visible stars with them; these are presumably "cocoon stars" completely hidden by their veils of dust.

Neutral clouds (H I regions). Neutral hydrogen is dominant in clouds that have enough starlight to dissociate molecular hydrogen but lack hydrogen-ionizing photons from hot stars. These clouds can be seen as separate structures within the lower-density interstellar medium or else on the outer edges of the molecular clouds. Because a neutral cloud moves through space as a single entity, it often can be distinguished by the absorption line that its atoms or ions produce at their common radial velocity in the spectrum of a background star.

Neutral clouds have two possible temperatures (with little material at intermediate values), both determined by the balance of heating and cooling rates. Cold H I regions are at about 80 K; heating is provided by electrons ejected from the dust grains by interstellar ultraviolet radiation incident upon such a cloud from outside. Cooling is mainly by C^+ because passing electrons or hydrogen atoms can excite it from its normal energy state, the lowest, to one slightly higher, followed by emission of radiation at 158 micrometres. This line is observed to be very strong in the spectrum of the Galaxy as a whole, indicating that a great deal of energy is removed from interstellar gas by this process. Warm H I regions (about 8,000 K) are cooled by excitation of the $n = 2$ level of hydrogen, which is at a much higher energy than the lowest level of C^+ and therefore requires a higher temperature for its excitation. The density is much lower in the hotter regions, rendering the cooling by C^+ less efficient because it requires collisions for the excitation. At any particular density there is far more neutral hydrogen available for cooling than C^+. Clouds of either temperature can exist at the same pressure, so the interstellar medium separates itself into the two phases depending on the past history of each parcel of gas.

Reflection nebulae. If a cloud that would normally be a dark nebula happens to be illuminated by a nearby bright star not hot enough to ionize the cloud's hydrogen, the dust grains in the cloud reflect the starlight and give rise to a reflection nebula. The famous nebulosity in the Pleiades star cluster is of this type; it was discovered in 1912 that the spectrum of this nebula mimics the absorption lines of the nearby stars, whereas bright nebulae that emit their own light show characteristic emission lines quite unlike stars. The brightest reflection nebulae are illuminated by B-type stars that are very luminous but have temperatures lower than about 25,000 K, somewhat cooler than the O-type stars that would ionize the hydrogen in the gas and produce a diffuse emission nebula. The extent and brightness of reflection nebulae show conclusively that dust grains are excellent reflectors in the broad range of wavelengths extending from the ultraviolet (as determined from observations from space) through the visible. Optical observations suggest that about 60–70 percent of the light is reflected rather than absorbed, while the corresponding fraction for the whole Earth is only 35 percent and for the Moon a mere 5 percent. Grains reflect light almost as well as fresh snow, more because of their favourable size (which promotes scattering rather than absorption) than their chemical composition. Calculations show that even graphite, which is black in bulk, reflects visible light well when dispersed into small particles.

Illumination by B-type stars



Diffuse nebulae (H II regions). As noted above, clouds of gas and dust that contain stars hot enough to ionize their hydrogen are called diffuse nebulae, or H II regions. In contrast to dark or reflection nebulae, their spectrum consists of emission lines at various wavelengths charac-

Veil Nebula (NGC 6992) in the constellation Cygnus. It glows as it collides with dust and gas in interstellar space. Blue light is emitted from the hot leading edge of the nebula, where the most energetic collisions occur; the red glow is from hydrogen in the cooler gas.

A small part of the Cygnus Loop supernova remnant, which marks the edge of an expanding blast wave from an enormous stellar explosion that occurred some 15,000 years ago. The remnant is located in the constellation Cygnus the Swan.

Planetary Nebula Hen 1357, as photographed by the Hubble Space Telescope. It is located about 18,000 light-years from Earth and lies in the constellation Ara the Altar. This expanding cloud of gas was expelled from an aging star in the nebula's centre.

Lagoon Nebula (M8, NGC 6523) in the constellation Sagittarius. This bright diffuse nebula is so large that light from the stars involved does not penetrate its boundaries, and the bright nebula appears to be seen against a larger darker one.

Crab Nebula (M1, NGC 1952) in the constellation Taurus, a gaseous remnant of the galactic supernova of AD 1054, 6,000 light-years away, expanding at 1,125 kilometres per second.

Ring Nebula (M57, NGC 6720) in the constellation Lyra, a planetary nebula consisting mainly of gases thrown off by the star in the centre.

(Above) The inner part of the 30 Doradus Nebula, the most luminous nebula in the entire Local Group of galaxies. It is located in the Large Magellanic Cloud.

(Left) Bright nebulosity in the Pleiades (M45, NGC 1432), distance 490 light-years. Cluster stars provide the light, and surrounding clouds of dust reflect and scatter the rays from the stars.

A star-forming region in the Orion Nebula (M42, NGC 1976). This composite image shows an area one light-year square near the edge of a cavity of ionized hydrogen heated by ultraviolet radiation from a star cluster at the nebula's centre.

A plume of gas (lower right) in the Orion Nebula. This highly supersonic shock wave—moving at a speed of more than 238,000 kilometres per hour—was produced by a beam of material emanating from a newly formed star.

Plate 2: (Top left, top right, centre left) California Institute of Technology/Palomar Observatory (top left, top right) 1959, (centre left) 1961, (centre right) National Optical Astronomy Observatories, (bottom left, bottom right) National Aeronautics and Space Administration.

teristic of their ions. Like dark clouds, diffuse nebulae typically have little regular structure or sharp boundaries—hence their name. Their sizes and masses vary widely. There is even a faint region of ionized gas around the Sun and other comparatively cool stars, but it cannot be observed from nearby stars with existing instruments. The largest diffuse nebulae (none of which occur in the Milky Way Galaxy) are 500 light-years across and contain at least 100,000 solar masses of ionized gas. These enormous H II regions are powered by clusters of massive hot stars rather than by any single stellar body. A typical diffuse nebula within the Galaxy measures about 30 light-years in diameter and has an average density of about 10 atoms per cubic centimetre. The mass of such a cloud amounts to several hundred solar masses. The only diffuse nebula visible to the naked eye is the beautiful Orion Nebula (see Plate 2). Located in the constellation named for the Greek mythological hunter, it is seen as the central "star" in Orion's sword. The entire constellation is enveloped in faint emission nebulosity, powered by several stars in Orion's belt rather than by the star exciting the much smaller Orion Nebula itself. The largest diffuse nebula in terms of angular size is the Gum Nebula, named after its discoverer, the Australian astronomer Colin S. Gum. It measures 40° in angular diameter and is mainly ionized by two very hot stars (Zeta Puppis and Gamma Velorum).

Largest known diffuse nebulae

The spectra of H II regions show bright emission lines arising from two fundamentally different processes. The first are recombination lines, which are produced when any ion combines with an electron to form a neutral atom (or lower stage of ionization), radiating away some or all of the energy it had from its previous ionization. All elements produce these lines, but the lines are bright only for recombination of the very abundant ions H^+ and He^+. The observed lines are produced when the newly formed atom is in an excited energy level and cascades from that level to a lower one with the emission of a line photon. One of the brightest lines in diffuse nebulae, for example, is the red Hα line of hydrogen, arising either from recombination of an H^+ ion to the $n = 3$ level of a hydrogen atom or from a recombination to a higher level followed by a cascade to the $n = 3$ level. A hydrogen atom in the $n = 3$ level can undergo a transition to the $n = 2$ level with the emission of the Hα photon.

Forbidden lines

The second are what are termed forbidden lines, which are produced by the excitation of an atom or ion from its lowest level to a higher level by a collision with an electron, followed by the emission of a photon from the higher level downward to a lower one (not necessarily the lowest). The name forbidden is appropriate because these emission lines are not observed directly in the laboratory; the downward transition that produces the photon requires a relatively long time to take place, and in the laboratory the excited atom encounters another particle or the container walls before it emits the photon. This encounter allows the excited atom to give up its energy to its collision partner without radiating a photon. In a diffuse nebula it has time to produce the radiation before it can collide with another atom or ion. The strongest lines in most diffuse nebulae are the forbidden lines from either O^{++} (at 4959 and 5007 angstroms) or from O^+ (at 3726 and 3729 angstroms). These lines provide very strong cooling above about 10,000 K and act to limit the temperatures of H II regions to approximately that value, unless the abundance of oxygen is significantly lower than solar abundance, in which case higher temperatures can be reached.

Diffuse nebulae are almost always accompanied by dark nebulae on their borders. The Orion Nebula, for example, is merely a conspicuous ionized region on the nearby face of a much larger dark cloud; the diffuse nebula is almost entirely produced by the ionization provided by a single hot star, one of the four bright central stars (the Trapezium) identified by Huygens in 1656. The shape of the Orion Nebula appears at visible wavelengths as irregular (see Plate 2). However, much of this seeming chaos is spurious, caused by obscuration of dust in foreground neutral material rather than by the actual distribution of ionized material. Radio waves can penetrate the dust unhindered, and the radio emission from the ionized gas reveals it to be quite circular in shape and surprisingly symmetrical as seen in projection on the sky. The foreground dark material obscures about half of the ionized nebula.

In most cases, a diffuse nebula is found on the outer edge of a large molecular cloud in which star formation is occurring, induced by the very presence of the diffuse nebula. For instance, behind the bright Orion Nebula, deeper within the dark, cold Orion molecular cloud, new stars are being formed today. At present, none of the new stars is massive and hot enough to produce its own diffuse nebula, but presumably one of them eventually will be. When a diffuse nebula is produced from cold molecular gas by the formation of a hot star, the temperature is raised from roughly 25 to 8,000 K, and the number of particles per cubic centimetre is almost quadrupled because each H_2 molecule is split into two ions and two electrons. Gas pressure is proportional to the product of the temperature and number of particles per cubic centimetre (regardless of their mass, so electrons are as important as the much heavier ions). Thus, the pressure in a diffuse nebula is some 800 times the pressure of the cold gas from which it formed. The excess pressure causes a violent expansion of the gas into the dense cloud. Rapid star formation may occur in the compressed region, producing an expanding group of young stars. Such groups, the so-called O Associations (with O stars) or T Associations (with T Tauri stars), have been observed. The component stars simultaneously generate extremely fast outflows from their atmospheres (see below). These winds create regions of hot, tenuous gas surrounding the association. Eventually the massive stars in the association explode as supernovas, which further disturb the surrounding gas.

Region of new star formation

This picture of the evolution of diffuse and dark nebulae is one of constant turmoil, a few transient O stars serving to keep the material stirred, in constant motion, continually producing new stars and churning clouds of gas and dust. In this way some of the stellar thermonuclear energy is converted into the kinetic energy of interstellar gas.

Recently "ultracompact" H II regions have been discovered inside the molecular clouds in which they were formed. These nebulae are observed only at the wavelengths of radio and far-infrared radiation, which are able to penetrate the thick dust in the clouds. They are extremely bright at wavelengths of 50 micrometres, and the most luminous ones were detected throughout the Galaxy by the orbiting Infrared Astronomical Satellite (IRAS), which in 1983 mapped almost the entire sky at 12, 25, 60, and 100 micrometres. There are about 2,500 of these objects in the Galaxy, representing 10 to 20 percent of the total O-type star population. Usually only a light-month in size, 100 times smaller than a typical diffuse nebula, they show densities in the ionized region of 10^5 hydrogen atoms per cubic centimetre. They cannot be at rest with respect to the surrounding gas; if they were, the immense pressure exerted by their dense, hot gas would cause a violent expansion. (Their lifetimes would be only about 3,000 years—exceedingly short on an astronomical time scale—and not nearly as many could be seen as the number observed by astronomers.) Rather, their gas is kept confined because they are moving through the surrounding cloud at speeds of about 10 kilometres per second, and what is observed is the cloud of freshly ionized gas ahead of them that has not yet had time to expand. The ultracompact diffuse nebulae leave behind a trail of ionized material that is not as bright as the confined gas ahead of them. This trail gradually fades as it recombines after the ionizing star has passed. The radio radiation is produced by the ionized gas, but the far-infrared radiation is emitted by the 5,000 solar masses of surrounding dust warmed by the luminosity of the embedded star.

Ultra-compact H II regions

High-resolution studies of diffuse nebulae reveal one of the surprises that make the study of astrophysics delightful. Instead of the smooth structure that might be expected of a gas, a delicate tracery of luminous filaments can be detected, down to the smallest scale that can be resolved. In the Orion Nebula this is about 10 times the diameter of the orbit of Pluto around the Sun. Even finer detail may exist, and there is evidence from spectra that much of the matter may be gathered into dense condensations,

Luminous filaments

or knots, the rest of the space being comparatively empty. The time it would take unrestrained gas to fill a vacuum between the visible filaments is only about 200 years, much less time than the age of the nebula. The nebular gas is presumably restrained from expansion by the pressure of tenuous material, which has a temperature of a few million kelvins. Its pressure, however, is comparable to that in the visible "warm" (8,000 K) gas of the diffuse nebula. Hence, the density of the hot material is several hundred times lower, which effectively prevents it from radiating. Moreover, the material is invisible except in low-energy X rays. The space throughout the plane of the Galaxy is largely filled with this hot component, mainly produced and heated from supernovas. In diffuse nebulae, it also arises from the "wind" blown off the atmospheres of the exciting stars at speeds of up to 3,000 kilometres per second. This stellar wind creates a large cavity or bubble in the denser, cooler gas originally surrounding such a star. In the interior of the bubble, the radially flowing stellar wind passes through a transition in which its radial motion is converted into heat. The hot gas then fills most of the cavity (perhaps 90 percent or more) and serves to separate the filaments of the warm, comparatively dense diffuse nebula. Within the condensations of visible plasma, there are neutral globules in which the gas is quite cold (about 100 K) and dense enough (typically, 10,000 atoms per cubic centimetre) to have about the same pressure as the hot and warm materials. In short, a diffuse nebula is much more complicated than its visual radiation would suggest.

The most energetic diffuse nebulae in the Galaxy are revealed only by radio telescope—they are so heavily obscured by dust that they are inconspicuous optically. These nebulae have over 100 times more ionizations per second than does the Orion Nebula, too many to be provided by a single star (unless there are stars more luminous than any known within the Galaxy). Indeed, very high resolution images of the most luminous nebulae show there are clumps of ionized gas—probably ionized by tight groupings of single stars—embedded in rather diffuse gas that emit most of the radio radiation. Similar objects, about 200 light-years in diameter, are formed in other galaxies; if they were located at the Orion Nebula, they would cover the entire constellation of Orion with brightly glowing gas.

Supergiant nebulae

These supergiant nebulae are more than 10 times as luminous as any in the Galaxy. The entire Local Group—the cluster of galaxies consisting of the Galaxy, the great spiral galaxy in Andromeda, the smaller spiral in Triangulum, and more than 20 other stellar assemblages—contains but one supergiant nebula: the object called 30 Doradus, in the Large Magellanic Cloud (see Plate 2). This nebula requires over 1,000 times more ionizations per second than the Orion Nebula. It contains a stellar cluster called R136, the source of most of the energy radiated by the nebula. This grouping consists of dozens of the most massive known stars of the Galaxy, all packed into a volume only a thousandth of a typical stellar spacing in size. How such a cluster could form, in either case, is a fascinating puzzle. There are other supergiant nebulae outside of the Local Group, some of which radiate 10 times the energy of 30 Doradus.

Location of diffuse and dark nebulae in the Galaxy. One of the remarkable features of diffuse and dark nebulae is their concentration in the spiral arms in the plane of the Galaxy. While there is no definite boundary to the arms, which have irregularities and bifurcations, the nebulae in other spiral galaxies are strung out along these narrow lanes and form a beautifully symmetric system when viewed from another galaxy. The nebulae are remarkably close to the galactic plane; most are within 300 light-years, only 1 percent of the Sun's distance from the centre. The details of the explanation of why the gas is largely confined to the spiral arms is beyond the scope of this article (see GALAXIES: *The Milky Way Galaxy: Major components*). Briefly, the higher density of the stars in the arms produces sufficient gravity to hold the gas to them.

The question may be asked: why doesn't the gas simply condense into stars and disappear? The present rate of star formation is about one solar mass per year in the entire Galaxy, which contains something like 2×10^9 solar masses of gas. Clearly, if the gas received no return of material from stars, it would be depleted in roughly 2×10^9 years, about one-fifth the present age of the Galaxy. Several processes by which gas is returned to the interstellar medium from stars have been observed. Possibly the most important is the ejection of planetary nebula shells, discussed below; other processes are ejection of material from massive O- and B-type normal stars or from cool M giants and supergiants. This rate of gas ejection is roughly equal to the rate of star formation, so that the mass of free gas is declining very slowly.

Processes by which gas is returned to the interstellar medium

This cycling of the gas through stars presumably has had one major effect: the chemical composition of the gas has been changed by the nuclear reactions inside the stars. There is excellent evidence that the Galaxy originally consisted of 77 percent hydrogen by mass and that almost all of the rest of the constituent matter was helium. All heavy elements have been produced inside stars by being subjected to the exceedingly high temperatures and densities in the central regions. Thus, most of the atoms and molecules on the Earth, as well as in human bodies, owe their very existence to processes that occur within stars.

Chemical composition of diffuse nebulae. The composition of diffuse nebulae can be estimated by relating the strengths of the emission lines found in their spectra to the numbers of atoms producing them. Great strides have been made in calculating the necessary atomic properties. The principal difficulties in determining the abundances of elements from nebular emission lines are (1) the estimation of the nebular temperature, which is necessary because line emission for a given abundance increases rapidly with increasing temperature, and (2) the estimation of the abundances of stages of ionization of the element, if these stages do not have any observable lines. There are at least two reliable indicators of nebular temperatures. The first uses the relative strengths of lines arising from two or more upper levels of ions of elements heavier than helium. The levels must be reasonably different in energy. The ratio of line strengths depends sensitively on the electron temperature. Unfortunately, there are not many such diagnostic line pairs. The most frequently available pair is that of doubly ionized oxygen. The line from the upper level, at a wavelength of 4363 angstroms, is very faint, often less than 1 percent of the strong green line at 5007 angstroms. If there are fluctuations of temperature within a nebula, this method estimates the temperature to be too high. The second method of determining nebular temperature is based on the strengths of emission lines of hydrogen in very high quantum states, such as the transition between the 110 and 109 levels. Because the higher levels are closely spaced, the transitions between two higher levels have low energies and correspondingly long wavelengths—six centimetres, in this case. This radio wavelength implies that the line can be observed through large amounts of dust. There is some action originating in nebulae to amplify the emission by means of a mechanism fundamental to the laser and maser—namely, stimulated emission. The strength of a radio line depends on the nebular temperature. If there are regions of various temperatures within a nebula, such radio lines, in contrast to the forbidden lines, give an estimate that is lower than the true average. The two methods of estimating nebular temperature yield gratifyingly similar results when they are applied to the same object. This fact indicates that temperature fluctuations within a nebula may not be a serious problem.

All abundant chemical elements have some stages of ionization that are associated with observable emission lines from which the abundance of a given ion can be determined after the temperature has been estimated in the manner discussed above. The primary interest, though, is in the total abundance of the element and not simply that of an individual stage of ionization. Ions that have no observable lines are accounted for by theoretical calculations. Elaborate computer calculations predict the ionization structure of gas ionized by a hot star; the temperature of the star is determined by matching the observed stages of ionization with the computer model. The

Use of computer models

calculations then provide predictions of the abundances of the invisible ions. The correction for unobserved stages is of little significance for some elements (oxygen) but absolutely crucial for others (argon and carbon). The final estimates for—in order of decreasing reliability—oxygen, sulfur, nitrogen, and neon abundances in diffuse nebulae are comparable in accuracy to determinations of stellar composition. Those for carbon and argon, however, are more problematic. The well-established abundances have uncertainties of about 30 percent. Such determinations apply only to the portions of the elements in the gas phase. Solids (dust grains) do not produce emission lines.

In the Orion Nebula, the abundances of elements other than hydrogen are (in atoms per million hydrogen atoms) as follows: helium, 80,000; oxygen, 400; carbon, 320; neon, 70; nitrogen, 50; sulfur, 12; and argon, 4. One of the most enigmatic results of the Orion investigations is that the oxygen abundance in the nebula is only about 0.6 that in the Sun. This finding is most unexpected because supernovas presumably have been adding oxygen to the interstellar gas ever since the Sun formed some five billion years ago. Grains are probably not responsible for the "missing" oxygen in the Orion Nebula because the inner part of the nebula seems to be free of dust. Furthermore, nitrogen and neon, both unlikely to be found in dust grains, also are deficient in Orion in exactly the same proportion as oxygen. One possibility is that there are chemical inhomogeneities within the Galaxy and that the Sun formed from material richer than average in heavy elements.

It is, in fact, clear that the Galaxy is not chemically homogeneous at the present time. Observations of radio recombination lines show that there is a gradient, or variation, in the temperature of nebulae throughout the Galaxy. This gradient almost surely implies a variation in the principal coolant, oxygen, and presumably in other heavy elements as well. The oxygen abundance is perhaps twice the solar value at one-third the Sun's distance from the galactic centre, and down to two-thirds of the solar abundance at the most distant points for which reliable determinations can be made (about 1.5 times the Sun's distance, or 45,000 light-years). These differences in heavy-element content reflect varying amounts of nucleosynthesis by massive stars. Similar gradients are found in other galaxies.

Determining the compositions of nebulae outside the Galaxy

The composition of nebulae in other galaxies can be determined by direct optical observations of emission lines. This method is not practical throughout the Milky Way because of the obscuration of dust. The Large Magellanic Cloud has compositions that are uniformly about one-half those of the Orion Nebula for oxygen, neon, argon, and sulfur and are one-quarter those of Orion for carbon and nitrogen. It appears that the first group of elements must be manufactured together, presumably in massive stars, and ejected together into the interstellar gas that is currently observable. Stars of a different mass (probably lower) must produce carbon and nitrogen. Planetary nebulae (discussed below) also suggest the same scenario.

The abundance of helium in nebulae has received considerable attention because the helium content of the oldest objects provides clues to the origin of the universe. The value cited above for the Orion Nebula is in agreement with the predictions of the big-bang model, the prevailing cosmological theory according to which the universe began with an enormous explosion involving rapid expansion from a highly compressed primordial state. In order to determine the precise nature of this so-called big bang, a more precise estimate of helium abundance is needed than can be presently derived from nebulae.

Planetary nebulae. There are about 20,000 objects called planetary nebulae in the Galaxy, each representing gas expelled relatively recently from a central star very late in its evolution. By contrast, diffuse and dark nebulae are clouds of gas from which young stars form. Because of the obscuration of dust in the Galaxy, only about 1,500 planetary nebulae have been catalogued.

Forms and structure. Compared to the diffuse nebulae, planetary nebulae are small objects, having a radius, typically, of one light-year and containing a mass of gas equivalent to about 0.3 solar mass. One of the largest known planetary nebulae, the Helix Nebula (NGC 7293) in the constellation Aquarius, subtends an angle of about 20′ of arc—two-thirds the angular size of the full Moon.

Density of planetary nebulae

Planetary nebulae are considerably denser than most diffuse nebulae, typically containing 1,000–10,000 atoms per cubic centimetre within their dense regions, and have a surface brightness 1,000 times as large. Many are so far away that they appear stellar when photographed directly, but the conspicuous examples have an angular size up to 20′ of arc across, 10″–30″ being usual. Those that show a bright disk have much more regular forms than the chaotic diffuse nebulae, but there are still usually some brightness fluctuations over the disk. The planetaries generally have regular, sharp outer boundaries; often they have a relatively regular inner boundary as well, giving them an appearance like a ring. Many have two lobes of bright material, resembling arcs of a circle, connected by a bridge—somewhat resembling the letter Z.

Most planetaries show a central star, called the nucleus, which provides the ultraviolet radiation required for ionizing the gas in the ring or shell surrounding it. Those stars are among the hottest known and are in a state of comparatively rapid evolution.

As with diffuse nebulae, the overall structural regularity conceals large-scale fluctuations in density. High-resolution photographs of a planetary nebula usually reveal tiny knots and filaments down to the resolution limit of the photograph. The spectrum of the planetary nebula is basically the same as that of the diffuse nebula; it contains bright lines from hydrogen and helium recombinations and the forbidden lines (defined above) of other ions. In general, the spectra of planetaries differ from those of diffuse nebulae in that they show much higher degrees of ionization. In some planetaries most of the helium is doubly ionized, and appreciable amounts of five-times-ionized oxygen and argon and four-times-ionized neon exist. In diffuse nebulae helium is mainly once ionized and neon and argon only once or twice. This difference in the states of the atoms results from the temperature of the planetary nucleus (up to about 150,000 K), which is much higher than that of the exciting star of the diffuse nebula (less than 60,000 K for an O star, the hottest). One of the conspicuous features of planetaries is that the high stages of ionization are found close to the central star. The rare heavy ions, rather than hydrogen, absorb the photons of several hundred volts' energy. Beyond a certain distance from the central star, all the photons of energy sufficient to ionize a given species of ion have been absorbed, and that species therefore cannot exist farther out. Detailed theoretical calculations have rather successfully predicted the spectra of the best-observed nebulae.

The spectra of planetary nebulae reveal another interesting fact: they are expanding from the central star at 24 to 56 kilometres per second. The gravitational pull of the star is quite small at the distance of the shell from the star, so the shell will continue its expansion until it finally merges with the interstellar gas around it. The expansion is proportional to the distance from the central star, consistent with the entire mass of gas having been ejected at one brief period from the star in some sort of instability.

The distances of planetary nebulae. Not a single planetary nebula is close enough to the Sun to allow a direct determination of its distance; the nearest, reasonably bright one (Helix Nebula) is about 300 light-years away. It is necessary, therefore, to use indirect methods to find the distances. One method is to assume a nebular mass, estimate the true rate of emission of one of the hydrogen lines from the nebula (from the gas density and temperature), and compare this with the observed brightness. From the intrinsic and apparent brightness the distance can be found. One planetary, NGC 246, has a normal G star as a companion, whose distance can be estimated if it is similar in intrinsic brightness to nearby G stars of similar type. Once the distance is known, other quantities (such as size and mass) can easily be determined. Unfortunately, different methods of estimating distances give results differing by factors of more than two. A more reliable way of estimating distance is to consider the planetaries found in the

Reliance on indirect methods of determining distance to planetary nebulae

nearest external galaxies, such as the Andromeda Galaxy or the Magellanic Clouds. The distances to the galaxies are known from their other stars, such as the Cepheid variables. Even the most luminous planetary nebulae are very faint in other galaxies, and so only the few brightest and atypically massive nebulae can be studied.

From the best available average distance determination, the true size of any nebula can be found, within the limits of error, from its angular size; typically, planetary nebulae are found to be a few tenths of a light-year in radius. If this distance is divided by the expansion speed, the age of the nebula since ejection is obtained, with values up to roughly 30,000 years. After this time, the expanding gas becomes indistinguishable from the interstellar medium.

Chemical composition. The chemical composition of planetaries can be found from their spectra in the way discussed above for diffuse nebulae. Planetary nebulae definitely show signs of chemical enrichment from elements produced by nuclear processing within the central star. Some are carbon-rich, with twice as much carbon as oxygen, while the opposite is true for the Sun. Others are overabundant in nitrogen; the most luminous ones, observed in external galaxies, are conspicuous examples. Helium is modestly enhanced, up to a factor of two over the solar value. There is one object that contains almost no hydrogen; it is as if the gas had been ejected from the object at the very end of the nuclear-burning process. Planetary nebulae also show a clear indication of the general heavy-element abundance gradient in the Galaxy, presumably a reflection of the original composition of the stars that gave rise to the present nebulae.

Presence of cosmic dust

Some, but not all, planetary nebulae contain internal dust. In general, this dust cannot be seen directly but can be detected from the infrared radiation it emits after being heated by nebular and stellar radiation. The presence of dust implies that planetary nebulae are even richer in heavy elements than gas-phase abundance studies suggest.

Among nebulae so far discovered, two are particularly deviant in chemical composition: one is in the globular cluster M15 and the other in the halo (tenuous outer regions) of the Galaxy. Both have very low heavy-element content (down from normal by factors of about 50) but normal helium. Both objects are very old, suggesting that the primeval gas in the Galaxy had a low heavy-element content but an almost normal amount of helium. The origin of helium in the Galaxy was probably the initial explosion of the universe itself.

Positions in the Galaxy. One of the best indicators of the average age of astronomical objects is their position and motion in the Galaxy. The youngest are in the spiral arms, near the gas from which they have formed; the oldest are not concentrated in the plane of the Galaxy, nor are they found within the spiral arms. By these criteria, the planetaries reveal themselves to be rather middle-aged; they are moderately but not strongly concentrated in the plane; rather, they are concentrated toward the galactic centre, as the older objects are. Their motions in the Galaxy follow elliptical paths, whereas circular orbits are characteristic of younger stars. They belong to the type of distribution often called a "disk population," to distinguish them from the Population II (very old) and Population I (young) objects proposed by the German-American astronomer Walter Baade. It is likely that there is a wide variation in the ages of planetaries and that some are very young objects.

Evolution of planetary nebulae. A description of the evolution of a planetary nebula begins before the ejection of the nebula itself. As will be discussed below, the central star is a red giant before the ejection. In such a phase it experiences a rapid loss of mass, up to 0.01 Earth mass per day, in the form of a comparatively slowly expanding stellar wind. At this stage the red giant might be heavily obscured by dust, which forms from the heavy elements in the wind. Eventually the nature of both the star and its wind changes. The star becomes hotter because its hot core is exposed by the loss of the overlying atmosphere. The inner gas is ionized by radiation from the hot star. The ionization zone moves steadily outward through the slowly moving material of what was formerly the stellar wind. The expansion speed of the gas is typically 30 kilometres per second. Nebulae in this stage are bright but have starlike images as seen from the Earth, because they are too small to show a disk. The gas is at a relatively high density—about one million atoms per cubic centimetre—but becomes more dilute as the gas expands. During this stage the nebula is surrounded by neutral hydrogen. It appears to expand faster than the individual atoms of gas in it are moving; the ionized shell is "eating into" the neutral material as the density falls.

Red giant as the central star

The middle stage of evolution occurs when the density has dropped to the point at which the entire mass of gas is ionized. After this stage is reached, some of the ultraviolet radiation escapes into space, and the expansion of the nebula is caused entirely by the motion of the gas. Most planetaries are now in this middle stage. Finally the central star becomes less luminous and can no longer provide enough ultraviolet radiation to keep even the dilute nebula ionized. Once again the outer regions of the nebula become neutral and therefore invisible. Eventually the gas is mingled with the general interstellar gas.

Faint outer rings

A curious feature of several planetaries is that faint rings surrounding the bright, inner nebula can be observed. Possibly the outer rings are the remnants of a previous shell ejected earlier by the star. Alternately, they might be at the outer edge of the expanding neutral (and invisible) gas, which is ramming into quiescent interstellar gas originally present when the planetary ejection occurred. There would be a strong shock wave at this interface, and the shocked matter would be heated to several thousand kelvins, causing the emission. The matter would quickly radiate its heat and become cold and invisible again. The key to the choice of those alternatives would be the spectrum of the faint ring, if it could be determined.

The central stars. The central stars are known from their spectra to be very hot. A common type of spectrum has very broad emission lines of carbon or nitrogen, as well as of ionized helium, superimposed upon a bluish continuum. These spectra are indistinguishable from those from the very bright rare stars known as Wolf-Rayet stars, but the planetary nuclei are about 100 times fainter than true Wolf-Rayet objects. The stars appear to be losing some mass at the present time, though evidently not enough to contribute appreciably to the shell.

The presence of the nebula allows a fairly precise determination of the central star's evolution. The temperature of the star can be estimated from the nebula from the amounts of emission of ionized helium and hydrogen by a method devised by the Dutch astronomer H. Zanstra. The amount of ionized-helium radiation is determined by the number of photons of more than 54 volts' energy, while hydrogen is ionized by photons in excess of 13.6 volts. The relative numbers of photons in the two groups depend strongly on temperature, since the spectrum shifts dramatically to higher energies as the temperature of the star increases. Hence, the temperature can be found from the observed strengths of the hydrogen and helium lines. The rate of evolution of the stars can be determined from the sizes of their nebulae, as the time since ejection of the shell is the radius of the nebula divided by the expansion rate. The energy output, or luminosity, of the central star can be estimated from the brightness of the nebula, because the nebula is converting the star's invisible ultraviolet radiation (which contains the greater part of the star's luminous energy) into visible radiation.

The resulting theoretical description of the star's evolution is quite interesting. While there seem to be real differences in stars at a given stage, the trends are quite clear. The central stars in the youngest planetary nebulae are about as hot as the massive O and B stars—35,000–40,000 K—but roughly 10 times fainter. They have half the diameter of the Sun but are 1,000 times as luminous. As the nebula expands, the star increases its brightness and temperature, but its radius decreases steadily. It reaches a maximum energy output, when it is roughly 10,000 times as luminous as the Sun, about 5,000 years after the initial expansion. This is an amazingly small fraction of the star's age of several times 10^9 years; it represents a period equivalent to about half an hour in a human life. From

this point on the star becomes fainter, but for some time the temperature continues to increase while the shrinkage of the star continues. At its hottest the star is perhaps 200,000 K, almost five times hotter than the hottest of most of the stars. It then cools and after about 10,000 years becomes a very dense white dwarf star, scarcely larger than the Earth but with a density of thousands of kilograms per cubic centimetre. From this point it cools very slowly, becoming redder and fainter indefinitely.

Final stages of central star's evolution

While there is not yet a very detailed theoretical picture of this contraction, a few results have emerged rather clearly: (1) white dwarf stars must obtain nearly all of their energy from the contraction noted above, not from nuclear sources; therefore, (2) they must contain practically no hydrogen or helium, except perhaps in a very thin shell on their surfaces. These conditions would have to be met for the evolution to take place so quickly.

The absence of hydrogen in the star's interior is quite surprising; the planetary nebulae are all found to have a normal hydrogen abundance of about 1,000 times as many hydrogen atoms as heavy elements, such as oxygen. Thus, the mechanism of expulsion of the envelope must be very efficient at ejecting the hydrogen-rich outer layers of a star while leaving heavy-element-rich material behind.

The nature of the progenitor stars. The progenitor must have mass not much in excess of a solar mass because of the distribution of the planetaries in the Galaxy. Very massive stars are young and more closely confined than are nebulae to the galactic plane. Also, the mass of the nebula is roughly 0.3 solar mass, and the mass of a typical white dwarf (the final state of the central star) is roughly 0.7 solar mass. Next, the expansion velocity of the nebula is probably comparable with the velocity of escape from its progenitor, which implies that the progenitor was a red giant star, large and cool, completely unlike the small, hot, blue, nuclear star remaining after the ejection. Likely candidates are members of the class of long-period variable stars, which have about the right size and mass and are known to be unstable. Symbiotic stars (*i.e.,* stars with characteristics of both cool giants and very hot stars) also are candidates. Novas, stars that brighten temporarily while ejecting a shell explosively, are definitely not candidates; the nova shell is expanding at hundreds of kilometres per second.

The cause of the ejection is the outward force of radiation on the outer layers of red giant stars. The ejection is triggered by a rapid variation in the nuclear luminosity in the interior of the giant, caused by instability in the helium-burning shell. The ejection takes place during more than one phase of the giant's evolution. Nitrogen-rich nebulae develop during an early episode when convection inside the star carries nitrogen, produced from carbon in a series of nuclear reactions (*i.e.,* the carbon-nitrogen cycle of hydrogen burning), to the surface. A later ejection takes place with an enrichment of both nitrogen and helium, which also is produced by hydrogen burning. A still later phase occurs when convection carries carbon, the product of helium burning, to the surface.

Supernova remnants. The supernova phenomenon is a spectacular explosion in which a star ejects most of its mass in a violently expanding cloud of debris that soon becomes a nebula. At the brightest phase of the explosion, the expanding cloud radiates as much energy in a single day as the Sun has done in the past three million years. Such explosions occur roughly every 50 years within a large galaxy. They have been observed less frequently in the Milky Way Galaxy because most of them have been hidden by the obscuring clouds of dust. Galactic supernovas were observed in 1006 in Lupus, in 1054 in Taurus, in 1572 in Cassiopeia (Tycho's nova, named after Tycho Brahe, its observer), and finally in 1604 in Serpens, called Kepler's nova. The stars became bright enough to be visible in the daytime. The only naked-eye supernova to occur since 1604 was Supernova 1987A in the Large Magellanic Cloud (the galaxy nearest to the Milky Way system), but it was visible only from the Southern Hemisphere. On Feb. 23, 1987, a blue supergiant star brightened to gradually become third magnitude, easily visible at night, and has subsequently been followed in every wavelength band available to scientists. The spectrum showed hydrogen lines expanding at 12,000 kilometres per second, followed by a long period of slow decline that is expected to continue for years.

Known galactic supernovas

Supernova remnants evolve through four stages as they expand. At first, they expand so violently that they simply sweep all older interstellar material before them, acting as if they were expanding into a vacuum. The shocked gas, heated to millions of kelvins by the explosion, does not radiate its energy very well and is readily visible only in X-ray emissions. This stage typically lasts several hundred years, after which time the shell has a radius of about 10 light-years. As the expansion occurs, little energy is lost but the temperature falls because the same energy is spread into an ever-larger volume. The lower temperature favours more emission, and during the second phase the supernova remnant radiates its energy at the outermost, coolest layers. This phase can last thousands of years. The third stage occurs after the shell has swept up a mass of interstellar material that is comparable to or greater than its own; the expansion is then slowed substantially. The dense material, mostly interstellar at its outer edge, radiates away its remaining energy for hundreds of thousands of years. The final phase is reached when the pressure within the supernova remnant becomes comparable to the pressure of the interstellar medium outside the remnant, so that the remnant loses its distinct identity. In the later stages of expansion, the magnetic field of the galaxy is important in determining the motions of the weakly expanding gas. Even after the bulk of the material has merged with the local interstellar medium there might be regions of very hot gas remaining from the supernova explosion that produce soft X rays (*i.e.,* those of a few hundred volts) observable locally and also confine the clumps of the diffuse ionized gas and diffuse nebulae.

The recent galactic supernovas observed are in the first phases of the evolution suggested above. At the sites of Kepler's and Tycho's novas, there exist heavy obscuring clouds, and the optical objects remaining are now inconspicuous knots of glowing gas. Near Tycho's nova, in Cassiopeia, there are similar optically insignificant wisps that appear to be remnants of yet another supernova explosion. To a radio telescope, however, the situation is spectacularly different: the Cassiopeia remnant is the strongest radio source in the entire sky. Study of this remnant, called Cassiopeia A, reveals that a supernova explosion occurred there in approximately 1680, missed by observers because of the obscuring dust.

Strongest source of radio waves

The Crab Nebula. At the site of the 1054 supernova is one of the most remarkable objects in the sky, the Crab Nebula. Photographed in colour (Plate 2), it is revealed as a beautiful red, lacy network of long and sinuous, glowing hydrogen filaments surrounding a bluish, structureless region whose light is strongly polarized. The filaments emit the spectrum characteristic of a diffuse nebula. The gas is expanding at 1,100 kilometres per second—but still slower than the 6,400 kilometres per second in the shells of new supernovas in other galaxies. The bluish, amorphous inner region of the Crab Nebula is even more remarkable. The glow is produced by the so-called synchrotron radiation—*i.e.,* from electrons spiraling about a magnetic field at almost the speed of light. This radiation is dramatically different from what it would be if it were emitted from electrons moving at low speeds: it becomes (1) strongly concentrated in the forward direction, (2) spread out over a broad range of frequencies but with the average frequency increasing with the electron's energy, and (3) highly polarized. Electrons of many different energies produce radiation in a large range of wavelengths: radio, infrared, optical, and ultraviolet. Even X rays are emitted copiously by the Crab, which is the second-brightest X-ray source in the sky after Scorpius X-1 (an X-ray binary star), indicating that the electrons must have energies in the cosmic-ray range. After almost 1,000 years, the nebula is still losing 100,000 times as much energy per second as the Sun.

On the basis of this huge outpouring of energy, it is easy to calculate how long the nebula can shine without a new supply of energy. The electrons emitting the X rays should decay, or drop to lower energies, in about 30 years—

Source of energy for the Crab Nebula

far less than the age of the nebula. The source of energy within the Crab Nebula supplying energy to the electrons that emit the X rays was discovered in 1969 to be a pulsar designated NP 0532, the remains of the stellar body that exploded to form the nebula.

In the case of the Crab Nebula, the pulsar has been found to flash optically as well as at radio wavelengths, blinking on and off with the same period, owing to its rotation: 0.033099324 second (on June 28, 1969). This period is slowly increasing (at the rate of 0.0012 second per century), which implies the pulsar is slowing down and thereby losing its energy to the nebula. The corresponding rate of energy loss is about equal to the nebula's rate of energy loss, convincing evidence that a tiny, extremely dense pulsar can supply the energy to the nebula, which is about four light-years across.

The Crab Nebula is unique in being a young supernova remnant and relatively free from obscuration, while Tycho's and Kepler's supernovas are conspicuous radio sources, apparently radiating by synchrotron emission; in neither case has a detectable pulsar been found. The failure to detect pulsars at the sites of Kepler's and Tycho's novas, or Cassiopeia A, does not mean that they are not there; the radiation from the pulsar is probably strongly beamed, and the Earth may not be located in the direction to which the pulsars are sending their energy.

The Crab Nebula is still in a stage of violent expansion. The gas will continue to expand and the pulsar lose energy until the nebula enters a second stage: one in which the pulsar can no longer put much energy into the nebula, and the nebula expands like a hot bubble of gas into the cold surrounding interstellar gas. As the hot gas rams into the cold much faster than the speed of sound, a strong shock wave results. The cold gas is heated to several million kelvins as it is hit by the shock wave and then cools by radiating forbidden and recombination lines. Almost all the mass inside the shocked "bubble" will consist of this material swept up by the expanding shock wave.

The Cygnus Loop. As a general mechanism this picture seems well corroborated. The best-observed old supernova remnant is the Cygnus Loop (or the Veil Nebula; see Plate 1), a beautiful, filamentary object roughly in the form of a circular arc in Cygnus. Its patchiness is striking: the loop consists of a series of wisps rather than a continuous cloud of gas. The most likely interpretation of this patchiness is that the interstellar medium into which the shock wave is propagating contains small clouds of denser material; many lines of reasoning from other evidence lead to the same result. The present speed of the filaments is about 100 kilometres per second; the approximate age of the Cygnus Loop is 50,000 years.

Other supernova remnants. Many other such old supernova remnants in the Galaxy are recognized, because they are also sources of radio emission from synchrotron radiation. Optically, in general, they show a wispy appearance similar to that of the Cygnus Loop.

Supernova remnants modify the interstellar medium in two important ways: (1) They leave behind the elements that have been made in the presupernova star by a long process of heating and thermonuclear processing. Some very heavy elements are made in the extremely high temperatures right after the explosion. These elements are ejected into the supernova nebula and are finally merged with the interstellar medium. In this way the heavy-element content of the interstellar medium is increased. There is observational confirmation of this; both the Crab Nebula and the remnant of Tycho's supernova seem heavy-element rich. (2) Supernova remnants provide kinetic energy to the surrounding gas by their violent expansion, heating and accelerating the interstellar gas clouds.

Source of cosmic rays

In addition, they provide large quantities of very high energy cosmic rays by accelerating them in the expanding shock wave. These cosmic rays, as well as the X rays emitted by the remnant, heat the interstellar gas. Some supernovas explode within the hot phase of the interstellar medium that has remained from previous supernovas and from stellar winds. In this case, the violently expanding shock reheats the tenuous gas that fills most of the volume of space in a galaxy but makes up very little of its mass. Thus, supernovas serve to maintain a hot component of gas, which is revealed only in X rays.

Diffuse ionized gas. A recently recognized major component of interstellar gas has been discovered by means of its Hα emission line at 6563 angstroms, produced by a hydrogen atom dropping from the third to the second energy level. The American astronomer Ronald Reynolds and his collaborators have used a Fabry-Pérot interferometer to map and study this line and a few others (N^+, S^+, O^{++}). The Hα line is produced by an H^+ ion recombining with a free electron, exactly as in diffuse nebulae. Each Hα photon requires about two recombinations of an H^+ ion, and each of these recombinations must be balanced by an ionization. The Hα line is faint, but it is seen in every direction, and the total amount of energy required to produce it is amazingly large. The net energy requirement of the Hα is about 15 percent of the luminosity of all O and B stars that provide ionization for diffuse nebulae. This energy output is about equal to the total power provided by all known supernovas, but the latter radiate the large bulk of their energy in nonionizing radiation or in providing modest kinetic energies to large amounts of gas near the end of their expansion phase. Hence, supernovas cannot power the diffuse ionized gas. Other potential sources of ionization, such as very hot, highly evolved stars of various types, such as Wolf-Rayet stars, white dwarf stars, or neutron stars, all fall far short. Cosmic rays are very energetic particles rather inefficiently accelerated by supernovas and so are less able to provide the required power than supernovas themselves. Only normal galactic stars of types O and B, similar to those that ionize diffuse nebulae, are viable candidates.

Unlike H II regions, the diffuse ionized gas is found far from the galactic plane as well as close to it. Pulsars occasionally occur at large distances from the galactic plane. The pulses of radio radiation emitted by these objects are slowed in their passage through the interstellar medium by electrons from the ionized hydrogen. The delays of the pulses of various radio frequencies show that the electrons (and hence H^+) extend about 3,000 light-years above and below the plane, indicating a much greater distance than the 300-light-year thickness of the neutral hydrogen, diffuse nebulae, or O and B stars in general. In the diffuse ionized gas, the comparatively low stages of ionization of the common elements (O^+, N^+, S^+) are much more abundant relative to higher stages (O^{++}, N^{++}, S^{++}) as compared to typical diffuse nebulae. Such an effect is caused by the extremely low density of the diffuse ionized gas; in this case, even hot stars fail to produce high stages of ionization. Thus, it seems possible to explain the peculiar ionization of the diffuse ionized gas with ionization powered by O and B stars. However, there is a major problem associated with this explanation: the ionizing radiation must be able to reach the diffuse ionized gas from the stars, which are typically surrounded by neutral hydrogen clouds that should prevent any ionizing radiation from penetrating through them. Apparently the O and B stars are able to ionize passages through the clouds enveloping them, and a substantial part of the ionizing radiation can escape into the regions far from the galactic plane. No other explanation seems plausible.

Ionization powered by O and B stars

Nepal

The Kingdom of Nepal (Nepāli: Nepāl Adhirājya), lying along the southern slopes of the Himalayan mountain ranges, is a landlocked country located between India to the east, south, and west and the Tibet Autonomous Region of China to the north. Its territory, which has an area of 56,827 square miles (147,181 square kilometres), extends roughly 500 miles (800 kilometres) from east to west and 90 to 150 miles from north to south. Nepal, long under the rule of hereditary prime ministers favouring a policy of isolation, remained closed to the outside world until a palace revolt in 1950 restored the crown's authority in 1951; the country gained admission to the United Nations in 1955. In 1991 the kingdom established a multiparty parliamentary system.

Wedged between two giants, India and China, Nepal seeks to keep a balance between the two countries in its foreign policy—and thus to remain independent. A factor that contributes immensely to the geopolitical importance of the country is the fact that a strong Nepal can deny China access to the rich Gangetic Plain; Nepal thus marks the southern boundary of the Chinese sphere north of the Himalayas in Asia.

As a result of its years of geographic and self-imposed isolation, Nepal is one of the least developed nations of the world. In recent years many countries, including India, China, the United States, the United Kingdom, Japan, Denmark, Germany, Canada, and Switzerland, have provided economic assistance to Nepal. The extent of foreign aid to Nepal has been influenced to a considerable degree by the strategic position of the country between India and China.

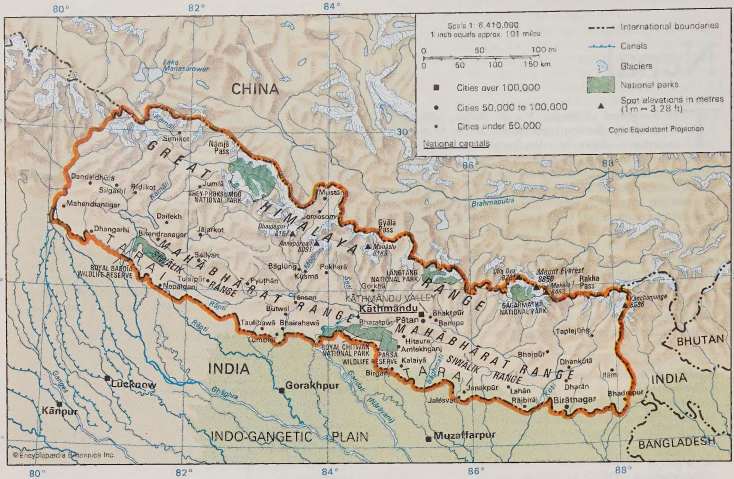
Physical and human geography

THE LAND

Relief. Nepal contains some of the most rugged and difficult mountain terrain in the world. Roughly 75 percent of the country is covered by mountains. From the south to the north, Nepal can be divided into four main physical belts, each of which extends east to west across the country. These are, first, the Tarai, a low, flat, fertile land adjacent to the border of India; second, the forested Churia foothills and the Inner Tarai zone, rising from the Tarai plain to the rugged Mahābhārat Range; third, the mid-mountain region between the Mahābhārat Range and the Great Himalayas; and, fourth, the Great Himalaya Range, rising to more than 29,000 feet (some 8,850 metres).

The Tarai forms the northern extension of the Gangetic Plain and varies in width from less than 16 to more than 20 miles, narrowing considerably in several places. A 10-mile-wide belt of rich agricultural land stretches along the southern part of the Tarai; the northern section, adjoining the foothills, is a marshy region in which wild animals abound and malaria is endemic.

The Churia Range, which is sparsely populated, rises in almost perpendicular escarpments to an altitude of more than 4,000 feet. Between the Churia Range to the south and the Mahābhārat Range to the north, there are broad basins from 2,000 to 3,000 feet high, about 10 miles wide, and 20 to 40 miles long; these basins are often referred to as the Inner Tarai. In many places they have been cleared of the forests and savanna grass to provide timber and areas for cultivation.



A complex system of mountain ranges, some 50 miles in width and varying in elevation from 8,000 to 14,000 feet, lie between the Mahābhārat Range and the Great Himalayas. The ridges of the Mahābhārat Range present a steep escarpment toward the south and a relatively gentle slope toward the north. To the north of the Mahābhārat Range, which encloses the valley of Kāthmāndu, are the more lofty ranges of the Inner Himalaya (Lesser Himalaya), rising to perpetually snow-covered peaks. The Kāthmāndu and the Pokharā valleys lying within this mid-mountain region are flat basins, formerly covered with lakes, that were formed by the deposition of fluvial and fluvioglacial material brought down by rivers and glaciers from the enclosing ranges during the four glacial and intervening warm phases of the Pleistocene Epoch (from about 1,600,000 to 10,000 years ago).

The Great Himalaya Range, ranging in elevation from 14,000 to more than 29,000 feet, contains many of the world's highest peaks—Everest, Kānchenjunga I, Lhotse I, Makālu I, Cho Oyu, Dhaulāgiri I, Manāslu I, and Annapūrna I—all of them above 26,400 feet. Except for scattered settlements in high mountain valleys, this entire area is uninhabited.

The Kāthmāndu Valley

Drainage. The Kāthmāndu Valley, the political and cultural hub of the nation, is drained by the Bāghmati River, flowing southward, which washes the steps of the sacred temple of Paśupatinātha (Pashupatinath) and rushes out of the valley through the deeply cut Chhobar gorge. Some sandy layers of the lacustrine beds act as aquifers (water-bearing strata of permeable rock, sand, or gravel), and springs occur in the Kāthmāndu Valley where the sands outcrop. The springwater often gushes out of dragon-shaped mouths of stone made by the Nepalese; it is then collected in tanks for drinking and washing and also for raising paddy nurseries in May, before the monsoon. Drained by the Seti River, the Pokharā Valley, 96 miles west of Kāthmāndu, is also a flat lacustrine basin. There are a few remnant lakes in the Pokharā basin, the largest being Phewa Lake, which is about two miles long and nearly a mile wide. North of the basin lies the Annapūrna massif of the Great Himalaya Range.

The major rivers of Nepal—the Kosi, Nārāyani (Gandak), and Karnāli, running southward across the strike of the Himalayan ranges—form transverse valleys with deep

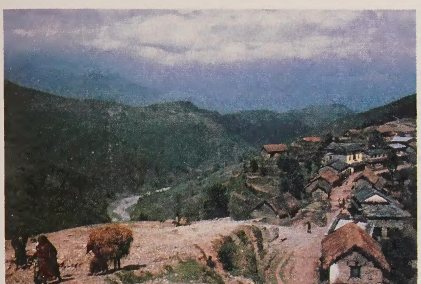
gorges, which are generally several thousand feet in depth from the crest of the bordering ranges. The watershed of these rivers lies not along the line of highest peaks in the Himalayas but to the north of it, usually in Tibet.



The rivers have considerable potential for development of hydroelectric power. Two irrigation-hydroelectric projects have been undertaken jointly with India on the Kosi and Nārāyani rivers. Discussions have been held to develop the enormous potential of the Karnāli River. A 60,000-kilowatt hydroelectric project at Kulekhani, funded by the World Bank, Kuwait, and Japan, began operation in 1982.

In the upper courses of all Nepalese rivers, which run through mountain regions, there are little or no flood problems. In low-lying areas of the Tarai plain, however, serious floods occur.

The rivers and small streams of the Tarai, especially those in which the dry season discharge is small, are polluted by large quantities of domestic waste thrown into them. Towns and villages have expanded without proper provision for sewage disposal facilities, and more industries have been established at selected centres in the Tarai. The polluted surface water in the Kāthmāndu and Pokharā valleys, as well as in the Tarai, are unacceptable for drinking.

Climate. Nepal's climate, influenced by elevation as well as by its location in a subtropical latitude, ranges from subtropical monsoon conditions in the Tarai, through a warm temperate climate between 4,000 and 7,000 feet in the mid-mountain region, to cool temperate conditions in the higher parts of mountains between 7,000 and 11,000 feet, to an Alpine climate at altitudes between 14,000 and 16,000 feet along the lower slopes of the Himalaya mountains. At altitudes above 16,000 feet the temperature is always below freezing and the surface covered by snow and ice. Rainfall is ample in the eastern portion of the Tarai (which receives from 70 to 75 inches [1,800 to 1,900 millimetres] a year at Biratnagar) and in the mountains, but the western portion of Nepal (where from 30 to 35 inches a year fall at Mahendranagar) is drier.

In Kāthmāndu Valley, average temperatures range from 50° F (10° C) in January to 78° F (26° C) in July, and the lowest and highest temperatures recorded have been 27° Temperatures

Naudanda village in the Annapūrna Range of the Himalayas, Nepal.
Cathlyn Melloan; EB, Inc.

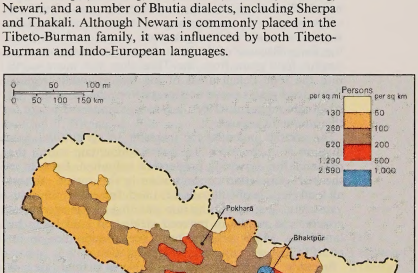
and 99° F (−3° and 37° C). The average annual rainfall is about 55 inches, most of which falls in the period from June to September. At Pokharā the temperature ranges from 40° F (4° C) in January to approximately 100° F (38° C) in June, just before the monsoon. In winter, temperatures during the day rise to 70° F (21° C), creating pleasant conditions, with cool nights and warm days. Because warm rain-bearing monsoon winds discharge most of their moisture as they encounter the Annapūrna range, rainfall is quite heavy (about 100 inches) in the Pokharā Valley.

Vegetation zones

Plant life. The natural vegetation of Nepal follows the pattern of climate and altitude. A tropical, moist zone of deciduous vegetation occurs in the Tarai and the Churia Range. These forests consist mainly of khair (*Acacia catechu*), a spring tree with yellow flowers and flat pods; sissoo (*Dalbergia sissoo*), an East Indian tree yielding dark brown durable timber; and sal (*Shorea robusta*), an East Indian timber tree with foliage providing food for lac insects (which deposit lac, a resinous substance used for the manufacture of shellac and varnishes, on the tree's twigs). On the Mahābhārat Range, at elevations between 5,000 and 10,000 feet, vegetation consists of a mixture of many species, chiefly pines, oaks, rhododendrons, poplars, walnuts, and larch. Between 10,000 and 12,000 feet, fir mixed with birch, as well as rhododendron, abound. In the mid-mountain region of Nepal a fairly dense population has cleared all but the most inaccessible parts of the forest, which are restricted to areas of steep slopes and rocky terrain. Similarly, all readily accessible parts of valuable sal forest in the Tarai have been devastated by overcutting and depletive practices. The vast forested area below the timber line in the Great Himalaya Range bears some of the most valuable forests in Nepal, containing spruce, fir, cypress, juniper, and birch. Alpine vegetation occupies higher parts of the Great Himalaya Range. Just below the snow line, between 14,000 and 15,000 feet, grassy vegetation affords favourable grazing ground in summer.

(P.P.K.)

Animal life. The forested areas of the Tarai are the home of tigers and leopards, gaurs (wild ox), occasional elephants and buffalo, and many deer; the deer include chital, or axis, deer (which have white-spotted bodies), sambar (a large Asiatic deer with coarse hair on the throat and strong antlers), and swamp deer. The Lesser Rāpti Valley, in south-central Nepal, is one of the last homes of the great Indian rhinoceros (*Rhinoceros unicornis*). Much poaching has gone on, as the horn of the rhinoceros is reputed to be valuable as an aphrodisiac, but in the 1960s the Nepal government organized protective measures.



There are few wild animals in the central zone because of the clearing of forests. Occasional leopards, bears, and smaller carnivores inhabit the forests and ravines, and muntjacs (a kind of small deer, also called the barking deer) are found in the woods. In the Alpine zone are musk deer, widely hunted for the musk pods they carry, the tahr (a Himalayan beardless wild goat), the goral (any of several goat antelopes, closely related to the Rocky Mountain goat), and wild sheep, which are preyed upon by wolves and snow leopards. Pheasant are common. The Yeti (bear-man, or Abominable Snowman) is said by the Sherpa to inhabit the high snow mountains but has eluded discovery by several expeditions. Strange tracks are often found in the snow, but it is believed that they are probably made by bears. River wildlife includes the mahseer, a large freshwater food and sport fish.

(R.R.Pr./M.Zu.)

THE PEOPLE

The large-scale migrations of Mongoloid groups from Tibet and Indo-Aryan people from northern India, which accompanied the early settlement of Nepal, have produced a diverse linguistic, ethnic, and religious pattern. Nepalese of Indo-Aryan ancestry comprise the people of the Tarai, the Pahari, the Newar, and the Tharus—the great majority of the total population. Indo-Aryan ancestry has been a source of prestige in Nepal for centuries, and the ruling families have been of Indo-Aryan and Hindu background. Most of the Tibeto-Nepalese groups—the Tamang, Rai, Limbu, Bhutia (including the Sherpa), and Sunwar—live in the north and east, while the Magar and Gurung inhabit west-central Nepal. The bulk of the famous Gurkha contingents in the British army have come from the Magar, Gurung, and Rai groups.

The principal and official language of Nepal is Nepāli (Gorkhali), spoken in the Tarai and the mid-mountain region. Nepāli, a derivative of Sanskrit, belongs to the Indo-Aryan branch of the Indo-European family. There are a number of regional dialects found in the Tarai and mountain areas. The languages of the north and east belong predominantly to the Tibeto-Burman family. These include Magar, Gurung, Rai, Limbu, Sunwar, Tamang, Newari, and a number of Bhutia dialects, including Sherpa and Thakali. Although Newari is commonly placed in the Tibeto-Burman family, it was influenced by both Tibeto-Burman and Indo-European languages.

Population density of Nepal.

In Nepal a vast majority of the population is Hindu, but a small percentage follows Buddhism or other religious faiths. Hindus and Buddhists tend to be concentrated in areas where Indian and Tibetan cultural influences, respectively, have been dominant.

Settlement patterns

Almost all Nepalese live in villages or in small market centres. Outside of Kāthmāndu, there are no major cities. Smaller urban centres (Birātnagar, Nepālganj, and Birganj) are located in the Tarai along the Indian border, and Pokharā is situated in a valley in the mid-mountain region. In addition, a few townships—such as Hitaura, Būtwal, and Dharān—have begun to emerge in the foothills and hill areas, where economic activity has developed.

THE ECONOMY

Landlocked, lacking substantial resources for economic development, and hampered by an inadequate transportation network, Nepal is one of the least developed nations in the world. The economy is heavily dependent on imports of basic materials and on foreign markets for its forest and agricultural products. Nepal imports essential commodities, such as fuel, construction materials, fertilizers, metals, and most consumer goods, and exports such products as rice, jute, timber, and textiles.

The political and administrative system of Nepal has not made those changes in trade, investment, and related economic policies that would expedite economic development and attract foreign capital. The government's development programs, which are funded by foreign aid, also have failed to respond directly to the needs of rural people.

Resources. Nepal's mineral resources are small, scattered, and barely developed. There are known deposits of coal (lignite), iron ore, magnesite, copper, cobalt, pyrite (used for making sulfuric acid), limestone, and mica. Nepal's great river systems provide immense potential for hydroelectric development. If developed and utilized within the country and exported to India (the principal market for power generated in Nepal), it could become a mainstay of the country's economy.

Agriculture. Agriculture—primarily the cultivation of rice, corn (maize), and wheat—engages most of Nepal's population and accounts for well over half of the country's export earnings. Yet agricultural productivity is very low. The low yields result from shortages of fertilizers and improved seed and from the use of inefficient techniques. Because only a tiny percentage of Nepal's cultivated land area is under irrigation, output depends upon the vagaries of the weather. Potatoes, sugarcane, and millet are other major crops. Cattle, buffalo, goats, and sheep are the principal livestock raised.

On the whole, Nepal has a small surplus in food grains. There are, however, major dislocations in supply and demand. Periods of shortage between harvests of various crops occur in the mountain areas. At the same time, substantial amounts of food grain are moved to India from the Tarai. Because of the lack of adequate transportation, surplus food grain from the Tarai does not move north into the food deficit areas of the mid-mountain region. Some food grains move northward from the Tarai and the mountain areas into Tibet, however, despite a shortage in the mountain regions.

The greatest potential for increases in agricultural production is in the Tarai. In the mid-mountain region the potential for increasing production is limited. Because of the high population concentration in this region, almost all land capable of cultivation is tilled. Increasing the cultivated land area by cutting into standing forests aggravates erosion and results in reduced yields and land losses by landslides. Major projects have been undertaken in an effort to halt soil erosion and deforestation.

Forestry. About one-third of Nepal's total area is forested; most of this area is state-owned. In spite of overcutting and poor management, timber represents one of the country's most valuable resources and is a major source of potential revenue. Exports of forest products constitute an important source of Indian rupees. Almost all timber is exported to India. The sawmills of the Timber Corporation of Nepal, a government-owned lumber-processing concern, supply Kāthmāndu Valley with construction and furniture wood.

Industry and trade. Industrial production represents a small but growing segment of economic activity. Most industries are small, localized operations based on the processing of agricultural products. The jute industry, centred in Birātnagar, is an important earner of foreign exchange. Sugar factories are located in Birātnagar, Birganj, and Bhairahawā. There are a sawmill and a meat-processing plant in Hitaura and a number of rice and oil mills in the Tarai. Other industries include brick and tile manufacture; processing of construction materials, paper, and food grain; cigarette manufacture; cement production; and brewing of beer. In general, there are more industrial enterprises in the private than in the public sector, although most of these are cottage industries. The main areas of manufacturing concentration are Birātnagar, the Birganj–Hitaura corridor, and the Kāthmāndu Valley.

Tourism

Tourism represents a small but expanding industry. Foreign tourism is primarily confined to the Kāthmāndu Valley, which is the only area equipped with the necessary hotels, food supplies, roads, and international transport services. There are, however, many areas outside the Kāthmāndu Valley with potential for the development of tourism; these include Pokharā, the Mount Everest area, and the Nārāyani area (where big game exists).

For geographic and historical reasons, nearly all of Nepal's trade is with India. Attempts have been made to diversify trade through agreements with such countries as Japan, South Korea, Pakistan, the United States, Germany, Poland, and China. The state trading agency, National Trading Limited, has expanded its activities by fostering the development of commercial entrepreneurial activity. Large-scale commercial activity has hitherto been in the hands of foreigners, primarily Indians.

Nepal's foreign trade and balance of payments have suffered setbacks, and exports have not increased enough to pay for imports of consumer goods and basic supplies. Nepal's dependence on the Indian market for most of its imports and exports and on the port of Calcutta for its access to the sea has been the source of periodic friction between the two countries.

Transportation. Transport facilities in Nepal are very limited; few independent nations in the world of comparable size have such little road mileage and so few motor vehicles. Construction of new roads has been undertaken since the 1970s with aid from India, China, Great Britain, and the United States. The main means of transportation has been the network of footpaths, which interlace the mountain terrain and valleys. Trails have evolved into main trade routes, which tend to follow the river systems.

The meagre road-transport facilities in Nepal are supplemented by only a few railway and air-transport links. Increased use of road transport has reduced the significance of the two narrow-gauge railroads that run from Amlekhganj to Raxaul (India) and from Janakpūr to Jaynagar (India). The Royal Nepal Airline Corporation, an autonomous government agency, is the only commercial airline. Together with Indian Airlines, it operates flights from Kāthmāndu to various points in India and other nearby countries. Domestic air service within the country has been expanded. The United States built the Kāthmāndu–Hitaura aerial ropeway in the 1950s, and it is still used for carrying goods into the capital. (L.E.R.)

Air transport

ADMINISTRATION AND SOCIAL CONDITIONS

Government. Although reforms in the 1950s began to move the kingdom toward a democratic political system, the crown dissolved Parliament in 1960 and subsequently banned political parties. Thereafter, Nepal became only nominally a constitutional monarchy, and the constitution of 1962 (amended 1967, 1976, and 1980) effectively gave the king autocratic control over a multitiered system of panchayats (local bodies, or councils). In the 1980s, political restrictions were eased, and organizations such as the Nepali Congress Party, the Communist Party of Nepal, numerous small left-leaning student groups, and several radical Nepalese antimonarchist groups were allowed to operate more or less openly. Political parties, however, were not again legalized until 1990, when nationwide unrest forced King Birendra to accept the formation of a multiparty parliamentary system.

A new constitution promulgated on Nov. 9, 1990, greatly reduced the power of the monarchy. The king remained the head of state, but effective executive power was given to the Council of Ministers, headed by the prime minister. Appointed by the king, the prime minister is required to be either the leader of the majority party in the House of Representatives (the lower house of Parliament) or, if there is no majority party, a representative who can form a coalition majority.

The king is constitutionally also a part of Parliament and is charged with giving assent to bills that have been passed by both legislative chambers—the House of Representa-

tives and the National Council (the upper house). The House of Representatives consists of 205 members popularly elected to five-year terms. The 60 members of the National Council hold six-year terms; 10 are nominated by the king, 35 are elected by the House of Representatives (of which 3 must be women), and 15 are selected by an electoral college. The constitution gives the House of Representatives considerably more power than the National Council.

All Nepalese citizens 18 and older are eligible to vote. Because most voters in Nepal are illiterate, candidates are chosen by party symbol (*e.g.*, a tree for the Nepali Congress Party and a sun for the United Marxist-Leninist Party of Nepal). Some voters, moreover, must travel long distances, in some cases for hours along mountain paths, in order to reach a polling station.

Prior to 1990 the country was divided for administrative purposes into 5 development regions, 14 zones, and 75 districts; in addition, there were corresponding regional, zonal, and district courts, as well as a Supreme Court. The 1990 constitution mandated the elimination of the regional and zonal courts, which were to be replaced by appellate courts. The administrative divisions themselves continued to exist as provisional units. (Ed.)

Armed forces and police. Nepal's armed forces consist of the Royal Nepalese Army, predominantly an infantry force. The Army Flight Department operates all aircraft. Except for a few simple weapons, all military supplies are imported. Nepal is famous for the fighting qualities of its Gurkha soldiers; nearly 10,000 of these serve in British Gurkha units, and 50,000 in Indian Gurkha units. The British maintain a recruiting centre at Dharān. Gurkha veterans are a valuable human resource of Nepal.

For police purposes the country is divided into three zones: eastern, central, and western, with headquarters at Birātnagar, Kāthmāndu, and Nepālganj, respectively. Each zonal headquarters, under a deputy inspector general of police, is responsible for several subsections composed of four to five police districts operating under a superintendent of police. A district superintendent is in charge of police stations in his area, and each station normally is supervised by a head constable.

Health and education. The Ministry of Health is responsible for the support and administration of public health services, including hospitals and health clinics. Although the government has taken steps to improve existing health centres and to establish new ones, health care remains inadequate. Malaria, tuberculosis, cholera, and typhoid are prevalent in spite of government projects to control or eradicate them. Ayurvedic medicine, the traditional Hindu system of medicine, is popular in Nepal.

The Ministry of Education and Culture is responsible for administration and supervision of all elementary and secondary education. Higher education has developed relatively recently. The first college was established in 1918, and Tribhuvan University in Kāthmāndu, with faculties of arts, sciences, commerce, and education, was chartered in 1959. The University Senate has sole legal responsibility for higher education and the authority to grant academic recognition to colleges but is largely dependent upon the Ministry of Education for funds.

Higher education

CULTURAL LIFE

The relaxation of censorship that followed the overthrow of Rana rule in 1951 encouraged a revival of artistic and intellectual expression. In literature and poetry, Nepāli works emphasize the cultural renaissance and national patriotism. King Mahendra, a poet whose Nepāli lyrics have been published in English translation under the name of M.B.B. Shah (for Mahendra Bir Bikram Shah), did much to promote the revival of arts and literature.

The cultural heritage of Nepal, particularly contributions made by the Newar of Kāthmāndu Valley to sculpture, painting, and architecture, is a source of great pride. Hindu and Buddhist religious values have provided the basic source of inspiration to Newar artisans. The themes of most artistic works have been primarily religious; the lives of the gods, saints, and heroes and the relationship of man to society and to the universe are expounded in sculpture, architecture, and drama. In Kāthmāndu Valley some 2,500 temples and shrines display the skill and highly developed aesthetic sense of Newar artisans.

Music and dance are favourite pastimes among the Nepalese. Religious ceremonies require the use of drums and wind instruments preserved from ancient times. Important in most religious and family occasions are devotional songs that have elements of both classical and folk music and that have been used by some contemporary musical revivalists in their attempt to bridge the gap between the two. The government-owned Radio Nepal broadcasts programs in Nepālī and English. The country's first television station, at Kāthmāndu, began broadcasting in 1986.

Newspapers and periodicals are published in Nepālī and in English. Newspapers are frequently sensational in tone and are poorly staffed and financed. *Gorkha Patra,* published by the government, occupies a commanding position in the Nepalese press. Nepalese newspaper readers rely on the foreign press, particularly Indian newspapers, which are flown daily into Kāthmāndu, for more sophisticated coverage of world and national news.

After 1960 King Mahendra required newspapers to obtain official clearance for all reports of political activity. Subsequently the government increased its censorship, and in 1985 the publication of many newspapers was suspended. In 1990, reflecting the change in the country's political climate, freedom of the press was restored. (P.P.K.)

For statistical data on the land and people of Nepal, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR.

History

PREHISTORY AND EARLY HISTORY

Nepal's rich prehistory consists mainly of the legendary traditions of the Newar, the indigenous community of Nepal Valley (now usually called Kāthmāndu Valley). There are usually both Buddhist and Brahmanic Hindu versions of these various legends. Both versions are accepted indiscriminately in the festivals associated with legendary events, a tribute to the remarkable synthesis that has been achieved in Nepal between the two related but divergent value systems.

References to Nepal Valley and Nepal's lower hill areas are found in the ancient Indian classics, suggesting that the Central Himalayan hills were closely related culturally and politically to the Gangetic Plain at least 2,500 years ago. Lumbini, Gautama Buddha's birthplace in southern Nepal, and Nepal Valley also figure prominently in Buddhist accounts. There is substantial archaeological evidence of an early Buddhist influence in Nepal, including a famous column inscribed by Aśoka (emperor of India, 3rd century BC) at Lumbinī and several shrines in the valley.

The Licchavi dynasty

A coherent dynastic history for Nepal Valley becomes possible, though with large gaps, with the rise of the Licchavi dynasty in the 4th or 5th century AD. Although the earlier Kirati dynasty had claimed the status of the Kshatriya caste of rulers and warriors, the Licchavis were probably the first ruling family in that area of plains Indian origin. This set a precedent for what became the normal pattern thereafter—Hindu kings claiming high-caste Indian origin ruling over a population much of which was neither Indo-Aryan nor Hindu.

The Licchavi dynastic chronicles, supplemented by numerous stone inscriptions, are particularly full from AD 500 to 700; a powerful, unified kingdom also emerged in Tibet during this period, and the Himalayan passes to the north of the valley were opened. Extensive cultural, trade, and political relations developed across the Himalayas, transforming the valley from a relatively remote backwater into the major intellectual and commercial centre between South and Central Asia. Nepal's contacts with China began in the mid-7th century with the exchange of several missions. But intermittent warfare between Tibet and China terminated this relationship; and, while there were briefly renewed contacts in subsequent centuries, these were reestablished on a continuing basis only in the late 18th century.

MIDDLE PERIOD

The Malla dynasty

The middle period in Nepalese history is usually considered coterminous with the rule of the Malla dynasty (10th–18th century) in Nepal Valley and surrounding areas. Although most of the Licchavi kings were devout Hindus, they did not impose Brahmanic social codes or values on their non-Hindu subjects; the Mallas perceived their responsibilities differently, however, and the great Malla ruler Jaya Sthiti (reigned *c.* 1382–95) introduced the first legal and social code strongly influenced by contemporary Hindu principles.

Jaya Sthiti's successor, Yakṣa Malla (reigned *c.* 1429–*c.* 1482), divided his kingdom among his three sons, thus creating the independent principalities of Kāthmāndu, Pātan, and Bhaktpūr (Bhādgāon) in the valley. Each of these states controlled territory in the surrounding hill areas, with particular importance attached to the trade routes northward to Tibet and southward to India that were vital to the valley's economy. There were also numerous small principalities in the western and eastern hill areas, whose independence was sustained through a delicate balance of power based upon traditional interrelationships and, in some cases, common ancestral origins (or claims thereto) among the ruling families. By the 16th century virtually all these principalities were ruled by dynasties claiming high-caste Indian origin whose members had fled to the hills in the wake of Muslim invasions of northern India.

In the early 18th century one of the principalities—Gorkha (also spelled Gurkha), ruled by the Shah family—began to assert a predominant role in the hills and even to pose a challenge to Nepal Valley. The Mallas, weakened by familial dissension and widespread social and economic discontent, were no match for the great Gorkha ruler Prithvi Narayan Shah. He conquered the valley in 1769 and moved his capital to Kāthmāndu shortly thereafter, providing the foundation for the modern state of Nepal.

MODERN PERIOD

The Shah dynasty

The Shah (or Sah) rulers faced tremendous and persistent problems in trying to centralize an area long characterized by extreme diversity and ethnic and regional parochialism. They established a centralized political system by absorbing dominant regional and local elites into the central administration at Kāthmāndu. This action neutralized potentially disintegrative political forces and involved them in national politics, but it also severely limited the centre's authority in outlying areas because local administration was based upon a compromise division of responsibilities between the local elites and the central administration.

From 1775 to 1951, Nepalese politics was characterized by confrontations between the royal family and several noble families. The position of the Shah dynasty was weakened by the fact that the two kings who ruled successively between 1777 and 1832 were minors when they ascended the throne. The regents and the nobility competed for political power, using the young rulers as puppets; both factions wanted a monopoly of political offices and power for their families, with their rivals exterminated, exiled to India, or placed in a subordinate status. This was achieved by the Thapa family (1806–37) and, even more extensively, by the Rana family (1846–1951). In these periods, the Shah ruler was relegated to an honorary position without power, while effective authority was concentrated in the hands of the leading members of the dominant family. Although intrafamilial arrangements on such questions as the succession and the distribution of responsibilities and spoils were achieved, no effective national political institutions were created. The excluded noble families had only two alternatives—to accept inferior posts in the administration and army or to conspire for the overthrow of the dominant family. Until 1950 and to some extent thereafter, Nepalese politics was basically conspiratorial in character, with familial loyalty taking precedence over loyalty to the crown or nation.

External relations, 1750–1950. Prithvi Narayan Shah (reigned 1742–75) and his successors established a unified state in the central Himalayas and launched an ambitious and remarkably vigorous program of expansion, seeking to bring the entire hill area, from Bhutan to Kashmir, under their authority. They made considerable progress, but successive setbacks in wars with China and Tibet (1788–92), with the Sikh kingdom in the Punjab (1809), with British India (1814–16), and again with Tibet (1854–56) frustrated Nepal and set the present boundaries of the kingdom.

Alliance with Great Britain

The British conquest of India in the 19th century posed a serious threat to Nepal—which expected to be another victim—and left the country with no real alternative but to seek an accommodation with the British to preserve its independence. This was accomplished by the Rana family regime after 1860 on terms that were mutually acceptable, if occasionally irritating, to both. Under this de facto alliance, Kāthmāndu permitted the recruitment of Nepalese for the highly valued Gurkha units in the British Indian Army and also accepted British "guidance" on foreign policy; in exchange, the British guaranteed the Rana regime against both foreign and domestic enemies and allowed it virtual autonomy in domestic affairs. Nepal, however, was also careful to maintain a friendly relationship with China and Tibet, both for economic reasons and to counterbalance British predominance in South Asia.

The British withdrawal from India in 1947 deprived the Ranas of a vital external source of support and exposed the regime to new dangers. Anti-Rana forces, composed mainly of Nepalese residents in India who had served their political apprenticeship in the Indian nationalist movement, formed an alliance with the Nepalese royal family, led by King Tribhuvan (reigned 1911–55), and launched a revolution in November 1950. With strong diplomatic support from New Delhi, the rebels accepted a settlement with the Ranas under which the sovereignty of the crown was restored and the revolutionary forces, led by the Nepali Congress Party, gained an ascendant position in the administration.

Constitutional government

Nepal since 1950. The introduction of a democratic political system in Nepal, a country accustomed to autocracy and with no deep democratic tradition or experience, proved a formidable task. A constitution was finally approved in 1959, under which general elections for a national assembly were held. The Nepali Congress won an overwhelming victory and was entrusted with the formation of Nepal's first popular government. But persistent controversy between the Cabinet and King Mahendra (reigned 1955–72) led the king to dismiss the Nepali Congress government in December 1960 and to imprison most of the party's leaders. The constitution of 1959 was abolished in 1962, and a new constitution was promulgated that established the crown as the real source of authority. King Mahendra obtained both Indian and Chinese acceptance of his regime, and the internal opposition was weak, disorganized, and discouraged. Mahendra died in January 1972 and was succeeded by his son Birendra, who was crowned in 1975.

Throughout the 1970s King Birendra sought to expedite economic development programs while maintaining the "nonparty" political system established by his father. The results were disappointing on both accounts, and by 1979 a systemic crisis was evident. To meet the first serious political challenge to the monarchy since 1960, King Birendra announced in May 1979 that a national referendum would be held to decide between a nonparty and multiparty (by implication, parliamentary) political system. In the referendum, which was held in May 1980, the political groups supporting the existing nonparty system won by the relatively small margin of 55 percent, accurately reflecting the sharp differences in the country on basic political issues.

It was in this context that King Birendra decided in 1980 to retain the 1962 constitution but to liberalize the political system by providing for direct popular election of the National Assembly. The government also permitted the "illegal" political parties, such as the Nepali Congress Party, to function under only minimal constraints. Elections were still formally held on a "partyless" basis, but many candidates ran informally and openly as members of political parties.

This partial movement toward a democratic parliamentary system satisfied neither the supporters of a multiparty

constitutional monarchy nor several more radical leftist factions, and in February 1990 a coalition of centrist and leftist opposition forces began a campaign demanding basic political reforms. A series of protests and strikes followed nationwide, and the royal government's efforts to suppress the movement with force were ineffectual. In April, as the situation in Kāthmāndu Valley worsened, King Birendra lifted the ban on political parties, abrogated the more repressive security ordinances, and on April 16 appointed a coalition interim government headed by the president of the Nepali Congress, K.S. Bhattarai, but also including the moderate faction of the communist movement, the United Leftist Front.

The policy objectives of the interim government were "to maintain law and order, develop a multiparty system on the basis of constitutional monarchy, draft a new constitution, and hold general elections" to a parliament. Within a year, all four tasks were accomplished with remarkable success despite the broad divergence of views among the major political organizations. A draft of the new constitution, prepared by a broadly representative government commission, was submitted to the Palace and the Cabinet on Sept. 10, 1990. In November, following two months of vigorous debate on a number of key issues—including the role of the king, the development of a secular state, emergency powers, and the status of Nepal's many languages—an amended version of the constitution was promulgated by King Birendra that provided for both a constitutional monarchy and a multiparty parliamentary political system.

General elections held on May 12, 1991, gave the Nepali Congress a majority in Parliament (110 of 205 seats), but the moderate United Marxist-Leftist Party (UML), with 69 seats, emerged as a strong opposition party. The two "Pancha" parties usually associated with the old system won only four seats. The elections were thus perceived to constitute a strong endorsement of the 1990 political changes, and G.P. Koirala, the brother of Nepal's first elected prime minister (1959–60), was nominated by the Nepali Congress and appointed by the king to head the new elected government.

Nepal emerged from this period of rapid political change facing a multitude of economic and social problems; among these were a stagnant economy and a variety of regional ethnic and religious movements, some of whose basic demands were not acceptable to the country's Hindu majority. Although overwhelming support existed for the new democratic constitutional monarchy system, at both the party and the public level, the democratic movement itself remained badly fractionalized and antagonistic, making more difficult the new government's attempt to introduce the kind of hard-hitting economic and social policies the panchayat governments had carefully avoided in an effort to mollify several small but important interest groups. (L.E.R.)

The 1990s were a period of political instability in Nepal. In 1994 the UML emerged as the largest party in the legislature and formed a minority government. However, it was defeated on a vote of no confidence the following year and replaced by a Nepali Congress-led coalition. By March 1997 the UML was back in government, though it was ousted again in October. In 1999 the Nepali Congress won a majority in the legislature, winning 110 seats, while the UML dropped to only 68. In late 1999 the Communist Party led a series of general strikes, which resulted in widespread violence. The killing of most members of the royal family by the crown prince (who also died, from self-inflicted wounds) in 2001 heightened tensions and threatened greater political and economic instability. (Ed.)

RANA (eds.), *Nepal and Non-Alignment* (1982); JAGADISH SHARMA, *Nepal, Struggle for Existence* (1986); EUGENE BRAMER MIHALY, *Foreign Aid and Politics in Nepal* (1965), on the effect of aid programs; LEO E. ROSE, *Nepal: Strategy for Survival* (1971), on relations with India and China; and SHANKAR KUMAR JHA (ed.), *Indo-Nepal Relations* (1989). (P.P.K./L.E.R.)

Nerves and Nervous Systems

All living organisms are able to detect changes within themselves and in their environments. Changes in the external environment include those of light, temperature, sound, motion, and odour, while changes in the internal environment include those in the position of the head and limbs as well as in the internal organs. Once detected, these internal and external changes must be analyzed and acted upon in order to preserve the integrity, well-being, and status quo of the organism. As life on Earth evolved and the environment became more complex, the survival of organisms depended upon how well they could respond to changes in their surroundings. One factor necessary for survival was a speedy reaction or response. Since communication from one cell to another by chemical means was too slow to be adequate for survival, a system evolved that allowed for faster reaction. That system was the nervous system, which is based upon the almost instantaneous transmission of electrical impulses from one region of the body to another along specialized nerve cells.

Nervous systems are of two general types, diffuse and centralized. In the diffuse type, found in lower invertebrate animals, there is no brain, and the nerve cells are distributed throughout the organism in a netlike pattern. In the centralized systems of the higher invertebrates and the vertebrate animals, some portion of the nervous system has a dominant role in coordinating information and directing responses. This centralization reaches its apogee in the vertebrates, which have a well-developed brain and spinal cord. Impulses are carried to and from the brain and spinal cord by nerve fibres that make up the peripheral nervous system.

This article begins with a discussion of the general features of nervous systems—that is, their function of responding to stimuli and the rather uniform electrochemical processes by which they carry out their response. Following a discussion of the various types of nervous systems, from the simplest to the most complex, are sections on the anatomy and functions of the human nervous system. The article concludes with a section on the most common neurological diseases and disorders.

For detailed discussion of the biochemical and physiological processes of which the nervous system forms a part, see CELLS; and GROWTH AND DEVELOPMENT, BIOLOGICAL. For description of receptors that initiate nerve impulses, see SENSORY RECEPTION. The organ systems that are supplied by nerves are described in MUSCLES AND MUSCLE SYSTEMS.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 323, 333, 421, and 423, and the *Index*. (S.D.E.)

FORM AND FUNCTION OF NERVOUS SYSTEMS

Stimulus–response coordination

The simplest type of living response is the direct one-to-one stimulus–response reaction. The change in the environment is the stimulus; the reaction of the organism to it is the response. In the case of single-celled organisms, the response is the result of a property of the cell fluid called irritability. In simple organisms, such as algae, protozoans, and fungi, a stereotyped response in which the organism moves toward or away from the stimulus is termed taxis. In larger and more complicated organisms—those in which response involves the synchronization and integration of events in different parts of the body—a control mechanism, or "controller," is located between the stimulus and the response. In multicellular organisms, this controller consists of two basic mechanisms by which integration is achieved—chemical regulation and nervous regulation.

Two mechanisms of coordination: chemical and nervous

In chemical regulation, substances called hormones are produced by well-defined groups of cells and are either diffused or carried by the blood to other areas of the body where they act on so-called target cells, influencing metabolism or inducing synthesis of other substances. The changes resulting from hormonal action are expressed in the organism as influences on, or alterations in, form, growth, reproduction, and behaviour.

Plants respond to a variety of external stimuli by utilizing hormones as controllers in a stimulus–response system. Directional responses of movement are known as tropisms and are called positive when the movement is toward the stimulus and negative when it is away from the stimulus. When a seed germinates, the growing stem turns upward toward the light, and the roots turn downward away from the light. Thus, the stem shows positive phototropism and negative geotropism, while the roots show negative phototropism and positive geotropism. In this example, light and gravity are the stimuli, and directional growth is the response. The controllers are certain hormones synthesized by cells in the tips of the plant stems. These hormones, known as auxins, diffuse through the tissues beneath the tip and concentrate toward the shade side, causing elongation of these cells and, thus, a bending of the tip toward the light. The end result is that the plant is maintained in an optimal condition with respect to light.

In animals, in addition to chemical regulation via the endocrine system, there is another integrative system called the nervous system. A nervous system can be defined as an organized group of cells, called neurons, specialized for the conduction of an impulse—an excited state—from a sensory receptor through a nerve network to an effector, the site at which the response occurs.

Advantages of nervous coordination

Organisms that possess a nervous system are capable of much more complex behaviour than are organisms that lack one. The nervous system, being specialized for the conduction of impulses, allows rapid responses to stimuli from the environment. Many of the responses mediated by the nervous system are directed toward preserving the status quo, or homeostasis, of the animal. Stimuli that tend to displace or disrupt some part of the organism call forth a response that results in reduction of the adverse effects and a return to a more normal condition. Organisms with a nervous system are also capable of a second group of functions that initiate a variety of behaviour patterns. Animals may go through periods of exploratory or appetitive behaviour, nest building, and migration. Although these activities are beneficial to the survival of the species, they are not always performed by the individual in response to an individual need or stimulus. Finally, learned behaviour can be superimposed on both the homeostatic and initiating functions of the nervous system.

INTRACELLULAR SYSTEMS

All living cells have the property of irritability, or responsiveness to environmental stimuli, which can affect the cell in different ways, producing, for example, electrical, chemical, or mechanical changes. These changes are expressed as a response, which may be the release of secretory products by gland cells, the contraction of muscle cells, the bending of a plant-stem cell, and the beating of whiplike "hairs," or cilia, by ciliated cells.

The responsiveness of a single cell can be illustrated by the behaviour of the relatively simple amoeba. Unlike some other protozoans, an amoeba lacks highly developed structures that function in the reception of stimuli and in the production or conduction of a response. The amoeba behaves as though it had a nervous system, however, because the general responsiveness of its cytoplasm serves the functions of a nervous system. An excitation produced by a stimulus is conducted to other parts of the cell and evokes a response by the animal. An amoeba will move to a region of a certain level of light. It will be attracted by chemicals given off by foods and exhibit a feeding response. It will also withdraw from a region with noxious chemicals and show an avoidance reaction upon contacting other objects.

ORGANELLE SYSTEMS

In more complex protozoans, specialized cellular structures, or organelles, serve as receptors of stimulus and as effectors of response. Receptors include stiff sensory bristles in ciliates and the light-sensitive eyespots of flagellates. Effectors include cilia (slender, hairlike projections from the cell surface), flagella (greatly elongated, whiplike cilia), and other organelles associated with drawing in food or with locomotion. Protozoans also have subcellular cytoplasmic filaments that, like muscle tissue, are contractile. The vigorous contraction of the stalked protozoan *Vorticella,* for example, is the result of contraction of a threadlike structure called a myoneme in the stalk.

Although protozoans clearly have specialized receptors and effectors, it is not certain that there are special conducting systems between the two. In a ciliate such as *Paramecium,* the beating of the cilia—which propels it along—is not random, but coordinated. Beating of the cilia begins at one end of the animal and moves in regularly spaced waves to the other end, suggesting that coordinating influences are conducted longitudinally. A system of fibrils connecting the bodies in which the cilia are rooted could provide conducting paths for the waves, but coordination of the cilia could also take place without such a system. Each cilium could respond to a stimulus carried over the cell surface from an adjacent cilium—in which case, coordination would be the result of a chain reaction from cilium to cilium.

Coordination in the *Paramecium*

The best evidence that formed structures are responsible for coordination comes from another ciliate, *Euplotes,* which has a specialized band of ciliary rows (membranelles) and widely separated tufts of cilia (cirri). By means of the coordinated action of these structures, *Euplotes* is capable of several complicated movements in addition to swimming (*e.g.,* turning sharply, moving backward, spinning). The five cirri at the rear are connected to the anterior end in an area known as the motorium. The fibres of the motorium apparently provide coordination between the cirri and the membranelles. The membranelles, cirri, and motorium constitute a neuromotor system.

NERVOUS SYSTEMS

The basic pattern of stimulus–response coordination in animals is an organization of receptor, adjustor, and effector units. External stimuli are received by the receptor cells, which, in most cases, are neurons. (In a few instances, a receptor is a non-nervous sensory epithelial cell, such as a hair cell of the inner ear or a taste cell, which stimulates adjacent neurons.) The stimulus is modified, or transduced, into an electrical impulse in the receptor neuron. This incoming excitation, or afferent impulse, then passes along an extension, or axon, of the receptor to an adjustor, called an interneuron. (All neurons are capable of conducting an impulse, which is a brief change in the electrical charge on the cell membrane. Such an impulse

can be transmitted, without loss in strength, many times along an axon until the message, or input, reaches another neuron, which in turn is excited.) The interneuron-adjustor selects, interprets, or modifies the input from the receptor and sends off an outgoing, or efferent, impulse to an efferent neuron, such as a motor neuron. The efferent neuron, in turn, makes contact with an effector such as a muscle or gland, which produces a response.

In the simplest arrangement, the receptor–adjustor–effector units form a functional group known as the reflex arc. Sensory cells carry afferent impulses to a central interneuron, which makes contact with a motor neuron. The motor neuron carries efferent impulses to the effector, which produces the response. Three types of neurons are involved in this reflex arc, but a two-neuron arc, in which the receptor makes contact directly with the motor neuron, also occurs. There, simple reflexes are prompt, short-lived, automatic, and involve only a part of the body. Examples of simple reflexes are the contraction of a muscle in response to stretch, the blink of the eye when the cornea is touched, and salivation at the sight of food. Reflexes of this type are usually involved in preserving homeostasis.

Simple and complex nervous systems

The differences between simple and complex nervous systems lie not in the basic units but in their arrangement. In higher nervous systems, there are more interneurons concentrated in the central nervous system (brain and spinal cord) that mediate the impulses between afferent and efferent neurons. Sensory impulses from particular receptors travel over specific neuronal pathways to the central nervous system. Within the central nervous system, though, the impulse can travel over multiple pathways formed by numerous neurons. Theoretically, the impulse can be distributed to any of the efferent motor neurons and produce a response in any of the effectors. It is also possible for many kinds of stimuli to produce the same response.

As a result of the integrative action of the interneuron, the behaviour of the organism is more than the simple sum of its reflexes; it is a unitary, integrated whole that exhibits coordination between many individual reflexes. Reflexes can occur in a complicated series or sequence producing elaborate behaviour patterns. Behaviour in such cases is characterized not by inherited, stereotyped responses but by flexibility and adaptability to circumstances. Many automatic, unconditioned reflexes can be modified by or adapted to new stimuli. The remarkable experiments of the Russian physiologist Pavlov, for example, showed that if an animal salivates at the sight of food while another stimulus, such as the sound of a bell, occurs simultaneously, the sound alone can induce salivation after several trials. This response, known as a conditioned reflex, is a form of learning. The animal's behaviour is no longer limited by fixed, inherited reflex arcs but can be modified by experience and exposure to an unlimited number of stimuli. The most evolved nervous systems are capable of even higher associative functions: of other forms of learning, of thinking, and of memory. The complex manipulation of the signals necessary for these functions depends to a great extent on the number and intricacy of arrangement of the pool of interneurons. (T.L.L./S.D.E.)

The nerve cell

The watershed of all studies of the nervous system was an observation made in 1889 by the Spanish scientist Santiago Ramón y Cajal, who reported that the nervous system is composed of individual units that are structurally independent of one another and whose internal contents do not come into direct contact. According to this hypothesis, now known as the neuron theory or neuron doctrine, each nerve cell communicates with others through contiguity rather than continuity. That is, communication between adjacent but separate cells must take place across the space and barriers separating them. It has since been proved that Ramón y Cajal's theory is not universally true, but his central idea—that communication in the nervous system is largely communication between independent nerve cells—has remained an accurate guiding principle for all further study.

There are two basic cell types within the nervous system: neurons and neuroglial cells.

THE NEURON

In the human brain there are approximately 10,000,000,000 neurons. Each neuron has its own identity, expressed by its interactions with other neurons and by its secretions; each also has its own function, depending on its intrinsic properties and location as well as its inputs from other select groups of neurons, its capacity to integrate those inputs, and its ability to transmit the information to another select group of neurons.

Three regions of the neuron

With few exceptions, most neurons consist of three distinct regions: (1) the cell body, or soma; (2) the nerve fibre, or axon; and (3) the receiving processes, or dendrites (Figure 1).

By courtesy of Alan Peters

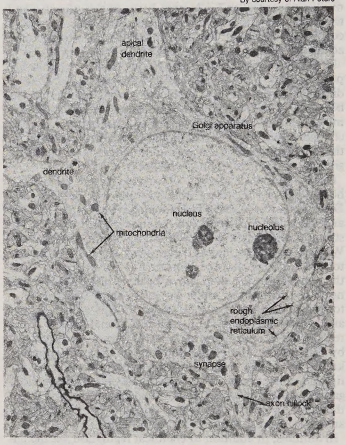

Figure 1: *A neuron from the visual cortex of a rat.*
The centre of the field is occupied by the soma, or cell body, of the neuron. Most of the soma is occupied by the nucleus, which contains a nucleolus. The double membrane of the nucleus is surrounded by cytoplasm, containing elements of the Golgi apparatus lying at the base of the apical dendrite. Mitochondria can be seen dispersed in the cytoplasm, which also contains the rough endoplasmic reticulum. Another dendrite is seen to the side, and the axon hillock is shown at the initial segment of the emerging axon. A synapse impinges onto the neuron close to the axon hillock.

The soma. *The plasma membrane.* The neuron is bounded by a plasma membrane, a structure so thin that its fine detail can be revealed only by high-resolution electron microscopy. About half of the membrane is the so-called lipid bilayer, two sheets of mainly phospholipids with a space between. One end of a phospholipid molecule is hydrophilic, or water attaching, and the other end is hydrophobic, or water repelling. The bilayer structure results when the hydrophilic ends of the phospholipid molecules in each sheet turn toward the watery mediums of both the cell interior and the extracellular environment, while the hydrophobic ends of the molecules turn in toward the space between the sheets. These lipid layers are not rigid structures; the loosely bonded phospholipid molecules can move laterally across the surfaces of the membrane, and the interior is in a highly liquid state.

Embedded within the lipid bilayer are proteins, which also "float" in the liquid environment of the membrane. These include glycoproteins containing polysaccharide chains, which function, along with other carbohydrates, as adhesion sites and recognition sites for attachment and

chemical interaction with other neurons. The proteins provide another basic and crucial function: those which penetrate the membrane can exist in more than one conformational state, or molecular shape, forming channels that allow ions to pass between the extracellular fluid and the cytoplasm, or internal contents of the cell. In other conformational states, they can block the passage of ions. This action is the fundamental mechanism that determines the excitability and pattern of electrical activity of the neuron.

A complex system of proteinaceous intracellular filaments are linked to the membrane proteins. This so-called cytoskeleton includes thin neurofilaments containing actin, thick neurofilaments similar to polymerized myosin, and microtubules composed of tubulin. The filaments are probably concerned with movement and translocation of the membrane proteins, while microtubules may anchor the proteins to the cytoplasm.

The nucleus. Each neuron contains a nucleus defining the location of the soma. The nucleus is surrounded by a double membrane, called the nuclear envelope, that fuses at intervals to form pores allowing molecular communication with the cytoplasm. Within the nucleus are the chromosomes, the genetic material of the cell, through which the nucleus controls synthesis of proteins and the growth and differentiation of the cell into its final form. Proteins synthesized in the neuron include enzymes, receptors, hormones, and structural proteins for the cytoskeleton.

Organelles of the cell. The endoplasmic reticulum (ER) is a widely spread membrane system within the neuron that is continuous with the nuclear envelope. It consists of series of tubules, flattened sacs called cisternae, and membrane-bounded spheres called vesicles. There are two types of ER.

Synthesis of protein in the neuron

The rough endoplasmic reticulum (RER) has rows of knobs called ribosomes on its surface. Ribosomes synthesize proteins that, for the most part, are transported out of the cell. The RER is found only in the soma.

The smooth endoplasmic reticulum (SER) consists of a network of tubules in the neuron soma that connects the RER with the Golgi apparatus. The tubules can also enter the axon at its initial segment and extend to the axon terminals.

The Golgi apparatus is a complex of flattened cisternae arranged in closely packed rows. Located close to and around the nucleus, it receives proteins synthesized in the RER and transferred to it via the SER. Once arrived at the Golgi apparatus, the proteins are attached to carbohydrates. The glycoproteins so formed are packaged into vesicles that leave the complex to be incorporated into the cell membrane.

The axon. The axon arises from the soma at a region called the axon hillock or initial segment. This is the region where the plasma membrane generates nerve impulses; the axon conducts these impulses away from the soma or dendrites toward other neurons. Large axons (arising from large somas) acquire an insulating myelin sheath and are known as myelinated or medullated fibres. Myelin is composed of 80 percent lipid and 20 percent protein; cholesterol is one of the major lipids, along with variable amounts of cerebrosides and phospholipids. Concentric layers of these lipids separated by thin layers of protein give rise to a high-resistance, low-capacitance electrical insulator interrupted at intervals by gaps called nodes of Ranvier, where the nerve membrane is exposed to the external environment. In the central nervous system, the myelin sheath is formed from glial cells called oligodendrocytes, while in peripheral nerves it is formed from Schwann cells (see below *The neuroglia*).

While the axon mainly conducts nerve impulses from the soma to the terminal, the terminal itself secretes chemical substances called neurotransmitters. The synthesis of these substances can occur in the terminal itself, but the synthesizing enzymes are formed by ribosomes in the soma and must be transported down the axon to the terminal. This process is known as axoplasmic flow; it occurs in both directions along the axon and may be facilitated by microtubules.

At the terminal of the axon, and sometimes along its length, are specialized structures that form junctions with other neurons and with muscle cells. These junctions are called synapses. Presynaptic terminals, when seen by light microscopy, look like small knobs; when examined under high-resolution electron microscopy, they are seen to contain many organelles. The most numerous of these are synaptic vesicles, which, filled with neurotransmitters, are often clumped in areas of the terminal membrane that appear to be thickened. The thickened areas are known as presynaptic dense projections, or active zones.

Axon terminals at the synapse

The presynaptic terminal is unmyelinated and is separated from the neuron or muscle cell onto which it impinges by a gap called the synaptic cleft, across which the neurotransmitters diffuse when released from the vesicles. In nerve–muscle junctions the synaptic cleft contains a structure called the basal lamina. This structure holds an enzyme that destroys neurotransmitters and thus regulates the amount that reaches the postsynaptic receptors on the receiving cell. Most knowledge of postsynaptic neurotransmitter receptors comes from studies of the receptor on muscle cells. This receptor, called the end plate, is a glycoprotein composed of five subunits. Other neurotransmitter receptors do not have the same structure, but they are all proteins and probably have subunits with a central channel that is activated by the neurotransmitter.

While the chemically mediated synapse described above forms the majority of synapses in nervous systems of vertebrates, there are other types of synapses in vertebrate brains and, in especially great numbers, in invertebrate and fish nervous systems. At these synapses there is no synaptic gap; instead, there are so-called gap junctions, direct channels between neurons that establish a continuity between the cytoplasm of adjacent cells and a structural symmetry between the pre- and postsynaptic sites. Rapid neuronal communication at these junctions is probably not chemical but electrical in nature. (For further discussion, see below *Transmission of information in the nervous system: Transmission at the synapse.*)

The dendrites. Besides the axon, neurons have other branches called dendrites. These are usually shorter than axons and are unmyelinated. Traditionally, dendrites are thought to form receiving surfaces for synaptic input from other neurons. In many dendrites these surfaces are provided by specialized structures called dendritic spines, which, by providing discrete regions for the reception of nerve impulses, isolate changes in electrical current from the main dendritic trunk.

The traditional view of dendritic function presumes that only axons conduct nerve impulses and only dendrites receive them, but it has been shown that dendrites can form synapses with dendrites and that axons and even somata can receive impulses. Indeed, some neurons have no axon; in these cases nervous transmission is carried out by the dendrites.

THE NEUROGLIA

Neurons form a minority of the cells in the nervous system. Exceeding them in number by at least 10 to 1 are neuroglial cells, which exist in the nervous systems of invertebrates as well as vertebrates. Neuroglia can be distinguished from neurons by the lack of axons and the presence of only one type of process. In addition, they do not form synapses, and they retain the ability to divide throughout their life span. While neurons and neuroglia lie in close apposition to one another, there are no direct junctional specializations, such as gap junctions, between the two types. Gap junctions do exist between neuroglial cells, raising questions about their functions and properties.

Differences between neuroglia and neurons

Types of neuroglia. Apart from conventional histological and electron-microscopic techniques, immunologic techniques are used to identify different neuroglial cell types. By staining the cells with antibodies that bind to specific protein constituents of different neuroglia, neurologists have been able to discern two (in some opinions three) main groups: (1) astrocytes, subdivided into fibrous and protoplasmic types; (2) oligodendrocytes, subdivided into interfascicular and perineuronal types; and sometimes (3) microglia.

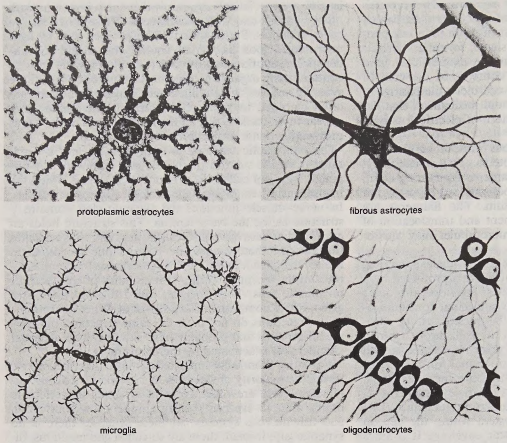

Figure 2: Neuroglial cells.
After del Rio-Hortega in W. Bloom and D.W. Fawcett, *A Textbook of Histology* (1986), W.B. Saunders Co., Philadelphia; reprinted by permission

Fibrous astrocytes are prevalent among myelinated nerve fibres in the white matter of the central nervous system. Organelles seen in the somata of neurons are also seen in astrocytes, but they appear to be much sparser. These cells are characterized by the presence of numerous fibrils in their cytoplasm. The main processes exit the cell in a radial direction (hence the name astrocyte, meaning "star-shaped cell"), forming expansions and end feet at the surfaces of vascular capillaries.

Unlike fibrous astrocytes, protoplasmic astrocytes occur in the gray matter of the central nervous system. They have fewer fibrils within their cytoplasm, and cytoplasmic organelles are sparse, so that the somata are shaped by surrounding neurons and fibres. The processes of protoplasmic astrocytes also make contact with capillaries.

Oligodendrocytes have few cytoplasmic fibrils but a well-developed Golgi apparatus. They can be distinguished from astrocytes by the greater density of both cytoplasm and nucleus, the absence of fibrils and glycogen in the cytoplasm, and large numbers of microtubules in the processes. Interfascicular oligodendrocytes are aligned in rows between the nerve fibres of the white matter of the central nervous system. In gray matter perineuronal oligodendrocytes are located in close approximation with the somata of neurons. In the peripheral nervous system, neuroglia that are equivalent to oligodendrocytes are called Schwann cells.

Microglial cells are small, crenate cells with dark cytoplasm and a dark nucleus. It is uncertain whether they are merely damaged neuroglial cells or occur as a separate group in living tissue.

Neuroglial functions. The term neuroglia means "nerve glue," and these cells were originally thought to be structural supports for neurons. This is still thought to be plausible, but other functions of the neuroglia are now generally accepted. It has long been known that oligodendrocytes and Schwann cells produce the myelin sheath around neuronal axons. Studies show that some constituent of the axonal surface stimulates Schwann cell proliferation and that the type of axon determines whether there is loose or tight myelination of the axon. In tight myelination a glial cell wraps itself like a rolled sheet around a length of axon until the fibre is covered by several layers. Between segments of myelin wrapping are exposed sections called nodes of Ranvier, which are important in the transmission of nerve impulses. Myelinated nerve fibres are found only in vertebrate animals, leading biologists to conclude that they are an adaptation to transmission over relatively long distances.

Formation of myelin

Another well-defined role of neuroglial cells is in repair following injury to the central nervous system. It has been well documented that astrocytes divide after injury to the nervous system and that they occupy the spaces left by injured neurons. The role of oligodendrocytes after injury is not so clear, but evidence suggests that they can proliferate and form myelin sheaths.

When neurons of the peripheral nervous system are cut, they undergo a process of degeneration followed by regeneration, the fibres regenerating in such a way that they return to their original target sites. Schwann cells that remain after nerve degeneration apparently mark the route. This route direction is also performed by astrocytes during development of the central nervous system. In the developing cerebral cortex and cerebellum of primates, astrocytes project long processes to certain locations, and neurons migrate along these processes to arrive at their final locations. Thus, neuronal organization is brought about to some extent by the neuroglia.

Functions in synaptic transmission

Astrocytes are also believed to have high-affinity uptake systems for neurotransmitters such as glutamate and gamma-aminobutyric acid (GABA). This function is important in the modulation of synaptic transmission. Uptake systems tend to terminate neurotransmitter action at the synapses and perhaps also act as storage systems for the neurotransmitters when they are needed. For instance, when motor nerves are cut, the nerve terminals degenerate and their original sites are occupied by Schwann cells. It has been found not only that electrical signals can be recorded on muscle cell receptors in the absence of any form of stimulation but also that currents applied to the Schwann cells evoke neurotransmitter release. Apparently, the synthesis of neuro-transmitters by neurons also requires the presence of neuroglial cells in the vicinity.

In the past it was thought that neuroglia were not electrically excitable, but it has been shown that neuroglial cells in vitro have voltage-sensitive properties similar to those of excitable neurons. If electrical activity similar to that occurring in neurons were generated in neuroglial cells in vivo, the implications for glial–neuronal interaction would be enormous. Such proof is not available, however.

Finally, the environment surrounding neurons in the brain consists of a network of very narrow extracellular clefts. In 1907 the Italian biologist Emilio Lugaro suggested that neuroglial cells exchange substances with the extracellular fluid and in this way exert control on the neuronal environment. It has since been shown that glucose, amino acids, and ions—all of which influence neuronal function—are exchanged between the extracellular space and neuroglial cells. After high levels of neuronal activity, for instance, neuroglial cells can take up and spatially buffer potassium ions and thus maintain normal neuronal function.

Transmission of information in the nervous system

In the nervous systems of animals at all levels of the evolutionary scale, the signals containing information about a particular stimulus are electrical in nature. In the past the nerve fibre and its contents were compared to a metal wire, while the membrane was compared to insulation around the wire. This comparison was erroneous for a number of reasons. First, the charge carriers in nerves are ions, not electrons, and the density of ions in the axon is much less than that of electrons in a metal wire. Second, the membrane of an axon is not a perfect insulator, so that the movement of current along the axon is not complete. Finally, nerve fibres are smaller than most wires, so that the currents they can carry are limited in amplitude.

THE IONIC BASIS OF ELECTRICAL SIGNALS

Ions are atoms or groups of atoms that gain an electrical charge by losing or acquiring electrons. For example, in the reaction that forms salt from sodium and chlorine, each sodium atom "donates" an electron, which is negatively charged, to a chlorine atom. The result is sodium chloride (NaCl), composed of one positively charged sodium ion (Na^+) and one negatively charged chloride ion (Cl^-).

Positive and negative charge

A positively charged ion is called a cation; a negatively charged ion, an anion. The number of charges carried by an ion is called its valence. Na^+ and Cl^-, which respectively lose and acquire one electron, have a valence of one, while calcium ions (Ca^{2+}), which lose two electrons, have a valence of two.

The electrical events that constitute signaling in the nervous system depend upon the distribution of ions on either side of the nerve membrane. Underlying these distributions and their change are crucial physicochemical principles.

Distribution of ions across a membrane. *Diffusion of uncharged molecules.* Molecules in solution move randomly, the energy for their movement being derived from thermal energy. When a permeable membrane (a membrane that allows molecules to cross it) divides a heavily concentrated solution from a lightly concentrated solution, there occurs a diffusion of molecules through the membrane and down their concentration gradient—that is, from the fluid with the higher concentration to that with the lower concentration. The number of molecules moving per unit of time is called the flow rate, or flux rate. Diffusion continues until the concentrations on both sides of the membrane are equal. A condition of no net flux is then established with an equal, random diffusion of molecules in both directions. This is called the equilibrium state.

A membrane with pores allowing passage of molecules of only a particular size is called a semipermeable membrane. The semipermeable membrane imposes a condition of restricted diffusion. In that case the flux rate of the diffusing material is controlled by the permeability of the membrane, which in turn is dictated by the size of the pores and is given a unit of measure called the permeability coefficient.

Diffusion of water. The water molecule, like other molecules, diffuses down its concentration gradient. If a rigid vessel contains water on one side of a semipermeable membrane and an impermeant substance (a substance that cannot cross the membrane) on the other side, the water tends to cross the membrane, diluting the substance and increasing the hydrostatic pressure on the other side (Figure 3). The pressure then will tend to push water back across the membrane in opposition to the net flux. When the pressure built up equals the diffusion of water in the opposite direction, no net flux occurs and equilibrium is established. The migration of water (or any solvent) across a membrane is called osmosis, and the pressure necessary to establish equilibrium is called osmotic pressure. Water moves from a region of low osmotic pressure to a region of high osmotic pressure.

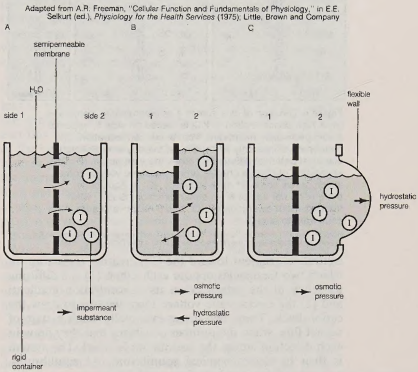

Figure 3: *Diffusion of water across a semipermeable membrane.* (A) Water diffuses down its concentration gradient from side 1 to side 2 of a rigid container. (B) The net flux of water creates a hydrostatic pressure, tending to force the water back to side 1. (C) If the wall of side 2 is flexible, the hydrostatic pressure causes an increase in the volume of side 2.

The above example refers to water in a container with rigid walls. The neuron, however, has somewhat flexible walls, so that as water enters it, the cell tends to increase in volume, or swell. There is a direct relation between osmotic pressure across the plasma membrane and the final volume of a cell at equilibrium, so that if the osmotic pressure of the cell exterior is halved, the equilibrium volume of the cell will be twice its original.

Diffusion of ions. When potassium chloride (KCl) is placed into solution, the elements separate into potassium cations (K^+) and chloride anions (Cl^-). The ions follow much the same principles of diffusion as uncharged molecules. For example, if a highly concentrated solution of KCl is separated from a lower concentration by a semipermeable membrane—one that is permeable to cations only—then K^+ from the higher concentration diffuses across the membrane, following its concentration gradient to the region of lower concentration (Figure 4). Cl^-, being blocked by the membrane, remains behind. At this point the diffusion of ions creates conditions quite different from the diffusion of uncharged molecules and water molecules. The movement of cations toward the less concentrated solution creates a separation of electrical charge across the membrane—that is, a greater number of positively charged ions will have moved to the side with the less concentrated solution of KCl, and the side of the membrane with the higher concentration will have a more negative charge. This separation of charge—actually a difference in electrical potential—is called the potential difference, and it is the starting point of all electrical events in nervous systems. When present in the plasma membrane of the neuron, it transforms the neuron into an electrolytic cell that is capable, upon stimulation, of generating and transmitting electrical impulses.

Separation of electrical charge

Complicating the ionic diffusion process is the phenomenon that opposite charges attract. This means that, in the example above, some of the K^+ diffusing across the membrane is electrostatically drawn back up its con-

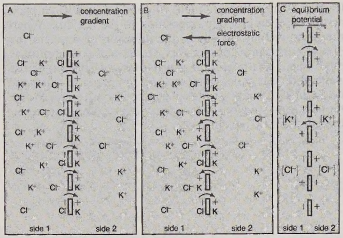

Figure 4: *Diffusion of ions across a semipermeable membrane.* (A) A high concentration of KCl is placed on side 1, opposite a semipermeable membrane from a low concentration. The membrane allows only K^+ to diffuse, thereby establishing an electrical potential difference across the membrane. (B) The separation of charge creates an electrostatic voltage force, which draws some K^+ back to side 1. (C) At equilibrium, there is no net flux of K^+ in either direction. Side 1, with the higher concentration of KCl, has a negative charge compared to side 2.

Adapted from A.R. Freeman, "Cellular Function and Fundamentals of Physiology," in E.E. Selkurt (ed.), *Physiology for the Health Services* (1975). Little, Brown and Company

centration gradient toward the Cl^-, creating a situation in which two tendencies oppose each other: (1) the diffusing tendency of the cation down its concentration gradient; and (2) the electrostatic voltage force tending to draw the cation back. These two forces eventually reach a state of no net flux, when the number of cations that they draw in each direction across the membrane is equal. The system is then in electrochemical equilibrium. At equilibrium, one side of the membrane may still have a more negative charge than the other. In that case the potential difference is called the equilibrium potential. (It is also called the Nernst potential, after Walther Nernst, the German physical chemist who, in the late 19th century, developed equations for calculating the electrical potential at which there is no longer a net flux of a specific ion across a membrane.)

The law of electroneutrality states that in any single ionic solution a sum of negative electrical charges attracts an equal sum of positive electrical charges. If a solution of KCl is divided into two parts by a membrane, permeable to both ions, then the equal concentration of KCl across the membrane preserves chemical equilibrium between the two sides, while the equal concentrations of K^+ and Cl^- on each side preserve electroneutrality on each side as well (Figure 5). This equilibrium can be upset by the addition to side 1 of a large number of K^+ and an equal charge of impermeant anions (that is, negatively charged ions other than Cl^- that cannot permeate the membrane). In that case electroneutrality on side 1 is preserved, since the sum of positive charges added to that side is equaled by the sum of added negative charges. However, chemical equilibrium between side 1 and side 2 is not preserved, since side 1 now has a greater concentration of ions than side 2. Therefore, K^+ diffuses down its concentration gradient, crossing the membrane to side 2 while drawing Cl^- with it to preserve electroneutrality. Diffusion continues until a new state of electrochemical equilibrium is reached. Researchers have found that this occurs at a point at which the ratio of K^+ concentration on side 2 to that on side 1 is equal to the ratio of Cl^- concentration on side 1 to that on side 2. Stated mathematically, equilibrium is reached when

$$\frac{[K^+]_{\text{side 2}}}{[K^+]_{\text{side 1}}} = \frac{[Cl^-]_{\text{side 1}}}{[Cl^-]_{\text{side 2}}}.$$

This is known as the Donnan equilibrium, after Frederick George Donnan, the British chemist who in 1911 first measured the changes brought about by adding an impermeant substance to one side of a divided solution at equilibrium.

In the new state of equilibrium, both side 1 and side 2 are electrically neutral, since the impermeant anions added to side 1 are equaled by the added K^+, and the K^+ that has diffused to side 2 is balanced by the Cl^- electrostatically drawn along with it. But the entire solution is not at osmotic equilibrium, because the larger amount of ions on side 1 tends to draw water from side 2. Osmotic equilibrium can be established by the addition of ions to side 2. Indeed, in the neuron, osmotic equilibrium is maintained partly because large amounts of K^+ and impermeant anions inside the cell are balanced by large amounts of salt outside.

The neuronal membrane. The principles outlined above can be applied to the neuron and its ionic contents.

The plasma membrane of the neuron is semipermeable, being highly permeable to K^+ and slightly permeable to Cl^- and Na^+. In the extracellular fluid, electroneutrality is preserved by a balance between a high concentration of Na^+ on the one hand and a high concentration of Cl^- as well as small quantities of impermeant anions such as bicarbonate, phosphate, and sulfate on the other. In the cytoplasm, where K^+ concentration is high, the concentration of Cl^- is much below that necessary to balance the sum of the positive charges. Electroneutrality is maintained there by negatively charged impermeant proteins and phosphates. Osmotic balance is maintained between the extracellular fluid and the cytoplasm by movement of water through the plasma membrane when the total concentration of particles on one side is not equal to that on the other.

The electrical potential of the neuron

These three characteristics of the neuron—semipermeability of the membrane, osmotic balance, and electroneutrality on each side—create an equilibrium electrical potential at which the inside of the membrane is more negative than the outside. In most neurons this potential, called the membrane potential, is between −60 and −75 millivolts (mV; the minus sign indicates that the inner surface is negative). When the inside of the plasma membrane has a negative charge compared to the outside, the neuron is said to be polarized. Any change in membrane potential tending to make the inside even more negative is called hyperpolarization, while any change tending to make it less negative is called depolarization.

As stated above, the Nernst potential is the potential difference that exists across a membrane when a particular ion, having reached equilibrium between the tendency to diffuse down its concentration gradient and the tendency to be drawn back by other ions, is in a state of no net flux. Given such information as the energy of the dissolved substances, the temperature of the solution, and the concentrations of ions on each side of the membrane, researchers using the Nernst equation can predict the potential difference that will exist if the membrane is permeable to any one of the ions in solution. The plasma membrane of the neuron is highly permeable to K^+, and in fact the recorded membrane potential of most neurons (−60 to −75 millivolts) is close to that predicted by the Nernst equation for K^+. However, it is not exactly the

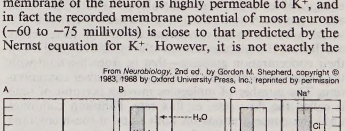

Figure 5: *Establishment of electrochemical and osmotic equilibrium.*
(A) A solution of KCl divided by a permeable membrane reaches electrochemical equilibrium, with both sides maintaining equal concentrations of KCl and each side maintaining equal positive (K^+) and negative (Cl^-) charges. (B) With the addition to side 1 of K^+ and an anion (A^-) that cannot permeate the membrane, equilibrium is upset. K^+ diffuses to side 2, drawing an equal charge of Cl^-. A new electrochemical equilibrium is reached at which each side maintains equal positive and negative charges, but side 1 has a higher concentration of ions than side 2. This causes the osmosis of water (H_2O) from side 2 to side 1. (C) Osmotic equilibrium is established by the addition of salt (NaCl) to side 2, creating an equal concentration of ions across the membrane.

same, because K^+ is not the only ion affecting the membrane potential. The membrane is also slightly permeable to Na^+ and Cl^-. The permeability to Na^+ may be low, but the high concentration of this cation outside the cell and the slightly negative electric charge inside the cell tend to drive Na^+ inward. This in turn causes the inside of the cell to depolarize, placing K^+ out of equilibrium. As a consequence, K^+ leaves the cell until an equilibrium state is reached in which the leak inward of Na^+ is equaled by the leak outward of K^+ and there is no net flux of ions. There is also a tendency for Cl^- to permeate the membrane, since that ion is at higher concentration outside the neuron than inside. Therefore, for an equilibrium state to be produced, the sum of all three net currents must equal zero.

Given the concentrations of all three ions on each side of the membrane and the relative permeability of the membrane to each ion, researchers can calculate the combined effect of K^+, Na^+, and Cl^- on the membrane potential by using the so-called constant-field equation. This equation, by including relative permeability as an important factor, takes into account the phenomenon that the more permeable a membrane is to a particular ion, the greater is the influence of that ion on membrane potential. The permeance of Na^+, for example, is only a fraction of that of K^+, and the permeance of Cl^- is lower yet; therefore, while the membrane potential is highly sensitive to changes in the concentration of K^+, it is less affected by changes in Na^+ and almost unaffected by changes in Cl^-.

TRANSMISSION IN THE NEURON

The discussion above demonstrates that the electrical potential existing in neurons is based on the distribution of ions across the plasma membrane and that this distribution comes about through permeation of the membrane. In fact, ions are almost always hydrated in the form of ion–water complexes, which have great difficulty in penetrating the hydrophobic lipid bilayer of the plasma membrane. Permeation actually occurs through protein structures embedded in the lipid bilayer and spanning the membrane from cytoplasm to extracellular fluid. Sometimes pumping ions from one side to the other and sometimes merely providing channels through which diffusing ions can flow past the lipid molecules, these structures maintain the ionic distribution that keeps the membrane polarized, and they also allow the abrupt changes in distribution that create nerve impulses. The protein structures are described in detail in *Ion transport.* Following is a discussion of the electrical events, created by movement of ions, that lead to nervous transmission in the neuron.

Resting potential. The electrical potential across the nerve membrane can be measured by placing one microelectrode within the neuron (usually in the soma) and a second microelectrode in the extracellular fluid. The microelectrode consists of a sharp-tipped glass capillary tube filled with a conducting solution. Upon penetration of the neuron, the potential at the tip of the electrode becomes electrically negative in relation to the outside electrode. As described above, the value of this negative charge is usually between −60 and −75 millivolts. This is the membrane potential of the neuron at rest (*i.e.,* when it is not generating a nerve impulse), and for this reason it is called the resting potential.

The resting potential is maintained by the sodium–potassium pump, which steadily discharges more positive charge from the cell than it allows in, and by the relatively high permeance of K^+, which leaks out of the cell through its membrane channels faster than Na^+ leaks in.

Localized potential. When a physical stimulus such as touch, taste, or colour acts on a sensory receptor cell specifically designed to respond to that stimulus, then the energy of the stimulus (*e.g.,* mechanical, chemical, light) is transduced, or transformed, into an electrical response. This response is the receptor potential, a type of local potential that, when it reaches high enough amplitude, generates the nerve impulse. (Another type of local potential is the postsynaptic potential, which originates in chemical receptors at the synaptic cleft. See below *Transmission at the synapse: Chemical transmission.*)

Response to stimulation

Sensory receptors transduce stimuli into electrical responses by activating ion channels in their membranes. For example, in the stretch receptors of neurons attached to muscle cells, the stretching action of the muscle is thought to put a mechanical stress on protein filaments of the cytoskeleton, which in turn alter the shape of ion channels, inducing them to open and allowing cations to diffuse into the cell. Receptor cells sensitive to chemical and light energy, on the other hand, activate ion channels through the so-called second-messenger system. Under this system, stimulated receptor molecules on the surface of the cell membrane catalyze a series of enzymatic reactions within the cytoplasm; these reactions in turn release energy, which activates the ion channels.

By permitting a flux of Na^+ into the cell, the opening of ion channels slightly depolarizes the membrane. The extent to which the membrane is depolarized depends upon the extent to which the sodium channels are activated, and this in turn depends upon the strength and duration of the original stimulus at the receptor. If depolarization reaches what is called the threshold potential, it triggers the nerve impulse, or action potential (see below). If it does not reach that amplitude, then the neuron remains at rest, and the local potential, through a process called passive spread, diffuses along the nerve fibre and back out through the membrane.

When it is of the postsynaptic type, the local potential usually begins in the dendrites and spreads toward the soma and axon. It is at the initial segment of the axon where, if the local potential is of threshold amplitude, the nerve impulse is generated.

Action potential. *Depolarization.* Because it varies in amplitude, the local potential is said to be graded. The greater the influx of positive charge—and, consequently, depolarization of the membrane—the higher the grade. Beginning at the resting potential of a neuron (for instance, −75 millivolts), a local potential can be of any grade up to the threshold potential (for instance, −58 millivolts). At threshold, voltage-dependent sodium channels become fully activated, and Na^+ pours into the cell. Almost instantly, the membrane actually reverses polarity, the inside acquiring a positive charge in relation to the outside. This reverse polarity constitutes the nerve impulse. It is called the action potential because the positive charge then flows through the cytoplasm, activating sodium channels the entire length of the nerve fibre. This series of activations,

Generation of the nerve impulse

From *Neurobiology*, 2nd ed., by Gordon M. Shepherd, copyright © 1983, 1988 by Oxford University Press, Inc.; reprinted by permission

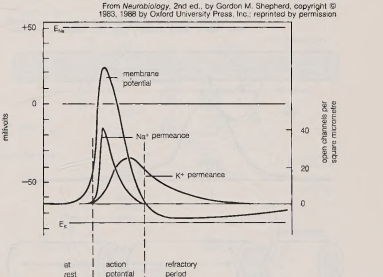

Figure 6: *Changes in ion permeance underlying the action potential.*
Electrical potential is graded at left in millivolts, ion permeance at right in open channels per square micrometre of membrane. At rest, with no channels open, the membrane potential is close to E_K, the equilibrium potential of K^+. When sodium channels open, the membrane depolarizes. Generation of the action potential brings the membrane potential close to E_{Na}, the equilibrium potential of Na^+. When sodium channels close (lowering Na^+ permeance) and potassium channels open (raising K^+ permeance), the membrane repolarizes. During the refractory period, while potassium channels remain open, the membrane is hyperpolarized.

by propagating the action potential along the fibre with virtually no reduction in amplitude, gives the nerve impulse its regenerative property.

Researchers call the nerve impulse an "all-or-none" reaction, since between threshold potential and fully activated potential there are no gradations. The neuron is either at rest with a polarized membrane, or it is conducting a nerve impulse at reverse polarization. The reverse polarity of active neurons is measured at about +30 millivolts. This is close to the Nernst potential for Na^+—that is, the membrane potential at which electrochemical equilibrium would be established if the membrane were completely permeable to Na^+.

Repolarization. As instantaneous as the opening of sodium channels at threshold potential is their closing at the peak of the action potential. This is called sodium inactivation, and it is caused by gates within the channel that are sensitive to depolarization. Following sodium inactivation is the opening of potassium channels, which allows the diffusion of K^+ out of the cell. The combined effect of sodium inactivation, which blocks the influx of cations, and potassium activation, which causes the efflux of other cations, is the immediate return of the cell membrane to a polarized state, with the inside negative in relation to the outside. After repolarization there is a period during which a second action potential cannot be initiated, no matter how large a stimulus current is applied to the neuron. This is called the absolute refractory period, and it is followed by a relative refractory period, during which another action potential can be generated, but only by a greater stimulus current than that originally needed. This period is followed in turn by the return of the neuronal properties to the threshold levels originally required for the initiation of action potentials.

Conduction. The sequence of sodium activation–sodium inactivation–potassium activation creates a nerve impulse that is brief in duration, lasting only a few milliseconds, and that travels down the nerve fibre like a wave, the membrane depolarizing in front of the current and repolarizing behind. Because nerve impulses are not graded in amplitude, it is not the size of the action potential that is important in processing information within the nervous system; rather, it is the number and frequency with which the impulses are fired.

As stated above, the action potential is propagated along the axon without any decrease in amplitude with distance. However, the velocity of conduction along the

nerve fibre is dependent upon several factors. First is the outside diameter of the nerve fibre. The fastest conduction velocity occurs in the largest diameter nerve fibres. This phenomenon has formed the basis for classifying mammalian nerve fibres into groups in order of decreasing diameter and decreasing conduction velocity. Another factor is the temperature of the nerve fibre. Conduction velocity increases at high temperature and decreases at low. Indeed, nerve conduction can be blocked by the local application of cold to a nerve fibre. Conduction velocity is also affected by myelination of the nerve fibre. Since ions cannot cross the lipid content of the myelin sheath, they spread passively down the nerve fibre until reaching the unmyelinated nodes of Ranvier. The nodes of Ranvier are packed with a high concentration of ion channels, which, upon stimulation, propagate the nerve impulse to the next node. In this manner the action potential jumps quickly from node to node along the fibre in a process called saltatory conduction (from Latin *saltare,* "to jump"; see Figure 7).

Factors affecting the velocity of transmission

TRANSMISSION AT THE SYNAPSE

Once an action potential has been generated at the axon hillock, it is conducted the length of the axon until it reaches the terminals, the fingerlike extensions of the neuron that abut other neurons and muscle cells (see above *The nerve cell: The neuron*). At this point there exist two methods for transmitting the action potential from one cell to the other. In electrical transmission, the ionic current flows directly through channels that couple the cells. In chemical transmission, a chemical substance called the neurotransmitter passes from one cell to the other, stimulating the second cell to generate its own action potential.

Electrical transmission. This method of transmitting nerve impulses, while far less common than chemical transmission, has been found in the nervous systems of invertebrates and lower vertebrates as well as in the central nervous systems of some mammals. Transmission takes place through so-called gap junctions, which are protein channels that link the cellular contents of adjacent neurons. Direct diffusion of ions through these junctions allows the action potential to be transmitted with little or no delay and distortion, in effect synchronizing the response of an entire group of neurons. The channels often allow ions to diffuse in both directions, but some gated channels restrict transmission to only one direction.

Gap junctions

Chemical transmission. There are two classic preparations for the study of chemical transmission at the synapse.

One is the vertebrate neuromuscular junction, and the other is the giant synapse of the squid *Loligo*. These sites have the advantage of being readily accessible for recording by electrodes—especially the squid synapse, which is large enough that electrodes can be inserted directly into the presynaptic terminal and the postsynaptic fibre. In addition, only a single synapse is involved at these sites, whereas a single neuron of the central nervous system may have many synapses with many other neurons, each with a different neurotransmitter.

Neurotransmitter release. Two factors are essential for the release of the neurotransmitter from the presynaptic terminal: (1) depolarization of the terminal and (2) the presence of calcium ions (Ca^{2+}) in the extracellular fluid. The membrane of the presynaptic terminal contains voltage-dependent calcium channels that open when the membrane is depolarized by a nerve impulse, allowing Ca^{2+} to diffuse into the terminal along its concentration gradient (see Figure 9). Following the entrance of Ca^{2+} is the release of neurotransmitter. The scheme may be depicted as follows:

depolarization → calcium entry → neurotransmitter release

What happens in the time between Ca^{2+} entry and transmitter release is uncertain. Ca^{2+} is known to be sequestered by certain organelles within the terminal, including the endoplasmic reticulum. The ions may attach to the membranes of synaptic vesicles, in some way facilitating their fusion with the nerve terminal membrane. They may also be removed from the terminal by exchange with extracellular Na^+—a mechanism known to occur at some neuronal membranes. What is certain is that when the concentration of Ca^{2+} is increased within the terminal, then the probability of transmitter release is also increased.

Release of neurotransmitter in synaptic vesicles

Neurotransmitter substances are packed into small, membrane-bound spheres called synaptic vesicles. Each vesicle contains thousands of neurotransmitter molecules, and there are thousands of vesicles in each axon terminal. Once stimulated by Ca^{2+}, the vesicles move through the cytoplasm and fuse their membranes with the plasma membrane of the terminal. The transmitter molecules are then expelled from the vesicles into the synaptic cleft. This expulsion process is called exocytosis. Vesicle membranes are then recovered from the plasma membrane through endocytosis. In this process the membranes are surrounded by a protein coat at the lateral margins of the synapse and are then transferred to cisternae, which form in the terminal during nerve stimulation. There the vesicles lose their coats, are probably refilled with neurotransmitter, and pinch off from the cisternae to become synaptic vesicles once more.

Because the neurotransmitter chemicals are packed into separate, almost identically sized vesicles, their release into the synaptic cleft is said to be quantal—that is, rather than flowing from the terminal in a growing stream, they are expelled in parcels, each vesicle adding its contents incrementally to the contents released from other parcels. This quantal release of neurotransmitter has a critical influence on the electrical potential created in the postsynaptic membrane.

Postsynaptic potential. After neurotransmitter is released from the presynaptic terminal, it diffuses across the synaptic cleft and binds to receptor proteins on the postsynaptic membrane. Some receptors are ion channels that open or close when their molecular configuration is altered by the binding action of the neurotransmitter. Others are membrane proteins that, upon activation, catalyze second-messenger reactions within the postsynaptic cell; these reactions in turn open or close the ion channels. Whether acting upon ion channels directly or indirectly, the neurotransmitter molecules bring about a sudden change in the membrane's permeability to specific ions. Exactly which ions now permeate the membrane vary according to the neurotransmitters and their receptors (see below *Neurotransmitters and neuromodulators*), but the net result of a change in ion diffusion is a change in electrical potential across the membrane. This change is called the postsynaptic potential, or PSP. (In reference to the neuromuscular synapse, it is also called the end-plate potential, or EPP.)

Excitatory and inhibitory postsynaptic potentials

The most common potential change is depolarization, caused by a net influx of cations (usually Na^+). Because this infusion of positive charge brings the membrane potential toward the threshold at which the nerve impulse is generated, it is called an excitatory postsynaptic potential (EPSP). Other neurotransmitters stimulate a net efflux of positive charge (usually in the form of K^+ diffusing out of the cell), leaving the inside of the membrane more negative. Because this hyperpolarization draws the membrane potential farther from threshold, making it more difficult to generate a nerve impulse, it is called an inhibitory postsynaptic potential (IPSP). The interaction of competing EPSPs and IPSPs at the hundreds or even thousands of synapses on a single neuron determines whether the nerve impulse arriving at the presynaptic terminals will be regenerated in the postsynaptic membrane.

The PSP is a type of local potential, having properties similar to the electrical potential set up at sensory receptor neurons (see above *Transmission in the neuron: Localized potential*). Like the receptor potential, the PSP is a graded response, varying in amplitude according to the duration and amount of stimulation by neurotransmitter substances. At the neuromuscular junction, brief depolarizations measuring no more than one millivolt can be observed in the postsynaptic muscle membrane, even when it is at rest. These tiny electrical events, called miniature end-plate potentials (MEPPs) or miniature postsynaptic potentials (MPSPs), are caused by the random release of single quanta of neurotransmitter from a resting presynaptic terminal. The EPP is actually made up of multiple MEPPs, which arise when an activated terminal releases hundreds of neurotransmitter quanta. A series of EPPs, or a number of them stimulated simultaneously at many synapses, can then bring the cell to the threshold of the action potential. This combined action of EPPs is called summation.

In contrast to electrical transmission, which takes place with almost no delay, chemical transmission shows what is called the synaptic delay. Recordings from squid synapses and neuromuscular junctions of the frog reveal a delay of from 0.5 to 4.0 milliseconds between the onset of action

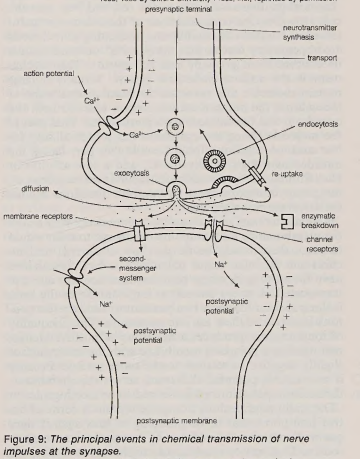

Figure 9: *The principal events in chemical transmission of nerve impulses at the synapse.*
The arrival of the nerve impulse at the presynaptic terminal stimulates the release of neurotransmitter into the synaptic gap. Before inactivation, the neurotransmitter molecules stimulate the regeneration of the impulse in the postsynaptic membrane.

potential at the nerve terminal and action potential at the postsynaptic site. This may be accounted for by three factors. First, diffusion of the neurotransmitter across the synaptic cleft takes approximately 0.05 millisecond. Second, the response of the postsynaptic receptor takes about 0.15 millisecond. This leaves 0.30 to 3.80 milliseconds for other processes. A third process, called mobilization of the transmitter, is traditionally postulated as taking up the remaining time, but evidence suggests that the time is occupied at least partially by the opening of calcium channels to allow the entry of Ca^{2+} into the presynaptic terminal.

Brief duration of the nerve impulse

Inactivation. A series of nerve impulses arriving in rapid succession at the axon terminal is accurately reproduced as a series in the postsynaptic cell because the quanta of neurotransmitter released by each impulse are inactivated as soon as they stimulate the receptor proteins. Neurotransmitter inactivation is carried out by a combination of three processes. First, the neurotransmitter molecules simply diffuse out of the narrow synaptic cleft. Second, they are taken back into the presynaptic terminal by transmitter-sensitive transport molecules. Third, they are metabolized into inactive compounds by enzymes in the synaptic cleft.

ION TRANSPORT

As was stated above, the lipid bilayer of the neuronal membrane tends to repel electrically charged, hydrated ions, making virtually impossible the movement across the membrane that is necessary for the generation of nerve impulses. The transmembrane movement of ions is actually carried out by molecular mechanism—specifically, by protein molecules embedded in the lipid layers. One mechanism, the sodium–potassium pump, maintains the resting potential, and another, the various ion channels, helps create the action potential.

Active transport: the sodium–potassium pump. Since the plasma membrane of the neuron is highly permeable to K^+ and slightly permeable to Na^+, and since neither of these ions is in a state of equilibrium (Na^+ being at higher concentration outside the cell than inside and K^+ at higher concentration inside), then a natural occurrence should be the diffusion of both ions down their electrochemical gradients—K^+ out of the cell and Na^+ into the cell. However, the concentrations of these ions are maintained at constant disequilibrium, indicating that there is a compensatory mechanism moving Na^+ outward against its concentration gradient and K^+ inward. This mechanism is the sodium–potassium pump. Actually a large protein molecule that traverses the plasma membrane of the neuron, the pump presents receptor areas to both the cytoplasm and the extracellular environment. That part of the molecule facing the cytoplasm has a high affinity for Na^+ and a low affinity for K^+, while that part facing the outside has a high affinity for K^+ and a low affinity for Na^+. Stimulated by the action of the ions on its receptors, the pump transports them in opposite directions against their concentration gradients.

If equal amounts of Na^+ and K^+ were transported across the membrane by the pump, the net charge transfer would be zero; there would be no net flow of current and no effect on the membrane potential. In fact, researchers have found that in many neurons three sodium ions are transported for every potassium ion; sometimes the ratio is three sodium for every two potassium, and in a few neurons it is two sodium for one potassium. This inequality of ionic transfer produces a net efflux of positive charge, maintaining a polarized membrane with the inner surface slightly negative in relation to the outer surface. Because it creates this potential difference across the membrane, the sodium–potassium pump is said to be electrogenic.

Maintaining a polarized membrane

The sodium–potassium pump carries out a form of active transport—that is, its pumping of ions against their gradients requires the addition of energy from an outside source. That source is adenosine triphosphate (ATP), the principal energy-carrying molecule of the cell. ATP is formed by an inorganic phosphate molecule held in high-energy linkage with a molecule of adenosine diphosphate (ADP). When an enzyme in the pump, called sodium–potassium–ATPase, splits the phosphate from the ADP, the energy released powers the transport action of the pump.

Passive transport: membrane channels. The sodium–potassium pump sets the membrane potential of the neuron by keeping the concentrations of Na^+ and K^+ at constant disequilibrium. The sudden shift from a resting to an active state, when the neuron generates a nerve impulse, is caused by a sudden movement of ions across the membrane—specifically, a flux of Na^+ into the cell. Given the relative impermeability of the plasma membrane to Na^+, this influx itself implies a sudden change in permeability. Beginning in the 19th century, researchers puzzled over the mechanism by which this change could occur. The idea arose that there must exist pores, or channels, through which the ions could diffuse, passing the barrier posed by the lipid bilayer. However, for years only the gross currents accompanying ionic movement could be measured, and it was only by inference that the presence of membrane channels could be postulated.

The breakthrough came in the 1970s and '80s with the development of the patch-clamp technique, which enabled investigators to directly measure currents flowing across single ion channels in the membrane. The patch-clamp technique electrically isolates a small patch of neuron or muscle cell membrane by applying the tip of a micropipette filled with conducting solution to the membrane and forming a tight seal with it. As single channels in the patch undergo various transitional states between fully open and fully closed, the times of opening and closing are recorded and the amplitudes and duration of the currents are measured.

Since the pioneering studies, the electrical and biochemical properties of certain channels have been characterized. Known as "voltage dependent" when activated by changes in the membrane potential and "neurotransmitter sensitive" when activated by neurotransmitter substances, these channels are protein structures that span the membrane from the extracellular space to the cytoplasm. They are believed to be cylindrical, with a hollow, water-filled pore wider than the ion passing through it except at one region called the selectivity filter. This filter makes each channel specific to one type of ion.

The sodium channel. Voltage-sensitive sodium channels have been characterized with respect to their subunit structure and their amino acid sequences. The principal protein component is known to be a glycoprotein containing 1,820 amino acids. Four similar "transmembrane domains," of about 300 amino acids each, surround a central aqueous pore through which the ions pass. The selectivity filter is a constriction of the channel ringed by negatively charged carbonyl oxygens, which repel anions but attract cations. Also within the channel are thought to be two types of charged particles forming the gates that control the diffusion of Na^+. One gate closes at polarization and opens at depolarization; the other closes at depolarization.

Structure of a channel protein

Investigators believe that the resting, activated, and inactivated states of the sodium channel are due to voltage-dependent conformational changes in the glycoprotein component. These changes result from effects of the electrical field on the charges and dipoles of the amino acids within the protein. With a large electrical field applied to it, the protein has been observed to change its conformation from a stable, closed resting state to a stable, open state in which the net charge or the location of the charge on the protein is changed.

The potassium channel. There are several types of voltage-dependent potassium channels, each having its own physiological and pharmacological properties. A single neuron may contain more than one type.

The best-known flow of K^+ is the outward current following depolarization of the membrane. This occurs through the so-called delayed rectifier channel (I_{DR}), which, activated by the influx of Na^+, counteracts the effect of that cation by allowing the discharge of K^+. By repolarizing the membrane in this way, the I_{DR} channel restricts the duration of the nerve impulse and participates in the regulation of repetitive firing of the neuron.

Another outward K^+ current, occurring with little delay after depolarization, is the so-called A current. The I_A channels are opened by depolarization following hyperpolarization. By increasing the interval between action potentials, they help a neuron fire repetitively at low frequencies.

Another type of potassium channel, the $I_{K(Ca)}$ channel, is activated by high concentrations of intracellular Ca^{2+}. The opening of these channels results in hyperpolarization of the membrane, so that they appear to slow the repetitive firing of nerve impulses.

The I_M channel is opened by depolarization but is deactivated only by the neurotransmitter acetylcholine. This property may serve to regulate the sensitivity of neurons to synaptic input.

A final type of potassium channel is the anomalous, or inward, rectifier channel (I_{IR}). This channel closes with depolarization and opens with hyperpolarization. By allowing an unusual inward diffusion of K^+, the I_{IR} channel prolongs depolarization of the neuron and helps produce long-lasting nerve impulses.

The calcium channel. As with potassium channels, there is more than one type of calcium channel. The inward calcium current has been shown to be slower than the sodium current. Studies show the presence of at least two types in certain neurons of the central nervous system—a long-lasting current activated at positive potential and a transient current activated at more negative potential. Patch-clamp studies show two corresponding types of calcium channel: a large conductance channel that gives rise to a long-lasting current at positive membrane potentials and a low conductance channel that gives rise to a transient current at more negative potentials. In some neurons a third channel current has been measured that is transient and can only be activated at high negative potential.

Anion channels. Evidence points to channels that pass anions such as Cl^-, but their existence is difficult to prove. Single-channel recordings of cultured tissue have shown selective Cl^- channels that are voltage dependent and of high conductance. Channels with lower conductance have been demonstrated in reconstituted artificial membranes as well as in neurons.

NEUROTRANSMITTERS AND NEUROMODULATORS

The traditional models for the study of neurotransmitter release are either the neuromuscular junction of the frog, crayfish, and rat or the giant synapse of the squid. These synapses are relatively simple in their structure, with a single axon terminal forming an identifiable synapse at the postsynaptic membrane of a muscle fibre or neuron. Recordings can be obtained from these single-synaptic junctions in response to the release of a single neurotransmitter. At neurons of the central nervous system, on the other hand, the situation is more complex. Each central neuron has several synapses with other neurons at various locations, such as on the dendrites, soma, and initial segment of the axon. Several neurotransmitters, therefore—some excitatory and others inhibitory—may be involved in the final integrated response of a central neuron, making their identities difficult to determine.

Further complicating the study of neurotransmitter action is the presence not only of multiple transmitter substances but also of neuromodulators. These are substances that do not directly activate ion-channel receptors but that, acting in concert with neurotransmitters, enhance the excitatory or inhibitory responses of the receptors. It is often impossible to discern, in the presence of many substances, which are transmitters and which are modulators. Such is the case with many of the neuropeptides (see below *Neuroactive peptides*).

The second-messenger system

In addition to the multiplicity of transmitters and modulators is a multiplicity of receptors. Some receptors directly open ion channels, while others activate the second-messenger system. This is any of a number of reactions that take place in the cytoplasm or plasma membrane and indirectly act upon the ion channels. One second-messenger system involves the activation by receptor proteins of so-called linking proteins, which move across the membrane, bind to channel proteins, and open the channels. Another system is the cyclic adenosine monophosphate (cAMP) system. In this chain reaction, receptor proteins activate linking proteins, which then activate the enzymes that synthesize cAMP. The cAMP molecules activate other enzymes that, in turn, activate ion channels.

Whether they activate channels directly or through a second-messenger system, neurotransmitters are considered to be primary messengers. Criteria have been defined that, when fulfilled, allow an investigator to identify a substance as a true neurotransmitter for a specific neuron. In many situations, all the criteria are not satisfied. While this does not necessarily mean that the substance is not a neurotransmitter, it does mean that the argument for its being so is considerably weakened. The criteria are as follows:

1. The presynaptic neuron.
   - *a.* Enzymes should be present for synthesis of the neurotransmitter.
   - *b.* The neurotransmitter should be released in pharmacologically identifiable form.
   - *c.* Enzymes that destroy the neurotransmitter may be present in the synaptic gap. Because some neurotransmitters are inactivated by uptake back into the presynaptic terminal or into surrounding glial cells, the presence of catabolic enzymes is not a mandatory requirement.
2. The postsynaptic site.
   - *a.* Application of the substance under experimental conditions must be able to reproduce the specific events of normal transmission.
   - *b.* Under experimental conditions the action of the substance must be mimicked or facilitated by the same agents that are known to elicit identical responses in nerve stimulation. Conversely, the action of chemicals that block the substance must be the same in actual nerve stimulation as they are in experimental application of the suspected neurotransmitter.

Described below are the principal proved or suggested neurotransmitters of the mammalian nervous system and their corresponding receptors.

Acetylcholine. This was the first neurotransmitter whose actions were proved to fulfill the criteria given above. Although early studies of acetylcholine were undertaken at neuromuscular junctions, where it is especially concentrated, the concept leading to the identification of the substance as a neurotransmitter of the central nervous system is a landmark in neuroscience. The concept is called Dale's principle after Sir Henry Dale, a British physiologist who, in 1935, stated that a neurotransmitter released at one axon terminal of a neuron can be presumed to be released at other axon terminals of the same neuron. (Dale's principle refers only to the presynaptic neuron, as the responses of different postsynaptic receptors to a single neurotransmitter can vary in the same or different neurons.) The first application of Dale's principle was at the mammalian spinal cord, from which motor neurons send their axons to striated muscles, where the terminals are observed to release acetylcholine. According to Dale's principle, all of the branches of a single motor neuron axon should release acetylcholine—including the terminals in the spinal cord. In fact, it was found that some collateral branches leave the motor axons and reenter the gray matter of the spinal cord, where they synapse onto spinal interneurons. The neurotransmitter released at these terminals is acetylcholine. High concentrations of the acetylcholine-synthesizing enzyme, choline acetyltransferase, and the enzyme for its breakdown, acetylcholinesterase, are also found in motor neuron regions of the spinal cord.

Cholinergic receptors

Acetylcholine receptors (also called cholinergic receptors) appear in clusters on muscle-cell membranes opposite the active zones of presynaptic terminals. Their density at these receptor regions is between 7,000 and 30,000 sites per square micrometre. The number drops drastically even a few nanometres (billionths of a metre) away from the receptor region, so that sensitivity to acetylcholine is about 50 to 100 times less one millimetre from the receptor region than it is at the receptor site itself. Cholinergic receptors also exist on the presynaptic terminals of neu-

rons that release acetylcholine as well as on terminals that release other neurotransmitters. These receptors are called autoreceptors, and they probably regulate the release of neurotransmitter at the terminal.

There are two main categories of cholinergic receptor, nicotinic and muscarinic. In the first years of the 20th century, they were differentiated by their responses to the alkaloids nicotine and muscarine, but advanced biochemical techniques have shown a more fundamental difference. The nicotinic receptor is a channel protein that, upon binding by acetylcholine, opens to allow diffusion of cations. The muscarinic receptor, on the other hand, is a membrane protein; upon stimulation by neurotransmitter, it causes the opening of ion channels indirectly, through a second messenger. For this reason, the action of a muscarinic synapse is relatively slow. Muscarinic receptors predominate at higher levels of the central nervous system, while nicotinic receptors, which are much faster acting, are more prevalent at neurons of the spinal cord and at neuromuscular junctions in skeletal muscle.

The nicotinic receptor channel has been purified and shown to be a glycoprotein composed of five subunits (Figure 10). Two so-called alpha- (α-) subunits contain the two acetylcholine-binding sites associated with the channel. Three other subunits—a beta- (β-) subunit, a gamma- (γ-) subunit, and a delta- (δ-) subunit—complete the protein. High-resolution electron microscopy with optical image reconstruction, as well as freeze-fracture electron microscopy, reveal a highly symmetrical structure, looking from the top somewhat like a life belt, with the presumed channel in the centre. About one-third of the protein protrudes from the plasma membrane, while the rest is embedded in the membrane or protruding into the cell.

Patch-clamp techniques give information on single channel currents and, hence, on the conductance and kinetics of the cholinergic receptor channel. At the neuromuscular junction, approximately 20,000 univalent ions carry the charge across a single activated channel, and a quantum of acetylcholine activates about 1,500 channels. The time constant for the decay of the MEPP is the same as that for channel closing. The time constant for channel closing is voltage dependent, with depolarization shortening the duration of open channels and hyperpolarization lengthening the duration.

Studies show that nicotinic acetylcholine-activated channels allow cations to permeate the membrane with no specificity—that is, all cations can diffuse through the channels indiscriminately. Because the resting membrane is already near the equilibrium potential of K^+, this means that much more Na^+ and Ca^{2+} diffuse into the cell than K^+ out, causing depolarization and excitation of the neuron or muscle cell. However, in certain molluscan neurons, nicotinic acetylcholine receptors can also activate Cl^- channels, causing hyperpolarization of the postsynaptic membrane and inhibition of the cell's excitability. With respect to muscarinic receptors, the situation is not clear. Second messengers may be involved, and potassium channels may be activated.

Epinephrine and norepinephrine. These related hormones, also called adrenaline and noradrenaline, act to increase the heart rate, blood pressure, and levels of sugar and fat in the blood. They are secreted into the bloodstream by the adrenal glands in response to stress, but they are also synthesized and released as neurotransmitters by axon terminals in the central nervous system and in sympathetic fibres of the autonomic system.

Adrenergic receptors

Receptors sensitive to norepinephrine and epinephrine are called adrenergic receptors. They are divided into two types, α and β. These are further classified into subtypes α_1, α_2, β_1, and β_2.

Both types of adrenergic receptor produce changes in the postsynaptic membrane potential by acting upon ion channels specific to K^+ and Ca^{2+}. They differ in the mechanisms that, upon stimulation by neurotransmitter, they employ to activate those channels. Stimulated β_1 receptors bind to linking proteins that in turn bind to calcium channels, changing their shape and altering their permeability to the cation. More important, the linking proteins stimulate the synthesis of cAMP, which, through another

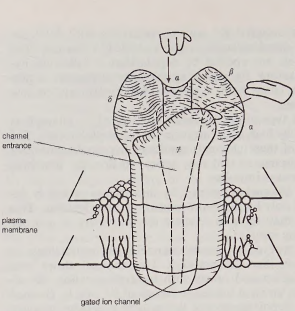

Figure 10: *The cholinergic channel receptor.*
The two α-subunits and the β-, γ-, and δ-subunits are arranged symmetrically around a central channel.

Kistler *et al.*, "Structure and Function of an Acetylcholine Receptor," *Biophysical Journal*, no. 37 (1982), reproduced by copyright permission of the Biophysical Society

series of reactions, opens potassium channels. The efflux of K^+ tends to hyperpolarize the postsynaptic membrane, inhibiting the generation of a nerve impulse. The β_2 receptor has been found on glial cells.

The α_2 receptor activates potassium channels in both the postsynaptic and presynaptic membranes, probably via linking proteins and the synthesis of cAMP. The α_1 receptor acts on calcium channels through a series of reactions linked to the lipid molecules of the plasma membrane.

Both epinephrine and norepinephrine are terminated by uptake back into the presynaptic terminals, where they are enzymatically degraded or inactivated.

For a discussion of the effects of adrenergic transmission on organs and muscles, see below *Functions of the human nervous system: The autonomic system.*

Dopamine. This precursor of norepinephrine acts as a neurotransmitter at certain synapses of the brain. Disorders at these synapses have been implicated in schizophrenia and Parkinson's disease.

There are two types of dopaminergic receptor, called the D_1 and the D_2. The former catalyzes the synthesis of $cAMP$, and the latter inhibits its synthesis. These reactions then regulate calcium and potassium channels in the postsynaptic membrane. Dopaminergic receptors also exist on the presynaptic membrane. The neurotransmitter is terminated by uptake into the presynaptic terminal.

Serotonin (5-hydroxytryptamine). Although the brain has only a small percentage of the serotonin found in the body, there appears to be a strong relationship between the levels of this neurotransmitter at some regions of the brain and certain behavioral patterns, including sleep, sexual urge, and mood. At synapses of the peripheral nervous system, it seems to prime muscle cells for an excitatory response to other neurotransmitters.

Serotonin receptors, or 5HT receptors, activate calcium and potassium channels through linking proteins and the cAMP second-messenger systems. After acting on the postsynaptic receptors, the neurotransmitter is taken up by the presynaptic terminal and enzymatically degraded.

Amino acids. Several amino acids exist in the central nervous system in extremely high concentrations, but their ubiquity makes their identification as true neurotransmitters difficult. Furthermore, because some of them are essential components of metabolic reactions, their presence within a neuron does not prove that they function as neurotransmitters. Nevertheless, there is enough evidence that some amino acids act as either excitatory or inhibitory transmitters. The excitatory amino acids include glutamic acid (or glutamate) and aspartic acid (or aspartate), and the inhibitory amino acids include gamma-aminobutyric acid (GABA) and glycine.

Excitatory amino acids. Glutamate is the most abundant amino acid in the brain. Unlike acetylcholine, glu-

Excitatory neurotransmitter in the spinal cord

tamate does not vary greatly in concentration from one region to the next. However, the dorsal gray matter of the spinal cord, which contains terminals of incoming dorsal roots, has large concentrations of glutamate. Aspartate, on the other hand, is believed to be concentrated in the interneurons of the ventral gray matter.

At postsynaptic receptor sites glutamate depolarizes the membrane by opening nonspecific cation channels, which allow a net influx of Na^+ and Ca^{2+}. Of the excitatory amino acid receptors, the N-methyl-D-aspartic acid (NMDA) receptor has been thoroughly characterized. Patch-clamp studies show that this receptor is influenced by the presence of magnesium ions (Mg^{2+}). In the absence of Mg^{2+}, activated NMDA receptors open nonspecific cationic channels with no variation when the voltage is changed. With Mg^{2+} added to the extracellular medium, though, the frequency of channel openings is reduced when the membrane is hyperpolarized. Both glutamate and aspartate are probably inactivated by uptake systems at the presynaptic terminals and at glial cells surrounding some of the synaptic junctions.

Inhibitory amino acids. GABA and glycine are proved to cause hyperpolarization of the postsynaptic membrane. GABA is widely distributed in the brain, being especially prevalent at higher levels of the central nervous system. It is produced from glutamate by the enzyme glutamic acid decarboxylase (GAD). Consequently, the concentrations of GABA and GAD parallel each other in the nervous system.

At postsynaptic receptor sites GABA opens chloride channels, causing in most cells a hyperpolarization of the membrane as Cl^- diffuses inward to reach its equilibrium potential. It must be pointed out, however, that GABA inhibits presynaptic nerve fibres as well. At certain synaptic junctions the release of neurotransmitter is modulated by the binding to presynaptic receptors of neurotransmitter released from other neurons. A classic example of this is at the axon terminals of incoming dorsal roots in the dorsal gray matter. Projecting onto these terminals are other terminals that release GABA. Although GABA causes an increased Cl^- conductance at these terminals, the result is depolarization, not hyperpolarization, of the membrane. This is because the resting membrane potential of the receiving nerve terminal is much more negative than the Cl^- equilibrium potential. This means that as Cl^- flows into the terminal to reach equilibrium, the membrane is actually depolarized. The effect at the terminal is a decrease in neurotransmitter release.

Unlike GABA, glycine is found mostly at lower levels of the central nervous system, including the spinal cord, medulla oblongata, and pons. It is a major inhibitor released by interneurons to suppress motoneuronal activity. Like GABA, glycine acts by increasing Cl^- conductance at the postsynaptic membrane, although it acts at a clearly different receptor.

It appears that at least two molecules of glycine and GABA must bind to their respective receptors to activate a chloride channel. The action of both neurotransmitters is terminated by uptake back into the presynaptic terminal or into surrounding glial cells.

Histamine. The main difficulty in proving that this substance acts as a neurotransmitter is the lack of adequate techniques for identification. There is little doubt that histamine exists in the brain, but it appears to be present in at least two distinct compartments—in mast cells (non-neuronal connective-tissue cells) and in nerve endings. The actions of histamine are unclear; it is reported to act as a depressor of neuronal activity at some sites and as an excitor at others.

Adenosine triphosphate. ATP may also be a neurotransmitter, particularly at primary sensory endings in the spinal cord. However, its ubiquitous distribution and participation in many energy-conversion reactions makes its role as a neurotransmitter difficult to establish.

Neuroactive peptides. Neuroactive peptides are sequences of amino acids, usually longer than amino acid neurotransmitters yet shorter than hormones or proteins. Unlike the classic neurotransmitters described above, which are formed by enzymes near the presynaptic terminals, neuroactive peptides are assembled by ribosomes attached to the endoplasmic reticulum. From there they are transferred to the Golgi apparatus, where they are packed into secretory vesicles and transported to the terminals. Some peptides are secreted by so-called neuroendocrine cells of the hypothalamus or pituitary gland. Because they are released into the capillary system of the bloodstream and act at distant sites of the body, these are called neurohormones. Other peptides are released into the synaptic cleft between neurons of the central nervous system (including the hypothalamus). Many of these so-called neuropeptides fulfill some criteria of neurotransmitters, evoking excitatory or inhibitory responses in postsynaptic ion channels, yet it is still uncertain to what extent they act as true neurotransmitters or as neuromodulators.

Distinction between neurotransmitters and neuropeptides

Distinguishing neuropeptides from the classic neurotransmitters is the longevity of their action. While acetylcholine, for example, acts upon synaptic receptors for only a few milliseconds, neuropeptides have a course of action lasting from several seconds to several days. Also, neuropeptides are released in much lower concentrations than are transmitter substances, although the peptides have a much higher potency.

The list of neuropeptides is not yet complete. Among those peptides known to affect synaptic transmission are substance P, neurotensin, somatostatin, vasoactive intestinal peptide, cholecystokinin, and the opioid peptides. The best studied are the opioid peptides, so called because opiate drugs such as morphine are known to bind to their receptors and mimic their pain-killing and mood-altering actions. All opioid peptides belong to three genetically distinct families: the β-endorphins, the enkephalins, and the dynorphins.

It has long been known that opioids and opiate drugs have varied and powerful effects on pain, mood, sleep, sedation, and the cough reflex—apart from effects on the gastrointestinal tract and the cardiovascular system. It is not surprising, therefore, that there are multiple receptors for these substances. There may in fact be as many as eight different types of opioid receptor, but the four best described are designated mu (μ), kappa (κ), delta (δ), and sigma (σ). The μ receptors, which readily bind morphine, are believed to mediate euphoria, respiratory depression, and physical addiction and to block pain pathways in the brain. The κ receptors bind preferentially to dynorphin and are believed to mediate analgesia and sedation at the spinal cord. The δ receptors, located primarily in the limbic portions of the brain, bind enkephalin. They may be responsible for dysphoria (extreme depression), hallucination, and respiratory and vasomotor stimulation. The σ receptors are perhaps involved in alterations of affective behaviour, but their functions are unclear. They are found in the hippocampus.

Inhibitory mechanisms of opioid receptors

The opioid receptors mediate their effects mainly by inhibiting regeneration of the nerve impulse at the postsynaptic membrane. They do this by opening potassium channels or closing calcium channels, causing a net outflow of positive charge that keeps the postsynaptic membrane from reaching threshold potential. As with other neuropeptides, it is not known whether all the opioid receptors are activated by the opioids alone or by a combination of opioid and other transmitter substances. For this reason it is uncertain whether the opioid peptides are true neurotransmitters or are neuromodulators.

The presence of peptides within certain structures of the central nervous system is well established; more important, peptides are often found in the same neurons with classic neurotransmitters or with other peptides. For example, substance P can be found in the same neurons of the brain stem as serotonin. In the sympathetic system, norepinephrine is found with somatostatin in some neurons and with enkephalin in others.

Because some neuropeptides and transmitters are stored in the same vesicles and secreted together in response to stimulation, a form of interaction between the substances appears likely. The interaction could take place at presynaptic terminals, altering the release of neurotransmitter, or it could take place postsynaptically, altering the effect of neurotransmitter. At the neuromuscular junction of the

lobster, for example, the neurotransmitters serotonin and octopamine and the neuropeptide proctolin can act presynaptically to alter the amounts of GABA or glutamate released from the nerve terminals. In a similar manner, at some regions of the central nervous system opioid peptides inhibit the release of norepinephrine, acetylcholine, dopamine, and substance P.

The discovery of more than one type of neuroactive substance in one set of axon terminals has disproved an assumption implied by Dale's principle—that a single neuron synthesizes and secretes a single neurotransmitter. Also called into doubt is another assumption—that a single neuron secretes a single set of neurotransmitters at all of its synapses. Researchers are finding evidence that different synapses of the same neuron act somewhat independently. This may mean that different areas of a single neuron synthesize different neuroactive substances. Such a phenomenon would be another example of the metabolic and functional complexity of the nervous system.

(S.D.E.)

EVOLUTION AND DEVELOPMENT OF THE NERVOUS SYSTEM

The study of the evolutionary development of the nervous system traditionally concentrated on the structural differences that exist at various levels of the phylogenetic scale, but certain functional characteristics, including biochemical and biophysical processes laid down early in evolution and amazingly well conserved to the present, can no longer be ignored. Two basic aspects of the evolution of the nervous system must be considered: first, how primitive systems serve newer functions, and, second, how the formation of new systems serves newer functional requirements.

Early theories on the evolutionary origin of the nervous system argued for a three-stage process: first, the development of non-nervous "independent effectors," such as muscle cells; second, the appearance of non-nervous receptors responding to certain modalities in a receptor-effector mechanism; and finally, the formation of a "protoneuron," from which primitive nerves and ganglia evolved. This model is no longer considered valid. In primitive systems there appear to be many examples of non-nervous electrical conduction. For instance, large areas of epithelium covering the swimming bells in the hydrozoan order Siphonophora (which contains certain families of jellyfish) contain neither nerve nor muscle, yet depolarizing potentials between cells of the epithelium have been recorded. Similar examples from other systems in related orders suggest that the evolution of the nervous system may have begun with non-nervous epithelial tissue. The conduction of electrical potentials from one epithelial cell to the next may well have been via so-called tight junctions, in which the plasma membranes of adjacent cells fuse to form sheets of cells. Tight junctions have low electrical resistance and high permeability to molecules. They also occur in great numbers in embryos, suggesting that the electrical potentials of cells joined in this manner serve as a driving force for the movement of ions and even nutritive substances from one cell to the next. These phenomena suggest that electrically mediated junctional transmission is older than chemically mediated synaptic transmission, which would require that some epithelial cells secrete chemical substances.

Possible origin of nerve cells

Many investigators believe that neurons originated from endothelial secretory cells that could secrete chemical substances, respond to stimulation, and conduct impulses. Specialization may then have brought about an outer receptor surface and an inner conducting fibre. In fact, neurosecretory cells can propagate action potentials, and many neurons secrete chemical substances, called neurohormones, that influence the growth and regeneration of cells at other sites of the body. Some researchers suggest that neurons first appeared as neurosecretory growth-regulating cells in which elongated processes were later adapted to rapid conduction and chemical transmission by release of transmitters at their endings.

There is an amazing consistency in neurotransmitters present in different organisms of a given phylum, although different phyla may show striking differences. Thus, in vertebrates, including fishes, amphibians, reptiles, birds, and mammals, the motor neurons (neurons whose fibres innervate striated muscle) are always cholinergic; in arthropods, on the other hand, they are not cholinergic, although the sensory neurons do secrete acetylcholine. The number of known neurotransmitter substances in the animal kingdom is indeed small, and their presence in more primitive organisms as well as in nervous systems of later vertebrates shows a striking conservation of these substances throughout evolution.

Natural selection of nervous systems

If later organisms evolved from single-celled ancestors, then there must have been some system for the transmission of information from one evolutionary stage to the next. These conditions have been defined as: (1) a stable means for encoding, transmitting, and decoding characteristics from one generation to the next, (2) the possibility of alterations in the code taking place by mutation or sexual recombination, and (3) a means of selecting only those characteristics for transmission that are favourable for survival. As mentioned above (see *Stimulus–response coordination*), protozoans (single-celled organisms) move toward places that are favourable for survival, such as areas with optimal conditions of light and temperature. As the metazoans (multicelled organisms) developed, entire groups of cells probably tended to move toward favourable conditions, and when the number of cells became very large, a system of internal communication—in effect, a nervous system—developed. Two general types developed: the diffuse nervous system and the centralized nervous system.

Diffuse nervous systems

The diffuse nervous system is the most primitive nervous system. In diffuse systems nerve cells are distributed throughout the organism, usually beneath the outer epidermal layer. Large concentrations of nerve cells—as in the brain—are not found in these systems, though there may be ganglia, or small local concentrations of neurons. Diffuse systems are found in cnidarians (hydroids, jellyfish, sea anemones, corals) and in ctenophores, or comb jellies. However, the primitive nervous systems of these animals do not preclude prolonged and coordinated responses and integrated behaviour to the simplest stimuli. An example is the movement of the sea anemone *Calliactis* onto the shell of the hermit crab *Pagurus* in response to a factor present in the outer layer of the empty mollusk shell occupied by the crab. This movement requires integration of the highest order.

Most cnidarians, such as those of the genus *Hydra*, have what is called a nerve net—a meshlike system of individual and separate nerve cells and fibres dispersed over the organism (Figure 11A). Species of *Hydra* have two nets, one located between the epidermis and the musculature and the second associated with the gastrodermis. Connections occur at various points between the two nets, with individual neurons making contact but not fusing, thereby forming structures similar to the chemically mediated synapses of vertebrates. Several specializations occur within various species. In *Hydra* the neurons are slightly more concentrated in a ring near the pedal disk and the hypostome (the "mouth"), but in jellyfish of a related genus the nerve fibres form a thick ring at the margin of the bell to form "through" conduction pathways.

The nervous systems of cnidarians correspond to their radially symmetrical bodies, in which similar parts are arranged symmetrically around a hollow gut cavity called

the coelenteron. In some species nerve fibres course along the radial canals, where there may be arranged sensory bodies, called rhopalia, which contain ganglionic concentrations of neurons. In the sea anemone *Metridium* some of the nerve fibres are seven to eight millimetres long and form a system for fast conduction of nerve impulses. Such specializations may have allowed the evolution of different functions. Certainly the rapid coordination of swimming movements requires a fast-conducting pathway, while feeding relies on the nerve net. Integrative activity is likely to occur at the sensory ganglia, which may represent the first forms of a centralized nervous system.

Comparison with mammalian nervous transmission

The terminals forming synapselike structures in nerve nets contain synaptic vesicles that are believed to be packed with neurotransmitters and neuroactive peptides. Peptides present in *Hydra* nervous systems also exist in mammalian systems as neuromodulators, neurohormones, or even possible neurotransmitters.

Transmission in the nerve net is relatively slow compared with that in other nervous systems (0.04 metre per second in radial fibres of *Calliactis* compared with 100 metres per second in some fibres of the dog). Many repetitive stimuli may be required to elicit responses at these synapses. Long refractory periods are also characteristic of nerve nets, having durations about 150 to 300 times those seen at mammalian nerve fibres.

Finally, pacemaker systems are present in animals with nerve nets. In the sea anemone *Metridium* these systems are expressed in a series of spontaneous rhythmic movements that occur in the absence of any detectable stimulus. The question remains whether the movements originate from a "command" neuron or group of neurons or whether they arise without neuronal stimulation. It has been postulated that pacemaking cells were present in epithelial conducting systems known not to be nervous but that eventually evolved into neuronal tissue.

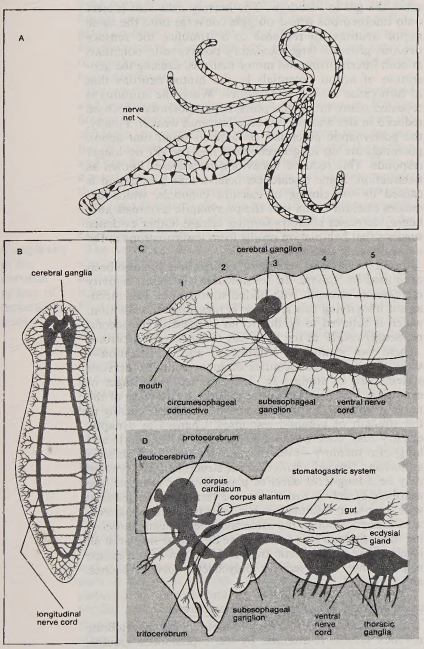

Figure 11: *Invertebrate nervous systems.* (A) The nerve net of *Hydra*, (B) central nervous system of a flatworm, composed of a brain (cerebral ganglia) and longitudinal nerve cords, (C) annelid, moderately cephalized with a brain, ventral nerve cord, and ventral ganglia, and (D) arthropod, highly cephalized and compartmentalized.

Centralized nervous systems

The development of the nerve net allowed an organism to engage in several different behaviours, including feeding and swimming. The development in the net of rapidly conducting bundles of fibres and of pacemaker systems allowed rapid withdrawal and rhythmic swimming activities, respectively, in some cnidarians. However, it is at the level of the flatworms (phylum Platyhelminthes) that there appears a longitudinal nerve cord and an anterior collection of nerve cells that can be called a brain (Figure 11B). Furthermore, there are well-defined sensory and motor pathways as well as coordinating interneurons. Although nerve nets and pacemaker activity are still present in the flatworms, the presence of ganglia or a brain concentrated at the cephalic (head) end of the organisms represents a simple beginning to the complex centralized systems that develop at higher levels of the phylogenetic tree.

SIMPLE BILATERAL SYSTEMS

The flatworms were the first invertebrates to exhibit bilateral symmetry and also the first to develop a central nervous system with a brain. The nervous system of a free-living flatworm such as *Planaria* consists of a brain, longitudinal nerve cords, and peripheral nerve plexuses (interlacing networks of peripheral nerves; from Latin *plectere,* "to braid"). Located in the anterior portion of the animal, the brain is composed of two cephalic ganglia joined by a broad connection called a commissure. Longitudinal nerve cords, usually three to five pairs, extend posteriorly from the brain; they are connected by transverse commissures, and smaller, lateral nerves extend from the cords. The lateral nerves give rise to the peripheral nerve plexuses. The submuscular nerve plexus, consisting of sensory cells, ganglion cells, and their processes, is situated in the loose tissue (mesenchyme) below the subepidermal musculature. A much finer subepidermal plexus is located at the bases of the epithelial cells above the muscular layer.

Rudimentary brain of the flatworm

Planaria are richly supplied with sensory receptors. Single sensory cells in the nerve plexuses are widely scattered over the animal. Sensory organs also are present and include ciliated pits and grooves, auricles, the frontal organ, statocyst, and eyes. The ciliated pits and grooves contain chemical receptors, or chemoreceptors, which permit the animal to detect food. The statocyst is responsible for balancing and such reactions as rising to the surface of the water or sinking. The eyes, or ocelli, may occur as a pair situated anteriorly or may be scattered abundantly over the head region depending on the species. Short optic nerves connect the eyes with the brain.

Seven types of nerve cell bodies and two types of neuroglia have been described in *Planaria.* Removal of the brain results in the abolition of such functions as food finding and recognition and severe deficits in locomotion. However, the nerve cords by themselves can mediate a certain amount of locomotion as well as righting and avoidance reactions.

Nematodes (phylum Aschelminthes) have a high degree of centralization, with three-quarters of all nerve cells concentrated in a group of anteriorly placed ganglia and no peripheral plexuses or nets. They usually have eight longitudinal cords, commissures between dorsal and ventral cords, six cephalic nerves, a few special ganglia and nerves in the tail, and two sympathetic systems (one anterior and one posterior).

MODERATELY CEPHALIZED SYSTEMS

Basic similarities in the nervous systems of the annelid worms, mollusks, and arthropods include an anteriorly situated brain, connectives running from the brain around the esophagus and joining paired longitudinal cords, and

ventral nerve cords with ganglia along their length. The trend toward greater centralization and cephalization of nervous functions is continued within these groups, reaching its peak in the higher mollusks and arthropods.

Annelids. The brain of most annelids (phylum Annelida, segmented worms, including the leeches and terrestrial earthworms) is relatively simple in structure (Figure 11C). The earthworm brain is a bilobed mass lying above the pharynx in the third body segment. Sensory nerves leave the brain and run forward into the prostomium (extreme anterior end) and first segment. The brain of the active, predatory polychaetes (a class of marine worms) is more complicated. In some, the brain can be divided into a forebrain, midbrain, and hindbrain; a single pair of circumesophageal or circumpharyngeal connectives leave the brain, surround the anterior gut, and connect with the ventral nerve cord.

Divided brain of the segmented worm

The most primitive annelids have a pair of ventral nerve cords joined by transverse connectives; the most advanced forms have the cords fused to form a single cord. A ganglionic swelling of the cord is found in each body segment, with the most anterior ganglion, the subpharyngeal ganglion, being the most prominent. Two to five pairs of lateral nerves leave each ganglion to innervate the body wall of that segment. A subepidermal nerve plexus occurs over the whole body. Another plexus, called the enteric, stomodaeal, or sympathetic system, is found in the wall of the gut.

Giant axons, usually few in number, are found running the length of the cord. They may belong to one cell or be composed of many neurons. These axons are capable of very rapid conduction of impulses to the segmental muscles; their main function is to permit the worm to contract very rapidly as a defense against predators.

The usual slow crawling movements of worms are mediated by a series of reflex arcs. During crawling, the contraction of muscles in one segment stimulates stretch receptors in the muscle. Impulses are carried over sensory nerves to the cord, causing motor neurons to send impulses to the longitudinal muscles, which then contract. The longitudinal pull activates stretch receptors in the following segment, and a wave of contraction moves along the worm.

Studies of the nervous systems of annelids show certain behavioral capabilities, including perception, motor coordination, and learning. Because the neuronal organization behind these capabilities can be deduced, they may give an indication of the mechanisms underlying similar patterns of activity and behaviours at other levels of the phylogenetic scale.

Rhythmic nerve impulses in the leech

Two rhythmic movements generated by the leech, the heartbeat and swimming rhythm, have been extensively studied. The coordinated heartbeat rhythm is produced by heart excitor motor neurons, which show rhythmic activity in which bursts of action potentials alternate with bursts of inhibitory synaptic potentials derived from rhythmically firing inhibitory interneurons. The heartbeat appears to be produced by a central rhythm generator. The swimming movement, on the other hand, is generated by a neuronal network requiring many more cells. These neuronal oscillators may in fact form the basis for neuronal generators of rhythmic movements in other animals at higher levels of the phylogenetic scale.

Simple mollusks. The nervous systems of the more primitive mollusks (snails, slugs, and bivalves such as clams and mussels) conform to the basic annelid plan but are modified to conform with the unusual anatomy of these animals. In snails a pair of cerebral ganglia constitutes the brain, which overlies the esophagus. Nerves leave the brain anteriorly to supply the eyes, tentacles, and a pair of buccal ganglia. These last ganglia, also called the stomatogastric head ganglia, innervate the pharynx, salivary glands, and a plexus on the esophagus and stomach. Other nerve cords—the pedal cords—leave the cerebral ganglia ventrally and terminate in a pair of pedal ganglia, which innervate the foot muscles. Another pair of nerve cords—the visceral cords—leave the brain and run posteriorly to the visceral ganglia. The pleural ganglion, supplying the mantle, or fleshy lining of the shell, and the parietal ganglion, innervating the lateral body wall and mantle, are located along the visceral nerves. Intestinal ganglia connected with the pleural ganglia innervate the gills, osphradium (a chemical sense organ), and mantle. Because of the torsion that occurred during the evolutionary history of the snails, some components of the nervous system are twisted and located in asymmetrical positions. In addition, there has been some migration forward and fusion of ganglia. Sense organs of snails include eyes, tentacles, statocysts, and osphradia.

In the bivalves, a cerebropleural ganglion is situated on either side of the esophagus. An upper pair of nerve cords leaves these ganglia and runs posteriorly to the visceroparietal (visceral) ganglia. The visceral ganglia supply the mantle, adductor muscles (which close the shell), and internal organs. A second pair of nerve cords runs ventrally to the pedal ganglia. Most of the sense organs are found at the edge of the mantle. In the scallop, for example, the eyes are set in a row. They are well developed and consist of a cornea, a lens, and a retina, in which the photoreceptor cells are not placed superficially (an arrangement much like that in the vertebrate retina).

Elementary forms of learning and memory have been studied at a cellular level by analysis of the neuronal activity of the marine snail *Aplysia californica.* This simple mollusk withdraws its gill and siphon in response to a mild tactile stimulus. The neural circuit for this reflex consists of a sensory component from the siphon that forms single-synapse junctions with motor neurons that cause the gill to withdraw. The sensory cells also project onto interneurons whose outputs converge onto the same motor neurons. In response to a stimulus, the sensory neurons generate large excitatory postsynaptic potentials at both interneurons and motor neurons, causing the generation of action potentials in the motor neurons that in turn cause the gill to withdraw. When the stimulus is repeated many times, the postsynaptic potentials become reduced in size and the response becomes weaker. Finally, the postsynaptic potentials become so small that action potentials are no longer generated and the gill no longer responds. This reduced behavioral response is known as habituation. Some researchers believe that habituation is caused by the closing of calcium channels, which decreases calcium influx into the presynaptic terminals and, hence, decreases neurotransmitter release. Other evidence suggests that habituation results from fewer neurons in the network being activated.

Synaptic transmission in the snail

Another behavioral paradigm, sensitization, has also been examined in *Aplysia.* In sensitization the reflex activity increases in strength with added stimulation. The mechanism underlying this response is presynaptic facilitation, which is believed to be due to an increase in the second messenger cAMP in the terminals of the sensory neurons.

These two examples—habituation and sensitization—show that important features of more complex nervous systems can be studied in organisms at lower stages of evolution. First is what can be called the plasticity of the nervous system, the phenomenon of changes occurring in the strength of synaptic responses. Changes in synaptic efficacy may underlie certain mechanisms for short- and long-term memory—even in more complex animals such as humans. Second, changes in the structure of the synapse may be a long-term effect of plasticity. For example, the numbers of active zones at nerve terminals are reduced with long-term habituation but increased with long-term sensitization. Finally, the molecular mechanisms underlying these changes may be the same or at least similar at all levels of the phylogenetic tree. Habituation of the escape response has been seen in polychaete worms, roaches, and crayfish.

COMPLEXLY COMPARTMENTALIZED SYSTEMS

The highest degree of development of the invertebrate nervous system is attained by the cephalopods (squids, cuttlefishes, and octopuses) among the mollusks and by the insects and spiders among the arthropods. Although the basic plan of these nervous systems is similar to that of the annelids, there are several advances. First, there is a high degree of cephalization, with nervous functions con-

centrated in the head region of the animal. In addition, ganglia are fused and farther forward, and nerve cells, less abundant in the peripheral nervous system, are situated in the brain or ganglia so that the nerve cords consist only of nerve fibres. Finally, control and coordination of specific functions, such as locomotion and feeding, are compartmentalized in particular parts of the nervous system.

Complex mollusks. The complex nervous system of the cephalopods is correlated with the active movement and predatory habits of these animals. Most of the ganglia typical of mollusks are concentrated or fused in a brain that encircles the esophagus. Nerves extend from the brain to ganglia at the base of the arms or tentacles and from the ganglia the length of the arms. A pair of large pallial nerves connects the brain with a pair of stellate ganglia on the inner surface of the mantle. The stomatogastric ganglia supply nerves to the digestive tract.

A great variety of body functions are centralized in the brain and compartmentalized to specific brain regions. These activities may be local, simple, and uncoordinated with other regions or may be extensive, complex, and coordinated, involving large groups of muscles. The highest centres of the cephalopod brain are the associative areas, which are believed to be concerned with discrimination between objects, learning, and memory.

Giant-fibre system of the squid

The giant-fibre system—also seen in earthworms and insects—is very well developed in the squid. The diameter of giant fibres is many times greater than the diameter of most other nerve fibres. Giant neurons in the brain send fibres to the retractor muscles of the head and the funnel or to the stellate ganglion. Fibres from the stellate ganglion fuse to form giant fibres that innervate the mantle. Because of their large size, these fibres are capable of rapid conduction, which, in turn, permits extremely rapid movement.

The eyes of cephalopods are especially well developed and bear close resemblance to the vertebrate eye. The eye fits into a socket of cartilaginous plates separate from the cartilages that protect the brain, and external muscles permit its movement. A transparent cornea covers the surface and can be focused for both near and far objects. There is a pupil formed by an iris diaphragm, which can regulate the amount of light reaching the retina. The retina contains light-sensitive cells. The axons of the photoreceptors, or rod cells, form the optic nerves, which terminate in the extremely large optic lobes of the brain.

Complexity of the nervous system of cephalopods

The cephalopods are strikingly different in many respects from other molluscan classes. The nervous system as described above is more highly developed and, consequently, the behavioral repertoire much more complex. First, the animals are predators; they move, they use their eyes in search of food, they use receptors in their arms for detection of tactile or chemical stimuli, and they have exceptionally fast muscle action. Second, they have an enormous flexibility of response, discriminating between palatable and unpalatable prey and "learning" to attack or not to attack. They can also change colour to blend into their environment if needed.

The mollusks as a whole provide an important link in the developing complexity of the nervous system. Indeed, the presence in their systems of vertebrate as well as natural molluscan neuroactive peptides may give some clue to the true place of these animals in the phylogenetic scale.

Arthropods. The other complex compartmentalized nervous system is found in arthropods (Figure 11D). The arthropodan brain consists of three main regions: the protocerebrum, deutocerebrum, and tritocerebrum. The anterior protocerebrum, which receives the nerves of the eyes and other organs forward, contains centres or neuropils such as the optic centres and bodies known as corpora pedunculata. The neuropils function as integrative systems for the anterior sense organs, especially the eyes, and in control of movement; they also are the centres for the initiation of complex behaviour. The deutocerebrum contains the association centres for the first antennae. The posterior tritocerebrum contains association neuropils for the second antennae (of crustaceans) and gives rise to nerves that innervate the mouthparts and the anterior digestive canal. The latter constitute the stomatogastric system, which regulates the intake of food and the movement of the gut necessary for digestion. This system bears a resemblance to the vertebrate autonomic system (see below).

The ventral nerve cord, connected to the brain by the circumesophageal connectives, is composed of a double row of ganglia connected longitudinally by connectives and transversely by commissures. Different groups of arthropods exhibit different degrees of fusion of the ganglia. In insects the first ganglion, the subesophageal, is formed by fusion of three pairs of ganglia; it sends nerves to the mouthparts and to the salivary glands. The segmental ganglia in the thorax and abdomen provide nerves to the appendages, dorsal muscles, sense organs, and heart. Insects have 3 pairs of thoracic ganglia and up to 10 abdominal ganglia.

The most common sensory receptors in arthropods are the cuticular hairs, many of which are mechanoreceptors, sensitive to touch, vibration, water currents, or sound waves; some hairs are chemoreceptors, which detect odours or chemicals in the water. Hairs situated near the joints are stimulated by body movements and thus provide a sense of the position of the joint or appendage during locomotion or flight. Many sensory cells and organs are concentrated in the antennae, and a statocyst is found at the base of each antenna.

Spiders have several pairs of simple eyes with cup-shaped retinas. Crustaceans and insects, however, have a pair of well-developed compound eyes, each consisting of a large number of visual units called ommatidia. Each ommatidium contains six to eight sensory receptors arranged under a cornea and refractile cone and is surrounded by pigment cells, which adjust the intensity of light. Each ommatidium can act as a separate eye, capable of responding to its own visual field. Such an arrangement seems particularly well suited for detecting movement across a wide visual field.

Specialized neurons in insects

In spite of the small size of insects, some of their nerve cells and axons are larger in diameter than any neuron in the human nervous system. The number of insect neurons is relatively small, so that each neuron must be capable of dealing with a maximum amount of information. Evasive behaviour requires mechanisms of this sort—as exemplified by the jumping muscle of the grasshopper, which is supplied by only a few motor axons, while those muscles of a human required for a similar purpose have tens of thousands of axons. Another example is the ear of a noctuid moth. Each ear is essentially a tympanic membrane forming the outer wall of an air-filled cavity in the thorax. A five-tissue strand, the acoustic sensillum, runs from the centre of the tympanic membrane across the tympanic cavity to a nearby skeletal support. This sensillum has two acoustic sensory receptors, called A cells. From the central end of each A cell, an axon passes within the sensillum to the skeletal support and then in the tympanic nerve to the thoracic ganglia of the moth.

The A cells encode the intensity of ultrasound by the frequency with which they fire action potentials. Each ear is capable of responding differently to different stimuli, so that differences between the two ears in the duration of the action potentials and response times could allow for binaural detection of the source of a sound. The impulses are conducted to the pterothoracic ganglion, where they must then influence muscles used for avoidance of predators. The important point here is that two A cells provide enough information with speed to allow the moth to take evasive behaviour.

Clearly, simplicity of the neural circuitry is required for speedy response; while some information may be sacrificed, escape will not be compromised. In fact, the quick evasion of predators has probably influenced the evolution of the giant-fibre systems of worms and squid as well as crustaceans and insects. These giant fibres conduct impulses at much higher conduction velocities than do smaller axons, while the information-handling capacity of many small axons acting together is far greater than that of giant axons. Under these circumstances it is clear that different systems evolved in the invertebrate nervous system in response to different qualities of stimuli in the environment to which the organism had to react—one responsible for survival and the other for information.

Neurosecretory cells in crustaceans and arthropods

Neurosecretory cells, which have been identified in all the major invertebrate groups, reach their highest degree of development in the arthropods. The principal system of insects consists of neurosecretory cells in the protocerebrum of the brain. The axons of these cells form nerves that innervate structures called corpora cardiaca, situated just posterior to the brain. A corpus cardiacum is an organ in which neurosecretory products are stored in the nerve terminals for later release into the vascular system.

The neurosecretory cells of the protocerebrum manufacture a hormone called ecdysiotropin, or brain hormone. Sensory nerve impulses reaching the brain regulate the release of the hormone from the nerve endings into the blood within the corpora cardiaca. The hormone then stimulates a non-neural endocrine gland, the ecdysial gland, located in the thorax. The ecdysial glands in turn release a hormone, ecdysone, which initiates molting during larval development and also stimulates differentiation into adult tissues. Another hormone, however, the juvenile hormone, keeps tissue in a juvenile or larval form. This hormone is released by the corpora allata, another pair of non-neural endocrine glands, located behind the corpora cardiaca. The successive life stages in insect development are, therefore, determined by the varying levels of ecdysone and juvenile hormone.

The vertebrate system

The nervous system of vertebrates has two main divisions: the central nervous system, consisting of the brain and spinal cord, and the peripheral nervous system, which in humans includes 12 pairs of cranial nerves, 31 pairs of spinal nerves, and the autonomic, or involuntary, nervous system. Because the arrangement of nerve cells and their fibres is so complex, it is helpful to understand some basic terms used in describing the vertebrate nervous system.

Anatomical structures such as the nervous system are described according to their position. In four-legged animals the upper (back) surface is called dorsal and the lower (belly) surface ventral. The terms anterior, cranial, cephalic, or rostral refer to the head end of the body; posterior, or caudal, to the tail end. In humans, since they stand erect, the situation is more complicated: dorsal becomes equivalent to posterior, and ventral is the same as anterior; cranial is often called superior, and caudal inferior. Objects near the middle plane of the body are medial and those farther away are lateral. Proximal refers to structures nearest the central bulk of a structure and distal to ones away from it. In referring to another structure, if it is located on the same side of the body, it is known as ipsilateral; if it is on the opposite side, it is contralateral.

Neurons are often gathered into localized masses. In the peripheral nervous system these accumulations are called ganglia; in the central nervous system they are called nuclei. Portions of the central nervous system in which unmyelinated neurons and neuroglia predominate are called gray matter; areas in which myelinated neurons dominate are called white matter. Efferent, or motor, nerve fibres carry impulses away from the central nervous system; afferent, or sensory, fibres carry impulses toward the central nervous system. Visceral fibres innervate the viscera such as the heart and intestine, and somatic fibres innervate the body-wall structures such as skin and muscle. In the central nervous system the nerve fibres are organized in bundles called tracts, or fasciculi. Ascending tracts carry impulses along the spinal cord toward the brain, and descending tracts carry them from the brain or higher regions in the spinal cord to lower regions. The tracts are often named according to their origin and termination; for example, the corticospinal tract consists of fibres running from the cerebral cortex in the brain to the spinal cord.

THE PRIMITIVE CONDITION

Predecessors of the spinal cord

The vertebrates constitute an advanced subdivision of the phylum Chordata. All chordates at some time in their life history have a rodlike bar called the notochord running the length of the body. Lower chordates (acorn worms, tunicates, and amphioxus), which lack a vertebral column, illustrate the most primitive features of the chordate nervous system. In these animals the nerve cord is a rather uniform-appearing dorsally placed tube with a hollow cavity, which corresponds roughly to the spinal cord of the vertebrates, suggesting that the spinal cord is the most primitive component of the central nervous system.

In amphioxus and in the lowest vertebrates such as lampreys, the sensory fibres and motor fibres leave the cord in dorsal and ventral roots to supply the adjacent body segments (myotomes). The dorsal and ventral roots remain separate nerves and arise at alternate positions along the cord. In lower fishes there is still alternation of dorsal and ventral roots, but the roots unite in a single spinal nerve. In higher vertebrates the two roots unite in a single spinal nerve and leave the cord at the same level, one above the other. Each spinal nerve supplies a single myotome. When appendages (fins, wings, arms, and legs) develop from several myotomes, the nerves continue to supply their original segments, and branches of the spinal nerves become interwoven to form plexuses.

The brain of vertebrates developed by the accumulation of nerve cells at the cephalic end of the nerve cord. At first this diffuse collection of nerve cells regulated the reflex activity of spinal motor neurons. These cells are comparable to the reticular formation occupying the brain stem of higher vertebrates. The brain stem, thus, is the oldest portion of the brain.

ENCEPHALIZATION

Early in the evolution of vertebrates, a special sensory system became associated with each major part of the brain: the olfactory organs with the forebrain, the eye with the midbrain, and the ear and related organs with the hindbrain. Each of the three sections, furthermore, developed dorsal outgrowths of gray matter forming, respectively, the cerebrum, the midbrain roof, or tectum, and the cerebellum. With these developments the three-part brain stem was then transformed into a brain of five regions: telencephalon, diencephalon, mesencephalon, metencephalon, and myelencephalon (Figure 12). The addition of these nerve centres to the primitive brain stem allowed greater coordination and association between the sensory and motor fibres.

In tracing the development of the parts of the brain in the different vertebrate classes, some general features are apparent (Figure 13). There is a correlation between the

From A. Romer, *The Vertebrate Body*, 3rd ed. (1962); W.B. Saunders Company, Philadelphia

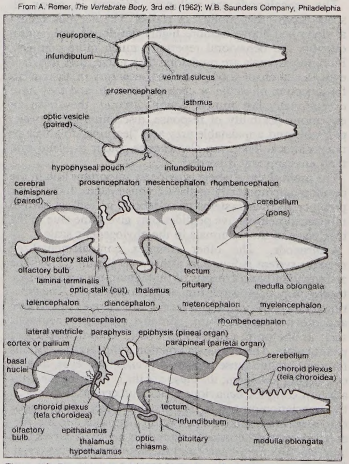

Figure 12: Development of principal vertebrate brain divisions.

size of a particular part of the brain and its importance in the life of the animal in question. Some neural structures (*e.g.*, olfactory bulb) have considerable size and importance in more primitive forms but are less conspicuous in most recent forms. Progressing from primitive to recent forms, there is a gradual cephalic shift of function from the lower brain stem to the higher cerebral cortex.

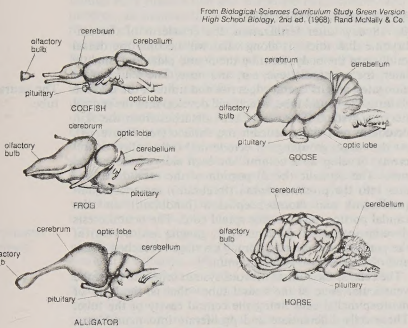

Figure 13: Representative series of vertebrate brains illustrating the evolutionary development of the brain.

The hindbrain is comparable to an enlarged, anterior section of the spinal cord. In the gray matter are dorsal sensory and ventral motor columns similar to those present in the cord. The longitudinal continuity of these columns is preserved in the earlier vertebrates, but in more recent vertebrates the columns break up into discrete nuclei that serve some of the cranial nerves. The hindbrain exerts partial control over the spinal motor neurons through the reticular formation. Fish and tailed amphibians, in addition, have a pair of giant cells called the cells of Mauthner, which exert some control over the local spinal-cord reflexes responsible for the rhythmic swimming undulations and the flip-tail escape response characteristic of these animals.

The hindbrain is the area of reception of one of the main sensory systems, the acoustico-lateralis system, which consists of the ear (hearing and equilibrium) and the lateral-line organs (vibration and pressure). The latter, situated in rows along the head and body, are retained in fish but disappear in the land vertebrates.

The cerebellum originated as a specialized part of the acoustico-lateralis area. The oldest part of the cerebellum—the archicerebellum—is concerned with equilibrium and connected with the inner ear and the lateral-line system. The anterior lobe of the cerebellum represents the paleocerebellum, an area that regulates equilibrium and muscle tone; it constitutes the main mass of the cerebellum in fish, reptiles, and birds. In mammals the development of the cerebral cortex and its connections with the cerebellum are correlated with the appearance of the large cerebellar hemispheres. This new part of the cerebellum, or neocerebellum, coordinates skilled movements initiated at cortical levels. In mammals a great mass of fibres connects the brain stem to the cerebellum; this region forms the pons, which, together with the cerebellum, constitutes the metencephalon. The caudal part of the hindbrain remains as the medulla (myelencephalon).

The midbrain (mesencephalon) and diencephalon constitute the anterior portion of the brain stem. Sensory and motor nuclei for cranial nerves extend from the hindbrain to the midbrain. The roof of the midbrain, or tectum, developed as the primary visual centre. The optic lobes, especially prominent in fish and birds, are a part of this area. In fish and amphibians the tectum is the major centre of the nervous system and wields the greatest influence on body activity. While this area is still significant in reptiles and birds, it is supplanted in importance by the cerebral hemispheres. In mammals the midbrain is greatly reduced in importance. Instead, most of the optic sensations are relayed to the cerebral cortex. With development of the cerebral cortex, the thalamus becomes less significant as an association area and more important as a relay centre for sensory impulses. Centres for visceral sensations and visceral motor responses become established in the hypothalamus.

DOMINANCE OF THE CEREBRUM

Original function of the cerebral hemispheres

Ascending the vertebrate scale, the cerebral hemispheres become more and more important as association centres. The cerebral hemispheres begin their development as paired outgrowths of the forebrain and serve as centres of olfactory reception. In the older vertebrates the forebrain is divided into the olfactory bulb—where the olfactory nerve fibres end—and the cerebral hemisphere. The hemisphere at this time, referred to as the paleopallium, is merely an olfactory lobe serving as an association area for olfactory impulses. The olfactory lobes are prominent in animals such as amphibians, but in birds and primates in which sense of smell is less important the lobes are reduced in extent. In amphibians the hemispheres consist of three parts: the paleopallium (olfactory lobe), archipallium, and basal nuclei. These areas of gray matter are located deep to the surface. All three areas receive olfactory stimuli and discharge impulses to the brain stem. The archipallium is a correlation centre and forerunner of the mammalian hippocampus. The basal nuclei are equivalent to the corpus striatum and function as association areas with connections with the thalamus. In primitive reptiles the basal nuclei have moved to the inner part of the hemisphere, whereas the other areas of gray matter have moved toward the surface. In advanced reptiles a new association centre, the neopallium, appears between paleopallium and archipallium. In birds there is nothing corresponding to the neopallium, but the basal ganglia (that is, the corpus striatum) are enormously expanded. In mammals the neopallium becomes greatly enlarged to exceed all the other parts of the brain in size. This region assumes more and more of the higher types of neural activity in correlation, association, and learning. At first the neopallium expands to envelop the other brain structures. The archipallium becomes folded into a small area on the median part of the hemispheres, where it remains as the hippocampus. The paleopallium (olfactory lobes) constitutes a small ventral region on the hemisphere, the pyriform lobe. The corpus striatum (old basal nuclei) becomes a central part of the hemisphere. Further expansion of the neopallium in primates and humans causes extensive folding and results in a very convoluted surface of the brain. (T.L.L./S.D.E.)

ANATOMY OF THE HUMAN NERVOUS SYSTEM

Development

Almost all neurons are generated during prenatal life, and they are not replaced by new neurons during postnatal life. Morphologically, the nervous system first appears about 18 days after conception, with the genesis of the neural plate. Functionally, it appears with the first sign of reflex activity during the second prenatal month, when stimulation by touch of the upper lip has been shown to evoke an avoidance-withdrawal response of the head. Many reflexes of the head, trunk, and extremities can be elicited in the third month.

During its development the nervous system undergoes remarkable changes to attain its complex organization. In order to produce the estimated one trillion neurons present in the mature brain, an average of 2.5 million neurons

must be generated per minute during the entire prenatal life. This includes the formation of neuronal circuits comprising 100 trillion synapses, as each potential neuron is ultimately connected with either a selected set of other neurons or specific targets such as sensory endings. Moreover, synaptic connections with other neurons are made at precise locations on the cell membranes of the target neurons. The totality of these events is not thought to be the exclusive product of the genetic code, for there are simply not enough genes to account for such complexity. Rather, the differentiation and subsequent development of embryonic cells into mature neurons and glial cells are achieved by two sets of influences: (1) specific subsets of genes, and (2) environmental stimuli from within and outside the organism. Genetic influences are critical to the development of the nervous system in ordered and temporally timed sequences. Cell differentiation, for example, depends on a series of signals that regulate transcription; this is the process in which DNA molecules give rise to RNA molecules, which in turn express the genetic messages that control cellular activity. Environmental influences derived from the embryo itself include cellular signals that consist of diffusible molecular factors (see below *Neuronal development*). External environmental factors include nutrition, sensory experience, social interaction, and even learning. All of these latter are essential for the proper differentiation of individual neurons and for fine-tuning the details of synaptic connections. Thus, the nervous system requires continuous stimulation over an entire lifetime in order to sustain optimal functional activity.

NEURONAL DEVELOPMENT

The embryonic disk

In the second week of prenatal life, the rapidly growing blastocyst (the bundle of cells into which a fertilized ovum divides) flattens into what is called the embryonic disk. This soon acquires three layers: the ectoderm (outer layer), endoderm (inner layer), and mesoderm (middle layer). Within the mesoderm grows the notochord, an axial rod that serves as a temporary backbone. Both the mesoderm and notochord release a chemical molecular factor that instructs and induces adjacent undifferentiated ectoderm cells to form the neural plate. This includes a population of neural precursor cells, known as neuroepithelial cells, which develop into the neural tube (see below *Morphologic development*). Neuroepithelial cells then commence to divide, diversify, and give rise to immature neurons and neuroglia, which in turn migrate from the neural tube to their final location. Each neuron forms dendrites and an axon; axons elongate and form branches, the terminals of which form synaptic connections with a select set of target neurons or muscle fibres.

The remarkable events of this early development involve an orderly migration of billions of neurons, the growth of their axons (many of which extend widely throughout the brain), and the formation of thousands of synapses between individual axons and their target neurons. This migration and growth are dependent, at least in part, on chemical and physical guidance cues. The growing tips of axons (called growth cones) apparently recognize and respond to various molecular cues, which guide axons and some branches to their appropriate targets but eliminate other branches that try to synapse with inappropriate targets. Once a synaptic connection has been established, a target cell releases a so-called trophic factor (some of which have been identified) that is essential for the survival of the neuron synapsing with it. One example is nerve growth factor (NGF), a diffusable protein essential for the survival of sensory and sympathetic neurons. Physical guidance cues are seen in the migration of immature neurons along a preexistent scaffold of glial fibres through a process called contact guidance.

In some regions of the nervous system, initial synaptic contacts are precise and stable, indicative of an initial specificity of neuronal recognition. In other regions the initial contacts are not precise and stable and are followed later by an ordered reorganization, including the elimination of many synapses. The instability of some synaptic connections persists until a so-called critical period, prior to which environmental influences have a significant role in fine-tuning many connections. Following the critical period, synaptic connections become stable and are unlikely to be altered by environmental influences. This suggests that certain skills and sensory activities can be influenced during development (including postnatal life), and for some intellectual skills this adaptability presumably persists into adulthood and old age.

MORPHOLOGIC DEVELOPMENT

By 18 days after fertilization, the ectoderm of the embryonic disk thickens along what will become the dorsal midline of the body, forming the neural plate and, slightly later, the primordial eye, ear, and nose. The neural plate elongates, and its lateral edges rise and unite in the midline to form the neural tube, which will develop into the central nervous system. The neural tube detaches from the skin ectoderm and sinks beneath the surface (see Figure 14). At this stage, groupings of ectodermal cells, called neural crests, develop as a column on each side of the neural tube. The cephalic (head) portion of the tube differentiates into the prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain), and the caudal portion becomes the spinal cord. The neural crests develop into most elements (*e.g.*, ganglia and nerves) of the peripheral nervous system. This stage is reached at the end of the first embryonic month.

The neural tube

The cells of the central nervous system originate from the ventricular zone of the neural tube—that is, the layer of neuroepithelial cells lining the central cavity of the tube. These cells differentiate and proliferate into neuroblasts, which are the progenitors of neurons, and glioblasts, from which neuroglia develop. With a few exceptions, the neuroblasts, glioblasts, and their derived cells do not divide and multiply once they have migrated from the ventricular zone into the gray and white matter of the nervous system. With some exceptions, all neurons are generated

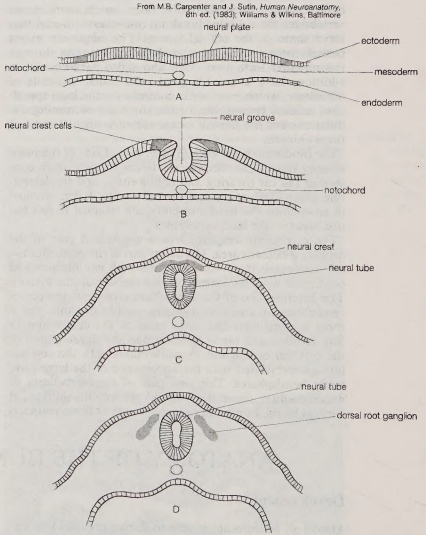

Figure 14: *Cross section of the embryonic disk, showing formation of the neural tube.*
(A) Thickening of the neural plate. (B) Infolding of the neural groove. (C) Closure of the neural groove to form the neural tube. (D) Development of the neural crests into dorsal root ganglia.

before birth, although all are not fully differentiated. This effectively implies that an individual is born with a full complement of nerve cells. (One exception is that the neurons of the olfactory nerve are generated and replaced continuously throughout life.)

By mid-fetal life the slender primordial brain of the neural-tube stage differentiates into a globular-shaped brain. Although fully mature size and shape are not attained until puberty, the main outlines of the brain are recognizable by the end of the third fetal month. This early development is the product of several factors: the formation of three flexures (cephalic, pontine, and cervical; see Figure 15); the differential enlargement of various regions, especially the cerebrum and cerebellum; the massive growth of the cerebral hemispheres over the sides of the midbrain and of the cerebellum at the hindbrain; and the formation of convolutions (sulci and gyri) in the cerebral cortex and of folia in the cerebellar cortex. The central and calcarine sulci are discernible by the fifth fetal month, and all major gyri and sulci are normally present by the seventh month. Many minor sulci and gyri appear after birth. By two years after birth, the size of the brain and the proportion of its parts are basically those of the adult.

Postnatal growth

The postnatal growth of the human brain is rapid and massive, especially during the first two years. The typical brain of a full-term infant weighs 350 grams (12 ounces) at birth, 1,000 grams at the end of the first year, about 1,300 grams at puberty, and about 1,500 grams at adulthood. This increase is attributable mainly to the growth of preexisting neurons, new glial cells, and the myelination of axons. The trebling of weight during the first year (a growth rate unique to humans) may be an adaptation that is essential to the survival of human beings as a species with a large brain. Birth occurs at a developmental stage when the infant is not so helpless as to be unable to survive yet is small enough to be delivered out of the maternal pelvis. If the brain were much larger (enough, say, to support intelligent behaviour), normal delivery would not be possible.

Between the ages of 20 and 75, it is estimated that an average of 50,000 neurons atrophy or die each day. In a healthy person, this loss is roughly equal to 10 percent of the original neuronal complement. Indeed, by the age of 75, the weight of the brain is reduced from its maximum at maturity by about one-tenth, the flow of blood through the brain by almost one-fifth, and the number of functional taste buds by about two-thirds. A loss of neurons does not necessarily imply a comparable loss of function, however; some loss may be compensated for by the formation from viable neurons of new branches of nerve fibres and by the formation of new synapses. (C.R.N.)

The central nervous system

The central nervous system consists of the brain and spinal cord, both derived from the embryonic neural tube. Both parts are invested by protective membranes called the meninges, and both float in a crystal-clear cerebrospinal fluid. The brain is encased in a bony vault, the neurocranium, while the cylindrical and elongated spinal cord lies in the vertebral canal, which is formed by successive vertebrae connected by dense ligaments.

THE BRAIN

The brain is a relatively small organ, weighing about 1,500 grams and constituting about 2 percent of total body weight. Three major divisions of the brain are recognized: (1) the massive, paired cerebral hemispheres (cerebrum), derived from the telencephalon; (2) the brain stem, from which all true cranial nerves emerge, consisting of the thalamus and hypothalamus, the midbrain, the pons, and the medulla oblongata (also known as the diencephalon, the mesencephalon, the metencephalon, and the myelencephalon); and (3) the cerebellum ("little brain"), derived from the pons, or metencephalon. The terms telencephalon, diencephalon, mesencephalon, metencephalon, and myelencephalon denote five distinct embryonic subdivisions derived from separate vesicles in the rostral neural tube (see Figure 15).

The cerebral hemispheres

Telencephalon. The paired cerebral hemispheres are mirror-image duplicates composed of a gray cellular mantle called the cerebral cortex, an underlying mass of white matter composed of myelinated nerve fibres, and collections of subcortical neuronal masses known as the basal ganglia. Each hemisphere receives impulses conveying the senses of touch and vision largely from the contralateral half (that is, the opposite side) of the body, while auditory input comes from both sides. Pathways conveying the senses of smell and taste to the cerebral cortex are ipsilateral (that is, they do not cross to the opposite hemisphere). In turn, each cerebral hemisphere supplies motor function to the opposite side of the body, the side from which it receives sensory input.

In spite of this arrangement, the cerebral hemispheres are not functionally equal. In each individual, one hemisphere is dominant, the dominant hemisphere being concerned with language, mathematical and analytical functions, and handedness. The nondominant hemisphere is concerned with simple spatial concepts, recognition of faces, some aspects of music, and emotion. (For further discussion of cerebral dominance, see below *Functions of the human nervous system: Higher cerebral functions*.)

The hemispheres are partially separated from each other by the longitudinal fissure (see Figure 16), but in central regions this fissure extends only as deep as a broad interhemispheric commissure called the corpus callosum. It is through the corpus callosum that corresponding regions of the cerebral hemispheres are connected by various nerve projections.

Lobes of the cerebral cortex. The cortical mantle is highly convoluted; the crest of a single convolution is known as a gyrus, while the fissure between two gyri is known as a sulcus. Sulci and gyri form a more or less constant pattern, on the basis of which each cerebral hemisphere is divided into six so-called lobes: (1) frontal, (2) parietal, (3) temporal, (4) occipital, (5) central (or insular), and (6) limbic. Two important sulci located on the lateral aspect (that is, the side surface) of each hemisphere help to distinguish these lobes. The central sulcus separates the frontal and parietal lobes, and the deeper lateral sulcus forms the boundary between the temporal lobe and the frontal and parietal lobes (see Figure 16).

The frontal lobe, largest of all the lobes of the brain,

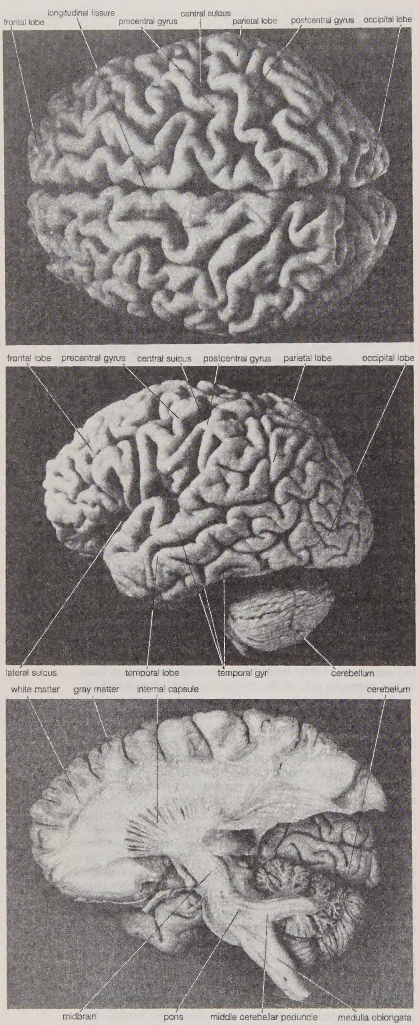

Figure 16: *Photographs of the human brain.*

lies rostral to the central sulcus (that is, toward the nose from the sulcus). The precentral gyrus, located rostral to the central sulcus, constitutes the primary motor region of the brain; when parts of this gyrus are given electrical stimulation in conscious patients (operated upon under local anesthesia), they produce localized movements on the opposite side of the body that are interpreted by the patients as voluntary. Injury to parts of this gyrus results in paralysis on the contralateral half of the body.

Parts of the inferior frontal lobe (close to the lateral sulcus) constitute Broca's area, a region concerned with neural mechanisms that convert thoughts into speech (see below *Functions of the human nervous system* and Figure 32).

The parietal lobe, posterior to the central sulcus, is divided into three parts: (1) a postcentral gyrus, (2) a superior parietal lobule, and (3) an inferior parietal lobule. The postcentral gyrus receives sensory input, both superficial and deep, from the contralateral half of the body. The sequential representation is the same as in the primary motor area, with sensations from the head area being represented in inferior parts of the gyrus and impulses from the lower extremities represented above. Lesions in the postcentral gyrus result in impaired sensation from cutaneous (surface) and deep parts of the contralateral half of the body. The superior parietal lobule, located caudal to the postcentral gyrus, lies superior to the interparietal sulcus. This lobule is regarded as an association cortex, part of which may be concerned with motor function. The inferior parietal lobule (composed of the angular and supramarginal gyri) is a cortical region concerned with the integration of multiple sensory signals. Lesions in this lobule produce various syndromes of a devastating nature.

Sensory cortex

In the parietal and frontal lobes, each primary sensory or motor area is close to, or surrounded by, a smaller secondary area (see Figure 29). The primary sensory area receives input only from relay nuclei in the thalamus, while the secondary sensory area receives input from the thalamus, the primary sensory area, or both. The motor regions receive input from the thalamus as well as the sensory areas of the cerebral cortex.

The temporal lobe, inferior to the lateral sulcus, fills the middle fossa of the skull. Near the margin of the lateral sulcus, two transverse temporal gyri constitute the primary auditory area of the brain. Audition is represented here in a tonotopic fashion—that is, with different frequencies represented on different parts of the area. The transverse gyri are surrounded by a less finely tuned secondary auditory area (see Figure 31).

A medial, or inner, protrusion near the ventral surface of the temporal lobe, known as the uncus, constitutes a large part of the primary olfactory area. The outer surface of this lobe is an association area made up of the superior, middle, and inferior temporal gyri.

The occipital lobe lies caudal to (that is, below and behind) the parieto-occipital sulcus. As seen on the medial aspect of the hemisphere, this sulcus joins the calcarine sulcus in a Y-shaped formation. Cortex on both banks of the calcarine sulcus constitutes the primary visual area (see Figure 31), which receives input from the contralateral visual field via the optic radiation. The visual field is represented near the calcarine sulcus in a retinotopic fashion—that is, with upper quadrants of the visual field laid out along the inferior bank of the sulcus and lower quadrants of the visual field represented on the upper bank. Central vision is represented most caudally and peripheral vision rostrally. Lesions in the calcarine cortex—or in the optic radiation, which projects to it—produce blindness in the contralateral visual field.

The insular, or central, lobe is an invaginated triangular area on the medial surface of the lateral sulcus; it can be seen in the intact brain only by separating the frontal and parietal lobes from the temporal lobe. Branches of the middle cerebral artery cover the surface of the insula.

The limbic lobe is a synthetic lobe on the medial margin (or limbus) of the hemisphere. Composed of adjacent portions of the frontal, parietal, and temporal lobes that surround the corpus callosum, it is concerned with visceral, autonomic, and related somatic behavioral activities. This

region of the cerebral cortex receives inputs from thalamic nuclei that are connected with parts of the hypothalamus and with the hippocampal formation, a primitive cortical structure within the inferior horn of the lateral ventricle (see Figure 17).

White matter. Beneath the cerebral cortex is a mass of white matter, which is composed of nerve fibres projecting to and from the cerebral cortex, commissural systems connecting the two hemispheres via the corpus callosum, and association fibres connecting different regions of a single hemisphere. Myelinated fibres projecting to and from the cerebral cortex form a concentrated fan-shaped band, known as the internal capsule (see Figure 16). In horizontal sections of the brain (see Figure 18), the internal capsule can be seen to consist of two parts: (1) an anterior limb, between the caudate nucleus and the putamen; and (2) a larger posterior limb, running between the thalamus and the globus pallidus and putamen. These two limbs form an obtuse angle with the apex directed toward the centre of the brain; the junction is called the genu.

The internal capsule

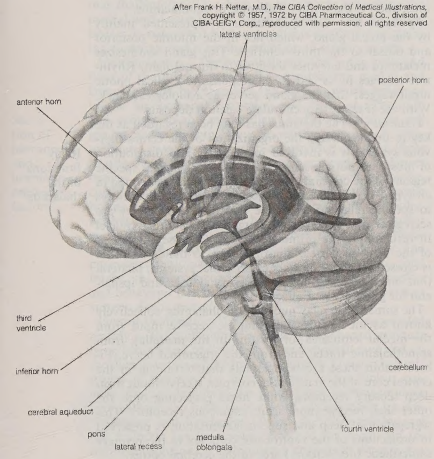

Figure 17: Lateral view of the cerebrum, cerebellum, and brain stem, highlighting features of the ventricular system.

Ventricles. Deep within the white matter are fluid-filled cavities that form the ventricular system. These cavities include a pair of C-shaped lateral ventricles with anterior, inferior, and posterior "horns" protruding into the frontal, temporal, and occipital lobes, respectively (see Figure 17). Most of the cerebrospinal fluid is produced in the ventricles. About 70 percent of the fluid produced by the central nervous system is secreted by the choroid plexus, a collection of blood vessels in the walls of the lateral ventricles. The fluid drains via interventricular foramina, or openings, into a slitlike third ventricle, which, situated along the midline of the brain, separates the symmetrical halves of the thalamus and hypothalamus (see Figure 18). From there it passes through the cerebral aqueduct in the midbrain and into the fourth ventricle in the hindbrain. Openings in the fourth ventricle permit cerebrospinal fluid to enter so-called subarachnoid spaces surrounding both brain and spinal cord.

Basal ganglia. Deep within the cerebral hemispheres, large gray masses or nerve cells, called nuclei, form components of the basal ganglia. Four nuclei can be distinguished: (1) the caudate nucleus, (2) the putamen, (3) the globus pallidus, and (4) the amygdala. Phylogenetically, the amygdala is the oldest of the basal ganglia and is therefore often referred to as the archistriatum; the globus pallidus is known as the paleostriatum, and the caudate nucleus and putamen are together known as the neostriatum, or simply striatum. The putamen and the adjacent globus pallidus are referred to descriptively as the lentiform nucleus, while the caudate nucleus, putamen, and globus pallidus form the corpus striatum.

The caudate nucleus and the putamen are continuous rostrally and ventrally (see Figure 18), and they have similar cytology (cellular makeup), cytochemical features, and functions, but they also have slightly different connections. The putamen lies deep within the cortex of the insular lobe, while the caudate nucleus has a C-shaped configuration that parallels the lateral ventricle. The head of the caudate nucleus protrudes into the anterior horn of the lateral ventricle, the body lies above and lateral to the thalamus, and the tail is in the roof of the inferior horn of the lateral ventricle. The tail of the caudate nucleus ends in relationship to the amygdaloid nuclear complex, which lies in the temporal lobe beneath the cortex of the uncus.

The caudate nucleus and putamen

There is an enormous number of neurons within the caudate nucleus and putamen; these are of two basic types, spiny and aspiny. Spiny striatal neurons are medium-size cells with radiating dendrites that are studded with spines. Axons of these cells project beyond the boundaries of the neostriatum. All afferent systems entering the neostriatum terminate upon the dendritic spines of spiny striatal neurons, and all output is via axons of the same neurons. Chemically, spiny striatal neurons are heterogeneous—that is, most contain more than one neurotransmitter. Neurotransmitters identified in spiny striatal neurons are gamma-aminobutyric acid (GABA), substance P, and enkephalin, with overwhelming dominance by GABA.

Aspiny striatal neurons have smooth dendrites and short axons confined to the caudate nucleus or putamen. Small aspiny striatal neurons secrete GABA, neuropeptide Y, somatostatin, or some combination of these. The largest aspiny neurons are evenly distributed cholinergic neurons that play a crucial role in maintaining the balance of dopamine and GABA.

Because the caudate nucleus and putamen receive varied and diverse inputs from multiple sources that utilize different neurotransmitters, they are regarded as the receptive component of the corpus striatum. The most massive input originates from virtually all regions of the cerebral cortex, with the connecting corticostriate fibres containing the excitatory neurotransmitter glutamate. In addition, afferent fibres originating from the substantia nigra in the midbrain or from intralaminar thalamic nuclei in the diencephalon project to the caudate nucleus or the putamen. The neurotransmitter secreted by thalamostriate neurons has not been identified, while neurons from the substantia nigra synthesize dopamine. All striatal afferent systems terminate in patchy arrays referred to as strisomes; areas not receiving terminals are called the matrix. Striatal efferent systems—that is, spiny neurons containing GABA, substance P, and enkephalin—project in a specific pattern onto the globus pallidus and the substantia nigra; GABA, an inhibitory neurotransmitter, is dominant in all neostriatal projections.

The globus pallidus, consisting of two cytologically similar wedge-shaped segments, the lateral and the medial, lies between the putamen and the internal capsule (see Figure 18). Fibres terminating on the pallidum arise mostly from the caudate nucleus and putamen; these so-called striatopallidal fibres converge on the globus pallidus like spokes of a wheel. Both segments of the pallidum receive GABAergic terminals, but in addition the medial segment receives substance P fibres, and the lateral segment receives enkephalinergic projections. The output of the entire corpus striatum (*i.e.*, the caudate nucleus, putamen, and globus pallidus together) arises from GABAergic cells in the medial pallidal segment and in the substantia nigra, both of which receive fibres from the striatum. GABAergic cells in the medial pallidal segment and the substantia nigra project to different nuclei in the thalamus; these in turn influence distinct regions of the cortex concerned with motor function. The lateral segment of the globus pallidus, on the other hand, projects almost exclusively to the subthalamic nucleus (in the ventral thalamus), from

The globus pallidus

which it receives a reciprocal input. No part of the corpus striatum projects fibres to spinal levels.

Pathological processes involving the corpus striatum and related nuclei are associated with a variety of specific syndromes characterized by abnormal involuntary movements (collectively referred to as dyskinesia) and significant alterations of muscle tone (see below *Nervous system diseases and disorders: The basal ganglia*). Parkinson's disease and Huntington's disease are among the more prevalent syndromes; each appears related to deficiencies in the synthesis of particular neurotransmitters.

The amygdala, located ventral to the corpus striatum in medial parts of the temporal lobe, is an almond-shaped nucleus underlying the uncus. Although it receives olfactory inputs, it plays no role in olfactory perception. This nucleus also has reciprocal connections with the hypothalamus, the basal forebrain, and multiple regions of the cerebral cortex. It plays important roles in visceral, endocrine, and cognitive functions related to motivational behaviour.

Diencephalon. The diencephalon consists of a pair of egg-shaped nuclear masses that lie on each side of the third ventricle and medial to the posterior limb of the internal capsule (see Figure 18). Four subdivisions are recognized: (1) the epithalamus, (2) the thalamus, (3) the hypothalamus, and (4) the ventral thalamus, or subthalamus.

Epithalamus. The epithalamus is represented mainly by the pineal gland, which lies in the midline posterior and dorsal to the third ventricle. This gland synthesizes melatonin and enzymes sensitive to diurnal light. Rhythmic changes in its activity in response to cyclical photic input suggest that the gland serves as a biological clock. With age it tends to accumulate calcium deposits.

Thalamus. The thalamus has long been regarded as the key to understanding the organization of the central nervous system. It is involved in the relay and distribution of most, but not all, sensory and motor signals to specific regions of the cerebral cortex. Sensory signals generated in all types of receptors are projected by complex pathways to specific relay nuclei in the thalamus, where they are segregated and systematically organized. The relay nuclei in turn supply the primary and secondary sensory areas of the cerebral cortex. Sensory input to thalamic nuclei is crossed for the somesthetic and visual systems, bilateral (but mainly crossed) for the auditory system, and ipsilateral for gustatory and olfactory sense.

Relay functions of the thalamus

The somesthetic relay nuclei of the thalamus, collectively known as the ventrobasal complex, receive input from the medial lemniscus (originating in the medulla), from spinothalamic tracts, and from the trigeminal nerve. Fibres within these ascending tracts that terminate in the central core of the ventrobasal complex receive input from deep sensory receptors, while fibres projecting onto the outer shell receive input from cutaneous receptors. This segregation of deep and superficial sensation is preserved in projections of the ventrobasal complex to the primary somesthetic (*i.e.*, sensory) area of the cerebral cortex.

The medial and lateral geniculate bodies form what is called the metathalamus. Fibres of the optic nerve end in the lateral geniculate body, which consists of six cellular laminae, or layers, folded into a horseshoe configuration. Each lamina represents a complete map of the contralateral visual hemifield, and all laminae are in perfect registration. Cells in all layers of the lateral geniculate body project via the optic radiation to the visual areas of the cerebral cortex. The medial geniculate body receives auditory impulses from the inferior colliculus of the midbrain and relays them to the auditory areas on the temporal lobe. Only the ventral nucleus of the medial geniculate body is laminated and tonotopically organized; this part projects to the primary auditory area and is finely tuned. Other subdivisions of the medial geniculate body project to the belt of secondary auditory cortex surrounding the primary area.

Major output from the cerebellum projects to specific thalamic relay nuclei in a pattern similar to that for somesthetic input. The thalamic relay nuclei in turn provide a major input to the primary motor area of the frontal lobe. This large system appears to provide coordinating and controlling influences that result in the appropriate force, sequence, and direction of voluntary motor activities. Output from the corpus striatum, on the other hand, is relayed by thalamic nuclei that have access to the supplementary and premotor areas. The supplementary motor

area, located on the medial aspect of the hemisphere (see Figure 29), exerts modifying influences upon the primary motor area and appears to be involved in programming skilled motor sequences. The premotor area, rostral to the primary motor area, plays a role in sensorially guided movements.

Other major thalamic nuclei, besides those involved in relaying sensory impulses or controlling influences from the cerebellum and corpus striatum, include the anterior nuclear group, the mediodorsal nucleus, and the pulvinar. The anterior nuclear group receives input from the hypothalamus and projects upon parts of the limbic lobe (*i.e.,* the cingulate gyrus). The mediodorsal nucleus, part of the medial nuclear group, has reciprocal connections with large parts of the frontal lobe rostral to the motor areas. The pulvinar is a huge posterior nuclear complex that, along with the mediodorsal nucleus, has projections to association areas of the cortex.

Output ascending from the reticular formation of the brain stem is relayed to the cerebral cortex by intralaminar thalamic nuclei, which lie in laminae separating the medial and ventrolateral thalamic nuclei. This ascending system is concerned with arousal mechanisms, maintaining alertness, and directing attention to sensory events.

Hypothalamus. The hypothalamus lies in the walls and floor of the third ventricle. It is divided into medial and lateral groups by fibres of the fornix, which originate in the hippocampal formation and adjacent subiculum and project to the mammillary body. Well-defined cell groups in the hypothalamus secrete hormones (*i.e.,* oxytocin and vasopressin) that are transported by nerve fibres to the neurohypophysis; other neurosecretory neurons convey hormone-releasing factors (*e.g.,* growth hormone, corticosteroids, thyrotropic hormone, and gonadotropic hormone) via a vascular portal system to the adenohypophysis. In this way the hypothalamus controls major endocrine functions; specific regions of the hypothalamus are also concerned with control of sympathetic and parasympathetic activities, temperature regulation, food intake, the reproductive cycle, and emotional expression and behaviour (see below *Functions of the human nervous system: Emotion and behaviour*).

Secretion of hormones and hormone-releasing factors

Ventral thalamus. The ventral thalamus is represented mainly by the subthalamic nucleus, a lens-shaped structure lying behind and to the sides of the hypothalamus and on the dorsal surface of the internal capsule. The subthalamic region is traversed by fibres related to the globus pallidus. Discrete lesions in the subthalamic nucleus produce hemiballism, the most violent form of dyskinesia known.

Midbrain and hindbrain. Below the diencephalon are the midbrain (or mesencephalon) and the hindbrain (or rhombencephalon). The hindbrain consists of the pons (or metencephalon) and the medulla oblongata (or myelencephalon). These parts of the brain stem are characterized by three main features: (1) a roof plate superior to the cerebral aqueduct and fourth ventricle; (2) a central core of gray matter, known as the reticular formation; and (3) a massive basal collection of fibres descending from the cerebral cortex to the brain stem and spinal cord.

The roof plate of the midbrain is formed by two paired rounded eminences, the superior and inferior colliculi. The superior colliculus receives input from the retina and the visual cortex and participates in a variety of visual reflexes, particularly the tracking of objects in the contralateral visual field. The inferior colliculus receives both crossed and uncrossed auditory fibres and projects upon the medial geniculate body, the auditory relay nucleus of the thalamus (see above *Diencephalon*). In the hindbrain the roof plate is formed by the cerebellum and a membrane containing the choroid plexus of the fourth ventricle.

The reticular formation contains a core collection of cells of various sizes that project to the thalamus, the cerebellum, and the spinal cord. Surrounding this core are long ascending and descending tracts in which various cranial nerve nuclei are embedded.

Fibres derived from the cerebral cortex lie on or near the ventral surface of the midbrain, pons, and medulla. At the midbrain they gather into two bundles called the crura cerebri; from there they descend into the pons, where most terminate upon cell nuclei that project into the cerebellum. These constitute the corticopontine tract. The other major tract, called the corticospinal tract, forms the medullary pyramids before descending to the spinal cord.

Midbrain. The midbrain contains the nuclear complex of the oculomotor nerve as well as the trochlear nucleus; these cranial nerves innervate muscles that move the eye and control the shape of the lens and the diameter of the pupil. In addition, between the midbrain reticular formation (known here as the tegmentum) and the crus cerebri is a large, pigmented structure called the substantia nigra (see Figure 18). This nucleus consists of two parts, the pars reticulata and the pars compacta. Cells of the pars compacta contain the black pigment melanin; these synthesize dopamine and project to cells of either the caudate nucleus or the putamen but not to both. By exercising an inhibitory action on large aspiny cholinergic neurons in the neostriatum, the dopaminergic cells of the pars compacta influence the output of the neurotransmitter GABA from spiny striatal neurons. These spiny neurons in turn project to cells of the pars reticulata, which, by projecting fibres to the thalamus, are in effect part of the output system of the corpus striatum.

The substantia nigra

At the caudal midbrain, crossed fibres of the superior cerebellar peduncle (the major output system of the cerebellum) surround and partially terminate in a large, centrally located structure known as the red nucleus. Most crossed ascending fibres of this bundle project to thalamic nuclei, which have access to the primary motor cortex. A smaller number of fibres synapse on large cells in caudal regions of the red nucleus; these give rise to the crossed fibres of the rubrospinal tract (see below *The spinal cord: Descending spinal tracts*).

Pons. The pons consists of two parts: the tegmentum, a phylogenetically older part that contains the reticular formation; and the pontine nuclei, a larger part composed of masses of neurons that lie among large bundles of longitudinal and transverse fibres.

Fibres originating from neurons in all major lobes of the cerebral cortex terminate upon the pontine nuclei, which in turn project to the opposite cerebellar hemisphere. These massive crossed fibres form the middle cerebellar peduncle (see Figures 16 and 19)—in effect serving as the

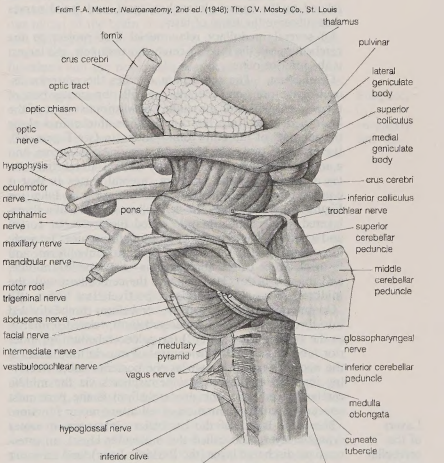

Figure 19: The lateral surface of the brain stem, showing attached cranial nerves.

bridge that connects each cerebral hemisphere with the opposite half of the cerebellum.

The reticular formation in the pontine tegmentum contains multiple cell groups that exert facilitating influences upon motor function. It also contains the nuclei of several cranial nerves. The facial nerve and the two components of the vestibulocochlear nerve, for example, emerge from and enter the brain stem at the junction of the pons, medulla, and cerebellum. Motor nuclei for the trigeminal nerve lie in the upper pons. Located on the periphery of the pons are long ascending and descending tracts that connect the brain to the spinal cord.

Medulla oblongata. The medulla, the most caudal segment of the brain stem, appears as a conical expansion of the spinal cord (see Figures 18 and 19). Both the pons and the medulla are separated from the overlying cerebellum by the fourth ventricle, and cerebrospinal fluid entering the fourth ventricle from the cerebral aqueduct passes into the cisterna magna, a subarachnoid space surrounding the medulla and the cerebellum, via foramina in the lateral recesses and in the midline of the ventricle.

Decussation of nerve fibres

At the transition from the medulla to the spinal cord, there are two major decussations, or crossings, of nerve fibres. The corticospinal decussation is the site at which 90 percent of the fibres of the medullary pyramid cross and enter the dorsolateral funiculus of the spinal cord (see Figure 21). Signals conveyed by this tract provide the basis for voluntary motor function on the opposite side of the body (see below *The spinal cord: Descending spinal tracts*). In the other decussation, sensory fibres ascending in the fasciculus gracilis and fasciculus cuneatus of the spinal cord terminate upon large nuclear masses on the dorsal surface of the medulla. Known as the nuclei gracilis and cuneatus, these masses give rise to fibres that decussate above the corticospinal tract and form a major ascending sensory pathway known as the medial lemniscus. Present at all brain-stem levels, the medial lemniscus projects upon the somesthetic relay nuclei of the thalamus.

The medulla contains nuclei associated with the hypoglossal, accessory, vagus, and glossopharyngeal cranial nerves. In addition, it contains portions of the vestibular nuclear complex, parts of the trigeminal nuclear complex concerned with pain and thermal sense, and solitary nuclei related to the vagus, glossopharyngeal, and facial nerves that subserve the sense of taste.

Of several medullary relay nuclei that project to the cerebellum via the inferior cerebellar peduncle, the largest is the inferior olive.

Cerebellum. The cerebellum overlies the posterior aspect of the pons and medulla and fills the greater part of the posterior fossa of the skull. This distinctive part of the brain is derived from the rhombic lips, thickenings along the margins of the embryonic hindbrain (see Figure 15). It consists of two paired lateral lobes, or hemispheres, and a midline portion known as the vermis. Cerebellar cortex appears very different from cerebral cortex in that it consists of small, leaflike laminae, referred to as folia (see Figure 16). Structurally the cerebellum consists of a three-layered, gray cellular mantle called the cerebellar cortex and a core of white matter containing four paired intrinsic (*i.e.,* deep) nuclei, the dentate, globose, emboliform, and fastigial. Three paired fibre bundles—the superior, middle, and inferior peduncles—connect the cerebellum with the midbrain, pons, and medulla, respectively (see Figure 19).

On an embryological basis the cerebellum can be divided into three parts: (1) the archicerebellum, related primarily to the vestibular system; (2) the paleocerebellum, or anterior lobe, concerned with control of muscle tone; and (3) the neocerebellum, known as the posterior lobe. Receiving input from the cerebral hemispheres via the middle cerebellar peduncle, the neocerebellum is the part most concerned with coordination of voluntary motor function.

Layers of the cerebellar cortex

The three layers of the cerebellar cortex are an outer synaptic layer (also called the molecular layer), an intermediate discharge layer (the Purkinje layer), and an inner receptive layer (the granular layer). Sensory input from all sorts of receptors are conveyed to specific regions of the receptive layer, which consists of enormous numbers of small nerve cells (hence the name granular) that project axons into the synaptic layer. There they excite the dendrites of the Purkinje cells, which in turn project axons to portions of the four intrinsic nuclei and upon dorsal portions of the lateral vestibular nucleus. Because most Purkinje cells are GABAergic and therefore exert strong inhibitory influences upon the cells that receive their terminals, all sensory input into the cerebellum results in inhibitory impulses being exerted upon the deep cerebellar nuclei and parts of the vestibular nucleus. Cells of all deep cerebellar nuclei, on the other hand, are excitatory (secreting the neurotransmitter glutamate) and project upon parts of the thalamus, red nucleus, vestibular nuclei, and reticular formation.

The cerebellum thus functions as a kind of computer, providing a quick and clear response to any set of sensory signals. It plays no role in sensory perception, but it exerts profound influences upon equilibrium, muscle tone, and the coordination of voluntary motor function. Lesions of the cerebellum produce a constellation of disturbances, including intention tremor, ataxia, hypotonus, easy fatigability, and disturbances of speech.

THE SPINAL CORD

The spinal cord is an elongated cylindrical structure, about 45 centimetres (18 inches) long, that extends from the medulla oblongata of the hindbrain to a level between the first and second lumbar vertebrae of the backbone. The terminal part of the spinal cord is called the conus medullaris. Associated with local regions of the spinal cord and imposing upon it an external segmentation are 31 pairs of spinal nerves, each of which receives and furnishes one dorsal and one ventral root (see Figure 25). On this basis the spinal cord is divided into the following segments: 8 cervical (C), 12 thoracic (T), 5 lumbar (L), 5 sacral (S), and 1 coccygeal (Coc). Spinal nerve roots emerge via

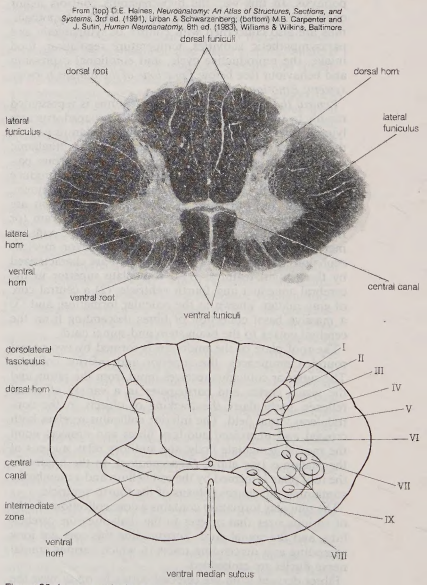

Figure 20: *Lower cervical section of the spinal cord.* (Top) Photograph of a cross section, with the white matter stained dark. (Bottom) Schematic drawing showing cytoarchitectural lamination.

intervertebral foramina; lumbar and sacral spinal roots, descending for some distance within the subarachnoid space before reaching the appropriate foramina, produce a group of nerve roots about the conus medullaris known as the cauda equina. Two enlargements of the spinal cord are evident: (1) a cervical enlargment (C_5 through T_1), which provides innervation for the upper extremity, and (2) a lumbosacral enlargement (L_1 through S_2), which innervates the lower extremity.

Appearance in cross section

A cross section of the spinal cord reveals long tracts of myelinated nerve fibres (known as white matter) arranged around the periphery of a symmetrical, butterfly-shaped cellular matrix of gray matter (see Figure 20). The gray matter forms three pairs of horns throughout most of the spinal cord: (1) the dorsal horns, composed of sensory neurons; (2) the lateral horns, well defined in thoracic segments and composed of visceral neurons; and (3) the ventral horns, especially large in the cord enlargements and composed of motor neurons. The white matter forming the ascending and descending spinal tracts falls in three paired funiculi, or sectors: the dorsal or posterior funiculi, lying between the dorsal horns; the lateral funiculi, lying on each side of the spinal cord between the dorsal-root entry zones and the emergence of the ventral roots; and the ventral funiculi, lying between the ventral median sulcus and each ventral-root zone.

Gray matter. The cellular gray matter has a "cytoarchitectural lamination" in which nine laminae are customarily indicated by Roman numerals (see Figure 20, bottom). Laminae I to V, forming the dorsal horns, receive sensory input. Lamina VII forms the intermediate zone at the base of all horns. Lamina IX is composed of clusters of large (alpha) motor neurons, whose axons innervate striated muscle, and small (gamma) motor neurons, which innervate contractile elements of the muscle spindle. Axons of both alpha and gamma motor neurons emerge via the ventral roots. Laminae VII and VIII have variable configurations, and lamina VI is present only in the cervical and lumbosacral enlargements. In addition, cells surrounding the central canal of the spinal cord form an area often referred to as lamina X.

All primary sensory neurons that enter the spinal cord originate in ganglia that are located in the intervertebral foramina. Peripheral processes of the nerve cells in these ganglia convey sensation from various receptors, and central processes of the same cells enter the spinal cord dorsolaterally as bundles of nerve filaments. Fibres conveying specific forms of sensation follow separate pathways. Impulses concerned with pain and noxious stimuli largely end upon cells in parts of laminae I and II, while impulses associated with tactile sense end in lamina IV or on processes of cells in that lamina. Signals from stretch receptors (*i.e.,* muscle spindles and tendon organs) end upon cells in parts of laminae V, VI, and VII; collaterals of these fibres involved in the stretch reflex project into lamina IX.

Virtually all parts of the spinal gray contain interneurons, which connect various cell groups. Many interneurons have short axons distributed locally, but some have axons that extend for several spinal segments. Some interneurons may modulate or change the character of signals, while others play key roles in transmission and in patterned reflexes.

Ascending spinal tracts. Sensory tracts ascending in the white matter of the spinal cord arise either from cells of spinal ganglia or from intrinsic neurons within the gray matter that receive primary sensory input.

The fasciculi gracilis and cuneatus

Dorsal column. The largest ascending tracts, the fasciculi gracilis and cuneatus, arise from spinal ganglion cells and ascend in the dorsal funiculus to the medulla. The fasciculus gracilis receives fibres from ganglia below thoracic 6, while spinal ganglia from higher segments of the spinal cord project fibres into the fasciculus cuneatus. The fasciculi terminate upon large nuclear masses (the nuclei gracilis and cuneatus) in the medulla. Cells of these nuclei give rise to fibres that cross completely and form the medial lemniscus; the medial lemniscus in turn projects to the ventrobasal nuclear complex of the thalamus. In this way, the dorsal column/medial lemniscal system conveys signals associated with tactile, pressure, and kinesthetic (or positional) sense to sensory areas of the cerebral cortex.

Spinothalamic tracts. Fibres concerned with pain, thermal sense, and light touch enter the lateral-root entry zone and then ascend or descend near the periphery of the spinal cord before entering superficial laminae of the dorsal horn—largely parts of laminae I, IV, and V. Cells in these laminae then give rise to fibres of the two spinothalamic tracts. Those crossing in the ventral white commissure (ventral to the central canal) form the lateral spinothalamic tract, which, ascending in the ventral part of the lateral funiculus, conveys signals related to pain and thermal sense. The anterior spinothalamic tract arises from fibres that cross the midline in the same fashion but ascend more anteriorly in the spinal cord; these convey impulses related to light touch. At medullary levels the two spinothalamic tracts tend to merge and cannot be distinguished as separate entities. Many of the fibres, or collaterals, of the spinothalamic tracts end upon cell groups in the reticular formation, while the principal tracts convey sensory impulses to relay nuclei in the thalamus.

Spinocerebellar tracts. Impulses from stretch receptors are carried by large-diameter fibres that synapse upon cells in deep laminae of the dorsal horn or in lamina VII. The posterior spinocerebellar tract arises from the dorsal nucleus of Clarke and ascends peripherally in the dorsal part of the lateral funiculus. The anterior spinocerebellar tract ascends on the ventral margin of the lateral funiculus. Both tracts transmit signals to portions of the anterior lobe of the cerebellum and are involved in mechanisms that automatically regulate muscle tone without reaching consciousness.

Descending spinal tracts. Tracts descending to the spinal cord are concerned with voluntary motor function, muscle tone, reflexes and equilibrium, visceral innervation, and modulation of ascending sensory signals. The largest and most important, the corticospinal tract, originates in broad regions of the cerebral cortex. Smaller descending tracts, which include the rubrospinal tract, the vestibulospinal tract, and the reticulospinal tract, originate in discrete and diffuse nuclei in the midbrain, pons, and medulla. Most of these brain-stem nuclei themselves receive input from the cerebral cortex, the cerebellar cortex, deep nuclei of the cerebellum, or some combination of these.

In addition, autonomic tracts, which descend from various nuclei in the brain stem to preganglionic sympathetic and parasympathetic neurons in the spinal cord, constitute a vital link between the centres that regulate visceral functions and the nerve cells that actually effect changes.

Function in voluntary activity

Corticospinal tract. Universally regarded as the single most important tract concerned with skilled voluntary activity, the corticospinal tract originates from pyramid-shaped cells in the premotor, primary motor, and primary sensory cortex. Containing about one million fibres, it forms a significant part of the posterior limb of the internal capsule and is a major constituent of the crus cerebri in the midbrain. As the fibres emerge from the pons, they form compact bundles on the ventral surface of the medulla, known as the medullary pyramids (see Figure 19). In the lower medulla about 90 percent of the fibres of the corticospinal tract decussate and descend in the dorsal part of the lateral funiculus of the spinal cord. Of the fibres that do not cross in the medulla, approximately 8 percent cross in cervical spinal segments (see Figure 21). As the tract descends, fibres and collaterals are given off at all segmental levels, synapsing upon interneurons in lamina VII and upon motor neurons in lamina IX. Approximately 50 percent of the corticospinal fibres terminate within cervical segments.

At birth, few of the fibres of the corticospinal tract are myelinated; myelination takes place during the first year after birth, parallel to the acquisition of motor skills. Because the tract passes through, or close to, nearly every major division of the neuraxis, it is vulnerable to vascular and other kinds of lesions. A relatively small lesion in the posterior limb of the internal capsule, for example, may result in contralateral hemiparesis, which is characterized by weakness, spasticity, greatly increased deep tendon reflexes, and certain abnormal reflexes.

Rubrospinal tract. The rubrospinal tract arises from

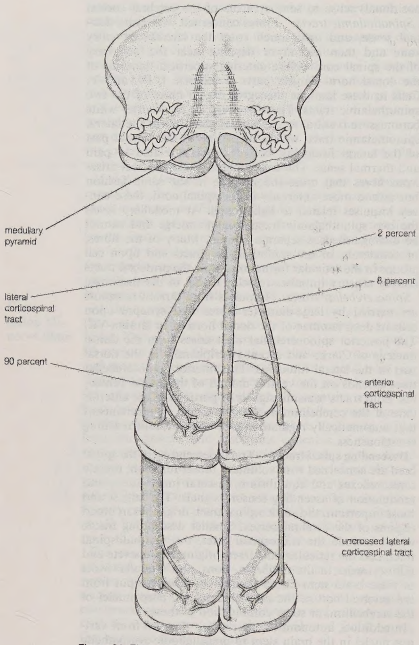

Figure 21: The decussation of the medullary pyramids and the formation of the corticospinal system in the spinal cord.
From M.B. Carpenter, *Core Text of Neuroanatomy*, 4th ed. (1991); Williams & Wilkins, Baltimore

cells in the caudal part of the red nucleus, an encapsulated cell group in the midbrain tegmentum (see Figure 18). Fibres of this tract decussate at midbrain levels, descend in the lateral funiculus of the spinal cord (overlapping ventral parts of the corticospinal tract), enter the spinal gray, and terminate on interneurons in lamina VII. Through these crossed rubrospinal projections, the red nucleus exerts a facilitating influence on flexor alpha motor neurons and a reciprocal inhibiting influence on extensor alpha motor neurons. Because cells of the red nucleus receive input from the motor cortex (via corticorubral projections) and from globose and emboliform nuclei of the cerebellum (via the superior cerebellar peduncle), the rubrospinal tract effectively brings flexor muscle tone under the control of these two regions of the brain.

Vestibulospinal tract. The vestibulospinal tract originates from cells of the lateral vestibular nucleus, which lies in the floor of the fourth ventricle. Fibres of this tract descend the length of the spinal cord in the ventral and lateral funiculi without crossing, enter laminae VIII and IX of the anterior horn, and end upon both alpha and gamma motor neurons, which innervate ordinary muscle fibres and fibres of the muscle spindle (see below *Functions of the human nervous system: Movement*). Cells of the lateral vestibular nucleus receive facilitating impulses from labyrinthine receptors in the utricle and from fastigial nuclei in the cerebellum. In addition, inhibitory influences upon these cells are conveyed by direct projections from Purkinje cells in the anterior lobe of the cerebellum. Thus, the vestibulospinal tract mediates the influences of the vestibular end organ and the cerebellum upon extensor muscle tone.

Mediation of balance and coordination functions

A smaller number of vestibular projections, originating from the medial and inferior vestibular nuclei, descend ipsilaterally in the medial longitudinal fasciculus only to cervical levels. These fibres exert excitatory and inhibitory effects upon cervical motor neurons.

Reticulospinal tract. The reticulospinal tracts arise from relatively large but restricted regions of the reticular formation of the pons and medulla—the same cells that project ascending processes to intralaminar thalamic nuclei and play an important role in maintaining alertness and the conscious state. The pontine reticulospinal tract arises from aggregations of cells in the pontine reticular formation, descends ipsilaterally as the largest component of the medial longitudinal fasciculus, and terminates among cells in laminae VII and VIII. Fibres of this tract exert facilitating influences upon voluntary movements, muscle tone, and a variety of spinal reflexes. The medullary reticulospinal tract, originating from reticular neurons on both sides of the median raphe, descends in the ventral part of the lateral funiculus and terminates at all spinal levels upon cells in laminae VII and IX. The medullary reticulospinal tract inhibits the same motor activities that are facilitated by the pontine reticulospinal tract. Both tracts receive input from regions of the motor cortex.

Autonomic pathways. Descending fibre systems concerned with visceral and autonomic activities emanate from collections of cells at various levels of the brain stem. For example, hypothalamic nuclei project to visceral nuclei in both the medulla and spinal cord; in the spinal cord these direct hypothalamospinal projections terminate upon cells of the intermediolateral cell column in thoracic, lumbar, and sacral segments. Preganglionic parasympathetic neurons originating in the oculomotor nuclear complex in the midbrain project not only to the ciliary ganglion but also directly to spinal levels. Some of these fibres reach lumbar segments of the spinal cord, most of them terminating in parts of laminae I and V. Pigmented cells in an area of the rostral pons known as the isthmus form a blackish blue collection visible in gross brain sections; known as the locus ceruleus, these cells are rich in norepinephrine and distribute this neurotransmitter widely to all regions of the brain and spinal cord. Fibres from the locus ceruleus descend to spinal levels without crossing and are distributed to terminals in the anterior horn, the intermediate zone, and the dorsal horn. Other noradrenergic cell groups in the pons, near the motor nucleus of the facial nerve, project uncrossed noradrenergic fibres that terminate in the intermediolateral cell column (that is, lamina VII of the lateral horn). Postganglionic sympathetic neurons associated with this system have direct effects upon the cardiovascular system. Cells in the nucleus of the solitary tract project crossed fibres to the phrenic nerve nucleus (in cervical segments 3 through 5), the intermediate zone, and the anterior horn at thoracic levels; these innervate respiratory muscles. (Ed.)

The peripheral nervous system

The peripheral nervous system is a channel for the relay of sensory and motor impulses between the central nervous system on the one hand and the body surface, skeletal muscles, and internal organs on the other hand. It is composed of (1) spinal nerves, (2) cranial nerves, and (3) certain parts of the autonomic nervous system. As in the central nervous system, peripheral nervous pathways are made up of neurons (that is, nerve cell bodies and their axons and dendrites) as well as the points at which one neuron communicates with the next (that is, the synapse). The structures commonly known as nerves (or by such names as roots, rami, trunks, and branches) are actually composed of orderly arrangements of the axonal and dendritic processes of many nerve cell bodies.

Ganglia

The cell bodies of peripheral neurons are often found grouped into clusters called ganglia. Based on the type of nerve cell bodies found in ganglia, they may be classified as either sensory or motor. Sensory ganglia are found as oval swellings on the dorsal roots of spinal nerves,

and they are also found on the roots of certain cranial nerves. The sensory neurons making up these ganglia are unipolar. Shaped much like a golf ball on a tee, they have round or slightly oval cell bodies with concentrically located nuclei, and they give rise to a single fibre that undergoes a T-shaped bifurcation, one branch going to the periphery and the other entering the brain or spinal cord. There are no synaptic contacts between neurons in a sensory ganglion.

Motor ganglia are associated with neurons of the autonomic nervous system. Many of these are found in the sympathetic trunks, two long chains of ganglia lying along each side of the vertebral column from the base of the skull to the coccyx; these are referred to as paravertebral. Other motor ganglia (called prevertebral) are found near internal organs innervated by their projecting fibres, while still others (called terminal ganglia) are found on the surfaces or within the walls of the target organs themselves. Motor ganglia contain multipolar cell bodies, which have irregular shapes and eccentrically located nuclei and which project several dendritic and axonal processes. Preganglionic fibres originating from the brain or spinal cord enter motor (autonomic) ganglia, where they synapse on multipolar cell bodies. These postganglionic cells, in turn, send their processes to visceral structures.

SPINAL NERVES

Sensory input from the body surface, from joint, tendon, and muscle receptors, and from internal organs passes centrally through the dorsal roots of the spinal cord. Fibres from motor cells in the spinal cord exit via the ventral roots and course to their peripheral targets (autonomic ganglia or skeletal muscle). The spinal nerve is formed by the joining of dorsal and ventral roots, and it is the basic structural and functional unit on which the peripheral nervous system is built.

Structure of the spinal nerve. In humans there are 31 pairs of spinal nerves. In descending order from the most rostral end of the spinal cord, there are 8 cervical (designated C_1–C_8), 12 thoracic (T_1–T_{12}), 5 lumbar (L_1–L_5), 5 sacral (S_1–S_5), and 1 coccygeal (Coc_1). Each spinal nerve exits the vertebral canal through an opening called the intervertebral foramen (see Figure 25). The first spinal nerve (C_1) exits between the skull and the first cervical vertebra; consequently, spinal nerves C_1–C_7 exit above the correspondingly numbered vertebrae. Spinal nerve C_8, however, exits between the 7th cervical and first thoracic vertebrae, so that, beginning with T_1, all other spinal nerves exit below their corresponding vertebrae.

Just outside the intervertebral foramen, two branches, known as the gray and white rami communicates, connect the spinal nerve with the sympathetic trunk. These rami, along with the sympathetic trunk and more distal ganglia, are concerned with the innervation of visceral structures. In addition, small meningeal branches leave the spinal nerve and gray ramus and reenter the vertebral canal, where they innervate dura and blood vessels.

Ventral and dorsal rami

More peripherally, the spinal nerve divides into ventral and dorsal rami (see Figure 22). All dorsal rami (with the exception of those from C_1, S_4, S_5, and Coc_1) have medial and lateral branches, which innervate deep back muscles and overlying skin. The medial and lateral branches of the dorsal rami of spinal nerves C_2–C_8 supply both muscles and skin of the neck. Those of T_1–T_6 are mostly cutaneous (that is, supplying only the skin), while those from T_7–T_{12} are mainly muscular. Dorsal rami from L_1–L_3 have both sensory and motor fibres, while those from L_4–L_5 are only muscular. Dorsal rami of S_1–S_3 may also be divided into medial and lateral branches, serving deep muscles of the lower back as well as cutaneous areas of the lower buttocks and perianal area. Undivided dorsal rami from S_4, S_5, and Coc_1 also send cutaneous branches to the gluteal and perianal regions.

Ventral rami of the spinal nerves carry sensory and motor fibres for the innervation of the muscles, joints, and skin of the lateral and ventral body walls and the extremities (see below *Plexuses of the ventral rami*). Both dorsal and ventral rami also contain autonomic fibres.

Functional components. Because spinal nerves contain both sensory fibres (from the dorsal roots) and motor fibres (from the ventral roots), they are known as mixed nerves. When individual fibres of a spinal nerve are identified by their specific function, they may be categorized as one of four types: (1) general somatic afferent, (2) general visceral afferent, (3) general somatic efferent, and (4) general visceral efferent. The term somatic refers to the body wall (broadly defined to include skeletal muscles as well as the surface of the skin), and visceral refers to structures composed of smooth muscle, cardiac muscle, or glandular epithelium (or a combination of these). Efferent fibres carry motor information to skeletal muscle and to autonomic ganglia (and then to visceral structures), and afferent fibres carry sensory information from them.

General somatic afferent receptors are sensitive to pain, thermal sensation, touch and pressure, and changes in the position of the body. (Pain and temperature sensation coming from the surface of the body are called exteroceptive, while sensory information arising from tendons, muscles, or joint capsules are called proprioceptive.) General visceral afferent receptors are found in organs of the thorax, abdomen, and pelvis; their fibres convey, for example, pain information from the digestive tract. Both types of afferent fibre project centrally from cell bodies in dorsal-root ganglia.

Carrying motor information

General somatic efferent fibres originate from large ventral-horn cells and distribute to skeletal muscles in the body wall and in the extremities. General visceral efferent fibres also arise from cell bodies located within the spinal cord, but they exit only at thoracic and upper lumbar levels or at sacral levels (more specifically, at levels T_1–L_2 and S_2–S_4). Fibres from T_1–L_2 enter the sympathetic trunk, where they either form synaptic contacts within a ganglion, ascend or descend within the trunk, or exit the trunk and proceed to ganglia situated closer to their target organs. Fibres from S_2–S_4, on the other hand, leave the cord as the pelvic nerve and proceed to terminal ganglia located in the target organs. Postganglionic fibres arising from ganglia in the sympathetic trunk rejoin the spinal nerves and distribute to blood vessels, sweat glands, and arrector pili muscles, while postganglionic fibres arising from prevertebral and terminal ganglia innervate viscera of the thorax, abdomen, and pelvis.

Plexuses of the ventral rami. All plexuses arising from the ventral rami of spinal nerves contain sensory, motor, and autonomic fibres. The plexuses are the cervical, brachial, lumbar, sacral, and coccygeal.

Cervical plexus. Cervical levels C_1–C_4 are the main contributors to the cervical plexus; in addition, small branches link C_1 and C_2 with the vagus nerve, C_1 and C_2 with the

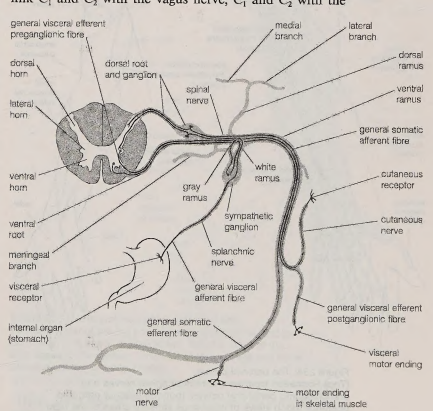

Figure 22: A typical spinal nerve.

hypoglossal nerve, and C_2–C_4 with the accessory nerve. Sensory branches of the cervical plexus are the lesser occipital nerve (to scalp behind the ear), the great auricular nerve (to the ear and to the skin over the mastoid and parotid areas), transverse cervical cutaneous nerves (to lateral and ventral neck surfaces), and supraclavicular nerves (along the clavicle, shoulder, and upper chest). Motor branches serve muscles that stabilize and flex the neck, muscles that stabilize the hyoid bone (to assist in actions like swallowing), and muscles that elevate the upper ribs.

Originating from C_4, with small contributions from C_3 and C_5, are the phrenic nerves, which carry sensory information from parts of the pleura and pericardium and motor impulses to muscles of the diaphragm. Injury to the phrenic nerves would paralyze the diaphragm and render breathing difficult or impossible.

Brachial plexus. Cervical levels C_5–C_8 and thoracic level T_1 contribute to the formation of the brachial plexus; small fascicles also arrive from C_4 and T_2 (see Figure 23A). Spinal nerves from these levels converge to form superior (C_5 and C_6), middle (C_7), and inferior (C_8 and T_1) trunks, which in turn split into anterior and posterior divisions. The divisions then form cords (posterior, lateral, and medial), which provide motor, sensory, and autonomic fibres to the shoulder and upper extremity.

Innervation of the shoulder, arm, and hand

Nerves to shoulder and pectoral muscles include the dorsal scapular (to the rhomboid muscles), suprascapular (to supraspinatus and infraspinatus), medial and lateral pectoral (to pectoralis minor and major), long thoracic (to serratus anterior), thoracodorsal (to latissimus dorsi), and subscapular (to teres major and subscapular). The axillary nerve carries motor fibres to the deltoid and teres minor muscles as well as sensory fibres to the lateral surface of the shoulder and upper arm. The biceps, brachialis, and coracobrachialis muscles, as well as the lateral surface of the forearm, are served by the musculocutaneous nerve.

The three major nerves of the arm, forearm, and hand are the radial, median, and ulnar (see Figure 23B). The radial nerve innervates the triceps, anconeus, and brachioradialis muscles, eight extensors of the wrist and digits, and one abductor of the hand; it is also sensory to part of the hand. The median nerve branches in the forearm to serve the palmaris longus, two pronator muscles, four flexor muscles, thenar muscles, and lumbrical muscles; most of these serve the wrist and hand. The ulnar nerve serves two flexor muscles and a variety of small muscles of the wrist and hand.

Cutaneous innervation of the upper extremity originates, via the brachial plexus, from spinal cord levels C_5–T_2. The shoulder is served by supraclavicular branches (C_3, C_4) of the cervical plexus, while the anterior and lateral aspects of the arm and forearm have sensory innervation via the axillary (C_5, C_6), nerve as well as the dorsal (C_5, C_6), lateral (C_5, C_6), and medial (C_8, T_1) antebrachial cutaneous nerves. These same nerves have branches that wrap around to serve portions of the posterior and medial surfaces of the extremity. The palm of the hand is served by the median (C_6–C_8) and ulnar (C_8, T_1) nerves. The ulnar nerve also wraps around to serve medial areas of the dorsum, or back, of the hand. A line drawn down the midline of the ring finger represents the junction of the ulnar-radial distribution on the back of the hand and the ulnar-median distribution on the palm (see Figure 23A). A small part of the thumb and the distal thirds of the index, middle, and lateral surface of the ring finger are served by the median nerve. The inner aspect of the arm and adjacent armpit is served by intercostobrachial and posterior and medial brachial cutaneous nerves (T_1–T_2).

Lumbar plexus. Spinal nerves from lumbar levels L_1–L_4 contribute to the formation of the lumbar plexus, which, along with the sacral plexus, provides motor, sensory, and autonomic fibres to gluteal and inguinal regions and to the lower extremity. Lumbar roots are organized into dorsal and ventral divisions.

Minor cutaneous and muscular branches of the lumbar plexus include the iliohypogastric, genitofemoral, and ilioinguinal (projecting to the lower abdomen and to inguinal and genital regions) and the lateral femoral cutaneous nerve (to skin on the lateral thigh). Two major branches are the obturator and femoral nerves. The obturator enters the thigh through the obturator foramen; motor branches proceed to the obturator internus and gracilis muscles as well as the adductor muscles, while sensory branches supply the articular capsule of the knee joint. An accessory obturator nerve supplies the pectineus muscle of the thigh and is sensory to the hip joint.

The sartorius muscle and medial and anterior surfaces of the thigh are served by branches of the anterior division of the femoral nerve. The posterior division of the femoral nerve provides sensory fibres to the inner surface of the leg (saphenous nerve), to the quadriceps muscles (muscu-

lar branches), the hip and knee joints, and the articularis genu muscle.

Sacral plexus. The ventral rami of L_4 and S_1–S_3 form the sacral plexus, with contributions from L_5 and S_4. Branches from this plexus innervate gluteal muscles, muscles forming the internal surface of the pelvic basin (including those forming the levator ani), and muscles that run between the femur and pelvis to stabilize the hip joint (such as the obturator, piriformis, and quadratus femoris muscles). These muscles lend their names to the nerves that innervate them. Cutaneous branches from the plexus serve the buttocks, perineum, and posterior surface of the thigh.

Innervation of the leg and foot

The major nerve of the sacral plexus, and the largest in the body, is the sciatic (see Figure 23B). Formed by the joining of ventral and dorsal divisions of the plexus, it passes through the greater sciatic foramen and descends in back of the thigh. There, sciatic branches innervate the biceps femoris, semitendinosus and semimembranosus muscles, and part of the adductor magnus muscle. In the popliteal fossa (just above the knee) the sciatic nerve divides into the tibial nerve and the common fibular (or peroneal) nerve. The tibial nerve (from the dorsal division) continues distally in the calf and innervates the gastrocnemius muscle, deep leg muscles such as the popliteus, soleus, and tibialis posterior, and the flexor muscles, lumbrical muscles, and other muscles of the ankle and plantar aspects of the foot. The peroneal nerve, from the ventral division, passes to the anterior surface of the leg and innervates the tibialis anterior, the fibularis muscles, and extensor muscles that elevate the foot and fan the toes. Cutaneous branches from the tibial and common fibular nerves serve the outer sides of the leg and the top and bottom of the foot and toes.

Coccygeal plexus. The ventral rami of S_4, S_5, and Coc_1 form the coccygeal plexus, from which small anococcygeal nerves arise to innervate the skin over the coccyx (tailbone) and around the anus.

CRANIAL NERVES

Cranial nerves can be thought of as modified spinal nerves, since the "general" functional fibre types found in spinal nerves also are found in cranial nerves but are supplemented by "special" afferent or efferent fibres. Fibres conveying olfaction (in cranial nerve I) and taste (in cranial nerves VII, IX, and X) are classified as special visceral afferent, while the designation of special somatic afferent is applied to fibres conveying vision (cranial nerve II) and equilibrium and hearing (cranial nerve VIII). Skeletal muscles that arise from the branchial (pharyngeal) arches are innervated by fibres of cranial nerves V, VII, IX, and X; these are classified as special visceral efferent fibres.

The 12 pairs of cranial nerves are commonly identified either by name or by Roman or Arabic numeral.

Olfactory nerve (CN I or 1). Bipolar cells in the nasal mucosa give rise to axons that enter the cranial cavity through foramina in the cribriform plate of the ethmoid bone. These cells and their axons, totaling about 20–24 in number, make up the olfactory nerve. Once in the cranial cavity, the fibres terminate in a small oval structure resting on the cribriform plate called the olfactory bulb (see Figure 24). As stated above, the functional component of olfactory fibres is special visceral afferent. Injury or disease of the olfactory nerve may result in anosmia, an inability to detect odours; this may also dull the sense of taste.

Optic nerve (CN II or 2). Rods and cones in the retina of the eye receive information from the visual fields and, through intermediary cells, convey this input to retinal ganglion cells. Ganglion cell axons converge at the optic disc, pass through the sclera, and form the optic nerve. The optic nerve from each eye enters the skull via the optic foramen and joins its opposite to form the optic chiasm. At the chiasm, fibres from the nasal halves of each retina cross, while those from the temporal halves remain uncrossed. In this way the optic tracts, which extend from the chiasm to the thalamus, contain fibres conveying information from both eyes. Injury to one optic nerve therefore results in total blindness in that eye, while damage to the optic tract on one side results in partial blindness in both eyes.

Crossing of optic nerve fibres

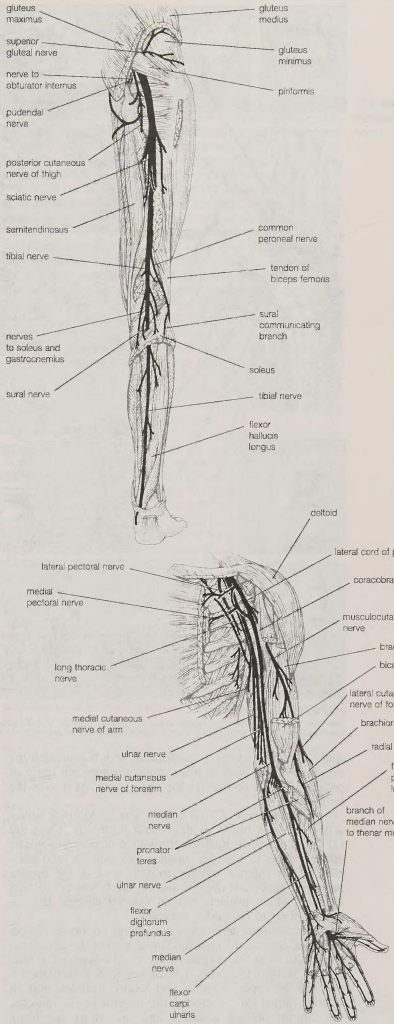

Figure 23B: *Nerves of the right leg and left arm.* Posterior view of the leg showing the sciatic nerve and its branches, part of the sacral plexus. Anterior view of the arm showing the median, ulnar, and radial nerves and other branches of the brachial plexus.

space around the brain is continuous with that around the optic nerve, increases in intracranial pressure can result in papilledema, or damage to the optic nerve, as it exits the bulb of the eye.

Oculomotor nerve (CN III or 3). The oculomotor nerves arise from two nuclei in the rostral midbrain. These are (1) the oculomotor nucleus, the source of general somatic efferent fibres to superior, medial, and inferior recti muscles, to the inferior oblique muscle, and to the levator palpebrae superious muscle; and (2) the Edinger-Westphal nucleus, which projects general visceral efferent preganglionic fibres to the ciliary ganglion.

The oculomotor nerve exits the ventral midbrain, pierces the dura, courses through the lateral wall of the cavernous sinus, and exits the cranial cavity via the superior orbital fissure. Within the orbit it branches into a superior ramus (to the superior rectus and levator muscles) and an inferior ramus (to the medial and inferior rectus muscles, the inferior oblique muscles, and the ciliary ganglion). Postganglionic fibres from the ciliary ganglion innervate the sphincter pupillae muscle of the iris as well as the ciliary muscle.

With the exception of the levator palpebrae superioris muscle, which is innervated bilaterally, oculomotor neurons project primarily to orbital muscles on the same side of the head. A lesion of the oculomotor nerve will result in paralysis of the three rectus muscles and the inferior oblique muscle (causing the eye to rotate downward and slightly outward), paralysis of the levator palpebrae superious muscle (drooping of the eyelids), and paralysis of the sphincter pupillae and ciliary muscles (so that the iris will remain dilated and the lens will not accommodate).

Trochlear nerve (CN IV or 4). The fourth cranial nerve is unique for three reasons. First, it is the only cranial nerve to exit the dorsal side of the brain stem. Second, fibres from the trochlear nucleus cross in the midbrain before they exit, so that trochlear neurons innervate the contralateral (opposite side) superior oblique muscle of the eye. Third, trochlear fibres have a long intracranial course before piercing the dura.

The trochlear nucleus is located in the caudal midbrain; the functional component of these cells is general somatic efferent. After exiting at the dorsal side of the midbrain, the trochlear nerve loops around the midbrain, pierces the dura, and passes through the lateral wall of the cavernous sinus. It then enters the orbit through the superior orbital fissure and innervates only the superior oblique muscle, which rotates the eye downward and slightly outward. Damage to the trochlear nerve will result in a loss of this eye movement and may produce double vision (diplopia).

Trigeminal nerve (CN V or 5). The trigeminal nerve is the largest of the cranial nerves. It has both motor and sensory components, the sensory fibres being general somatic afferent and the motor fibres being special visceral

efferent. Most of the cell bodies of sensory fibres are located in the trigeminal ganglion, which is attached to the pons by the trigeminal root (see Figure 19). These convey pain and thermal sensations from the face, oral and nasal cavities, and parts of the dura and nasal sinuses, sensations of deep pressure, and information from sensory endings in muscles. Trigeminal motor fibres, projecting from nuclei in the pons, serve the muscles of mastication.

Lesions of the trigeminal nerve result in sensory losses over the face or in the oral cavity. Damage to motor fibres results in paralysis of the masticatory muscles; as a result, the jaw may hang open or deviate toward the uninjured side when opened. Trigeminal neuralgia, or tic douloureux, is an intense idiopathic pain originating mainly from areas supplied by sensory fibres of the maxillary and mandibular branches of this nerve.

Threefold division of the trigeminal nerve

The trigeminal ganglion gives rise to three large nerves, the ophthalmic, maxillary, and mandibular.

Ophthalmic nerve. The ophthalmic nerve passes through the wall of the cavernous sinus and enters the orbit via the superior orbital fissure. Branches in the orbit are (1) the lacrimal nerve, serving the lacrimal gland, part of the upper eyelid, and the conjunctiva; (2) the nasociliary nerve, serving the mucosal lining of part of the nasal cavity, the tentorium cerebelli and some of the dura of the anterior cranial fossa, and skin on the dorsum and tip of the nose; and (3) the frontal nerve, serving the skin on the upper eyelid and the forehead and scalp above the eyes up to the vertex of the head.

Maxillary nerve. The maxillary nerve courses through the cavernous sinus below the ophthalmic nerve and passes through the foramen rotundum into the orbital cavity. Branches of the maxillary nerve are (1) the meningeal branches, which serve the dura of the middle cranial fossa; (2) the alveolar nerves, serving the upper teeth and gingiva and the lining of the maxillary sinus; (3) the nasal and palatine nerves, which serve portions of the nasal cavity and the mucosa of the hard and soft palate; and (4) the infraorbital, zygomaticotemporal, and zygomaticofacial nerves, serving the upper lip, the lateral surfaces of the nose, the lower eyelid and conjunctiva, and skin on the cheek and the side of the head behind the eye.

Mandibular nerve. The mandibular nerve exits the cranial cavity via the foramen ovale and serves (1) the meninges of middle and parts of the anterior cranial fossae (meningeal branches); (2) the temporomandibular joint, skin over part of the ear, and skin over the sides of the head above the ears (auriculotemporal nerve); (3) oral mucosa, the anterior two-thirds of the tongue, gingiva adjacent to the tongue, and the floor of the mouth (lingual nerve); and (4) the mandibular teeth (inferior alveolar nerve). Skin over the lateral and anterior surfaces of the mandible and the lower lip is served by cutaneous branches of the mandibular nerve.

Trigeminal motor fibres exit the cranial cavity via the foramen ovale along with the mandibular nerve. They serve the muscles of mastication (temporalis, masseter, medial and lateral pterygoid), three muscles involved in aspects of swallowing (anterior portions of the digastric muscle, the mylohyoid muscle, and the tensor veli palatini), and a muscle that has a damping effect on loud noises by stabilizing the tympanic membrane (tensor tympani).

Abducens nerve (CN VI or 6). From its nucleus in the caudal pons, the abducens nerve exits the brain stem at the pons-medulla junction, pierces the dura, passes through the cavernous sinus close to the internal carotid artery, and exits the cranial vault via the superior orbital fissure. In the orbit the abducens nerve innervates the lateral rectus muscle, which turns the eye outward. Damage to the abducens nerve results in a tendency for the eye to deviate medially, or "cross." Double vision may result on attempted lateral gaze.

Facial nerve (CN VII or 7). The facial nerve is composed of a large root that innervates facial muscles and a small root (known as the intermediate nerve) that contains sensory and autonomic fibres.

From the facial nucleus in the pons, facial motor fibres enter the internal auditory meatus, pass through the temporal bone, exit the skull via the stylomastoid foramen, and fan out over each side of the face forward of the ear. Fibres of the facial nerve are special visceral efferent; they innervate small muscles of the external ear, the platysma, the stapedius, the occipitofrontalis, the stylohyoid posterior belly of the digastric, the buccinator, and the muscles of facial expression.

The intermediate nerve

The intermediate nerve contains autonomic (parasympathetic) as well as general and special sensory fibres. Preganglionic autonomic fibres, classified as general visceral efferent, project from the superior salivatory nucleus in the pons. Exiting with the facial nerve, they pass to the pterygopalatine ganglion via the greater petrosal nerve (a branch of the facial nerve) and to the submandibular ganglion by way of the chorda tympani nerve (another branch of the facial nerve, which joins the lingual branch of the mandibular nerve). Postganglionic fibres from the pterygopalatine ganglion innervate nasal and palatine glands and the lacrimal gland, while those from the submandibular ganglion serve submandibular and sublingual salivary glands. Among the sensory components of the intermediate nerve, general somatic afferent fibres relay sensation from the caudal surface of the ear, while special visceral afferent fibres originate from taste buds in the anterior two-thirds of the tongue, course in the lingual branch of the mandibular nerve, and then join the facial nerve via the chorda tympani branch. Both somatic and visceral afferent fibres have cell bodies in the geniculate ganglion, which is located on the facial nerve as it passes through the facial canal in the temporal bone.

Injury to the facial nerve at the brain stem produces a paralysis of facial muscles known as Bell's palsy as well as a loss of taste sensation from the anterior two-thirds of the tongue. If damage occurs at the stylomastoid foramen, facial muscles will be paralyzed but taste will be intact.

Vestibulocochlear nerve (CN VIII or 8). This cranial nerve has a vestibular part, which functions in balance, equilibrium, and orientation in three-dimensional space, and a cochlear part, which functions in hearing. The functional component of these fibres is special somatic afferent; they originate from receptors located in the temporal bone.

Vestibular receptors are located in the semicircular canals, which provide input on rotatory movements (angular acceleration), and in the utricle and saccule, which generate information on linear acceleration and the influence of gravitational pull. This information is relayed by the vestibular fibres, whose bipolar cell bodies are located in the vestibular (Scarpa's) ganglion. The central processes of these neurons exit the temporal bone via the internal acoustic meatus and enter the brain stem alongside the facial nerve.

Auditory receptors of the cochlear division are in the organ of Corti and follow the spiral shape (about 2.5 turns) of the cochlea. Air movement against the eardrum produces mechanical actions by the ossicles of the ear, which, in turn, cause movement of fluid in the spiral cochlea. This fluid movement is transduced by the organ of Corti into nerve impulses interpreted as auditory information. The bipolar cells of the spiral (Corti's) ganglion give rise to central processes that course with the vestibular nerve. At the brain stem, cochlear fibres separate from vestibular fibres to end in the dorsal and ventral cochlear nuclei.

Lesions of the vestibular root result in eye movement disorders (nystagmus), unsteady gait with a tendency to fall toward the side of the lesion, nausea, and vertigo. Damage to the cochlea or cochlear nerve results in complete deafness, ringing in the ear (tinnitus), or both.

Glossopharyngeal nerve (CN IX or 9). The ninth cranial nerve, which exits the skull through the jugular foramen, has both motor and sensory components. Cell bodies of motor neurons, located in the nucleus ambiguus in the medulla, project as special visceral efferent fibres to the stylopharyngeal muscle. The action of the stylopharyngeus is to elevate the pharynx, as in gagging or swallowing. In addition, the inferior salivatory nucleus of the medulla sends general visceral efferent fibres to the otic ganglion via the lesser petrosal branch of the ninth nerve; postganglionic otic fibres distribute to the parotid salivary gland.

Innervation of the pharynx and tongue

Among the sensory components, special visceral afferent fibres convey taste sensation from the back third of the

tongue via lingual branches of the nerve. General visceral afferent fibres from the pharynx, the back of the tongue, parts of the soft palate and eustachian tube, and the carotid body and carotid sinus have their cell bodies in the superior and inferior ganglia, which are situated, respectively, within the jugular foramen and just outside the cranium. Sensory fibres in the carotid branch detect increased blood pressure in the carotid sinus and send impulses into the medulla that ultimately produce a reduction in heart rate and arterial pressure; this is known as the carotid sinus reflex.

Vagus nerve (CN X or 10). The vagus nerve has the most extensive distribution in the body of all the cranial nerves, innervating structures as diverse as the external surface of the eardrum and internal organs of the abdomen. The root of the nerve exits the cranial cavity via the jugular foramen. Within the foramen is the superior ganglion, containing cell bodies of general somatic afferent fibres, and just external to the foramen is the inferior ganglion, containing visceral afferent cells.

Pain and temperature sensations from the eardrum and external auditory canal, and pain fibres from the dura of the posterior cranial fossa, are conveyed on general somatic afferent fibres in the auricular and meningeal branches of the nerve. Taste buds on the root of the tongue and on the epiglottis contribute special visceral afferent fibres to the superior laryngeal branch. General visceral afferent fibres conveying sensation from the lower pharynx, larynx, trachea, esophagus, and organs of the thorax and abdomen to the left (splenic) flexure of the colon converge to form the posterior (or right) and anterior (or left) vagal nerves. Right and left vagal nerves are joined in the thorax by cardiac, pulmonary, and esophageal branches. In addition, general visceral afferent fibres from the larynx below the vocal folds join the vagus via the recurrent laryngeal nerves, while comparable input from the upper larynx and pharynx is relayed by the superior laryngeal nerves and by pharyngeal branches of the vagus. A vagal branch to the carotid body usually arises from the inferior ganglion.

Motor functions of the vagus nerve

Motor fibres of the vagus nerve include special visceral efferent fibres arising from the nucleus ambiguus of the medulla and innervating pharyngeal constrictor muscles and palatine muscles via pharyngeal branches of the vagus as well as the superior laryngeal nerve. All laryngeal musculature (excluding the cricothyroid but including the muscles of the vocal folds) are innervated by fibres arising in the nucleus ambiguus. Cells of the dorsal motor nucleus in the medulla distribute general visceral efferent fibres to plexuses or ganglia serving the pharynx, larynx, esophagus, and lungs. In addition, cardiac branches arise from plexuses in the lower neck and upper thorax, and, once in the abdomen, the vagus gives rise to gastric, coeliac, hepatic, renal, intestinal, and splenic branches or plexuses.

Damage to one vagus nerve results in hoarseness and difficulty in swallowing and speaking. Injury to both nerves results in increased heart rate, paralysis of pharyngeal and laryngeal musculature, atonia of the esophagus and intestinal musculature, vomiting, and loss of visceral reflexes. Such a lesion is usually life-threatening, as paralysis of laryngeal muscles can result in asphyxiation.

Accessory nerve (CN XI or 11). The accessory nerve is formed by fibres from the medulla (known as the cranial root) and by fibres from cervical levels C_1–C_4 (known as the spinal root). The cranial root originates from the nucleus ambiguus and exits the medulla below the vagus. Its fibres join the vagus and distribute to some muscles of the pharynx and larynx via pharyngeal and recurrent laryngeal branches of that nerve. For this reason, the cranial part of the accessory nerve is, for all practical purposes, part of the vagus nerve.

Fibres that arise from spinal levels exit the cord, coalesce and ascend as the spinal root of the accessory nerve, enter the cranial cavity through the foramen magnum, and then immediately leave through the jugular foramen. The accessory nerve then branches into the sternocleidomastoid muscle, which tilts the head toward one shoulder with an upward rotation of the face to the opposite side, and the trapezius muscle, which stabilizes and elevates (or shrugs) the shoulder.

Hypoglossal nerve (CN XII or 12). The hypoglossal nerve innervates certain muscles that control movement of the tongue. From the hypoglossal nucleus in the medulla, general somatic efferent fibres exit the cranial cavity through the hypoglossal canal and enter the neck in close proximity to the accessory and vagus nerves and the internal carotid artery. The nerve then loops down and forward into the floor of the mouth and branches into the tongue musculature from underneath. Hypoglossal fibres end in intrinsic tongue muscles, which modify the shape of the tongue (as in rolling the edges), as well as in extrinsic muscles that are responsible for changing its position in the mouth.

A lesion of the hypoglossal nerve on one side of the head would result in paralysis of intrinsic and extrinsic musculature on the same side. The tongue would atrophy and, on attempted protrusion, would deviate toward the side of the lesion. (D.E.H.)

The autonomic nervous system

Maintenance of bodily functions

The autonomic nervous system is a part of the peripheral nervous system that functions to regulate the basic visceral processes needed for the maintenance of normal bodily functions. It operates independently of voluntary control, although certain events, such as emotional stress, fear, sexual excitement, and alterations in the sleep-wakefulness cycle, change the level of autonomic activity.

The autonomic system is usually defined as a motor system that innervates three major types of tissue: cardiac muscle, smooth muscle, and glands. However, this definition needs to be expanded to encompass the fact that it also relays visceral sensory information into the central nervous system and processes it in such a way as to make alterations in the activity of specific autonomic motor outflows, such as those that control the heart, blood vessels, and other visceral organs. It also causes the release of certain hormones involved in energy metabolism (*e.g.*, insulin, glucagon, epinephrine) or cardiovascular functions (*e.g.*, renin, vasopressin). These integrated responses maintain the normal internal environment of the body in an equilibrium state called homeostasis.

The autonomic system consists of two major divisions: the sympathetic nervous system and the parasympathetic nervous system. These often function in antagonistic ways. The motor outflow of both systems is formed by two serially connected sets of neurons. The first set, called preganglionic neurons, originates in the brain stem or the spinal cord, and the second set, called ganglion cells or postganglionic neurons, lies outside the central nervous system in collections of nerve cells called autonomic ganglia. Parasympathetic ganglia tend to lie close to or within the organs or tissues that their neurons innervate, whereas sympathetic ganglia lie at a more distant site from their target organs. Both systems have associated sensory fibres that send feedback information into the central nervous system regarding the functional condition of target tissues.

A third division of the autonomic system, termed the enteric nervous system, consists of a collection of neurons embedded within the wall of the entire gastrointestinal tract and its derivatives. This system controls gastrointestinal motility and secretions.

SYMPATHETIC NERVOUS SYSTEM

Sympathetic preganglionic neurons originate in the lateral horns of the 12 thoracic and the first 2 or 3 lumbar segments of the spinal cord. (For this reason the sympathetic system is sometimes referred to as the thoracolumbar outflow.) The axons of these neurons exit the spinal cord in the ventral roots and then synapse on either sympathetic ganglion cells or specialized cells in the adrenal gland called chromaffin cells.

Sympathetic ganglia. Sympathetic ganglia can be divided into two major groups, paravertebral and prevertebral (or preaortic), on the basis of their location within the body. Paravertebral ganglia generally lie on each side of the vertebrae and are connected to form the sympathetic chain or trunk (see Figure 25). There are usually 21 or 22 pairs of these ganglia: 3 in the cervical region,

The sympathetic trunk

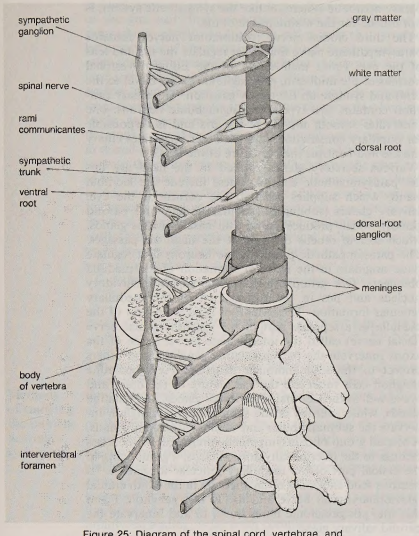

Figure 25: Diagram of the spinal cord, vertebrae, and sympathetic trunk (shown on one side only). Dorsal rami of the spinal nerves are not shown.
From E. Gardner, *Fundamentals of Neurology*, 5th ed. (1968); W.B. Saunders Co.

10 to 11 in the thoracic region, 4 in the lumbar region, 4 in the sacral region, and a single, unpaired ganglion lying in front of the coccyx called the ganglion impar. The three cervical sympathetic ganglia are the superior cervical ganglion, the middle cervical ganglion, and the cervicothoracic ganglion (also called the stellate ganglion). The superior ganglion innervates viscera of the head; the middle and stellate ganglia innervate viscera of the neck, thorax (*i.e.*, the bronchi and heart), and upper limb. The thoracic sympathetic ganglia innervate the trunk region, and the lumbar and sacral sympathetic ganglia innervate the pelvic floor and lower limb. All the paravertebral ganglia provide sympathetic innervation to blood vessels in muscle and skin, arrector pili muscles attached to hairs, and sweat glands (see Figure 26).

The three preaortic ganglia are the celiac, superior mesenteric, and inferior mesenteric. Lying on the anterior surface of the aorta, they provide axons that are distributed with the three major gastrointestinal arteries arising from the aorta. The three ganglia retain a pattern of innervation that originates in the embryo. Thus, the celiac ganglion innervates structures derived from the embryonic foregut, including the stomach, liver, pancreas, duodenum, and the first part of the small intestine; the superior mesenteric ganglion innervates the small intestine, which is derived from the embryonic midgut; and the inferior mesenteric ganglion innervates embryonic hindgut derivatives, which include the descending colon, sigmoid colon, rectum, urinary bladder, and sexual organs.

Neurotransmitters and receptors. Upon reaching their target organs by traveling with the blood vessels that supply them, sympathetic fibres terminate as a series of varicosities close to the end organ. Because of this anatomical arrangement, autonomic transmission takes place across a junction rather than a synapse. "Presynaptic" sites can be identified because they contain aggregations of synaptic vesicles and membrane thickenings; postjunctional membranes, on the other hand, rarely possess morphological specializations, but they do contain specific receptors for various neurotransmitters. The distance between pre- and postsynaptic elements can be quite large as compared to typical synapses. For instance, the gap between cell membranes of a typical chemical synapse is 30–50 nanometres, while in blood vessels the distance is often greater than 100 nanometres and, in some cases, 1–2 micrometres (1,000–2,000 nanometres). Owing to these relatively large gaps between autonomic nerve terminals and their effector cells, transmitters tend to act slowly; they become inactivated rather slowly as well. To compensate for this apparent inefficiency, many effector cells, such as those in smooth and cardiac muscle, are connected by low-resistance pathways that allow for electrotonic coupling of the cells. In this way, if only one cell is activated, multiple cells will respond and work as a group.

Acetylcholine, norepinephrine, and other transmitters

At a first approximation, chemical transmission in the sympathetic system appears simple: preganglionic neurons use acetylcholine as a neurotransmitter, whereas most postganglionic neurons utilize norepinephrine (noradrenaline)—with the major exception that postganglionic neurons innervating sweat glands use acetylcholine (see Figure 26). On closer inspection, however, neurotransmission is seen to be more complex, because multiple chemicals are released, and each functions as a specific chemical code affecting different receptors on the target cell. In addition, these chemical codes are self-regulatory, in that they act on presynaptic receptors located on their own axon terminals.

The chemical codes are specific to certain tissues. For example, most sympathetic neurons that innervate blood vessels secrete both norepinephrine and neuropeptide Y, sympathetic neurons that innervate the submucosal neural plexus of the gut contain both norepinephrine and somatostatin, and sympathetic neurons that innervate sweat glands contain calcitonin gene-related peptide, vasoactive intestinal polypeptide, and acetylcholine. In addition, other chemicals besides the neuropeptides mentioned

From E. Gardner, *Fundamentals of Neurology*, 5th ed. (1968); W.B. Saunders Company

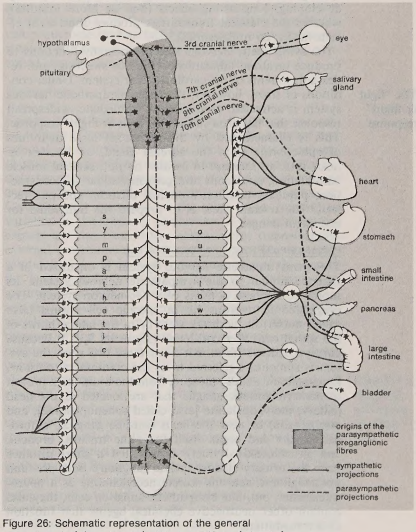

Figure 26: Schematic representation of the general arrangement of the autonomic nervous system. Autonomic fibres to the organs of the head and trunk are shown on the right side; the autonomic fibres on the left side represent the sympathetic outflow to blood vessels, sweat glands, and smooth muscle of hair follicles.

above are released from autonomic neurons along with the so-called classical neurotransmitters, norepinephrine and acetylcholine. For instance, some neurons synthesize a gas, nitric oxide, that functions as a novel type of neuronal messenger molecule. Thus, neural transmission in the autonomic nervous systems involves the release of combinations of different neuroactive agents that affect both pre- and postsynaptic receptors.

Neurotransmitters released from nerve terminals bind to specific receptors, which are specialized macromolecules embedded in the cell membrane. The binding action initiates a series of specific biochemical reactions in the target cell that produce a physiological response. These effects can be modified by various drugs that act as agonists or antagonists. In the sympathetic nervous system, for example, there are five types of adrenergic receptors (receptors binding epinephrine): α_1, α_2, β_1, β_2, and β_3. These are found in different combinations in various cells throughout the body. Activation of α_1 receptors in arterioles causes blood-vessel constriction, whereas stimulation of α_2 autoreceptors (receptors located in sympathetic presynaptic nerve endings) function to inhibit the release of norepinephrine. Other types of tissue have unique adrenergic receptors. Heart rate and myocardial contractility, for example, is controlled by β_1 receptors, bronchial smooth muscle relaxation is mediated by β_2 receptors, and lipolysis is controlled by β_3 receptors.

Cholinergic receptors (receptors binding acetylcholine) also are found in the sympathetic system (as well as the parasympathetic system). Nicotinic cholinergic receptors cause sympathetic postganglionic neurons, adrenal chromaffin cells, and parasympathetic postganglionic neurons to fire and release their chemicals. Muscarinic receptors are associated mainly with parasympathetic functions and are located in peripheral tissues (*e.g.,* glands, smooth muscle). Peptidergic receptors exist in target cells as well.

The length of time that each type of chemical acts on its target cell is variable. As a rule, peptides cause slowly developing, long-lasting effects (one or more minutes), whereas the classical transmitters produce short-term effects (about 25 milliseconds).

The sympathetic nervous system normally functions to produce localized adjustments (such as sweating) and reflex adjustments of the cardiovascular system. Under conditions of stress, however, the entire sympathetic nervous system is activated, producing an immediate, widespread response that has been called the "fight or flight" response. This is characterized by the release of large quantities of epinephrine from the adrenal gland, an increase in heart rate, an increase in cardiac output, skeletal muscle vasodilation, cutaneous and gastrointestinal vasoconstriction, pupillary dilation, bronchial dilation, and piloerection. The overall effect is to prepare the individual for imminent danger.

The "fight or flight" response

PARASYMPATHETIC NERVOUS SYSTEM

The parasympathetic nervous system is organized in a manner similar to the sympathetic nervous system. Its motor component consists of a two-neuron system. The preganglionic neurons lie in specific cell groups (also called nuclei) in the brain stem or in the lateral horns of the spinal cord at sacral levels (segments S_2–S_4). Because parasympathetic fibres exit from these two sites, the system is sometimes referred to as the craniosacral outflow. Preganglionic axons emerging from the brain stem project to parasympathetic ganglia that are located in the head (ciliary, pterygopalatine [also called sphenopalatine], and otic ganglia) or near the heart (cardiac ganglia), embedded in the end organ itself (*e.g.,* the trachea, bronchi, and gastrointestinal tract), or situated a short distance from the urinary bladder (pelvic ganglion). Both pre- and postganglionic neurons secrete acetylcholine as a neurotransmitter, but, like sympathetic ganglion cells, they also contain other neuroactive chemical agents that function as cotransmitters.

The parasympathetic nervous system modulates mainly visceral organs such as glands. These are never activated en masse as in the "fight or flight" sympathetic response. While providing important control of many tissues, the parasympathetic system, unlike the sympathetic system, is not crucial for the maintenance of life.

The third cranial nerve (oculomotor nerve) contains parasympathetic nerve fibres that regulate the iris and lens of the eye. From their origin in the Edinger-Westphal nucleus of the midbrain, preganglionic axons travel to the orbit and synapse on the ciliary ganglion. The ciliary ganglion contains two types of postganglionic neurons: one innervates smooth muscle of the iris and is responsible for pupillary constriction, and the other innervates ciliary muscle and controls the curvature of the lens.

Various secretory glands located in the head are under parasympathetic control. These include the lacrimal gland, which supplies tears to the cornea of the eye; salivary glands (sublingual, submandibular, and parotid glands), which produce saliva; and nasal mucous glands, which secrete mucus throughout the nasal air passages. The parasympathetic preganglionic neurons that regulate these originate in the reticular formation of the medulla oblongata. One group belongs to the superior salivatory nucleus and lies in the rostral part of the medullary reticular formation. These neurons send axons out of the medulla in a separate part of the seventh cranial nerve (facial nerve) called the intermediate nerve. Some of the axons innervate the pterygopalatine ganglion, and others project to the submandibular ganglion. Pterygopalatine ganglion cells innervate the vasculature of the brain and eye as well as the lacrimal gland, nasal glands, and palatine glands, while neurons of the submandibular ganglion innervate the submandibular and sublingual salivary glands. A second group of parasympathetic preganglionic neurons belongs to the inferior salivatory nucleus, a group lying in the caudal part of the medullary reticular formation. Its neurons send axons out of the medulla in the ninth cranial (glossopharyngeal) nerve and to the otic ganglion. From this site, postganglionic fibres travel to and innervate the parotid salivary gland.

Preganglionic parasympathetic fibres of the tenth cranial nerve (vagus) arise from two different sites in the medulla. Neurons that slow heart rate arise from a part of the ventral medulla called the nucleus ambiguus, while those that control the gastrointestinal tract arise from the dorsal vagal nucleus. After exiting the medulla in the vagus nerve and traveling to their respective organs, the fibres synapse on ganglion cells embedded in the organs themselves. The vagus nerve also contains visceral afferent fibres that carry sensory information from organs of the neck (larynx, pharynx, and trachea), chest (heart and lungs), and gastrointestinal tract into a visceral sensory nucleus located in the medulla and called the solitary tract nucleus.

Parasympathetic components of the vagus nerve

ENTERIC NERVOUS SYSTEM

The enteric nervous system is made up of two plexuses, or networks of neurons, embedded in the wall of the gastrointestinal tract. The outermost collection, lying between the inner circular and outer longitudinal smooth-muscle layers of the gut, is called the myenteric (or Auerbach's) plexus. Neurons of this plexus regulate the peristaltic waves, consisting of polarized muscular activity, that move digestive products from oral to anal openings. In addition, myenteric neurons control local muscular contractions that are responsible for stationary mixing and churning. The innermost group of neurons is called the submucosal (or Meissner's) plexus. This group regulates the configuration of the luminal surface, controls glandular secretions, alters electrolyte and water transport, and regulates local blood flow.

Three functional classes of intrinsic enteric neurons are recognized: sensory neurons, interneurons, and motor neurons. Sensory neurons, activated by either mechanical or chemical stimulation of the innermost surface of the gut, transmit information to interneurons located within the myenteric and submucosal plexi, and the interneurons relay the information to motor neurons. Motor neurons in turn modulate the activity of a variety of target cells, including mucous glands, smooth muscle cells, endocrine cells, epithelial cells, and blood vessels.

Extrinsic neural pathways also are involved in the control of gastrointestinal functions. Three types exist: intesti-

nofugal, sensory, and motor. Intestinofugal neurons reside in the gut wall; they send their axons to the preaortic sympathetic ganglia and control reflex arcs that involve large portions of the gastrointestinal tract. Sensory neurons relay information regarding distention (pain) and acidity into the central nervous system. There are two types of sensory neurons: sympathetic neurons, which originate from dorsal-root ganglia found at the thoracic and lumbar levels; and parasympathetic neurons, which originate in the nodose ganglion of the tenth cranial nerve (vagus) or in dorsal-root ganglia at sacral levels S_2–S_4. The former innervate the entire gastrointestinal tract from the pharynx to the left colic flexure, and the latter innervate the distal colon and rectum. Each portion of the gastrointestinal tract receives a dual sensory innervation: pain sensations travel via sympathetic afferents, and sensations that signal information regarding the chemical milieu of the gut travel by way of parasympathetic fibres and are not consciously perceived.

The third extrinsic pathway, exercising motor control over the gut, arises from parasympathetic preganglionic neurons found in the dorsal vagal nucleus of the medulla and from sympathetic preganglionic neurons in the lateral horns of the spinal cord. These outflows provide modulatory commands to the intrinsic enteric motor system and are nonessential in that basic functions can be maintained in their absence.

Motor innervation of the gut

Through the pathways described above, the parasympathetic system activates digestive processes while the sympathetic system inhibits them. The sympathetic system inhibits digestive processes by two mechanisms: (1) contraction of circular smooth muscle sphincters located in the distal portion of the stomach (pyloric sphincter), small intestine (ileo-cecal sphincter), and rectum (internal anal sphincter), which act as valves to prevent the oral-to-anal passage (as well as reverse passage) of digestive products; and (2) inhibition of motor neurons throughout the length of the gut. In contrast, the parasympathetic system provides messages only to myenteric motor neurons.

(A.D.L.)

FUNCTIONS OF THE HUMAN NERVOUS SYSTEM

The human nervous system differs from that of other mammals chiefly in the great enlargement and elaboration of the cerebral hemispheres. Much of what is known of the function of the brain is derived from observations of the effects of disease or by analogy with the results of experimentation on animals, particularly the monkey. Such sources of information are clearly inadequate for the elucidation of the nervous activity underlying many properties of the human brain—particularly speech and mental processes. It is not surprising, therefore, that knowledge of the functions of this uniquely complex system, although rapidly expanding, is far from complete.

Methods of studying the human nervous system

In the following account of the functions of the human nervous system, there are numerous references to tracts and to less well-defined connections between different regions of the brain and spinal cord. The identification of these pathways is not always a simple matter; indeed, in humans, many are incompletely known or are simply conjectural.

A great deal of information has been obtained by observing the spreading effects of axonal destruction. If a nerve fibre is severed, the length of axon farthest from the cell body, or soma, will be deprived of the axonal flow of metabolites and will begin to break up. The myelin sheath will also degenerate, so that, for some months after the injury, breakdown products of myelin will be seen under the microscope with special stains. This method is obviously of limited application in humans, as it requires precise lesions and subsequent examination before the myelin has been completely removed. The staining of degenerated axons and of the terminals that form synapses with other neurons is also possible using silver impregnation, but the techniques are laborious and results sometimes difficult to interpret.

That a damaged neuron should show degenerative changes, however difficult to detect, is not unexpected, but the interdependence of neurons is sometimes shown by transneuronal degeneration. Neurons deprived of major input from axons that have been destroyed may themselves atrophy. This phenomenon is called anterograde degeneration. In retrograde degeneration, similar changes may occur in neurons that have lost the main recipient of their outflow.

These anatomical methods are occasionally applicable to human disease. They can also be used postmortem when lesions in the central nervous system have been deliberately made—for example, in the surgical treatment of intractable pain. Some more recently developed techniques can be used only in experiments on animals, but these are not always relevant to humans. For example, normal biochemical constituents labeled with a radioactive isotope can be injected into neurons and then transported the length of the axon, where they can be detected by picking up the radioactivity on an X-ray plate.

An observation technique dependent on retrograde axonal flow has been used extensively to demonstrate the origin of fibre tracts. In this technique, the enzyme peroxidase is taken up by axon terminals and is transported up the axon to the soma, where it can be shown by appropriate staining.

The staining of neurotransmitter substances is possible in postmortem human material as well as in animals and is an important method. Success, however, is dependent on examining relatively fresh or frozen material, and results may be greatly affected by previous treatment with neurologically active drugs.

Electrical stimulation of a region of the nervous system gives rise to the generation of nerve impulses in centres receiving input from the site of stimulation. This method, using microelectrodes, has been widely used in animal studies. The precise path followed by the artificially generated impulse may be difficult to establish.

Receptors

Receptors are biological transducers, converting the various kinds of energy they receive from the external and internal environments into electrical impulses. They are of many kinds and are classified in many ways. Steady-state receptors, for example, generate impulses as long as a particular state such as temperature remains constant. Changing-state receptors, on the other hand, respond to variation in the intensity or position of the stimulus. Receptors are also classified as exteroceptive (reporting the external environment), interoceptive (sampling the environment of the body itself), and proprioceptive (sensing the posture and movements of the body). Exteroceptors are used for looking, listening, smelling, tasting, touching, and feeling. Interoceptors report the state of the bladder, the alimentary canal, the blood pressure, and the osmotic pressure of the blood plasma. Proprioceptors report the position and movements of parts of the body and the position of the body in space.

Classifying receptors according to stimulus

Receptors are also classified according to the kinds of stimulus to which they are sensitive. Chemical receptors, or chemoreceptors, are sensitive to substances taken into the mouth (taste or gustatory receptors), inhaled through the nose (smell or olfactory receptors), or found in the body itself (detectors of glucose or of acid–base balance in the blood). Receptors of the skin are classified as thermoreceptors, mechanoreceptors, and nociceptors—the last being sensitive to stimulation that is noxious, or likely to damage the tissues of the body.

Thermoreceptors of the skin are of two kinds, warmth and cold. Warmth fibres are excited by rising temperature and inhibited by falling temperature, and cold fibres respond in the opposite manner.

Mechanoreceptors in the skin are also of several different

types. Sensory nerve terminals around the base of hairs are activated by very slight movement of the hair, but they rapidly adapt to continued stimulation and stop firing. In hairless skin there are both rapidly and slowly adapting receptors. These can provide information about the force of mechanical stimulation. The Pacinian corpuscles, elaborate structures found in the skin of the fingers but also in other organs, are layers of fluid-filled membranes forming structures just visible to the naked eye at the terminals of axons. The precise function of the corpuscles is not fully known, but they are probably activated by rapidly changing or alternating stimuli such as vibration.

In some places receptors are massed together to form a sense organ, such as the eye or ear. At other places they are scattered, as are those of the skin and viscera. Receptors are connected to the central nervous system by afferent nerve fibres. The region or area in the periphery from which a neuron within the central nervous system receives input is called its receptive field. Receptive fields are changing and not fixed entities.

All receptors report two features of stimulation, its intensity and its site. Intensity is signaled by the frequency of nerve impulse discharge in a neuron and also by the number of afferent nerves reporting the stimulation. As the strength of a stimulus increases, the change in electrical potential of the receptor increases, and the frequency of nerve impulse generation likewise increases. (The relationship between the magnitude of the receptor potential and the frequency of nerve impulse generation is discussed above; see *Form and function of nervous systems.*)

Locating stimuli with multiple receptors

The location of a stimulus, whether in the environment or in the body, is readily resolved by the nervous system. Localization of stimuli in the environment depends to a great extent on having pairs of receptors, one on each side of the body. For example, people in early childhood learn that a loud sound is probably coming from a nearer source than a weak sound. They localize the sound by noticing the difference in intensity and the minimal difference in time of arrival at the ears, increasing these differences by turning the head.

Localization of a stimulus on the skin depends upon the arrangement of nerve fibres in the skin and in the deep tissues beneath the skin, as well as upon the overlap of receptive fields. Most mechanical stimuli indent the skin, stimulating nerve fibres in the connective tissue below the skin. Any point on the skin is supplied by at least three, and sometimes up to 40, nerve fibres, and no two points are supplied by precisely the same pattern of fibres (Figure 27).

Finer localization is achieved by what is called surround inhibition. In the retina, for example, there is an inhibitory area around the excited area. This mechanism accentuates the excited area, making it stand out. There can also be a mechanism called surround excitation, in which a central area is inhibited and the surrounding area excited. In both cases contrast is brought out and discrimination sharpened.

From P.W. Nathan, *Nervous System*, 2nd ed. (1982); Oxford University Press

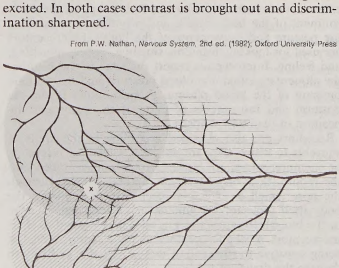

Figure 27: Diagram illustrating how a single point (x) on the skin is supplied by at least three nerve fibres.

In seeking information about the environment, the nervous system presents the most sensitive receptors to a stimulating object. At its simplest, this action is reflex. In the retina is a small region about the size of a pinhead, called the fovea, which is particularly sensitive to colour. When a part of the periphery of the visual field is excited, a reflex movement of the head and eyes focuses the light rays upon that part on the fovea. A similar reflex turns the head and eyes in the direction of a noise. As the English physiologist Charles Sherrington said in 1900, "In the limbs and mobile parts, when a spot of less discriminative sensitivity is touched, instinct moves the member, so that it brings to the object the part where its own sensitivity is delicate. . . ."

Reflex actions

Of the many kinds of neural activity, there is one simple kind in which a stimulus leads to an immediate action. This is reflex activity. The word reflex was introduced into biology by a 19th-century neurologist, Marshall Hall, who fashioned the word from Latin *reflexus* ("reflection") because he thought of the muscles as reflecting a stimulus much as a wall reflects a ball thrown against it. By reflex, Hall meant the automatic response of a muscle or several muscles to a stimulus that excites an afferent nerve. The word is now used to mean a certain kind of inborn central nervous activity, not involving consciousness, in which a particular stimulus, by exciting an afferent nerve, produces a stereotyped, immediate response of muscle or gland. If the same activity involves consciousness, it is not categorized as a reflex.

Reflex as unconscious activity

The anatomical pathway used in a reflex is called the reflex arc. It consists of an afferent (or sensory) nerve, usually one or more interneurons within the central nervous system, and an efferent (motor, secretory, or secretomotor) nerve. (For detailed description of the structures making up the reflex arc, see above *Anatomy of the human nervous system: The central nervous system.*)

Most reflexes have several synapses in the reflex arc. The stretch reflex is exceptional in that, with no interneuron in the arc, it has only one synapse between the afferent nerve fibre and the motor neuron (see below *Movement: The regulation of muscular contraction*). The flexor reflex, which removes a limb from a noxious stimulus, has a minimum of two interneurons and three synapses.

Probably the best-known reflex is the pupillary light reflex. If a light is flashed near one eye, the pupils of both eyes contract. Light is the stimulus, impulses reach the brain via the optic nerve, and the response is conveyed to the pupillary musculature by autonomic nerves that supply the eye.

Another ocular reflex is the lacrimal reflex. When something irritates the conjunctiva or cornea of the eye, nerve impulses pass along the trigeminal nerve and reach the midbrain. The efferent limb of this reflex arc is autonomic and mainly parasympathetic. These nerve fibres stimulate the lacrimal glands of the orbit, causing the outpouring of tears. Other reflexes of the midbrain and medulla oblongata are the cough and sneeze reflexes. The cough reflex is set off by an irritant in the trachea and the sneeze reflex by one in the nose. In both, the reflex response involves many muscles; this includes a temporary diversion of respiration from its usual biochemically ordered function in order to expel the irritant.

The first reflexes develop in the womb. By seven and a half weeks after conception, the first reflex can be observed: stimulation around the mouth of the fetus causes the lips to be turned toward the stimulus. By birth, sucking and swallowing reflexes are ready for use. Touching the baby's lips induces sucking, and touching the back of its throat induces swallowing.

Sensitization and habituation

Although the word stereotyped is used in the above definition, this does not mean that the reflex response is invariable and unchangeable. When a stimulus is repeated regularly, two changes occur in the reflex response—sensitization and habituation. Sensitization is an increase in response; in general it occurs during the first 10 to 20 responses. Habituation is a decrease in response; it contin-

ues until, eventually, the response is extinguished. When the stimulus is irregularly repeated, habituation does not occur or is minimal.

There are also long-term changes in reflexes, which may be seen in experimental spinal cord transections performed on kittens. Repeated stimulation of the skin below the level of the lesion, such as rubbing the same area for 20 minutes every day, causes a change in latency (the interval between the stimulus and the onset of response) of certain reflexes, with diminution and finally extinction of the response. Although this procedure takes several weeks, it shows that, with daily stimulation, one reflex response can be changed into another. Repeated activation of synapses increases their efficiency, causing some kind of lasting change. When this repeated stimulation is stopped, the reflex responses return to their original form, for there is a regression of synaptic function with disuse.

Although a reflex response is said to be rapid and immediate, some reflexes, called recruiting reflexes, can hardly be evoked by a single stimulus. Instead, they require increasing stimulation to induce the response. The reflex contraction of the bladder, for example, requires an increasing amount of urine to stretch the muscle and to obtain muscular contraction.

Reflexes can be changed by impulses from higher levels of the central nervous system. For example, the cough reflex can be suppressed easily, and even the gag reflex (the movements of incipient vomiting resulting from mechanical stimulation of the wall of the pharynx) can be suppressed with training.

The so-called conditioned reflexes are not reflexes at all but complicated acts of learned behaviour. Salivation is one such conditioned reflex. It occurs only when the person is conscious of the presence of food or when he imagines food.

Movement

Every movement of the body has to be correct for force, speed, and position. These aspects of movement are continuously reported to the central nervous system by receptors sensitive to the position, posture, equilibrium, and internal conditions of the body. These receptors are called proprioceptors, and those proprioceptors that keep a continuous report on the position of the limbs are the muscle spindles and tendon organs. (Proprioceptors reporting acceleration and direction of movement are located in the vestibular apparatus of the inner ear. For detailed discussion, see below *The vestibular system.*)

Forty-five percent of the weight of an adult male consists of muscle. The muscles of the trunk and limbs are known as skeletal muscles; they are attached to bones and produce movement at the joints. Skeletal muscles are innervated by efferent motor nerves and sometimes by efferent sympathetic and parasympathetic nerves. Muscles of the viscera (alimentary canal and bladder, for example) are called smooth muscle; they are innervated by efferent sympathetic and parasympathetic nerves.

The movements of the body are brought about by the harmonious contraction and relaxation of selected muscles. Contraction occurs when nerve impulses are transmitted across the neuromuscular junctions to the membrane covering each muscle fibre. Most of the muscles of the body are not continually contracting but are kept in a state ready to contract. The slightest movement or even the intention to move results in widespread activity of the muscles of the trunk and limbs.

Movements may be intrinsic to the body itself and carried out by muscles of the trunk and body cavity. Examples are those involved in breathing, swallowing, laughing, sneezing, urinating, and defecating. Other movements relate the body to the environment, either for moving or for signaling to other individuals. These are carried out by skeletal muscle.

Controlling movement at several levels of the nervous system

Movements can be organized at several levels of the nervous system. At the lowest level are movements of the viscera, some of which do not involve the central nervous system, being controlled by neurons of the autonomic nervous system within the viscera themselves.

At the next level is the spinal cord. If the spinal cord is cut across so that no nerve impulses reach it from the brain, certain movements of the trunk and limbs below the level of the injury can still occur. This state is called paraplegia; if the damage to the cord is above the upper limbs, it is called quadriplegia. Immediately after the cord has been divided, there is a state called spinal shock, when no movements of the skeletal muscles can be induced. Weeks or months later the period of shock passes and movements return. They are not commanded by the brain, however, and they are greatly augmented—that is, uncontrolled reflex movements may continue for minutes or hours, one reflex following another.

At a higher level, respiratory movements are controlled by the lower brain stem. The upper brain stem controls muscles of the eye, the bladder, and basic movements of walking and running. At the next level is the hypothalamus. It commands certain totalities of movement, such as those of vomiting, urinating and defecating, and curling up and going to sleep.

At the highest level is gray matter of the cerebral hemispheres, both the cortex and the subcortical basal ganglia. This is the level of conscious control of movements.

The natural phenomena included in movement cannot be neatly classified. The categories given above do not include some essential contributions, such as the influence of the cerebellum, occurring at every level. (P.W.N.)

THE REGULATION OF MUSCULAR CONTRACTION

Only a minority of the nerve fibres supplying a muscle are the ordinary motor fibres that actually make it contract. The rest are either afferent sensory fibres telling the central nervous system what the muscle is doing, or they are specialized motor fibres regulating the behaviour of the sensory nerve endings. If the constant feedback of proprioceptive information from the muscles, tendons, and joints is cut off, movements can still occur, but they cannot be adjusted in the face of external disturbances or readily modified to suit changing conditions; nor can new motor skills be developed. As stated above, the sensory receptors chiefly concerned with body movement are the muscle spindles and the tendon organs. The muscle spindle is vastly more complicated than the tendon organ, so that although it has been much more intensively studied, it is less well understood.

The simple knee-jerk reflex

The muscle spindle. The familiar knee jerk, tested routinely by physicians, is a spinal reflex in which a brief, rapid stretch excites muscle spindle afferent neurons, which then excite the motor neurons of the stretched muscle via a single synapse in the spinal cord. In this simplest of reflexes, which is not transmitted through interneurons of the spinal cord, virtually all the delay (approximately 0.02 second) occurs in the conduction of impulses to and from the spinal cord.

Information provided by muscle spindles is also put to elaborate use by the cerebellum and the cerebral cortex in ways that continue to elude detailed analysis. One example is kinesthesia, or the subjective sensory awareness of the position of limbs in space. It might be supposed (as it long was) that sensory receptors in joints, not the muscles, provide kinesthetic signals, since people are very aware of joint angle and not at all of the length of the various muscles involved. In fact, kinesthesia depends largely upon the integration within the cerebral cortex of signals from the muscle spindles.

Figures 28A and 28B are drawings of the tendon organ and muscle spindle made at the beginning of the 20th century with the aid of a light microscope. The tendon organ consists simply of an afferent nerve fibre that terminates in a number of branches upon slips of tendon where the tendons join onto muscle fibres. By lying in series with muscle, the tendon organ is well placed to signal muscular tension. In fact, the afferent fibre of the tendon organ has proved to be sufficiently sensitive to give a useful signal on the contraction of a single muscle fibre. In this way tendon organs provide a continuous flow of information on the level of muscular contraction.

The muscle spindle is much larger and more complicated; moreover, new features of its structure and function

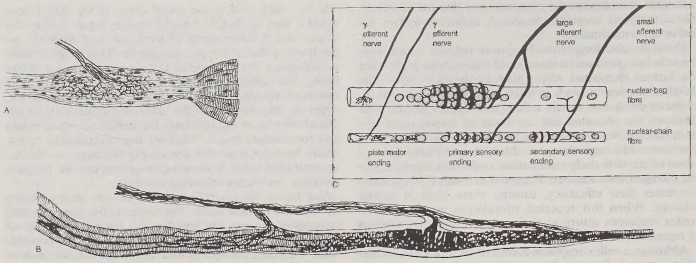

Figure 28: (A) The tendon organ as drawn in 1909 by the Spanish biologist Santiago Ramón y Cajal. The nerve fibre terminates on a tendon, with muscle fibres lying to the right. (B) The muscle spindle as drawn in 1898 by the Italian anatomist Angelo Ruffini, illustrating three types of nerve terminal—primary sensory endings, secondary sensory endings, and motor plates. (C) Simplified modern diagram of the central region (about one millimetre) of the muscle spindle. Two types of intrafusal fibre, the nuclear-bag and nuclear-chain, are shown, each having a distinct motor supply and different relationship to the two kinds of sensory ending. A given muscle spindle contains two to three bag fibres and four to six chain fibres.

From (A) S.R. Cajal, *Histologie du système nerveux de l'homme et des vertébrés* (1909), vol. 1, Maloine, Paris; (B) A. Ruffini, *Journal of Physiology* (1898), Physiological Society of Great Britain; (C) P.B.C. Matthews, *Physiological Review* (1964), The American Physiological Society

continue to be discovered. Within it are several specialized muscle fibres, known as intrafusal muscle fibres (from Latin *fusus*, "spindle"). The spindle is several millimetres long, and the approximately five intrafusal muscle fibres run throughout its length. They are considerably thinner and shorter than the ordinary skeletal muscle fibres, though they show similar contractions and have the same histological appearance. The characteristic central swelling of the spindle (giving it a shape reminiscent of the spindle of a spinning wheel) is produced by fluid contained in a capsule surrounding the central millimetre of the intrafusal fibres. Figure 28C illustrates this central region.

Sensory receptors of the muscle spindle

Classically, the nerve terminals are considered to be of three kinds, namely primary sensory endings, secondary sensory endings, and plate motor endings. There are approximately equal numbers of primary and secondary sensory endings, so that they may be considered equally important. However, the primary, or annulo-spiral, ending has traditionally attracted the most attention, largely through its prominent appearance and the simplicity of its chief reflex action, the tendon jerk. It consists of a large axon, which branches to wind spirals around the equatorial region of every intrafusal fibre. The secondary ending is supplied by a smaller axon. It has less dramatic "flower spray" terminals lying mostly upon the smaller intrafusal fibres to one side of the primary ending. The reflex actions of the secondary ending remain incompletely understood. The plate motor endings lie toward the ends of the intrafusal fibres. They are fairly similar to the ordinary motor end plates of the skeletal, or extrafusal, muscle fibres.

Two separate types of intrafusal muscle fibre are distinguished, both histologically and on their contractile properties, as nuclear-bag and nuclear-chain intrafusal fibres. These have since been further subdivided and the complexities multiply, but there is general agreement that just as the spindle has a dual afferent innervation, it also has a dual motor supply.

The working of this elaborate piece of biologic machinery is not yet fully understood. The muscle spindle lies "in parallel" with the main muscle fibres and so sends a signal whenever the muscle changes its length. Both types of sensory endings increase their discharge of impulses when the muscle is stretched and reduce their firing when the muscle is slackened. The primary ending differs from the secondary ending in two important respects: first, it is much more sensitive to changing length of the muscle; second, it is much more sensitive to small stimuli than large ones. Together, these properties explain the exquisite sensitivity of the primary sensory ending to the stimulus of a tendon tap, which has little effect on the secondary ending or on the tendon organ. The essential principle is that the ability of the muscle spindle to signal a wide range of movement is increased by its having two separate output channels of different sensitivity.

Motor endings of the muscle spindle

The motor supply of the muscle spindle is more complex. Most of the intrafusal fibres receive specialized fusimotor nerve fibres. These are much smaller than the motor axons innervating extrafusal muscle fibres and are given the name gamma (γ) efferents. As their sole function is to regulate the behaviour of the muscle spindles, their stimulation produces no significant contraction of the muscle as a whole. The γ efferents are of two functionally distinct kinds with different effects on the afferent fibres—especially on the primary ending. One type, the dynamic fusimotor axon, increases the normal sensitivity of the primary ending to movement; the other type, the static fusimotor axon, decreases its sensitivity, making it behave much more like a secondary ending. Thus, the two types of efferent fibre provide a means whereby the sensitivity of the muscle spindle to external stimuli may be regulated over a very wide range. Stimulation of both types also increases the rate of firing of the afferent fibres when the length of the muscle is constant; this is called a biasing action. It is believed that they produce these different effects by supplying different types of intrafusal fibre.

In addition to receiving specialized fusimotor fibres, the muscle spindle may also receive, though on a less regular basis, branches of the ordinary extrafusal motor axons. Called alpha (α) efferents, these fibres have either a static or dynamic effect. The physiologically important point is that most of the motor supply to the muscle spindles is largely independent of that of the ordinary muscle fibres, and only a small part is obligatorily coupled with them. The specific mechanisms by which the sensitivity of the spindle is regulated remain obscure; they may differ from muscle to muscle and for movements of different kinds.

Stretch reflexes including antagonistic muscles

Stretch reflexes. The primary afferents are responsible for the stretch reflex, in which pulling the tendon of a muscle causes the muscle to contract. As noted above, the basis for this simple spinal reflex is a monosynaptic excitation of the motor neurons of the stretched muscle. At the same time, however, motor neurons of the antagonist muscle (the muscle that moves the limb in the opposite direction) are inhibited. This action is mediated by an inhibitory interneuron interposed between the afferent neuron and the motor neuron. These reflexes have a transitory, or phasic, action, even though the afferent impulses continue unabated; this is probably because they become submerged in more complex delayed reflex responses elicited by the same and other afferent inputs.

Traditionally, it was thought that the stretch reflex provided uniquely for the automatic reflex control of stand-

ing, so that if the body swayed, then the stretched muscle would automatically take up the load and the antagonist would be switched off. This is now recognized to be only part of the process, since more powerful, slightly delayed reflex responses occur not only in the stretched muscle but also in others that help restore balance but have not themselves been stretched. Some of these late responses seem to be spinal reflexes, but in humans, with their huge brains, there is evidence that certain others are transcortical reflexes, in which the afferent impulse is transmitted at high speed up to the motor areas of the cerebral cortex to influence the level of ongoing voluntary motor impulses.

(P.B.C.M.)

THE BASIC ORGANIZATION OF MOVEMENT

Reciprocal innervation. Any cold, hot, or noxious stimulus striking the skin of the foot contracts the flexor muscle of that limb, relaxes the extensor muscles of the same limb, and extends the opposite limb. The purpose of these movements is to remove one limb from harm while shifting weight to the opposite limb. That is the first and immediate response, but a slower and longer-lasting reflex response is also possible. For example, noxious stimulation of the deep tissues of the limb can cause a prolonged discharge of impulses conducted by nonmyelinated afferent fibres to the spinal cord. The result is prolonged flexion of the damaged limb or at least a pattern of posture and movement favouring flexion. These effects last far longer than the original discharges from the afferent neurons of the damaged region—often continuing not for minutes but for weeks or months.

The flexor and extensor reflexes are only two examples of the sequential ordering of muscular contraction and relaxation. Underlying this basic organization is the principle of reciprocal innervation—the contraction of one muscle or group of muscles with the relaxation of muscles that have the opposite function. In reciprocal innervation, afferent nerve fibres from the contracting muscle excite inhibitory interneurons in the spinal cord; the interneurons, by inhibiting certain motor neurons, cause an antagonist muscle to relax.

Reciprocal innervation can be seen in eye movements. On looking to the right, the right lateral rectus and left medial rectus muscles contract, while the antagonist left lateral rectus and right medial rectus muscles relax. One eye cannot be turned without turning the other eye in the same direction (except in the movement of convergence, when both eyes turn medially toward the nose in looking at a near object).

Reciprocal innervation does not underlie all movement. For example, in order to fix the knee joint, antagonist muscles must contract simultaneously. Indeed, in the movement of walking, there are both reciprocal innervation and simultaneous contraction of different sets of muscle. Because this basic organization of movement takes place at lower levels of the nervous system, the training of skilled movements such as walking requires the suppression of some lower-level reflexes as well as a proper arrangement of the reciprocal inhibition and simultaneous contraction of antagonist muscles.

Posture. Posture is defined as the position and carriage of the limbs and the body as a whole. Except when lying down, the first postural requirement is to counteract the pull of gravity. This is done by the stretch reflexes. Gravity pulls the body—every part of the body—toward the ground. This force induces stretch reflexes to keep the lower limbs extended and the back upright. The muscles are not kept contracting all the time, however. As the posture alters and the centre of gravity changes, different muscles are stretched and contracted. Another important reflex is the extensor thrust reflex of the lower limb. Pressure on the foot stretches the ligaments of the sole, which causes reflex contraction of both flexor and extensor muscles, making the leg into a rigid pillar. As soon as the sole of the foot leaves the ground, the reflex response ceases, and the limb is free to move again.

The body is balanced when the centre of gravity is above the base formed by the feet. When the centre of gravity moves outside this base, the body starts to fall and has to bring the centre back to the base. Striding forward in walking depends on leaning forward so that the centre of gravity moves in front of the feet. When a baby is learning to walk, he must either take a step forward or fall down. Both happen; eventually the former happens more frequently than the latter.

Unconscious adjustment of posture

In addition to continuous postural adjustment for the changing centre of gravity, all movements require that certain parts of the body be fixed so that other parts can be supported as they move. For instance, when manipulating objects with the fingers, the forearm and arm are fixed. This does not mean that they do not move; they move so as to support the fine movements of the fingers. This changing postural fixation is carried out automatically and unconsciously. Before any movement is carried out, the essential posture is arranged and continues to be adjusted throughout the movement.

LOWER-LEVEL MECHANISMS OF MOVEMENT

The success of Charles Sherrington in opening up the physiology and pathology of movement by the study of reflexes caused a lack of interest in any other concept of movement, particularly in English-speaking lands. It was the German physiologist Erich Walter von Holst who, around the mid-20th century, first showed that many series of movements of invertebrates and vertebrates are organized not reflexly but endogenously. His general hypothesis was that within the gray matter there are networks of local neurons that generate alternating or cyclical patterns of movement. Von Holst proposed that these are the mechanisms of such rhythmically repeated movements as the movements of locomotion, breathing, scratching, feeding, and chewing.

In fish, von Holst demonstrated that the movements of the fins in swimming that need careful and correct timing and coordination continued even after the sensory dorsal roots of the spinal cord had been cut, so that there could be no sensory input to trigger reflexes. In these animals, command neurons in the lower medulla oblongata switch on the rhythmical movement built into the spinal cord, so that even when the brain has been cut out, the motor impulses and rhythmic movements continue.

Von Holst's theory differs from previous concepts in that it attributes little or no importance to the role of feedback from the parts of the body being moved. Instead, it proposes, as the essential mechanism of repetitive movements, certain central pacemakers or oscillators. The role of feedback, according to this theory, is merely to modulate the central oscillator. This is seen in the above example of swimming movements of fish and even in purring rhythms in cats, which continue after dorsal roots have been cut.

In certain kinds of movement the input of the dorsal roots is essential, but the movement needs to be defined in every case. For example, stepping movements of certain vertebrates, of which the mechanisms are within the spinal cord, can occur only with intact dorsal roots.

Higher levels of the brain can set spinal centres in motion, can stop them, and can change the amplitude and frequency of repetitive movements. In the case of humans, when the spinal cord is cut off from the brain by disease or trauma, the movements that occur are uncontrolled. The movements of locomotion, seen in lower vertebrates, do not occur. This is because the cerebral hemispheres in humans have taken over the organization of movements that in lower species are organized at lower levels of the central nervous system, such as the reticular formation of the brain stem and the spinal cord.

Within the centre of the brain stem the reticular formation consists of vast numbers of neurons and their interconnections. The majority of them have motor functions, and many of their fibres branch. This branching means that a single fibre can affect several different levels of the spinal cord. For example, one nerve fibre may excite motor neurons of the neck and of various regions of the back. This is one way in which commands from the higher neural level are sent to several segments of the spinal cord.

The movements of breathing are instigated and regu-

Regulation of rhythmic movement

lated by chemoreceptors in blood vessel walls, which sense carbon dioxide tension in the blood plasma. The essential drive or central rhythm generator consists of pacemaker neurons in the reticular formation of the pons and throughout the medulla oblongata. These neurons show rhythmic changes in electrical potential, which are relayed by reticulospinal tracts to the spinal neurons concerned with respiration. When this pathway is severed, breathing ceases.

Other movements intrinsic to the body are those needed for urination and defecation. Cats and dogs from which the cerebral cortex has been removed urinate and defecate in a normal manner. This is because nuclei in the midbrain near those that organize the movements of locomotion control these movements, so that urination and defecation occur whenever there are enough waste products to be expelled. This is also the condition of the healthy baby animal. But as the infant grows up, it learns to fit these events into the social circumstances of living, and this requires higher-level control by the cerebral hemispheres.

HIGHER-LEVEL MECHANISMS OF MOVEMENT

Because of the many differences in the movements used in standing, coughing, or laughing, or playing a scale on the piano, it is convenient to think of movements as lower and more automatic or as higher and less automatic. According to this concept, movements are not placed in totally different categories but are regarded as different in degree.

Cerebral hemispheres. Basic organizations of movement, such as reciprocal innervation, are organized at levels of the central nervous system lower than the cerebral hemispheres—both at the spinal and brain-stem level. Examples of brain-stem reflexes are turning of the eyes and head toward a light or sound. The same movements, of course, can also be organized consciously when one decides to turn the head and eyes to look. The cerebral hemispheres themselves can organize certain series of movements that are often referred to as programmed movements. These are movements that need to be performed so rapidly that there is no time for correction of error by local feedback. For this reason the program is arranged before the movements begin. Examples of such movements are those of a pianist performing a trill or of an athlete hitting a ball.

Most of the movements organized by the cerebral cortex are carried out automatically. But when a new series of movements is being learned, or when a movement is difficult, the attributes usually associated with the higher levels of the brain—such as planning, internal speech, remembering, and learning—are used. (For the role of the cerebral hemispheres in these higher mental activities, see below *Higher cerebral functions.*)

Motor areas of the brain

In the 19th century the first motor area of the cerebral cortex was discovered by electrical stimulation. Successive areas responding to electrical stimulation were numbered in the order of their discovery. Therefore, although motor and sensory areas are named numerically, no hierarchical organization is implied.

The first motor area to be discovered was the motor strip of the precentral gyrus; it became known as the primary motor area (Figure 29). Immediately behind it is the postcentral gyrus, found on electrical stimulation to be sensory; it was named the primary sensory area. Each of these areas displays a maplike correspondence with various body parts, the legs represented near the top of the hemispheres and the arms and face lower on the cortical surface. Each of these areas is to some extent both motor and sensory. The motor region, for example, receives inputs from the skin, joints, and muscles via the postcentral gyrus behind and the thalamus below.

Experiments in monkeys have shown that the motor strip is able to arrange activity of muscles to produce the correct force for the loading conditions of the limbs. To do this, it continually receives information from the primary sensory area both before and during the movement. Cutaneous areas having the greatest tactile acuity have the largest representative in the primary sensory area; these areas are connected to equally large areas in the primary motor area.

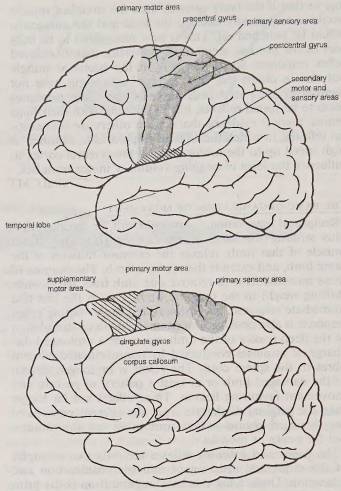

Figure 29: (Top) Lateral and (bottom) medial views of the cerebral hemispheres, showing motor and sensory areas.

Reproduced by permission of Catherine Parker Anthony and Gary A. Thibodeau, *Textbook of Anatomy & Physiology*, 12th ed. (1987), Times Mirror/Mosby College Publishing, St. Louis, adapted from K. Brodmann, "Feinere Anatomie des Grosshirns," in *Handbuch der Neurologie* (1910), Springer-Verlag, Berlin

In front of the motor strip is an area known as the premotor cortex or area. When this area is stimulated in a monkey, the animal turns its head and eyes as though it is looking in a particular direction. This cortical area, then, organizes the guiding of movements by vision and hearing.

An area labeled the secondary motor area is at the lower end of the precentral gyrus. It is secondary not only because it was discovered after the primary motor area but also because it does not function in a discrete manner like the primary area. Stimulation of this small area produces movements of large parts of the body. It is also a sensory area, as sensations in the parts of the body being moved are felt during stimulation.

The supplementary motor area

On the medial surface of the hemisphere, in front of the motor strip, is the supplementary motor area. Stimulation there can produce vocalization or can interrupt speech. There also may be large movements of both sides of the body—often symmetrical movements of the two limbs. Stimulation also produces movements of the opposite side, such as raising the upper limb and turning the head and eyes as if looking at something opposite. In experiments on monkeys, when the animal chooses to respond to one kind of sensation rather than to another, it is the supplementary area that is active rather than the precentral area. In this animal—it is unknown for humans—the fibres descending from the supplementary motor area run to the spinal cord and terminate throughout its whole length. Fibres are also sent to the precentral gyri of both hemispheres, the reticular formation of the pons, the hypothalamus, the midbrain, and many other masses of cerebral gray matter such as the caudate nucleus and the globus pallidus. The supplementary motor area is upstream from the primary motor area; it initiates movements, whereas the motor strip of the precentral gyrus is part of the apparatus for carrying them out.

Other regions of the cerebral hemisphere from which movements are produced on electrical stimulation are the insula and the surface of the temporal lobe. Stimulation of the anterior end of one temporal lobe causes movements of the head and body toward the other side. The insula

is a region below the frontal and temporal lobes hidden from the surface; stimulation there causes movements of the face, larynx, and neck.

Fibres from the anterior part of the cingulate gyrus are involved in the control of urination and defecation. The organization of these functions also depends on regions anterior to the cingulate gyrus in the medial wall of the frontal lobe. These regions form a part of the limbic lobe, which is responsible for some emotional states with their autonomic components.

Movements closely guided by vision have their own pathways. Occipital visual areas send fibres to the pons and from there to the cerebellum. Also just in front of the visual cortex in the parietal lobe are neurons organizing certain types of eye movement. In the monkey, these neurons are at rest during steady gaze, becoming active when the animal turns its eyes to look at something. That the movements constitute a high level of motor behaviour is shown by the activation of these neurons only when the animal is attempting to satisfy an appetite by using its upper limbs and hands; using the limbs for other purposes does not activate them. The neurons are also active when the animal is carrying out the movements of grooming, which also satisfies an innate drive.

One of the main pathways for cortically directed movement of the limbs is the corticospinal tract. This tract developed among animals that used their forelimbs for exploring and affecting the environment as well as for locomotion. It is largest in man. Fibres of the tract go to various regions of the brain stem and the spinal cord that organize movement. Excitation via the corticospinal tract is then brought to many muscles, all of them presumably working together in a coordinated manner. This is achieved by the anatomical arrangement of the motor neurons and by the termination of the corticospinal tract on interneurons, which convey a coordinated pattern of stimulation to the motor neurons.

The corticospinal tract is not merely a straight pathway to medullary and spinal motor neurons. Activity in this tract can suppress the input from cutaneous areas while facilitating proprioceptive input. This is probably a mechanism important in the organization of movement. The corticospinal neurons themselves receive constant input needed for internal feedback. This input comes from the cerebellum, much of it having originated in the muscles, joints, and skin of the body parts being moved.

The control of complex movement through sensory feedback

Cerebellum. Although a cycle of simple repetitive movements can be organized without sensory feedback, more sophisticated movements require feedback as well as what is called feed-forward control. This is provided by the cerebellum. Many parts of the brain have to be kept informed of movements being carried out in order to detect error and continually correct the movement. The cerebellum continuously receives inputs from the trunk, limbs, eyes, ears, and vestibular apparatus, maintaining in turn a continuous transfer of information to the motor parts of the thalamus and to the cerebral cortex.

As a movement is being prepared, a replica of the instructions is sent to the cerebellum; the cerebellum sends back its own information to the cortex. The cortex, meanwhile, sends information about the movement to various afferent neurons that are about to receive information from receptors in the body parts where the movement is about to begin. This comparison between instructions sent and movement performed is a fundamental requirement of all complicated movement. The discharge of impulses from motor to sensory regions is called the corollary discharge. The mechanisms involving the cerebellum do not come to consciousness. There are no sensory consequences of damage to the cerebellum, for the cerebellum is a motor structure.

As series of movements are learned and improved with practice, a replica of the movement is probably retained in the cerebral hemispheres. (The mechanisms of this postulated "replica" are as yet unknown.) Whenever the learned movements are repeated, they are formed and guided by the replica. This hypothesis of controlling movement by previously practiced patterns was developed by von Holst. He gave the name efference to the totality of motor impulses necessary for a movement, and he proposed that whenever the efference is produced it leaves an image of itself somewhere in the central nervous system. This image he called the efference copy. According to von Holst's theory, as the movement is repeated, afferent impulses return to the brain from receptors activated by muscular activity. These impulses are called the re-afference. There is then a comparison between the efference copy and the re-afference. When they are identical, the movement is "correct" in relation to its previous performance. When the re-afference differs from the efference copy, corrections have to be made so as to bring the present pattern of movement back to the original image left in the brain.

If the cerebellum is damaged or degenerates, any error between the movement being performed and the efference copy will no longer be corrected, and the postural adjustments sent from the cerebral hemispheres will no longer be implemented. The force and extent of movements also will be abnormal, the movement going too far or not far enough. The various muscles may not come into play at the right time, and there will be a disturbance in the relationship of antagonist muscles, so that the accurate arrival on target will be replaced by oscillation.

Basal ganglia. Most of what is known about the contribution of the basal ganglia has been obtained from studying abnormal conditions that occur when these nuclei are affected by disease. In Parkinson's disease there is a loss of the pigmented neurons of the substantia nigra, which release the neurotransmitter dopamine at synapses in the basal ganglia. Patients with this disease have a certain type of muscle stiffness called rigidity, a typical tremor, flexed posture, and difficulty in maintaining equilibrium. They have difficulty in starting movements, including walking, and they cannot put adequate force into fast movements. They have particular difficulty in changing from one movement to its opposite, in carrying out two movements simultaneously, and in stopping one movement while starting another.

The organization of posture, which is based on vestibular, proprioceptive, and visual input to the globus pallidus, is severely damaged when this region of the basal ganglia degenerates. As a changing posture of the various parts of the body is a prerequisite of every movement, this factor alone upsets all movement. Visual reflexes contributing to motion also act through the globus pallidus. When this structure is degenerate, what the patient sees may affect his ability to move. One patient may be unable to go forward if he has to pass through a narrow door, another may not be able to do so if he has to go into a wide expanse like a field. (P.W.N.)

The vestibular system

Animals have evolved sophisticated sensory receptors to detect features of the environment in which they live. In addition to the special senses such as hearing and sight, there are unobtrusive sensory systems such as the vestibular system, which is sensitive to acceleration.

Linear and angular acceleration

Acceleration can be considered as occurring in two forms—linear and angular. One familiar type of linear acceleration is gravity. Because this environmental feature, unlike any other encountered by an organism, is always present, highly sophisticated systems have developed to detect gravity and enable an animal to maintain its position relative to the earth. A common form of angular acceleration is that induced by rotation, such as a turning of the head. Through the vestibular apparatus these forces are detected and appropriate motor activities are organized to counter the postural perturbations that they induce.

RECEPTORS

The vestibular sensory organ is a paired structure located symmetrically on either side of the head within the inner ear. Inside each end organ are the hair cells, the detection units for both linear and angular acceleration. Extending from one surface of each hair cell are fine, hairlike cilia, displacement of which alters the electrical potential of the cell. Bending the cilia in one direction causes the cell membrane to depolarize while hyperpolarization is

induced by movement in the opposite direction. Changes in membrane potential induce alteration in the firing of nerve impulses by the afferent neurons supplying each hair cell. (For a discussion of the neurobiology of depolarization and hyperpolarization of cell membranes, see above *Form and function of nervous systems: Transmission of information in the nervous system.*)

The two types of acceleration are detected by two types of vestibular end organ. Linear acceleration is sensed by a pair of organs—the saccule and utricle—while there are three receptor organs—called semicircular canals—in each vestibular apparatus for the detection of angular acceleration.

Saccule and utricle. Each saccule and utricle has a single cluster, or macula, of hair cells located in the vertical and horizontal planes, respectively. Resting upon the hair cells is a gelatinous membrane in which are embedded calcareous granules known as otoliths. Changes in linear acceleration alter the pressure of the otoliths, causing changes in the distortion of the cilia and providing an adequate stimulus for membrane depolarization. Within each macula the hair cells are arranged in two groups oriented in opposite directions, so that the receptor functions in a push-pull fashion within each organ. Since many of the nerve fibres passing from the hair cells to the brain are constantly active, this push-pull arrangement makes the receptors a highly sensitive detection system for linear acceleration in the vertical and horizontal planes.

Semicircular canals. The angular acceleration detectors within the semicircular canals function in a different way. The three canals—which in fact are considerably more than a semicircle in circumference—are oriented at approximately right angles to one another. Two are vertically placed, and one is at about 30 degrees to the horizontal. In this arrangement the anterior canal of one side of the head is in the plane of the posterior canal of the other side. A ridge, or crista, covered by sensory hair cells is located at the end of each canal within an expanded chamber called the ampulla. The canals are filled with an endolymphatic fluid. Rotation of the canals about an axis passing through the centre of each semicircle causes the fluid to flow toward or away from the crista, generating a force that bends the cilia by displacement of a gelatinous plate resting upon the hairs. The cells of the vertical canals are oriented in such a way that centrifugal movement away from the cristae depolarizes the hair cell membranes, while the converse applies to the horizontal canal.

NERVE SUPPLY

As in the case of the utricle and saccule, some of the nerve fibres conveying information from the cells are constantly active. The hair cells receive nerve impulses from the brain (via efferent fibres) and send them to the central nervous system (via afferent fibres). Excitatory efferent fibres increase the sensitivity of the hair cells, while inhibitory fibres decrease sensitivity. This system gives the semicircular canals a plasticity that is essential to maintaining optimal activity under different environmental conditions—including such extraordinary states as the microgravity encountered in space travel.

The vestibular apparatus is supplied by neurons that make up the vestibular portion of the vestibulocochlear, or eighth cranial, nerve. The somata, or cell bodies, of the afferent fibres lie in the vestibular ganglion near the end organ. Most of the nerve fibres pass from there to vestibular nuclei in the pons, while others pass directly to the cerebellum. The efferent fibres of the vestibular nerve arise from nuclei in the pons.

VESTIBULAR FUNCTIONS

For vision to be effective, the retinal image must be stationary. This can be achieved only by maintaining the position of the eyes relative to the earth and using this stable platform for pursuing a moving target. The vestibular system plays a critical part in this, mainly through complex and incompletely understood connections between the vestibular apparatus and the musculature. Rotation of the head in any direction is detected by the semicircular canals, and a velocity signal is then passed via the vestibular nuclei to the somatic and extraocular muscles. In the case of the eye muscles, the velocity signal reaching the brain stem is in some way integrated with impulses signaling the eyes' position, thus ensuring that the eyes maintain their position relative to space and the object of regard. This integration partly occurs in the vestibular nuclei, the source of secondary neurons destined for the extraocular muscle nuclei of both sides.

Vestibulo-ocular reflex. When the head is oscillated, the eyes maintain their position in space but move in relation to the head. This so-called vestibulo-ocular reflex operates in both horizontal and vertical planes, owing to the arrangement of the three semicircular canals, and it maintains such stability that the object of vision does not oscillate until quite high velocities are attained. The other component of the vestibular system, the saccule and utricle, also contributes to the vestibulo-ocular reflex. Under normal circumstances the otolith receptors cause torsional movement of the eyes. For example, tilting the head toward one shoulder results in counter-rolling of the eyes, thereby stabilizing the image upon the retina. The two components of the vestibulo-ocular reflex also interact, enabling appropriate eye movements to be generated when both linear and angular accelerations are changing.

Importance of vestibular system to posture

While the vestibulo-ocular reflex is the best understood of the vestibulo-motor connections, information from the vestibular receptors is also known to be passed via vestibular and other brain-stem nuclei to the somatic musculature of the trunk and limbs. Through these pathways body posture is adjusted to counter acceleration forces applied to the vestibule. These reflexes are so important in maintaining vertical posture that devastating short-term consequences on posture are seen if the vestibulocochlear nerve is cut.

Conscious sensation. Besides maintaining input for the generation of motor reflexes, vestibular impulses reach consciousness and create a powerful sensation. A person being rotated knows when he is accelerating even in the absence of an object upon which he can fix his eyes. This occurs because acceleration is the adequate stimulus for the semicircular canals. Similarly, information detected by the otoliths is readily brought to consciousness—as occurs, for example, when a darkened elevator accelerates up or down. The pathways to the cerebral cortex, which mediate conscious sensation, are not fully known, but there is considerable evidence that areas of the parietal and temporal lobes receive connections via the thalamus.

One important aspect of vestibular physiology is the interaction of vestibular impulses, which signal changes of position, and impulses from other sensory receptors that signal changes in bodily movement. For example, when the head turns to one side about a vertical axis, not only is the horizontal canal of that side stimulated and that of the other side inhibited, but receptors in the neck joints and muscles are also stimulated, and the retina indicates movement if fixation is not maintained perfectly. This information is fed to the brain via sensory pathways in the spinal cord and various visual sensory systems. Therefore, within the vestibular nuclei of the pons, neurons that respond to acceleration signals from the semicircular canals receive impulses from other sources as well. Other information from visual and spinal sensory systems pass to the cerebellum, which also receives direct impulses from the vestibular apparatus that bypass the vestibular nuclei. In this way the cerebellum has the opportunity to compare signals and assess the degree of mismatch between them. (Such mismatch is an unpleasant experience and is important in the phenomenon of motion sickness. Motion sickness is often generated by a mismatch between the various inputs signaling orientation within space. People will frequently be seasick if they are below decks in rough weather and the visual system signals no movement while the vestibular system indicates motion.) In another example, the vestibulo-ocular reflex may be underactive, so that for a given head movement the eyes do not deviate sufficiently within the orbit and the object of regard does not remain stationary upon the retina. Thus, the image slips and cannot be seen clearly during movement. The cerebellum has the opportunity to detect this mismatch

Motion sickness

between the required position of the eyes with respect to the environment and the movement actually achieved. Through inhibitory connections to the vestibular nuclei, the cerebellum can then adjust the vestibulo-ocular reflex so that a more appropriate movement of the eyes is achieved with the next acceleration signal. In other words, there is a continual updating of the vestibulo-ocular reflex via the cerebellum or structures associated with it.

A similar situation also obtains for somatosensory input from the spinal cord. A dramatic demonstration of short-term adaptation via the visual system occurs when someone dons prisms that reverse the perception of the environment in the horizontal plane, making everything look upside down. The person is at first unable to move about because any rotation of the head results in apparent movement of the environment in the wrong direction. However, over a few days normal mobility gradually returns. Incredibly, during this time the vestibulo-ocular reflex is at first diminished in amplitude and then is reversed. Removal of the prisms results in a rapid return to the normal state. These experiments are a powerful demonstration of the plasticity of the vestibulo-ocular reflex, which can continue functioning throughout life in spite of the various insults that befall it. (P.Ru.)

The autonomic system

The autonomic nervous system is regulated by cell groups in the brain that process visceral information arriving in specific neural networks, integrate that information, and then issue specific regulatory instructions through the appropriate autonomic outflows. Each end organ is processed in a unique way by functionally specific sets of neurons in which there is often coordination of both the sympathetic and parasympathetic nervous systems.

THE EYE

Innervating smooth muscle of the eye

In order for the eye to function properly, specific autonomic functions must maintain adjustment of four types of smooth muscle: (1) smooth muscle of the iris, which controls the amount of light that passes through the pupil to the retina; (2) ciliary muscle on the inner aspect of the eye, which controls the ability to focus vision on nearby objects; (3) smooth muscle of arteries providing oxygen to the eye; and (4) the smooth muscle of veins that drain blood from the eye and affect intraocular pressure. In addition, the cornea must be kept moist by adequate secretion from the lacrimal gland.

Light reflex. When bright light is shined into an eye, the pupils of both eyes constrict. This response, termed the light reflex, is regulated by three structures: the retina, pretectum, and midbrain. In the retina is a three-neuron circuit consisting of light-sensitive photoreceptors (rods), bipolar cells, and retinal ganglion cells. The latter transmit luminosity information to the pretectum, where particular types of neurons relay the information to parasympathetic preganglionic neurons located in the Edinger-Westphal nucleus of the midbrain. These neurons send axons out of the ventral surface of the midbrain to synapse in the ciliary ganglion. From there, parasympathetic postganglionic neurons innervate the pupillary sphincter muscle, causing constriction.

Accommodation. In order to bring a nearby object into focus, several changes must occur in both the external and internal muscles of the eyes. The initial stimulus for accommodation is a blurred visual image that first reaches the visual cortex. From there, through a series of cortical connections, it reaches two specialized motor centres. One of these, located in the frontal cortex, sends motor commands to neurons in the oculomotor nucleus controlling the medial rectus muscles; this causes the eyes to converge. The other motor centre, located in the temporal lobe, functions as the accommodation area. Via multineuronal pathways, it activates specific parasympathetic pathways arising from the ciliary ganglion. This pathway causes the ciliary muscle to contract, thereby reducing tension on the lens and allowing it to become more rounded so the visual image of the near object can be focused on the central part of the retina. Concomitant with this change is a constriction of the iris, also under control of the oculomotor parasympathetic system, that acts to enhance the resolution of the lens.

THE URINARY SYSTEM

The kidney is involved in maintenance of water and electrolyte balance. It also produces vasoactive hormones such as renin, a proteolytic enzyme that initiates the formation of angiotensin II (a potent hormone involved in the regulation of blood pressure), and erythropoietin, a glycoprotein hormone important in formation of red blood cells. While the autonomic nervous system is not crucial to these functions, the fine-tuning of some of these processes is regulated by sympathetic fibres. There is no known parasympathetic innervation of the kidney.

Innervation of the bladder

In contrast to renal functions, the normal physiology of the urinary bladder depends entirely on the autonomic nervous system. For example, retention of urine is made possible by activation of sympathetic pathways originating from lateral horns in spinal segments T_{11}–L_2; these cause contraction of smooth muscle that forms the internal urinary sphincter. Working in concert with this sphincter is the external urinary sphincter, which is made up of skeletal muscle controlled by motor fibres of the pudendal nerve. These fibres, arising from ventral horns of segments S_2–S_4, provide tonic excitation of the external sphincter. Because they are under voluntary control, micturition is initiated by higher brain centres. The first command causes voluntary inhibition of the sacral motor outflow, resulting in relaxation of the external urinary sphincter. Simultaneously, an increase in abdominal pressure, caused by contraction of muscles of the abdominal wall, starts an initial flow of urine. This is followed by a reflex inhibition of sympathetic outflow, resulting in relaxation of the internal urinary sphincter, and by activation of parasympathetic outflow to smooth muscle that causes the bladder to contract and expel the urine.

SEXUAL FUNCTIONS

The sexual response in both males and females can be defined by three physiological events. The first stage begins with psychogenic events in higher neural centres, which travel through multineuronal pathways and cause excitation of sacral parasympathetic outflow innervating vascular tissues of the penis and clitoris. This results in dilation of these arteries and erection of the penis and clitoris. The second stage involves secretion of glandular fluids; this is mediated by sympathetic neurons arising in the T_{12}–L_2 levels of the lateral horns. In the male, it involves contraction of the epididymis, vas deferens, seminal vesicles, and prostate gland, with the overall effect of moving fluids into the urethra; at the same time, sympathetic activation causes a closure of the internal urinary sphincter to prevent retrograde ejaculation of semen into the bladder. In the female, the response involves mucous secretions of the greater vestibular glands, resulting in lubrication of the vaginal orifice.

The third phase is a muscular response. Somatic efferent fibres in the pudendal nerve produce rhythmic contrac-

tions of the bulbocavernous and ischiocavernosus muscles in the male; this produces ejaculation. In the female, homologous muscles of the pelvic floor undergo rhythmic contractions controlled by somatic efferent neurons from the S_2–S_4 ventral horns.

THE ADRENAL GLANDS

The adrenal glands lie above the kidney and are therefore sometimes referred to by the older term suprarenal glands. They have a cortex and a medulla. The former synthesizes and secretes steroid hormones that are essential for life, but it is not under autonomic control. The adrenal medulla, on the other hand, is innervated by sympathetic preganglionic neurons. Within the adrenal medulla are chromaffin cells, which are homologous to sympathetic neurons and, like sympathetic neurons, are developed from embryonic neural crest cells. Chromaffin cells produce epinephrine (adrenalin) and, to a much lesser extent, norepinephrine as well as other chemicals such as chromogranins, enkephalins, and neuropeptide Y—all of which are released into the bloodstream and act as hormones. Epinephrine, in particular, affects many different types of tissues throughout the body and has a particularly potent effect on cells that possess β-adrenergic receptors.

Release of epinephrine and other chemicals

The release of epinephrine prevents hypoglycemia (low blood sugar), through the following mechanism. By binding to α_2-adrenergic receptors embedded in the hormone-releasing cells of the pancreas, epinephrine inhibits the release of insulin. Since insulin promotes the absorption of glucose from the bloodstream into liver, skeletal muscle, and fat cells, inhibition of its release results in a greater amount of glucose that is available for entry into the brain. In addition, by binding to certain β-adrenergic receptors, epinephrine stimulates the release of glucagon, a pancreatic peptide hormone that acts in the liver to convert glycogen to glucose. Under emergency conditions, epinephrine causes even more widespread effects on glucose metabolism. Glycogen in the liver and skeletal muscle is broken down to glucose, fat held in adipose cells is converted to fatty acids and glycerol, and production of glucose and ketone bodies (β-hydroxybutyric acid, acetoacetic acid) is increased in the liver. All these substances can be used as energy sources for the body.

THE CARDIOVASCULAR SYSTEM

The function of the cardiovascular system is to maintain an adequate supply of oxygen to all tissues of the body. In order to maintain this function, the autonomic system must process visceral information and coordinate neural elements that innervate the heart, blood vessels, and respiration. In addition, certain hormones such as angiotensin II and vasopressin are released and act in concert with the autonomic nervous system.

Reflex pathways. The cardiovascular system is regulated by sets of neurons that form two major types of reflex circuit. One type is triggered by mechanoreceptors found in the major arteries near the heart and in the heart itself. Lying in the wall of the aortic arch and the carotid sinuses are receptors sensitive to high pressure. These are innervated by the aortic branch of the vagus nerve and by a branch of the glossopharyngeal nerve. Both branches send information regarding increases in arterial blood pressure into the medulla oblongata and synapse in the nucleus of the solitary tract. Another group of mechanoreceptors provides information about venous pressure and volume; these are low-pressure receptors located in the walls of the major veins as they enter the heart and within the walls of the atria. Low-pressure afferents also relay sensory information to the solitary tract.

Lowering blood pressure

The mechanoreceptors described above trigger what is called the baroreceptor reflex, which causes a decrease in the discharge of sympathetic vasomotor and cardiac outflows whenever an increase in blood pressure occurs. In addition, the baroreceptor reflex causes stimulation of vagal cardioinhibitory neurons, which produces a decrease in heart rate, a decrease in cardiac contractility, and dilation of peripheral blood vessels. Overall, the net effect is to lower blood pressure.

The second major class of afferents that trigger reflex responses are chemoreceptors found in the major arteries near the heart in loci close to the high-pressure mechanoreceptors. Functioning as oxygen sensors, these receptors are innervated by separate sets of fibres that travel parallel with the baroreceptor nerves, and they also project to the nucleus of the solitary tract. Overall, the chemoreceptor reflex regulates respiration, cardiac output, and regional blood flow, ensuring that proper amounts of oxygen are delivered to the brain and heart.

Vasopressin and cardiovascular regulation. Vasopressin is a peptide hormone that is synthesized in magnocellular neurons of the supraoptic and paraventricular nuclei of the hypothalamus. These neurons send their axons into the posterior lobe of the pituitary gland, from which vasopressin is released into nearby capillaries and distributed throughout the body.

Vasopressin has two main functions: volume regulation and vasomotor tone. It acts to increase water retention by increasing the permeability of kidney tubules to water as the kidney filters blood plasma. As more water is reabsorbed, extracellular fluid volume is increased, and this in turn increases venous volume and, ultimately, blood pressure. Under emergency conditions, vasopressin also selectively constricts certain vascular beds that are nonessential for life (*e.g.*, gastrointestinal, muscle); this shunts blood to critical tissues such as the heart or brain.

Two major stimuli trigger the release of this hormone: increases in extracellular fluid osmolality and decreases in blood volume (as in hemorrhage). Osmotic stimuli cause vasopressin to be released by acting on specialized brain centres called circumventricular organs. Surrounding the third and fourth ventricles of the brain and containing neurons with central projections that alter autonomic and neuroendocrine functions, these "osmosensitive" areas possess a unique vascular system that permits diffusion of large molecules such as peptides and ions to cross readily from the plasma to the brain. Normally, such chemical agents do not have free passage because the capillaries form a blood-brain barrier, but at these special sites they have direct access to central neurons. One of the areas, called the organum vasculosum of the lamina terminalis, lies in the third ventricle and is involved in osmo- and sodium regulation. Another circumventricular organ, called the subfornical organ, lies in the dorsal part of the third ventricle; it is particularly sensitive to hormones such as angiotensin II and signals changes needed for the regulation of salt and water balance. Both regions project directly to vasopressin-producing hypothalamic neurons. The area postrema, which lies on the floor of the fourth ventricle in the medulla, is the third site involved as a special chemical sensor of the plasma.

When blood is lost through hemorrhage, atrial receptors and baroreceptors relay volume and pressure information, via the vagus nerve, into the nucleus of the solitary tract. Neurons in this nucleus send commands to other relay neurons that project directly to the magnocellular hypothalamic neurons and cause the release of vasopressin.

Pain

THEORIES OF PAIN

There have always been two theories of the sensation of pain, a quantitative or intensity theory and a stimulus-specific theory. According to the former, pain results from excessive stimulation of every kind: *e.g.*, excessive heat or cold, excessive damage to the tissues. This theory in its simplest form entails the belief that the same afferent nerve fibres are activated by all of these various stimuli; pain is felt merely when they are conducting far more impulses than usual. But knowledge acquired in the 20th century has shown that the quantitative theory—at least in its classic form—is wrong. Peripheral nerve fibres have been found to be stimulus-specific, each one excited by certain forms of energy. The stimulus-specific theory proposes that pain results from interactions between various impulses arriving at the spinal cord and brain, that these impulses are brought to the spinal cord in certain non-myelinated and small myelinated fibres, and that the spe-

cific stimuli that excite these nerve fibres are noxious, or harmful.

Special receptors for reporting pain

In the somatic tissues there are certain kinds of nerve fibre that do not give rise to pain, no matter how many there are or how frequently they are stimulated. Included in this category are mechanoreceptors that report only deformation of the skin and the larger afferent nerve fibres from muscles and tendons that form part of the organization of posture and movement. No matter how they are excited, these receptors never give rise to pain. But the smaller fibres from these tissues do cause pain when they are excited mechanically or chemically.

Warmth and cold fibres are specific. Warmth fibres are excited by rising temperature and quieted by falling temperature, and cold fibres respond similarly with cold stimuli. Although pain arises from very hot and very cold stimulation and with intense forms of mechanical stimulation, this occurs only with the activation of afferent nerve fibres that specifically report noxious events. When no noxious events are occurring, these nerve fibres are silent.

In contrast, the quantitative theory seems to apply to the viscera, where afferent nerve fibres used in reflex organization also report events giving rise to pain. In the heart, for example, the same nerve fibres are excited by mechanical stimulation as are excited by chemical substances formed in the body that cause pain. Also, in the bladder, rectum, and colon, nerve fibres activated by substances that cause pain are the same as those activated by distension and contraction of the viscera. This means that the same nerve fibres are reporting the state that underlies the desire to urinate or defecate and the sensation underlying the pain felt when these organs are strongly contracting in an attempt to evacuate their contents. In the heart, rectum, and bladder, therefore, pain appears to be due to a summation of impulses in sensory nerve fibres and is not mediated by a special group of fibres reserved for reporting noxious events. It must be pointed out, however, that not all researchers accept the argument.

LOWER-LEVEL PAIN PATHWAYS

Tissues. *Normal conditions.* Not all the tissues making up the body give rise to pain; furthermore, each tissue must be stimulated in an appropriate way to invoke its particular sensation of pain. Skin, being the outer covering of the body, easily raises the warning of pain, but other tissues that do not come in direct contact with the outer environment are just the opposite. The brain, for example, can be pierced, cut, and burned in neurosurgery, while the patient would require only local anesthesia of the pain-sensitive scalp. The lung, liver, and spleen also do not give rise to pain, no matter how they are stimulated. Pain arises from hollow viscera when the passage of their contents is obstructed and the musculature must undergo strong contraction and stretching. Pain cannot be induced by cutting or burning the wall of the intestine, but pulling on the mesenteric tissue that fixes the intestines to the posterior wall of the abdomen causes pain. The reason for these differences is clear. Tissues are sensitive to the kinds of damage they are likely to meet during life and not to those that they probably will never meet.

Although the warning function of pain is obvious, it is not equivalent to nociception, the perception of forces likely to damage the tissues of the body. First, nociception can occur without pain and pain without nociception; also, the sensation of pain is only a part of the total act of nociception. There are reflex effects as well, such as a local reflex withdrawal from a sudden noxious stimulation of the skin. There are autonomic effects, such as a rise in blood pressure, quickening of the heart rate and respiration, and other excitatory sympathetic nervous effects. There may even be shrieking or howling, warning other animals that something dangerous and painful is occurring.

Acute and chronic pain

Pathological conditions. Acute and chronic pain differ in many ways. Acute pain occurs with sudden damage, such as stepping on a nail or biting the tongue. Chronic pain is the pain of pathological conditions—the pain that accompanies gout, arthritis, inflammation, or cancer. Each type of pain has effects on the nervous system.

The effect of acute inflammation of the joints on nerves reporting the state of the joint and on the central nervous system has been studied by inducing arthritis in animals. In this condition, locally formed chemical substances excite the small myelinated and nonmyelinated afferent fibres that report noxious events. Most of these nerves, sensitized by the inflammatory exudate, begin to fire impulses continuously. This flow of impulses to the dorsal-horn neurons of the spinal cord increases their excitability so that many of them also begin to fire continuously. Neurons that are normally excited only by noxious stimulation now respond to light touch as well. Meanwhile, motor neurons in related areas also fire spontaneously, and stimuli that would not normally cause withdrawal reflexes now cause a prolonged reflex response. There is no change in the motor neurons themselves; the change is in the firing threshold of peripheral neurons coming from the inflamed area and in the interneurons between the afferent nerve fibres and the motor neurons. These interneurons are ultimately connected to the brain, so that the state of increased sensitivity is passed on to related cerebral neurons. Eventually, neurons in the cerebral hemispheres continuously and spontaneously generate impulses. Other neurons of the brain start responding to movements of the affected joints that normally would not do so.

In some people with chronic painful conditions, the constant pain impulses change the character of neurons of the thalamus and cortex. For example, one patient who had had a toothache 10 days before he had an operation on the thalamus for parkinsonism suddenly got the pain of toothache again when the thalamus was stimulated electrically. Normally, no pain can be induced by stimulating that part of the thalamus.

Peripheral nerves. Most of the afferent nerves making up the dorsal roots are nonmyelinated fibres. These fibres are activated by warmth within a physiological range (and by higher temperatures likely to damage the body), by chemical substances (including those made in the body), and by strong mechanical stimulation such as pricking and crushing. The smaller myelinated fibres report mechanical stimulation of the skin, noxious stimulation, and cold.

As stated above, pain is not the inevitable result of the firing of nonmyelinated fibres reporting noxious events. These fibres may fire at a slow rate without causing pain; they may even continue to fire for an hour or so without pain. Furthermore, the pain threshold does not correspond with the onset of activity in the nonmyelinated fibres, for pain can increase while the discharge of nerve impulses decreases.

Spinal cord. The stimulus-specific organization of the peripheral nerve fibres is not continued within the spinal cord, as the various afferent nerve fibres do not transmit their impulses exclusively to neurons of only one kind of sensibility. In the dorsal horns (the spinal region that receives afferent impulses) a few neurons are purely nociceptive, but most neurons reporting noxious events receive both noxious and mechanoreceptive input. These latter are called convergent neurons. The size of the peripheral field (the area of the body from which it receives stimuli) of a dorsal-horn neuron continually varies, depending on the state of excitability of the neuron. Furthermore, events in the peripheral field affect future responses. For example, repeated input along a group of afferent nerve fibres produces a gradually decreasing response in the central nervous system. This is called habituation. Also, the region of decreased response spreads from local neurons that received the input to neighbouring neurons.

Changes in sensitivity to pain

The state of excitability of a dorsal-horn neuron depends on many variables. If it is very excitable, it will respond to impulses from many afferent peripheral nerve fibres; if it is relatively inexcitable, it will be affected only by those peripheral fibres that are habitually connected to it and located near it. A neuron excited by many afferent fibres receives input from a larger area than a neuron receiving only from the fibres most nearly related to it. For this reason the area of skin or deep tissue connected to neurons of the dorsal horn varies and changes. In experiments using damaged skin, it has been found that a barrage of nerve impulses from the damaged region increases the excitability of the dorsal-horn neurons. Once this hyper-

excitable state has been set up, it continues for a time without further input from peripheral nerves. In this state of local excitability, some dorsal-horn neurons receive an input from the area of damaged skin that they would not receive were the skin in a normal state.

The convergent neurons mentioned above can have their activity inhibited by tactile stimulation of a region near their peripheral fields or of a homologous region on the opposite side of the body. Also, their responsiveness to stimuli can be increased by damage to the skin in their peripheral fields.

From these convergent neurons and from other neurons of the dorsal horns, there arise tracts of long fibres that cross the midline and lead to the thalamus and other nuclei of the brain. These constitute the spinothalamic tracts. The other main pathway of pain impulses ends in the reticular formation of the medulla oblongata and pons and is known as the spinoreticular tract. It is believed that spinoreticular input to the brain serves the autonomic responses and emotional components associated with pain, whereas the spinothalamic serves conscious sensation, with its exact temporal and spatial aspects. Neurons around the central spinal canal that receive input from the bladder and colon and their overlying somatic tissues may be connected to an ascending tract that stays within the gray matter in the neighbourhood of the central canal.

HIGHER-LEVEL PAIN PATHWAYS

Inhibition of pain transmission

Brain. Many regions of the brain can influence the input arriving at the lower levels of the nervous system. This so-called descending inhibition can be selective, with different regions of the brain inhibiting certain inputs to the spinal cord. Some regions reduce mechanoreceptive input, and others reduce noxious and warmth inputs. Descending inhibition can also reduce input from the skin while increasing that related to movement.

Prominent regions of influence are those that themselves receive noxious input. For instance, the lateral reticular nuclei of the medulla oblongata cause a constant inhibition of input brought to the spinal cord by the nonmyelinated fibres. In the rat (in which the discovery was first made), descending inhibition can be so effective that a noxious input does not enter the spinal cord. In other words, normally painful stimuli cause no reaction or concern, and there is no change in blood pressure, respiration, and other reflex activities. In these circumstances it seems that pain simply is not felt.

Electrical stimulation of the nucleus ceruleus, a small nucleus with widely ranging axons, and the nucleus raphe magnus, a nucleus in the central reticular formation of the medulla, inhibits input from noxious stimulation of the skin, and it also inhibits activities of dorsal-horn neurons receiving mechanoreceptive input. Since it was discovered that pain could be obliterated in this manner, attempts have been made to stop the chronic pain of cancer and other conditions by implanting electrodes in the brain. These can be placed in relevant parts of the brain so that constant stimulation can inhibit the input coming from the region of the pain.

This built-in system for obliterating or reducing pain can normally be brought into play by stress. Furthermore, it has always been known that one pain can mask another. A volley of nerve impulses reaching the brain via the spinothalamic and spinoreticular tracts and causing a moderate degree of pain is stopped when the cells of origin of this tract are inhibited. Experiments have shown that this suppression can be brought about by a more severe pain or by a pain in a larger area of the body, which causes descending inhibition of neurons of the spinal tract. This descending inhibition is the main mechanism of acupuncture analgesia.

The reticular formation consists of a vast number of small interconnected neurons occupying the central area of the brain stem. Parts of the reticular formation, hypothalamus, and thalamus excite the cerebral hemispheres and keep the cerebral cortex active and alert—partly in response to noxious input. In fact, it may be said that pain reaches consciousness in the thalamus. The thalamus receives noxious input from the spinal cord in two regions, a lateral part called the ventrobasal complex and a medial part consisting of several nuclei. The ventrobasal complex is concerned with the accurate temporal and spatial localization of conscious sensation, while the medial nuclei are concerned with the emotional, affective, and autonomic components of pain and other sensations. The ventrobasal nuclei relay impulses to the sensory areas of the postcentral gyrus. Noxious stimuli also cause responses in many areas of the cortex and the deeper islands of gray matter. This is to be expected, for, of all sensations, pain is the least pure sensation: it startles, it excites, and it has unpleasant qualities. All these aspects of pain are added by different parts of the brain.

Central pain. Pain arising within the central nervous system when there is no damage to the body is known as central pain. The most common central pain is due to lesions in or near the thalamus and is called the thalamic syndrome. This condition is characterized by diminution in sensibility as well as severe pain when any stimulus exceeds a certain threshold.

With central pain there is both spontaneous pain and excessive pain on stimulation of all kinds. The pain may occur in the entire half of the body, affecting even visual and auditory inputs, or it may occur in a restricted region, such as the upper limb and side of the face or the lower limb.

Referred pain. The term referred pain is used to describe pain felt in a region where it does not originate but to which it is "referred." It is usually used to mean pain arising in hollow viscera and felt in somatic tissues, such as the body wall. Referred pain is always referred in one direction—from deep to superficial tissues. It is pain referred from an unknown or unfamiliar part of the body to a known or familiar part.

Mingling of visceral and somatic pain pathways

Certain regions of the dorsal horns of the spinal cord receive both nerve fibres from the viscera and nerve fibres reporting noxious events in the skin and musculature. For example, afferent nerve fibres from the heart come to the same regions as those from the muscles and skin of the chest wall and upper limbs. From these two body tissues, visceral and somatic, there is an intermingling of inputs, and there is similar convergence in the thalamus. This anatomical arrangement is likely to form the basis of referred pain, although the mere convergence of impulses from viscera and soma onto the same neurons does not alone account for the false localization of visceral pain. It is probable that in sensory areas of the brain, the skin is served by a large number of neurons, the muscles with fewer, and the viscera with least, the visceral representation in the cortex being very small compared to that of the somatic tissues. It is supposed that, as the input to these sensory regions of the cortex usually comes from the skin and body wall, localization of the visceral input will be to these tissues and not to the viscera, the cortical region of which is small and relatively unused.

Changes in the cerebral cortex. Normally, electrical stimulation of the sensory region of the postcentral gyrus does not cause pain. But in many patients who have a painful state on the opposite side of the body, such as a painful amputation stump or damage to the median nerve of the hand, stimulation of this region reproduces the pain. Pain also arises from stimulation of the white matter deep in this area.

In these cases the character of the sensory region of the cortex changes in such a manner that neurons that normally never cause pain when stimulated now invariably produce the pain from which the patient is suffering. Also, the cortical area subserving the limb enlarges. For instance, the sensory area receiving impulses from the opposite lower limb is normally at the upper end of the postcentral gyrus. If there is a painful amputation of the limb, then the area of cortex in which electrical stimulation induces the pain spreads downward from the normal area to include the trunk area and sometimes the upper limb area.

Perception

To the biologist, the life of animals (including that of humans) consists of seeking stimulation and responding

appropriately. A reflex occurs before an individual knows what struck him, what made him lift a foot or drop an object. It is biologically correct to be alarmed before one knows the reason. It is only after the immediate and automatic response that the cerebral cortex is involved and conscious perception begins.

Perception comes between simple sensation and complex cognitional behaviour. By the time people are able to talk about it, perception has become so automatic that they hardly realize that seeing what they see, hearing what they hear, is an interpretation. Each act of perception is a hypothesis based on prior experience: the world is made up of things people expect to see, hear, or smell, and any new sensory event is perceived in relation to what they already know. People perceive trees, not brown, upright masses and blotches of green against a background of blue, gray, and white. Once one has learned to understand speech, it is all but impossible to hear words as sibilants and diphthongs, sounds of lower and higher frequencies. In other words, recognizing a thing entails knowing its total shape or pattern. This is usually called by its German name, gestalt.

As well as perception of the external environment, there is perception of oneself. Information about one's position in space, for example, comes from vision, from vestibular receptors, and from somatic receptors in the skin and deep tissues. This information is collected in the vestibular nuclei and passed on to the thalamus. From there it is relayed to the central gyri and the parietal region of the cortex, where it becomes conscious perception. (For detailed discussion of the perception of movement, see above *The vestibular system.*)

Central function of the thalamus

GENERAL ORGANIZATION OF PERCEPTION

Perception relies on what are called the special senses—the visual, auditory, gustatory, and olfactory. Each begins with receptors grouped together in sensory end organs, where the sensory input is organized before it is sent on to the brain. At every synapse on a sensory pathway there is an important reorganization of impulses, so that by the time an input arrives at the thalamus, it is far from being the original input that stimulated the receptors.

The afferent parts of the thalamus fall into two divisions: a medial part, which is afferent but not sensory, and a ventral and lateral part, which is sensory. Nerve impulses reaching the medial part are derived from the reticular formation. This pathway is for emotional and other rapid reactions such as surprise, alarm, vigilance, and the readiness to react. The lateral part of the thalamus is a station on the way to areas of the cortex that are specific for each kind of sensation.

There are three somatosensory areas of the cortex (Figure 29). The primary sensory area occupies the postcentral gyrus immediately behind the motor strip. The secondary area is above the Sylvian fissure, behind the secondary motor area. The supplementary area is in the upper part of the parietal lobe on the medial surface of the hemisphere, just behind the primary area.

The primary area receives its input from the ventrolateral thalamus. The secondary area receives somatosensory input from the lateral part of the thalamus and also auditory and visual input from the medial and lateral geniculate nuclei. The primary and secondary areas are reciprocally connected.

The cerebral cortex (and the thalamus as well) is divided between nonspecific and specific sensory areas. Most neurons of the specific regions have small receptive fields in the periphery, respond to only one kind of stimulus, and follow the features of stimulation exactly. Most neurons of the nonspecific regions have large receptive fields and respond to many kinds of stimuli; many do not exactly reproduce the features of the stimulus.

Changes in the sensory areas of the brain

Although different regions of the body are normally represented by specific parts of the somatosensory regions of the cortex, the parts where afferent impulses arrive are not fixed. For example, the leg area is at the top of the postcentral gyrus, but when there is a painful state in the periphery—sciatica, for example—the leg area of the cortex can enlarge and occupy some of the arm area. Furthermore, injury to the peripheral nerves or brain may alter the sensory "map" of the cortex. These changes in the cortex and similar changes in anatomical function are referred to as plasticity.

From the somatosensory area, nerve fibres run to other regions of the cortex, traditionally called association areas. It is thought that these areas integrate sensory and motor information and that this integration allows objects to be recognized and located in space. With these regions acting upon all their inputs, the brain is carrying out those aspects of neural activity that are commonly labeled mental. It must be remembered, though, that researchers have not precisely answered the question of how and where the brain collects messages from all the sensory receptors and then sifts and arranges them so as to give a complete representation of the world and of the individual's place in the world.

ORGANIZATION OF THE SPECIAL SENSES

Of the special senses, the cerebral organization of the visual and auditory senses are better understood than that behind the olfactory and gustatory. For this reason, only the former two are discussed below.

Vision. Most investigations of the visual pathways in the brain have been carried out in the cat.

The area of the human brain concerned with vision comprises the entire occipital lobe and the posterior parts of the temporal and parietal lobes. The primary visual area, also called the striate cortex, is on the medial side of the occipital lobe and is surrounded by the secondary visual area (Figure 31). The visual cortex is sensitive to the position and orientation of edges, the direction and speed of movement of objects in the visual field, stereoscopic depth, brightness, and colour. These parallel functions combine to produce visual perception.

The ganglion neurons of the retina belong to three functional types, called Y-, X-, and W-cells. X-cells are neurons needed for high-resolution vision. Y-cells respond to fast movement, whereas X- and W-cells respond poorly to fast movement. Y-cells are larger than the others and have large peripheral fields; X-cells have small fields. In the retina, 50 to 55 percent of ganglion cells are W-type, 40 percent are X-type, and 5 to 10 percent are Y-type.

As constituent fibres of the optic nerves and optic tracts, X- and Y-cells connect to the lateral geniculate nucleus of the thalamus, while W-cells connect mainly to the superior colliculus of the midbrain. From these regions input from the X-cells goes mainly to the primary visual area, that from the Y-cells goes to the secondary visual area, and that from the W-cells goes to the area surrounding the secondary area. The collicular pathway serves movement detection and direction of gaze. The tract from the lateral geniculate nucleus is the pathway for visual acuity.

The primary area sends fibres back to the lateral geniculate nucleus, the superior colliculus, and the pupillary reflex centre for feedback control of input to the visual areas. It also sends fibres to the secondary area and to the visual area of the temporal lobe. The secondary area sends fibres to the temporal and parietal lobes. Also, fibres cross from visual areas of one cerebral hemisphere to the other in the corpus callosum. This link allows neurons of the two hemispheres with similar visual fields to make direct contact with each other.

Specialized visual neurons of the brain

Neurons of the striate cortex may form the first step in appreciation of orientation of objects in the visual field. It is thought, however, that excitation of cortical neurons is insufficient to account for orientation and that inhibition of other neurons in the visual cortex is also necessary. Whatever the mechanism, it has been found in experiments on cats and monkeys that individual neurons are activated by lines at different angles—for example, at 90 degrees to the horizontal or at an angle of 45 degrees.

Most neurons of the deeper layers are movement analyzers. Some are direction analyzers, activated by a line or an edge moving in one direction and silenced when it changes direction (the changed direction then activating other neurons). One neuron may be excited by a dark line on a bright background and another by a light line on a dark background. In other regions of the striate cortex

there are form analyzers; for example, some are activated by rectangles and others by stars. There are also position neurons, which show a strong response to a spot located in a certain position and a weak response to stimulation of a larger area; others respond only to simultaneous binocular stimulation. The striate cortex provides a fused, binocular picture of the world. There are also colour-specific neurons sensitive to red, green, or blue. Each of these neurons is excited by one colour and inhibited by another.

In the secondary visual area many neurons respond particularly to the direction of moving objects. Neurons activated by colour are not activated by white light. In the part of this area where there are many neurons responding to colour, the periphery of the visual field is not mapped; this is because there are no cones in the periphery of the retina (cones being the colour receptors). The peripheral field is mapped in an area with neurons responding to movement—notably in the region of the superior temporal gyrus.

It seems that one function of the pathway from the superior colliculus to the temporal and parietal cortices is as a tracking system, enabling the eyes and head to follow moving objects and keep them in the visual field. The pathway from the geniculate nucleus to the primary visual area may be said to perceive what the object is and also how and in what direction it moves.

Some neurons in the parietal cortex become active when a visual stimulus comes in from the edge of the visual field toward the centre, while others are excited by particular movements of the eyes. Other neurons react with remarkable specificity—for example, only when the visual stimulus approaches from the same direction as a stimulus moving on the skin of the animal, or during the act of reaching for an object and tracking it with the hand. These parietal neurons greatly depend on the state of vigilance. In monkeys that are apparently merely waiting for something to happen or that have nothing to which to turn their attention, the neurons are inactive or minimally active. But when the animal is looking at a visual target whose change it has to detect in order to obtain a reward, the parietal neurons become active.

A great number of neurons of the middle temporal area are sensitive to the direction of movement of a visual stimulus and to the size of an object. In the inferior temporal area are neurons concerned with shape and colour. The neurons of the superior temporal polysensory area respond best to moving stimuli—in particular to movements away from the centre of the visual field. Both these areas are concerned with the conjunction of visual stimuli and movement.

Brodmann, "Feinere Anatomie des Grosshirns," in *Handbuch der Neurologie* (1910), Springer-Verlag, Berlin

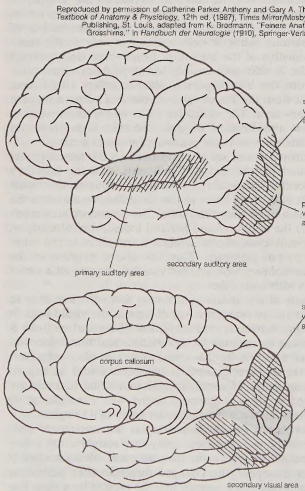

Figure 31: (Top) Lateral and (bottom) medial views of the cerebral hemispheres, showing visual and auditory areas.

Hearing. Much of the knowledge of the neurological organization of hearing has been acquired from studies on the bat, an animal that relies on acoustic information for its livelihood.

Specialized auditory neurons

In the cochlea (the specialized auditory end organ of the inner ear) the frequency of a pure tone is reported by the location of the reacting neurons in the basilar membrane, and the loudness of the sound is reported by the rate of discharge of nerve impulses. From the cochlea the auditory input is sent to many auditory nuclei. From there, it is sent on to the medial geniculate nucleus and the inferior colliculus, as with the relay stations of the retina. The auditory input finally goes to the primary and secondary auditory areas of the temporal lobes.

The auditory cortex provides the temporal and spatial frames of reference for the auditory data that it receives. In other words, it is sensitive to aspects of sound more complex than frequency. For instance, there are neurons that react only when a sound starts or stops. Other neurons are sensitive only to particular durations of sound. When a sound is repeated many times, some neurons respond, while others stop responding. There are neurons that are sensitive to differences of the intensity and timing of sounds reaching the two ears. Certain neurons that never respond to a note of constant frequency respond when the frequency falls or rises. There are others that respond to the rate of change of frequency, providing information on whether distance from the source of a sound is increasing or decreasing. Some neurons respond to the ipsilateral ear, others to the contralateral, and yet others to both ears.

Emotion and behaviour

PATHWAYS IN THE BRAIN

Importance of the hypothalamus

In order to carry out the correct behaviour—that is to say, correct in relation to the survival of the individual and the group—humans and other higher animals developed innate drives, desires, and emotions, and the ability to remember and learn. These fundamental features of living depend on the entire brain, yet there is one part of the brain that organizes metabolism, growth, sexual differentiation, and the desires and drives necessary to achieve these aspects of life. This is the hypothalamus and a region in front of it comprising the septal and preoptic areas. That such basic aspects of life might depend on a small region of the brain was conceived in the 1920s by the Swiss physiologist Walter Rudolf Hess and later amplified by Erich von Holst. Hess implanted electrodes in the hypothalamus and in septal and preoptic nuclei of cats, stimulated them, and observed the animals' behaviour. Finally, he made minute lesions by means of these electrodes and again observed the effects on behaviour. With this technique he showed that certain kinds of behaviour were organized essentially by just a few neurons in these regions of the brain. Later, von Holst stimulated electrodes by remote control after placing the animals in various biologically meaningful conditions.

When such acts result from the artificial stimulation of the neurons, the accompanying emotion also occurs, as do the movements expressing that emotion.

The hypothalamus, in company with the pituitary gland, controls the emission of hormones. It is in control of body temperature, maintains the blood pressure and the rate and force of the heartbeat, and controls the body's need for water and electrolytes. The maintenance of these and other changing events within normal limits is called homeostasis; this includes behaviour aimed at keeping the body in a correct and thus a comfortable environment.

The hypothalamus is also the centre for organizing the activity of the two parts of the autonomic system, the parasympathetic and the sympathetic (see above *The au-*

tonomic system). Above the hypothalamus, regions of the cerebral hemispheres most closely connected to the parasympathetic regions are the orbital surface of the frontal lobes, the insula, and the anterior part of the temporal lobe. The regions most closely connected to the sympathetic regions are the anterior nucleus of the thalamus, the hippocampus, and the nuclei connected to these structures.

In general, the regions of the cerebral hemispheres that are closely related to the hypothalamus are those parts that together constitute the limbic lobe, first considered as a unit and given its name in 1878 by the French anatomist Paul Broca. Together with related nuclei it is usually called the limbic system, consisting of the cingulate and parahippocampal gyri, the hippocampus, the amygdala, the septal and pre-optic nuclei, and their various connections.

The autonomic system also involves the hypothalamus in movement. The expression of emotion and signaling to others depend greatly on the sympathetic nervous system. Emotional expression is also carried out by regions of the cerebral hemispheres above the hypothalamus and by the midbrain below it.

HYPOTHALAMIC FUNCTIONS

Emotion. A great deal of behaviour in social animals, such as humans, involves social interaction. Although the whole brain contributes to social activities, certain parts of the cerebral hemispheres are particularly concerned. The operation of leucotomy, cutting through the white matter that connects parts of the frontal lobes with the thalamus, upsets this aspect of behaviour. This operation used to be performed for severe depression or obsessional neuroses. After the operation, patients lacked the usual inhibitions that were socially demanded, appearing to obey the first impulse that occurred to them. They told people what they thought of them without regard for the necessary conventions of civilization.

Which parts of the cerebral hemispheres produce emotion has been learned from patients with epilepsy and from operations under local anesthesia in which the electrical stimulation of the brain is carried out. The limbic lobe, including the hippocampus, is particularly important.

Inducing changes in emotion

Stimulating certain regions of the temporal lobes produces an intense feeling of fear or dread; stimulating nearby regions produces a feeling of isolation and loneliness, other regions a feeling of disgust, and yet others intense sorrow, depression, anxiety, and, occasionally, guilt. An ecstatic feeling can also occur in which it appears to patients that all problems have been or are just about to be solved.

In addition to these regions of the cerebral cortex and the hypothalamus, regions of the thalamus also contribute to the genesis of emotion. The hypothalamus itself does not initiate behaviour; that is done by the cerebral hemispheres—insofar as one may abstract any single part from the whole.

The defense reaction: fighting and fleeing. When certain neurons of the hypothalamus are excited, an animal either becomes aggressive and eventually attacks, or it flees. These two opposite ways of behaving are together called the defense reaction; both are in the repertoire of all vertebrates. The defense reaction is accompanied by strong sympathetic activity. Aggression is also influenced by the production of androgen hormones.

Mating. The total act of copulation is organized in the anterior part of the hypothalamus and the neighbouring septal region. In the male, erection of the penis and ejaculation are organized in this area, which is adjacent to the area for urination. Under normal circumstances the neurons that organize mating behaviour do so only when they receive relevant hormones in their blood supply. But when the septal region is electrically stimulated in conscious patients, sexual emotions and thoughts are produced.

There are visible differences between the male and female sexes in nuclei of the central nervous system related to reproduction. These differences are a form of sexual dimorphism.

Urination and defecation. Electrical stimulation in cats of regions in, and related to, the anterior part of the hypothalamus can induce the behaviour of expelling or retaining urine and feces. When electrodes planted in these regions are stimulated by radio waves, the cat stops whatever it is doing and behaves as though it were going to urinate or defecate. It goes through its usual behaviour of digging a hole, squatting, and assuming the correct posture, and then it passes urine or feces. At the end, it even goes through its customary ritual of hiding its excreta.

Eating and drinking. The eating and drinking centres are in the lateral and ventromedial regions of the hypothalamus, although such basic aspects of living concern most of the brain. If the lateral region is experimentally destroyed, the animal takes less food or stops eating altogether; if the ventromedial region is destroyed, it eats enormously. When neurons of the lateral region are electrically stimulated, the animal eats, and when those of the ventromedial area are stimulated, it stops eating. There is an increase in the activity of these neurons when a monkey looks at food, but only when it is hungry. In the lateral region are receptors that monitor blood glucose. They are stimulated into activity only when the blood glucose is low; satiety stops their response.

Hunger does not depend only on these glucose receptors. Severe hunger is associated with contractions of the stomach, which are felt almost as a sensation of pain. Yet neither is this an essential mechanism for feeling hungry, as patients who have had total removal of the stomach still feel hunger. In experiments in rats, it is found that stress may make the animal either increase or reduce the amount it eats. This is probably the same in humans.

When certain neurons in the same regions of the hypothalamus are experimentally destroyed, animals lose the urge to drink, although they continue to eat normally. Stimulation of these neurons make them drink excessively. The control of drinking depends on osmoreceptors throughout the hypothalamus. When the receptors detect a minimal increase in the concentration of dissolved substances in the extracellular fluid, which indicates cellular dehydration, the animal feels thirsty. A less important contributor is a reduction in blood volume. Dryness of the mouth can also be a component of thirst, noted by receptors in the mucous membrane. The feeling of having drunk enough depends not only on the hypothalamic neurons but also on receptors in the wall of the stomach, which report when the stomach is full.

Both glucose receptors and osmoreceptors are sensitive to the temperature of the passing blood. When the temperature starts to rise, one feels thirsty but not hungry; cooling the blood makes one feel hungry.

Temperature regulation. To maintain homeostasis, heat production and heat loss have to be balanced. This is achieved by both the somatomotor and sympathetic systems. The obvious behavioral way of keeping warm or cool is by moving into a correct environment. The posture of the body is also used, as is clearly seen in the behaviour of the cat. When lying in front of a fire, it is fully stretched out—in physiological terms, extended—thus presenting a large surface to the ambient air and losing heat. When it is cold, it curls itself up into a small volume—in physiological terms, fully flexed—thus presenting the smallest area to the ambient temperature. Humans also use these somatomotor methods.

The most important part of the nervous system for controlling body temperature is the sympathetic system. On a long-term basis, when the climate is cold, the sympathetic system produces heat by its control of certain fat cells called brown adipose tissue. From these cells, fatty acids are released, heat being produced by their chemical breakdown.

Body temperature fluctuates regularly within 24 hours; this is a type of circadian rhythm (see below). It also fluctuates in rhythm according to the menstrual cycle. During fever, the body temperature is set at a higher point than normally.

Reward and punishment. In a fundamental discovery made in 1954, James Olds and Peter Milner found that stimulation of certain regions of the brain of the rat acted as a reward in teaching the animals to run mazes and solve problems. The conclusion from such experiments is that stimulation gives the animals pleasure. The discovery

Reward centres of the brain

has also been confirmed in humans. These regions are called pleasure or reward centres. One important centre is in the septal region, and there are reward centres in the hypothalamus and in the temporal lobes of the cerebral hemispheres as well. When the septal region is stimulated in conscious patients undergoing neurosurgery, there are feelings of pleasure, optimism, euphoria, and happiness.

Regions of the brain also clearly cause rats distress when electrically stimulated; these are called aversive centres. However, the existence of an aversive centre is less certain than that of a reward centre. Electrodes stimulating neurons or neural pathways may cause an animal to have pain, anxiety, fear, or any unpleasant feeling or emotion. These pathways are not necessarily centres having the function of providing punishment in the sense that a reward centre provides pleasure. Therefore, it is not definitely known that connections to aversive centres punish the animal for biologically wrong behaviour, but it is thought that correct behaviour is rewarded by pleasure provided by neurons of the brain.

Circadian rhythms. Living organisms have inevitably become adapted to the orderly rhythms of the universe. These biologic cycles are called circadian rhythms, from the Latin *circa* ("about") and *dies* ("day"). They are essentially endogenous, built into the central nervous system. The rhythmical activities usually covered by the word circadian are sleeping and waking, rest and activity, taking in of fluid, formation of urine, body temperature, cardiac output, oxygen consumption, cell division, and the secreting activity of endocrine glands. The rhythms are upset by shift work and by rapid travel into different time zones. After long journeys it takes several days for the endogenous rhythm generator to become synchronized to the local time.

The alternation of night and day has been important in inducing rhythms affecting many physiological functions. Even in isolation, from clues giving information about light and dark, rhythms related to the time of day are maintained. Curiously, the endogenous sleep–wake rhythm deviates slightly from the Earth's 24-hour cycle; a bird's endogenous cycle is 23 hours, and the human cycle is 25 hours. In both cases the cycle is corrected by features of the environment. Such synchronizing agents are called zeitgebers ("time givers"). One zeitgeber is the Earth's magnetic field, which changes on a 24-hour cycle as the Earth turns on its axis. More obvious and important a zeitgeber is the alternation of dark and light.

One hypothalamic nucleus that is essential for the rhythms of sleeping, waking, rest, and activity is the suprachiasmatic nucleus. It is not surprising that this nucleus is adjacent to the incoming fibres from the eye, for the light–dark cycle appears to be the most important zeitgeber for circadian rhythms. The suprachiasmatic nucleus is most active in light. In experiments on the hamster, when the nucleus is destroyed, the rhythms of general activity, drinking, sleeping, waking, body temperature, and some endocrine secretion are disrupted. (P.W.N.)

Higher cerebral functions

The neurons of the cerebral cortex constitute the highest level of control in the hierarchy of the nervous system. Consequently, the terms higher cerebral functions and higher cortical functions are used by neurologists and neuroscientists to refer to all conscious mental activity of the kind normally described as thinking, remembering, and reasoning and to complex volitional behaviour such as speaking and carrying out purposive movement. They also refer to the processing of information in the cerebral cortex, most of which takes place unconsciously.

ANALYTICAL APPROACHES

Neuroscientists investigate the structure and functions of the cerebral cortex, but the processes involved in thinking are also studied by cognitive psychologists, who group the mental activities known to the neuroscientist as higher cortical functions under the headings cognitive function or human information processing. From this perspective, complex information processing is the hallmark of cognitive function. Cognitive science attempts to identify and define the processes involved in thinking without regard to their physiological basis. The resulting models of cognitive function resemble flowcharts for a computer program more than neural networks—and, indeed, they frequently make use of computer terminology and analogies.

Neuropsychology

The discipline of neuropsychology, by studying the relationship between behaviour and brain function, bridges the gap between neural and cognitive science. Examples of this bridging role include studies in which cognitive models are used as conceptual frameworks to help explain the behaviour of patients who have suffered damage to different parts of the brain. Thus, damage to the frontal lobes can be conceptualized as a failure of the "central executive" component of working memory, and a failure of the "generate" function in another model of mental imagery would fit with some of the consequences of left parietal lobe damage.

The analysis of changes in behaviour and ability following damage to the brain is by far the oldest and probably the most informative method adopted for studying higher cortical functions. Usually these changes take the form of what is known as a deficit—that is, an impairment of the ability to act or think in some way. With certain provisos, one can assume that the damaged part of the brain is involved in the function that has been lost. However, people vary considerably in their abilities, and most brain lesions occur in subjects whose behaviour has not been formally studied before they become ill. Lesions are rarely precisely congruent with the brain area responsible for a given function, and their exact location and extent can be difficult to determine even with modern imaging techniques. Abnormal behaviour after brain injury, therefore, is often difficult to attribute to precisely defined damage or dysfunction.

It would also be naive to suppose that a function is represented in a particular brain area just because it is disrupted after damage to that area. For example, a tennis champion does not play well with a broken ankle, but this would not lead one to conclude that the ankle is the centre in which athletic skill resides. Reasonably certain conclusions about brain–behaviour relationships, therefore, can be drawn only if similar well-defined changes occur reliably in a substantial number of patients suffering from similar lesions or disease states.

Pioneering studies of the brain

The most prominent series of observations clearly belonging to modern neuropsychology were made by Paul Broca in the years following 1861. He reported the cases of several patients whose speech had been affected following damage to the left frontal lobe and provided autopsy evidence of the location of the lesion. In making his famous statement, "We speak with the left hemisphere," he explicitly recognized the left hemisphere's control of language, one of the fundamental phenomena of higher cortical function.

In 1874, the German neurologist Carl Wernicke described a case in which a lesion in a different part of the left hemisphere, the posterior temporal region, affected language in a different way. In contrast to Broca's cases, language comprehension was more affected than language output. This meant that two different aspects of higher cortical function had been found to be localized in different parts of the brain. In the next few decades there was a rapid expansion in the number of cognitive processes studied and tentatively localized.

Wernicke was one of the first to recognize the importance of the interaction between connected brain areas and to think of higher cortical function as the buildup of complex mental processes through the coordinated activities of local regions dealing with relatively simple, predominantly sensory-motor functions. In doing so, he opposed the view of the brain as an equipotential organ acting en masse. Since his time, scientific fashion has swung between the localization and mass-action theories. Major changes in the 20th century have been both quantitative, with vast increases in knowledge, and methodological, with the discovery of new ways of studying the brain's anatomy and physiology and the introduction of better quantitative methods in the study of behaviour.

HEMISPHERIC ASYMMETRY, HANDEDNESS, AND CEREBRAL DOMINANCE

Broca's declaration that the left hemisphere is predominantly responsible for language-related behaviour is only the clearest and most dramatic example of an asymmetry of function in the human brain. This functional asymmetry is related to hand preference and probably to anatomical differences, although neither relationship is simple.

Dominance of the left hemisphere for language

Evidence from a number of converging sources, notably the high incidence of the language disturbance known as aphasia after left- but not right-hemisphere damage, indicates that the left hemisphere is dominant for the comprehension and expression of language in close to 99 percent of right-handed people. At least 60 percent of left-handed and ambidextrous people also have left-hemisphere language, but up to 30 percent have predominantly right-hemisphere language. The remainder have language represented to some degree in both hemispheres.

The posterior temporal region of the brain, which in the dominant hemisphere is one of the regions responsible for language, is physically asymmetrical; specifically, the area known as the planum temporale is larger in the left hemisphere in most people. This asymmetry is more common in right-handers, while left-handed individuals are likely to have more nearly symmetrical brains. Reduced anatomical asymmetry has also been found in people with right-hemisphere dominance for speech and in some developmental dyslexics (people with reading disorders). These results point to some relationship between handedness, cerebral dominance for language, anatomical asymmetry in the temporal lobe, and some aspects of language competence. Certainly, there is a tendency for right-handedness, left-hemisphere dominance for language, and a larger left planum temporale to go together. However, there are exceptions; for example, a few right-handers are right-hemisphere dominant for speech, and some right-handers who have left-hemisphere speech do not have a larger left planum temporale. In subjects who are atypical in one of these respects—for example, by being left-handed—the relationship between handedness, cerebral dominance, and anatomical asymmetry is much less consistent. It follows, therefore, that language is not invariably located in the hemisphere opposite the dominant hand or in the hemisphere with the larger planum temporale.

Studies of patients in whom the corpus callosum (the bundle of nerve fibres connecting the two halves of the brain) has been severed, allowing the two hemispheres to function largely independently, have revealed that the right hemisphere has more language competence than was hitherto supposed. These patients show evidence of comprehension of words presented to the isolated right hemisphere, although that hemisphere is not able to initiate speech. The speech of patients with a lesion of the right hemisphere may lack normal melodic quality, and they may have difficulty expressing and understanding such things as emotional overtones. They may also have difficulty appreciating some of the more subtle, connotative aspects of language, such as puns, figures of speech, and jokes. Nevertheless, the dominance of the left hemisphere for language, particularly the syntactic aspects of language and language output, is the clearest example yet discovered of the lateralization of higher cortical function.

The left hemisphere also appears to be more involved than the right in the programming of complex sequences of movement and in some aspects of awareness of one's own body. Thus, the disorders known as ideomotor and ideational apraxia are more common after left-hemisphere damage. In these disorders, the patient has difficulty carrying out actions involving several movements or the manipulation of objects in an appropriate and skillful way. The difficulty appears to be in programming the motor system to run off the sequence of movements required to perform a complex action in the appropriate order and with the appropriate timing.

A third category of deficits associated with left-hemisphere damage, disorder of the body image, is much more difficult to define. It includes a disorder called finger agnosia, in which the individual does not appear to "know" which finger is which, being unable to indicate which one the examiner touches without the aid of vision. Confusion of right and left is also found after left-hemisphere damage, making it appear that the left hemisphere is largely responsible for collating somatosensory information into a special awareness of the body called the body image. The phenomenon of the phantom limb, whereby patients "feel" sensations in amputated limbs, indicates that the brain's internal representation of the body may persist intact for some time after the loss of a body part. This internal representation appears to be maintained chiefly by the left hemisphere.

The special functions of the right hemisphere were recognized later than those of the left hemisphere, although a case of "imperception" reported by the English neurologist John Hughlings Jackson in 1876 foreshadowed later findings. Jackson's patient, who had a lesion in the posterior part of the right hemisphere, lost her way in familiar surroundings, failed to recognize familiar places and people, and had difficulty in dressing herself—all of which became well-recognized consequences of right-hemisphere damage. The right hemisphere, then, appears to be specialized for some aspects of higher-level visual perception, spatial orientation, and route finding (sense of direction), and it probably plays a dominant role in the recognition of objects and faces. The specialization of the right hemisphere, however, is less absolute than that of the left hemisphere in that these skills are less lateralized than language.

Specialized functions of the right hemisphere

There has been considerable speculation as to why the human brain should be functionally asymmetrical. Initially, both functional and anatomical asymmetry were thought, like language, to be a uniquely human trait, but less pronounced asymmetries have now been found in lower animals. One suggestion is that it is necessary to have language represented in a single hemisphere to avoid competition between the hemispheres for control of the muscles involved in speech. Another suggestion is that it is efficient to have the language system represented in a restricted area on one side of the brain because information needs to be transferred over short distances and fewer connections. A third suggestion is that the dominance of the left hemisphere over the right hand and skilled movement preceded its dominance over language. According to this view, language subsequently developed in the same hemisphere because language implies speech, which requires precise programming of sequences of movement in the articulatory musculature. All these views have something to recommend them, but none has been conclusively proved correct or has been generally accepted. Also, there remain some facts that are difficult to explain by any theory. For example, all the above theories would predict that bilateral and, in some cases, right-hemisphere language representation would be disadvantageous, but this does not seem to be generally true.

LANGUAGE

The language area of the brain surrounds the Sylvian fissure in the dominant hemisphere (Figure 32). This area

Brodmann, "Feinere Anatomie des Grosshirns," in *Handbuch der Neurologie* (1910), Springer-Verlag, Berlin

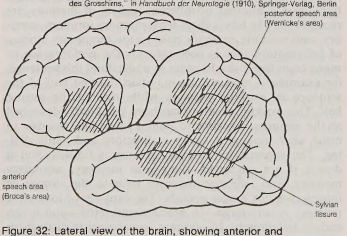

Figure 32: Lateral view of the brain, showing anterior and posterior speech areas (Broca's area and Wernicke's area).

Broca's and Wernicke's language areas

is divided into two major components named after the pioneers Paul Broca and Carl Wernicke. Broca's area lies in the third frontal convolution, just anterior to the face area of the motor cortex and just above the Sylvian fissure. This is often described as the motor, or expressive, speech area; damage to it results in Broca's aphasia, a language disorder characterized by deliberate, telegraphic speech with very simple grammatical structure though the speaker may be quite clear as to what he wishes to say and may communicate successfully. Wernicke's area is in the superior part of the posterior temporal lobe; it is close to the auditory cortex and is classically considered to be the receptive language, or language comprehension, centre. A patient with Wernicke's aphasia has difficulty understanding language; his own speech is typically fluent but is empty of content and characterized by circumlocutions, a high incidence of vague words like "thing," and sometimes neologisms and senseless "word salad." The entire posterior language area extends into the parietal lobe and is connected to Broca's area by a fibre tract called the arcuate fasciculus. Damage to this tract has been implicated in conduction aphasia, a disorder in which the patient can understand and speak but has difficulty in repeating what is said to him. The suggestion is that, in this condition, language can be comprehended by the posterior zone and spoken by the anterior zone, but it can not be easily shuttled from one to the other.

Distinction between aphasia and apraxia

It is important to note that aphasia is a disorder of language and not of speech (although an apraxia of speech, in which the programming of motor speech output is affected, may accompany aphasia). The writing and reading of aphasic patients, therefore, usually commits the same type of error as their speech, while the reverse is not the case. Isolated disorders of writing (dysgraphia) or, more commonly, reading (dyslexia) may occur as well, but these reflect a disruption of the additional processing required for these activities over and above that required for language.

One particular form of dyslexia deserves mention, as it is a clear example of a disconnection syndrome—a disorder resulting from the disconnection of two areas of the brain rather than from damage to a "centre." This is dyslexia without dysgraphia, or letter-by-letter reading, so called because it is not associated with writing disturbance and because the patients tend to attempt to read by spelling words out loud letter by letter. It usually results from a lesion in the posterior part of the left hemisphere that disconnects the visual areas of the brain from the language areas. This renders the language areas effectively blind, so that they cannot be brought to bear on visible language such as the written word. Writing is unaffected because the right hand is still connected to the left hemisphere, and, if letters can be spoken out loud correctly (which is not always the case), the patient will be able to hear himself say them and reintegrate them into words. Disconnection syndromes are an important concept in understanding behavioral disorders associated with brain damage. The possibility that deficits are caused by disconnection must always be borne in mind.

MEMORY

Memory is one of the most widely studied cognitive functions, and a number of different aspects of memory are recognized. The labels short-term memory, primary memory, and working memory refer to the temporary storage of information that is necessary for the performance of many cognitive tasks. In order to understand this sentence, for example, a reader must maintain the first half of the sentence in working memory while reading the second half. This working memory has been graphically described as the memory one uses to hold a telephone number in mind after looking it up in a directory and while dialing. The capacity of working memory is limited, and it decays if not rehearsed. Long-term memory, secondary memory, and reference memory refer to the storage of information for longer periods. The capacity of long-term memory is very large—in practice unlimited—and it can endure indefinitely. In addition, psychologists distinguish episodic memory, a memory of specific events or episodes normally described by the verb remember, from semantic memory, a knowledge of facts normally said to be known rather than remembered.

Importance of the limbic system

Almost certainly, memory is stored over wide areas of the brain rather than in any single location. However, amnesia, a disorder of memory, can occur after localized bilateral lesions in the limbic system—notably the hippocampus on the medial side of the temporal lobe, some parts of the thalamus, and their connections. This probably implies that these structures, rather than actually constituting a memory store, are important in the laying down of memories and in their recall when needed. Memory impairment resulting from damage in these areas is a disorder of long-term episodic memory and is predominantly an anterograde amnesia—that is, it typically affects the memory of events occurring after the illness or accident causing the amnesia more than it does memories of the past. Substantial retrograde amnesia (loss of the memory of events occurring before the onset of amnesia) rarely if ever occurs without significant anterograde amnesia as a result of brain damage, although it may occur alone in psychiatric illness.

Although amnesia is a disorder of long-term episodic memory and leaves short-term and semantic memory intact, both of the latter can be affected by brain damage. Some parietal lobe lesions may affect short-term memory without affecting long-term memory; this fact has contributed to a revision of the old theory that there are distinct short- and long-term stores, the latter being accessible only via the former. It has been suggested that short-term memory impairment—at least for verbal material—can be further subdivided into auditory and visual domains; however, these disorders manifest themselves in difficulty in understanding spoken and written language rather than in memory impairment (*i.e.*, they appear more like aphasia and dyslexia). Impairment of semantic memory, too, results in an impairment that resembles a loss of concepts or a language deficit more than it resembles what would usually be described as a memory impairment. Some forms of visual agnosia have been interpreted as semantic memory impairment, since the patients are unable to recognize objects such as chairs because they no longer "know" what chairs are or what they look like (or can no longer access that knowledge).

EXECUTIVE FUNCTIONS OF THE FRONTAL LOBES

The frontal lobes are the part of the brain most remote from sensory input and whose functions are most difficult to capture. They can be thought of as the executive that controls and directs the operation of the brain systems dealing with cognitive function. Indeed, the deficits seen after frontal lobe damage have been described as a "dysexecutive syndrome."

Consequences of damage to the frontal lobes

Frontal lobe damage can affect people in any of several ways, and the results are at once subtle and drastic. On the one hand, they may have difficulty initiating behaviour, in extreme cases being virtually unable to move or speak but more often simply having difficulty in getting started on a task. On the other, they may perseverate, being apparently unable to stop a behaviour once started. Rather than appearing apathetic and hypoactive, they are uninhibited, rude, and boorish. Such people may also have difficulty in planning and problem solving and may be incapable of creative thinking. Mild cases of this deficit can be revealed by a difficulty in solving mental arithmetic problems that are couched in words, even though it can be shown that the patient is capable of remembering the question and performing the required calculation. In such cases it appears that the patient simply cannot work out what to do, a difficulty described as a failure to select the appropriate cognitive strategy.

A unifying theme in these disorders is the notion of inadequate control or organization of pieces of behaviour that may in themselves be well formed. Frontal lobe patients are easily distracted. Although their deficits may be superficially less dramatic than those associated with posterior lesions, they can have a drastic effect on everyday function. Irritability and personality change are also frequently seen after frontal lobe damage. (G.Ra.)

NERVOUS SYSTEM DISEASES AND DISORDERS

Everything that the human being senses, considers, and effects and all the unlearned reflexes of the body depend upon the functioning of the nervous system. The skeleton and muscles support and transport the body, the heart sends it nourishment through the blood, and the alimentary system and lungs provide the nutrients; but the nervous system contains the epitome of the human being—the mind—and commands all perception, thought, and action. Its disturbance through disease or other malfunction leads to changes felt throughout the body. The most common or important of those diseases are discussed in this section.

Distinction between neurological and psychiatric illness

A distinction is usually drawn between structural or biochemical diseases of the nervous system (the province of the neurologist) and diseases of the mind (requiring the attention of a psychiatrist). This distinction is not, of course, absolute. Many organic brain diseases cause disorders of thought or mood, while the disorders of function that characterize mental disease are profoundly influenced by chemical factors. This section will be confined to those conditions generally regarded as organic nervous disease.

The first part describes the methods whereby neurologists obtain information about the problem—in other words, the history, the examination of the patient, and the laboratory investigations that can be employed. Next the anatomical sites of neurological disease are described, along with the principles used in localizing a disease within the nervous system. The third part gives an overview of pathological processes. Finally, an account is presented of the diseases of the nervous system, using a general classification based upon the primary or major site of the disease.

This scheme is not always possible to follow closely. For example, multiple sclerosis can affect the white matter of the cerebrum, the optic nerves, the cerebellum, or the spinal cord in any patient, so that allocating the disease to any one section must necessarily be arbitrary. Also, metabolic, toxic, inflammatory, and neoplastic diseases may behave similarly. The rule followed here is that the occurrence of various pathologies at different sites are recorded in the discussion of diseases affecting those sites, but a full description is given only in that part dealing with the site that the disease in question affects most consistently.

Acquisition of data

HISTORY

An old saying in medicine, "Listen to the patient; he is telling you the diagnosis," is especially true in neurology. The patient's description of his symptoms is the most valuable tool that the physician has for learning the nature and location of the disease. The patient who cannot give a history owing to coma or loss of speech presents a difficult challenge indeed.

Following are the symptoms most commonly presented to neurologists, with notes on their localizing value.

Symptoms of cortical or cerebral disease. *Altered consciousness.* One's ability to notice, attend to, and react to the environment is not an on–off phenomenon but a continuum. From full alertness a person can descend through drowsiness to stupor, a condition in which awareness is greatly reduced and the best motor response to stimulation is a groan or other vocal (but not verbal) reaction.

Coma

Deeper levels pass through light coma, in which strong stimulation produces only a clumsy motor response, to deep coma, in which there is only a reflex movement or no response at all. Such depression of consciousness occurs when there is impairment of the functions of the brain-stem reticular activating system or of the whole of the cerebral cortex. Brain-stem disorders can cause coma if the brain stem is compressed by other parts of the brain swollen through disease or if it is afflicted by local disease such as encephalitis, stroke, and concussion.

Diseases of the cortex causing coma include poisoning by sedative drugs, lack of glucose or oxygen in the blood, hemorrhage into the brain, and certain rare infiltrative disorders in which descent through the levels of consciousness occurs over weeks or months. Brief periods of unconsciousness, of which the patient may not be aware, occur in many forms of epilepsy, narcolepsy, repeated attacks of low blood sugar, and reduction in the supply of blood to the brain—particularly the brain stem.

Epilepsy is a condition in which excessive discharges of the neurons of the cerebral gray matter occur, causing maximal activation (rarely inhibition) of parts or all of the brain. This commonly causes visible seizures, but in a variety of epilepsy called petit mal or absence attacks, altered consciousness may be the only symptom. Disorders of sleep include inability to fall asleep or to stay asleep. This is seldom evidence of a neurological disorder and is commonly a psychiatric problem. Increased sleepiness, or hypersomnia, may be due to the causes of drowsiness mentioned above or to narcolepsy (see below *Diseases and disorders: The cranial nerves and brain stem*). Another cause of daytime drowsiness is sleep apnea, a disturbance of nocturnal sleep due to frequent brief episodes of obstructed breathing.

Headache. This is a common complaint of neurology patients. Tension headache is considered to be due to prolonged excessive contraction of the muscles that run front-to-back over the skull; this muscular tension often reflects mental tension. A persistent pressing or pulling pain, often with a throbbing component, is usually described. Migraine headaches may be combined with the foregoing or may be present as a throbbing, pounding pain with marked scalp tenderness, nausea and vomiting, dislike of noise and light, and irritability. (For further discussion of migraine, see below *Diseases and disorders: The cerebrum.*)

When pressure inside the cranium is increased, pain-sensitive structures in and around the brain are distorted and cause pain to be felt in an ill-localized area but often identifiably at the front or back of the head. This traction headache is potentially serious, since it may be caused by brain swelling, infection, bleeding, tumour, or obstructed flow of cerebrospinal fluid. Also, pain may be felt in the head region although the disorder causing the pain is situated elsewhere; an example is the facial pain sometimes felt with lack of blood to the heart. Local disease of such cranial structures as the jaw joints, the paranasal sinuses and teeth, the middle ear, and the skull bones themselves may also generate pain, requiring a careful, probing history in order to be identified as the cause of the headache.

Traction headache

Loss of memory. This symptom may have causes that are trivial or important. Poor concentration owing to preoccupation, fatigue, or depression is the most common cause, but widespread brain disease, vitamin deficiency, epilepsy, and dementia (loss of intellectual power) would have to be considered. When the period of memory loss is well defined, prominent causes are trauma to the head, seizures, poisoning (*e.g.*, with alcohol), and brief episodes of inadequate perfusion of the brain with blood. Some patients with severe mental problems such as hysteria claim to have totally lost their memory for past events and even for their own identities; this symptom is not encountered in people with organic brain disease.

Dementia

Disorders of concentration, attention, planning ability, and forethought—often combined with impaired social behaviour and emotional control and with reduced capacity to learn new things—characterize the problems of patients with dementia, a condition of global impairment of the highest intellectual powers. The most common single cause is Alzheimer's disease. Since dementia is the third most common cause of death (after diseases of the blood vessels and cancers), and since the average age of the Western Hemisphere population is increasing, dementia is attaining great importance in medical and social research. (See also below *Diseases and disorders: The cerebrum.*)

Patients with dementia—and those with almost any more localized brain disorder or general medical disease—are

at risk of developing a related but more acute syndrome called confusion or acute brain syndrome. In this case, patients lose their orientation in time, space, and person; they may show altered levels of consciousness, emotional instability sometimes amounting to terror, physical excitability, and agitation and disorderliness, as well as hallucinations and delusions to which they hold tenaciously despite reasonable counterargument. Of all the causes of acute brain syndrome, generalized metabolic diseases and intoxication with sedative drugs (including alcohol) are the most common.

Aphasia

Language and speech deficits. Aphasia is a failure to use language in communication. It is caused by damage to the part of the brain that controls language function—namely, the area encompassed by the back of the frontal lobe, the front of the parietal lobe, and the upper surface of the temporal lobe (usually on the left hemisphere but on the right in a small proportion of left-handed people; see above *Functions of the human nervous system: Higher cerebral functions*). Patients with aphasia may know exactly what they want to say, but they are unable to express it in spoken (and often written) words. With disease affecting the Wernicke's area farther back on the temporal lobe, the problem may be in comprehending the meaning of spoken or written language, so that normal speech sounds like a foreign tongue. Strokes are the most common cause of aphasia, but any focal brain disease can be responsible.

Similar problems of comprehension are apraxia and agnosia. Apraxia is an inability to perform a purposeful action; agnosia is a failure to comprehend the significance of a nonlanguage stimulus. Shown a comb or a key, an apraxic patient may be able to name it but may not know how to use it. Hearing a trumpet, an agnosic patient may be unable to recognize the origin of the sound.

Dysarthria, or difficulty in articulation, usually has a local cause in the nerves and muscles in and around the mouth or in their central connections. Problems in the production of speech sounds, called dysphonia, often indicate a problem affecting the larynx or the nerves and muscles of that structure. Since the cranial nerves supplying these areas originate in the brain stem, neurological disease of that region may be a cause.

Nonspecific symptoms. Alteration in mood is common in association with neurological disease, either as a result of the pathological process itself or of the patient's reaction to his awareness of disease. Although depression is most common, unusual euphoria or mood swings may occur with disease of the frontal lobes of the brain. Other nonspecific symptoms of brain disease are impairment of recent and (less often) remote memory, concentration, attention, energy, comprehension of concepts, reasoning, logical thinking, and ability to plan ahead. Any or all of these are impaired in patients with dementia (see above).

Pain is another important symptom. Although the central nervous system is not supplied with sensory fibres that report sensations of pain, severe pain can result from thalamic strokes. Also, headache, one of the most common symptoms expressed by patients, has both central and peripheral components, and many disorders affecting the peripheral nerves and muscles are painful. Neuralgias, or attacks of pain along the sensory nerves, are due to irritation of some of the cranial nerves or spinal roots. In each case the quality, severity, timing, location, and accompaniments of the pain may be sufficient to allow precise diagnosis.

Cranial nerves. Symptoms reflecting disease of the cranial nerves are even more varied than those suggesting cortical or cerebral disease.

Damage to the first (olfactory) nerve leads to anosmia, or loss of the sense of smell, on the side supplied by the nerve. Head injuries and compression by tumours are possible causes, though local nasal disease is more common. Hallucinations of smell occur in temporal lobe diseases such as epilepsy or tumour and also in depressive illnesses.

Disorders of the second (optic) nerve cause visual loss in the affected eye. In the early stages of disease, when the process is irritating the nerve rather than decreasing its conducting ability, positive phenomena such as streaks of light may be seen. When the optic pathways are affected within the brain, the precise location of the disease can be determined by testing the pattern of visual loss affecting both eyes. Pain in the eyes is sometimes due to neuritis of the optic nerves, but it is usually caused by ocular disease.

Double vision

When any of the three oculomotor nerves are affected, the eyes are not able to retain parallelism of their axes, so that light falls on different parts of the two retinas and patients complain of diplopia, or double vision. With central lesions, a disorder of ocular posture in which the eyes jerk spontaneously, known as nystagmus, may lead to complaints of jumping images.

Compression or other disease of the fifth (trigeminal) nerve causes complaints of facial numbness. Since some diseases of the brain stem can cause similar problems, precise inquiry and examination of signs localizing the disease to the brain stem are important. In trigeminal neuralgia, jabs of excruciating pain are felt on one side of the lower face, mainly in people over the age of 55 years.

The seventh (facial) nerve is damaged most commonly by swelling within the facial canal in the temporal bone, thought to be due to viral infection. This gives rise to Bell's palsy, a weakness of the muscles of the side of the face in which the mouth and eye cannot be closed tightly. Numerous other conditions affect the facial nerve.

When both divisions of the eighth (vestibulocochlear) nerve are affected by disease, there may be positive symptoms such as ringing in the ear (tinnitus) and a sensation of spinning (vertigo) as well as negative symptoms such as deafness.

Damage to the ninth through 12th cranial nerves, which have their nuclei of origin in the medulla oblongata, causes dysphonia, dysarthria, and dysphagia (difficulty in swallowing). All three are symptoms of the gravest import, since their causes often lead to further paralyses and to an inability to swallow or clear the airway of secretions that may be aspirated into the lungs. Involvement of the 11th (accessory) nerve leads to weakness of the neck muscles. Lesions of the 12th (hypoglossal) nerve, which supplies only the tongue, may have little clinical effect if unilateral, but if both sides are affected, speech and manipulation of food in the mouth are disturbed. (For description of the cranial-nerve pathways, see above *Anatomy of the human nervous system: The central nervous system.*)

Symptoms of the body and limbs. Symptoms expressed in the limbs and trunk and pointing to neurological disease include weakness and wasting of muscles, clumsiness, and unwanted movements. None of these is caused by disease of one particular site, so that only by thorough inquiry can the neurologist localize the problem. Thus, weakness can be due to any of the following: disorder of the upper motor neuron anywhere between the cortex, where it originates, and the ventral horn of the spinal cord; cerebellar disease; lack of energy or motivation as in hypothyroidism, dementia, or depression; disorders of the basal ganglia; or disorders of the motor unit, encompassing the lower motor neuron, the motor end plates, and the muscle fibres. Peripheral nerve diseases, end-plate disorders such as myasthenia gravis, and both genetic and acquired muscle diseases, can also be responsible. Finally, loss of feedback from sensory fibres of a limb also reduces muscular power.

The complaint of clumsiness has a similar list of potential causes. Weakness is a negative symptom—that is, it represents the loss of a normal function. Involuntary movements, however, are new (or positive) events. Chorea is a condition in which the face and distal parts of the limbs make brief, jerky, dissimilar, involuntary, and repetitive movements; the lesion is usually found in the caudate nuclei, where many pathologies may be the cause. Ballismus, a similar but more severe condition, is due to a lesion of the subthalamic nucleus. Patients with athetosis make slower, writhing, sinuous movements intermittently or continuously; dystonias are even slower movements or abnormal postures of the head or the limbs adopted by patients with certain basal ganglion diseases. Tics and habit spasms are of uncertain origin. In such cases, and when no pathology at all can be demonstrated, the condition may be labeled "functional," implying (usually erroneously) a psychological disorder.

Involuntary movement

Alterations of sensation may also be positive or negative; the former include tingling, burning, itching, and pain, while the latter consist of diminution or loss of some or all sensations. Sensations carried by large, heavily myelinated fibres, such as position sense, discriminative light touch, and vibration sense, tend to be affected together, as do those carried by the smaller, thinly myelinated or non-myelinated fibres, including pain, crude light touch, and temperature. As with the complaint of weakness, careful inquiry and examination are necessary to define the exact boundaries of abnormal sensation and thus to diagnose the site of the causative pathology.

Autonomic nerves. A last group of symptoms signifies involvement of the autonomic nervous system. Complaints of alteration in bladder or bowel habit or sensation, of increased or decreased sweating, of faintness (due to a drop in blood pressure after a change in posture), of impaired accommodation of vision, and of altered sexual potency are those most commonly met.

PHYSICAL EXAMINATION

While taking the history, the neurologist notes the patient's level of awareness, posture and gait, demeanour and expression, speech, and, to some extent, personality. He also looks for evidence of weakness, incoordination, wasting of certain muscle groups, and abnormal movements. The formal examination then begins with an examination of higher cerebral functions and proceeds methodically through an evaluation of the cranial nerves, motor systems, and sensory systems.

Higher cerebral functions. In order to evaluate the patient's orientation in place and time, tests of concentration, of recent and remote memory, and of ability to follow simple spoken or written commands, as well as other tests of language, are usually given. Comprehension, reasoning, and planning can be tested, for example, by asking about the similarities and differences between two objects (child/dwarf, fly/tree, wall/fence) or by asking the patient to explain the message or moral contained in a proverb.

Testing comprehension

Tests for apraxias and agnosias are helpful when cortical disease is suspected, as are tests measuring the ability to perform simple drawing and writing tests and to copy simple figures. Standardized tests for examining these functions apply quantitative measurements to any deficit, which can be analyzed further by more sophisticated testing at the hands of a clinical psychologist.

The process continues with examination of the head and neck, looking especially for local tenderness or deformity and for evidence in children of enlargement of the head, which may suggest hydrocephalus. The physician may also use a stethoscope to auscultate (listen to) the major blood vessels in the neck, listening also over the skull for sounds indicating unusual communication between arteries and veins. Irritation of the meninges, as occurs with intracranial infection or bleeding, leads to unusual stiffness on attempts to flex the neck passively, as well as to an inability to straighten the bent knee when the hip is flexed (a condition called Kernig's sign).

Cranial nerves. *Olfactory.* The ability to perceive (not identify) a mild odour, such as coffee, tar, or lemon, is tested.

Optic. The optic nerve head is the only part of the central nervous system accessible to vision; an ophthalmoscope is used for this purpose and to see the retinas and the small arteries and veins that lie upon them. Visual acuity is tested with a standard test card, and the visual field is examined by asking the patient to signal when he sees an object brought in toward the centre of vision from the periphery. A simple machine called a perimeter partly automates and quantifies this examination.

Oculomotor. The three oculomotor nerves are tested together by asking the patient to gaze in different directions on command and to follow a moving object with the eyes only. The character of any double vision is noted. The shape, size, and reactivity of the pupils—both to light and to close objects—are also tested.

Trigeminal. Motor functions are examined by asking the patient to clench the teeth and by testing the jaw reflex by tapping the chin. This is one of the few physiological reflexes that is normally not detected. The sensory functions of the nerve are examined by stimulating the face gently with the finger or cotton wool for light touch, cold steel for temperature, and a pin for scratch or pain sensation. This procedure is done for the three anatomical divisions of the nerve on each side of the face. Finally, cotton wool is touched to the cornea to assess the corneal reflex. Normally, an abrupt blink is produced.

Facial. This motor nerve is examined by asking the patient to screw up the eyes, bare the teeth, and try to whistle. The facial nerve also carries fibres subserving the function of taste on the front of the tongue, so that weak solutions of sugar, salt, lemon, or vinegar can be used to test its function. (Flavour—as opposed to the tastes of sweetness, saltiness, bitterness, and sourness—is mediated exclusively by the olfactory nerve, even for foods inside the mouth.)

Vestibulocochlear. For the cochlear nerve, hearing tests examine the overall acuity to the whispered voice. Rinne's test differentiates the patient's ability to hear the hum of a tuning fork held both beside the ear and with its foot on the mastoid bone of the skull behind the ear. If the sound is louder at the latter site, impairment of the conduction of vibrations through the chain of three small bones in the middle ear is likely, while if the former sound is louder, any deafness is likely due to disease of the inner ear or of the cochlear nerve. Weber's test consists of placing the tuning fork on the forehead; the sound is better perceived either in the ear without nerve deafness or (paradoxically) in the ear affected by mild middle-ear deafness. More sophisticated tests require the equipment found in a hospital or clinical audiometry laboratory.

Hearing tests

Tests of the vestibular nerve are not routinely performed. The usual screening procedure for postural vertigo is to await the appearance of vertigo or nystagmus while tipping the patient's head back and down 45 degrees. Further testing is done in an electronystagmography laboratory. It includes the assessment of nystagmus when the external ear canals are irrigated with warm or cool air or water, when the patient is rotated, or when he is made to gaze in various directions.

Glossopharyngeal and vagus. The usual tests are for the presence of touch sensation on the soft palate and the back of the throat (the latter usually eliciting a gagging reflex), the elevation of the palate on phonation (which should be symmetrical but rises to the stronger side in the presence of weakness on one side), the quality and loudness of the voice, and the normal slowing of the heartbeat when one carotid artery is compressed in the neck at the level of the carotid sinus.

Accessory. The sternocleidomastoid and trapezius muscles, supplied by this nerve, are tested by having the patient push his head forward and shrug his shoulders upward against the examiner's resistance.

Hypoglossal. Atrophy and weakness of the tongue muscles can be assessed by measuring the deviation of the tongue toward the weak side upon protrusion.

Motor systems. The presence of gait and postural disturbances, of abnormal movements, and of atrophy may be noticed when the patient is giving the history. Examination is then formalized and extended under five headings.

Inspection. Inspection of the body may show patterns of muscle atrophy. Depending on the pattern of atrophy, this suggests lesions in nerve roots, in more peripheral locations of the nerves, or in the muscles themselves with no involvement of nerves. Symmetrical, proximal atrophy is more likely to indicate primary muscle disease, while unilateral atrophy (*i.e.*, affecting only those muscles receiving their motor supply from a single nerve) naturally suggests a lesion of the supplying nerve.

Muscle atrophy

Fasciculations are brief, irregular, involuntary twitches of muscles that do not lead to the movement of a joint but that are visible and can be felt by the patient. If accompanied by atrophy and weakness, they may be symptoms of serious underlying motor neuron disease (see below *Diseases and disorders: The peripheral system*). Other abnormal movements, such as chorea and dystonia, are also noted, as are changes in the skin and joints caused by nerve or muscle disease.

Muscle tone. When the examiner flexes or extends the joints in a relaxed limb, a certain resistance, known as tone, is felt. This resistance decreases whenever the reflex arc is damaged (usually at the level of the peripheral motor or sensory nerve), but it may decrease with primary muscle or spinal cord disease. An increase in resistance occurs in the presence of a lesion of the upper motor neurons—that is, anywhere along the pathway from the motor cortex down to the pool of ventral horn neurons in the spinal cord—by which the muscles in question are supplied. This so-called hypertonia may increase against resistance and then suddenly give way ("clasp-knife spasticity"), or it may be constant throughout the range of movement ("plastic" or "lead-pipe" rigidity). In the presence of tremor this latter form has a ratchety feel to it, leading to the name cogwheel rigidity. Rigidity suggests a lesion of the basal ganglia, but spasticity implies disease of the direct corticospinal tracts.

Hypertonia

Power. Power is tested either by examining single muscles in cases where a local or lower motor lesion is suspected or by assessing the patient's strength in flexing or extending joints—in which case a number of muscles are tested at once. The latter method is employed when evidence of an upper motor lesion is being sought.

Reflex activity. Three main types of reflex activity are tested: an increase in the speed and strength of the reflex response, a decrease in response, and the presence of abnormal reflexes. Using a tendon hammer, the examiner taps a suitable tendon with the patient relaxed and observes the response—usually a single brief, brisk contraction of the appropriate muscle. Response is normally enhanced if muscles contract elsewhere in the body. When an upper motor neuron lesion is present, the response is excessive and the muscle may contract repeatedly.

The tendon tap

Tendon reflexes are diminished or absent in the presence of a lesion of the lower motor neuron, of the muscle itself, or of the afferent (sensory) side of the reflex arc. Superficial reflexes can be elicited by stroking the wall of the abdomen with a thin stick; this should cause the underlying muscles to contract. Unlike tendon reflexes, the superficial reflexes disappear in the presence of a corticospinal tract lesion.

The only abnormal reflex routinely detected is the plantar, or Babinski, response. Normally, the great toe curls downward when the examiner draws a stick up the sole of the foot. In the presence of a corticospinal tract lesion, it curls upward instead, and the other toes may fan out.

Coordination. Disease of the cerebellum leads to abnormalities of the rate, range, and force of voluntary movements and to disturbances of posture and gait. The jerky oscillations of the eyes constituting nystagmus are also notable. Tests employed to assess cerebellar function in the limbs include those of rapid alternating movements, the subject being asked to touch, successively, the examiner's finger held before him and his own nose, to run one heel down the opposite shin, or to perform piano-playing movements with the fingers on a resonating surface. The amount of agility and precision of control over the limbs is noted by the examiner.

Sensory systems. Because the examination can be so long and tedious that even the most cooperative patient may give misleading responses, an examiner does not attempt sensory testing except on a brief screening basis until he has a clear idea of the kind of problem for which he is looking. Questions to be answered are: Which (if any) modes of sensation are impaired? To what degree are they impaired? And in which areas? From the results of careful sensory testing it may be possible to localize the site of a lesion in the nervous system with great accuracy. To achieve this localization, it may be necessary to compare sensation in different dermatomes (areas of the body innervated by different spinal segments) or in areas supplied by different parts of the brain or spinal cord.

The stimuli employed include: the examiner's finger or a cotton-wool applicator or paintbrush, for testing sensations of light touch; steel or glass tubes filled with warm and cold water, for temperature; a pin, for superficial pain and scratch sensation; a tuning fork, for vibration; and, for the sense of passive movement of joints, gentle movement of a digit up or down outside the patient's range of vision. Discriminative touch can be tested by determining whether the patient can identify an object placed in his hand, can determine whether he is being touched by one or two ends of a blunt pair of compasses, or can identify where he was touched or what number or letter was drawn on his skin by the examiner. When disease of the contralateral parietal lobe is involved, many of these tests of discriminative sensation show abnormality; in such cases, simultaneous stimulation (usually visual or tactile) on both sides of the body leads to identification of only one stimulus—that on the side opposite the healthy lobe.

LABORATORY INVESTIGATION

Further useful data may be acquired from the results of the tests described below.

Electrical tests. A recording of the inherent electrical rhythms of the brain was first achieved by the German psychiatrist Hans Berger in the late 1920s. Today, electroencephalography is a routine procedure, used mainly to localize the origin of epileptic discharges (Figure 33) but also to localize and, occasionally, indicate the nature of destructive disease of the underlying brain. It is also employed to indicate the degree of generalized brain disease in such metabolic disorders as liver failure, and it may show characteristic patterns in some viral and slow-viral illnesses. It can only confirm a diagnosis of brain death made through other means.

Electroencephalography

From S.G. Bayliss in W. Pryse-Phillips, *Epilepsy* (1969), Butterworth Scientific Ltd.

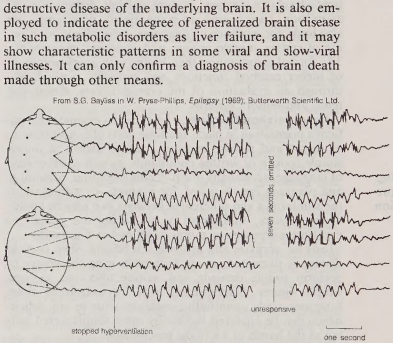

Figure 33: *An electroencephalogram (EEG) from a patient having an attack of petit mal epilepsy.* The sudden onset of abnormal discharges, recordable from all areas of the scalp as waves and spikes on the graph, is accompanied by loss of consciousness, without convulsion, for approximately 20 seconds.

The electroencephalogram (EEG) is produced by placing electrodes on or in the scalp and then recording the changes in electrical potential that take place while the subject is at rest or stimulated by flickering light, noise, or drugs.

Tiny voltages transmitted by the peripheral nerves are amplified in the central nervous system. When multiple stimuli are given and the electrical activity of the relevant cortical area is recorded for 10 to 1,000 milliseconds after each stimulus, consistent potential changes can be recorded by averaging the responses and eliminating background electrical "noise." These potential changes, recorded as waveforms on the EEG, are very similar in all humans. Their absence, delay, or distortion indicates disease in the central conducting pathways, thus allowing further localization of disease (but not indicating the nature of the responsible pathology). Computerization has allowed the generation of "maps" of electrical activity and the more precise localization of abnormal electrical discharges.

Stimulation may be of peripheral nerves using weak electrical shocks (somatosensory evoked potentials, or SEPs), of the auditory apparatus by click stimuli given through headphones (brain-stem evoked potentials, or BAEPs), or of the optic nerve using flashes of light or an alternating checkerboard pattern on a screen (visual evoked potentials, or VEPs). These tests are employed most commonly in the search for sites that show no clinical evidence of

disease (as in multiple sclerosis) and in the assessment of dementias, spinal-cord diseases, and disorders of the visual pathways. BAEPs are of particular value in the diagnosis of tumours at the base of the brain.

Techniques similar to those described above are used to study the function of the retinas (electroretinography) and the posture and movements of the eye (electronystagmography).

Techniques are under development whereby the brain can be harmlessly stimulated through the scalp and skull, either by brief electrical current or magnetic field, and the resulting muscle response recorded. The interval between stimulus and response can be measured and may indicate disease of the motor pathways.

Electromyography

Electrical examination of the peripheral nervous system is also possible. Electromyography (EMG) is the study of muscular electrical activity by means of fine needle electrodes inserted into the muscle. The waveforms recorded with primary disease of muscles differ somewhat from those found when the muscles are deprived of their motor innervation. This allows both improved precision in the detection of muscle involvement and differential diagnosis of the causative pathology. Single-fibre EMG (SFEMG) is a technique in which even fewer muscle fibres are examined. Particular attention is paid to the consistency of activation of single muscle fibres, since this varies widely in diseases of the motor end plate (see below *Diseases and disorders: The peripheral system*).

Measurement of the speed of conduction of impulses along sensory and motor fibres is possible with nerve conduction studies (NCS). These can localize the site or sites of peripheral nerve disease and may even indicate the nature of the disorder affecting them. They are almost painless and greatly augment the findings of clinical examination.

Biochemical tests. Few blood tests are of value in the diagnosis of neurological disease. The serum levels of a muscle enzyme, creatine kinase (CK), are increased in many muscle disorders, particularly the inherited muscular dystrophies and muscle inflammatory disease. Tests showing abnormal hematological and biochemical results may also help diagnose a number of inherited metabolic disorders and, of course, generalized medical conditions that affect the nervous system.

Spinal tap, or lumbar puncture

Study of the pressure and the cellular and biochemical composition of the cerebrospinal fluid is of great value in the diagnosis of central nervous system infections, some tumours, and multiple sclerosis. Cerebrospinal fluid is obtained almost painlessly by inserting a needle through the skin in the small of the back so that it passes deeply between the bony vertebrae into the fluid sac surrounding the spinal cord and nerve roots. (The needle is inserted below the termination of the spinal cord, so that the cord cannot be damaged.) Identification of one or two bands of protein in the fluid is a valuable aid in the diagnosis of multiple sclerosis and of other smouldering inflammatory diseases of the central nervous system.

Pathological examination. A diagnosis may be made by biopsy, the direct examination of surgically removed nerve, muscle, or brain tissue. Special stains are often employed to increase diagnostic accuracy. A number of conditions affecting the central and peripheral nervous systems can be differentiated only by their appearance under the electron microscope.

Radiological tests. *Conventional X rays.* Plain X rays are of relatively minor value in neurological diagnosis. Diseases affecting the skull bones (malformations, chronically raised intracranial pressure, a few metabolic diseases, tumours, and trauma) can be diagnosed with this procedure, as can disorders of the spinal column and a small number of benign cerebral tumours, but X rays employing the injection of iodine-containing "contrast media" or air are far more valuable. Such studies allow better visualization of the spine (myelography), of the fluid-containing ventricles of the brain (ventriculography), or of the arteries or veins within the cranium and neck (angiography and venography). In most cases, however, even contrast X rays give only a silhouette of the lesion or a definition of its blood supply. While this is of great diagnostic value in disorders of the blood vessels themselves (aneurysms, angiomas, large vessel disease), the location of the actual pathology elsewhere must usually be inferred.

X rays employing contrast media

The contrast medium is injected, often under a general anesthetic, into an artery, vein, or, during an operation, the ventricles. Injections into the cerebrospinal fluid at the lumbar area do not normally require anesthesia. All these procedures carry some risk of morbidity, even of mortality, but for many years they have been the mainstay of laboratory investigation of central nervous system disease.

Computerized axial tomography (CAT). The greatest advance in neurological diagnosis since the discovery of X rays occurred in the early 1970s when CAT scanning (also called computerized tomography, or CT, scanning), conceived by William Oldendorf and developed by Godfrey Hounsfield, became generally available. Although often employing contrast media to enhance the quality of the images obtained, this test is barely invasive. It allows visualization of three- to 10-millimetre sections of the brain, skull, spinal cord, and spine (as well as other parts of the body) in two dimensions and with enough clear distinction between black, gray, and white areas of the image to allow pathological diagnosis in many cases.

Magnetic resonance imaging (MRI). While CAT scanning is a pure X-ray technique, other computerized investigations yield data about the form or function of the central nervous system without the use of X rays. In MRI, the patient is placed within a magnetic coil, and radiofrequency energy is applied to the head. These harmless radio waves excite protons that form the nuclei of hydrogen atoms in the brain. The protons then give off measurable electrical energy, which, with the aid of a computer, can be used to construct a map of the tissue. Since MRI hardly visualizes bone, it gives excellent images of the intracranial and intraspinal contents (Figure 34).

By courtesy of Romeo Ethier

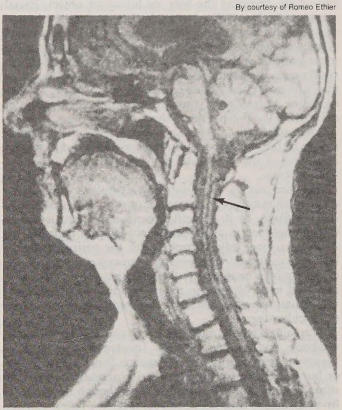

Figure 34: *Magnetic resonance image (MRI) of a patient with syringomyelia.*
An abnormal cavity in the spinal cord, called the syrinx, is indicated by the arrow.

Positron emission tomography (PET). Another noninvasive test, PET, employs inhaled or injected radioisotopes and computer techniques to map the metabolic activity of the brain. This is of particular value in the diagnosis of certain degenerative and metabolic disorders.

Doppler ultrasound studies. High-frequency sound waves can be used in a way similar to radar in order to show the form of deep body structures. In neurological diagnosis, demonstration of the echoes from midline structures and from the ventricular walls has proved valuable, but CAT and other scanning techniques are making such

tests unnecessary. Doppler studies of the carotid arteries in the neck, however, represent valuable noninvasive tests that can give useful information about the size and any deformity of these vessels.

Radioisotope scans. The blood–brain barrier keeps large molecules from passing into the brain or spinal cord from the blood. When this barrier is destroyed—as it is around tumours, blood clots, infarcts, or infections—fluid and dissolved solids can pass into the brain. Some radioisotopes injected into the bloodstream also cross into brain tissue and remain there. Measured by outside detectors, the radioactivity of the isotopes can then produce a map of the areas where the barrier has been destroyed. This technique has been valuable in the detection of the intracranial pathologies mentioned above, although the CAT scan is more accurate. Isotopes are also used to visualize cerebral blood flow in patients with cerebrovascular disease, as well as the flow patterns of cerebrospinal fluid in some cases of dementia and after skull fracture.

Crossing the blood–brain barrier

Localization

The nature and pattern of the symptoms and physical signs of neurological disease allow inferences to be drawn about the sites of the lesions causing them. The main sites are described below, with notes on some of the clinical features that lead to their localization.

LOWER-LEVEL SITES

Muscle. Muscle disease is frequently hereditary—in which case a positive family history may be obtained. One complaint suggesting muscular involvement in the disease is that of weakness, usually symmetrical and mainly affecting the proximal or girdle muscles. This type of weakness is noticed on climbing stairs, arising from a deep easy chair, brushing the hair, or lifting an object. Facial weakness leads to difficulty in whistling and to drooling of saliva. Weak masticatory muscles tire easily, so that food is chewed with difficulty, while bulbar muscle involvement leads to problems with phonation, articulation, and swallowing. Diseased muscles are often atrophied but they may also swell and be tender or subject to cramp. In the condition known as myotonia they continue to contract even when the patient wants them to relax.

Complaints of weakness

Motor end plate. The only symptoms resulting from a failure of the motor nerve impulse to cross to the muscle end plate at the neuromuscular junction are fatigability and weakness.

Peripheral nerves. Diffuse disease affecting the peripheral nerves may have a greater impact on either motor or sensory fibres, or it may affect both to an equal degree. Commonly, nerves are affected according to their length, the longest ones "dying back" from the periphery, being least able to sustain vital metabolic processes. In such cases of generalized neuropathy, the signs tend to be symmetrical and most obvious in the extremities. In other cases, individual nerves are affected as a result of compression or vascular disease.

Complaints when motor nerves are affected include weakness and muscle atrophy. Involvement of sensory nerves leads to numbness, paresthesia (tingling), shooting or burning pains, and hyperesthesia (undue sensitivity to stimuli, which are felt as painful even though innocuous). In both motor and sensory neuropathies, reflex activity is reduced or absent. Examination can show the patterns of weakness and atrophy or of sensory less based on the pathology and on which nerves are involved.

Spinal nerve roots. The symptoms and signs of involvement of spinal roots are the same as for peripheral-nerve involvement except that the territory of involvement conforms to the area supplied by the spinal roots rather than the nerves. Also, generalized symmetrical sensory loss is not seen in these cases.

Spinal cord. The structure of the spinal cord, with long ascending and descending fibre tracts and entering and emerging nerve roots, is reflected in the symptoms and signs of disease. There is often a combination of the signs of root lesions (often including pain) at the site of the pathology with signs of damage to the tracts below that level. For example, injury to the cord at mid-thoracic levels spares the arms which are innervated by fibres originating from higher segments, but it induces characteristic signs (abnormal posture, spastic tone, weakness, increased deep reflexes, and abnormal plantar reflexes) of damage to motor neurons originating below that level—as well as loss of bladder control.

Loss of function in ascending sensory pathways will lead to loss of superficial pain, temperature, crude light touch, and scratch sensation if the spinothalamic tract is damaged, but it will cause loss of sense of joint position, vibration, and discriminative light-touch sensation if the dorsal columns are the site of injury. Because of the crossing of its fibres shortly after they enter the cord, spinothalamic-tract lesions on the left side of the cord lead to loss of sensations on the right side of the body below the lesion. This is not true of lesions of the dorsal columns, which carry fibres originating from the same side of the body.

Loss of sensation

Damage to sympathetic autonomic fibres that run in the cervical portions of the spinal cord may lead to drooping of the eyelid and a smaller pupil on the same side as the injury.

HIGHER-LEVEL SITES

Brain stem. Damage to the brain stem threatens life, since so many of the control centres for bodily functions (for example, consciousness, respiration, and blood pressure), are situated there. As with lesions of the spinal cord, localization of the level of the lesion is made possible by noting which of the cranial nerve functions are affected. The horizontal extent of the lesion can be estimated by determining which of the vertically running pathways are involved.

As one example, a midline lesion of the medulla oblongata is likely to involve the pyramidal tracts (the descending motor pathway) and the medial lemnisci (the ascending tracts relaying sensory impulses from the dorsal columns of the spinal cord). This produces signs of an upper motor-neuron lesion and of dorsal-column-type sensory loss at all levels below the medulla. Such signs could theoretically be produced by a lesion anywhere between the mid-medulla and the third cervical segment of the spinal cord, but the added finding of 12th-nerve palsy with atrophy of the tongue accurately localizes the lesion in the midline of the medulla, low down, since that is where the nucleus of the 12th cranial nerve is situated.

A lesion of one side of the medulla spares the pyramidal tracts and medial lemnisci, but it involves the sympathetic pathways, the fibres entering the cerebellum in its inferior peduncle, some of the eighth, ninth, and 10th cranial nerve nuclei, and the descending nucleus and tract of the fifth cranial nerve on the side of the injury, as well as the ascending fibres of the spinothalamic tract from the opposite side of the body. Major features of the lesion, therefore, include: incoordination of voluntary limb movements, drooping eyelid and small pupil, and loss of light-touch and pinprick-pain sensation over the face (all on the side of the lesion); vertigo and vomiting; and loss of spinothalamic function (light-touch and pinprick pain again) on the opposite side of the body. Similar principles govern the localization of lesions of the brain stem at higher levels.

Cerebellum. With damage to the oldest part of the cerebellum, which lies deep in the midline, a patient has difficulty in maintaining an upright posture and may even be unable to sit up in bed. Nystagmus (jerky movements of the eyes at rest) is also likely. The vermis and anterior lobes of the cerebellum developed later in evolution; lesions there particularly influence gait. The lateral lobes represent the "newest" parts to develop; when they are damaged, ataxia (incoordination) of the limbs is found, so that rapid, alternating movements cannot be performed and all voluntary activity is disordered in rate, range, and force. As a result, arm and leg movements are awkward, irregular, and impaired by a tremor that may be so severe that self-care is impossible despite the absence of significant weakness.

Loss of co-ordinated movement

Basal ganglia and thalamus. Thalamic lesions lead to loss of all sensation on the opposite side of the body,

sometimes accompanied by extreme pain. Since tumours and strokes affecting this region are likely also to damage the fibres in the adjacent internal capsule, signs of damage to upper motor neurons may also be present at all lower levels, thus affecting the cranial nerves as well as the spinal segments. Disorders of eye movement and speech are also sometimes found with thalamic lesions.

Lesions of the hypothalamus have many effects upon the regulation of the body's metabolism, such as water and solute control, sexual activity, and appetite for food.

Basal-ganglion diseases lead to abnormal control over movement, manifesting itself as involuntary movements or as a reduction in the spontaneity or speed of voluntary movement.

Cerebral hemispheres. The frontal lobe is concerned with many of the components of intelligence (foresight, planning, and comprehension), with mood, with motor activity on the opposite side of the body, and (in the case of the dominant hemisphere) with speech production. Swelling of the underside of the frontal lobe may compress the first cranial nerves with resulting loss of smell sensations. Irritation of the frontal cortex may cause either generalized or focal motor epileptic seizures, the latter involving the opposite side of the body.

Damage to the dominant temporal lobe is manifested by difficulty with comprehension of spoken speech. The right temporal lobe (usually nondominant for speech) has a special role in the appreciation of nonlanguage sounds such as music. Irritation of a temporal lobe may lead to auditory or olfactory hallucinations. Memory functions are duplicated in the two temporal lobes; if one is damaged, there is little effect, but bilateral damage leads to a permanent, catastrophic inability to learn new data.

Loss of speech and purposeful movement

Parietal-lobe functions also differ on the two sides. In most people the left parietal lobe shares in the comprehension of spoken and written language and of arithmetic, interprets the difference between right and left, identifies body parts, and is responsible for determining how to perform meaningful motor actions. Damage to this lobe leads to forms of apraxia, the inability to perform purposeful actions. The right parietal lobe is concerned with visuospatial orientation, and damage typically leads to deficits such as dressing apraxia (inability to put on clothes), constructional apraxia (difficulty in creating or copying two- or three-dimensional forms), and a phenomenon called sensory competition, or sensory extinction, which is an inability to recognize two stimuli when both are presented together on opposite sides—most easily demonstrated in the realms of touch and vision. Each parietal lobe is also concerned with so-called cortical sensation or discriminative touch, the analysis and interpretation of touch sensations originating on the other side of the body. Damage can cause a form of agnosia, in which the sensation is present but the interpretation or comprehension is lacking. Irritation of a parietal lobe also leads to tactile hallucinations, the false perception of touch sensations on the other side of the body.

Loss of vision

The occipital lobes are almost exclusively concerned with the reception of visual impulses. Damage to one side leads to homonymous hemianopia, loss of all sight in the field of vision on the other side. This deficit applies to either eye: with a lesion of the right occipital lobe, for example, a patient is blind to any visual stimulus presented from the left side, whether to the right or to the left eye. This may be contrasted with the "blinkers" effect caused by compression of the optic chiasm, usually by a tumour arising out of the pituitary fossa. At the optic chiasm the optic nerve fibres from the nasal halves of the right and left retinas mingle and cross to the opposite side. Since the nasal retinas "see" the temporal fields (the right nasal retina receiving impulses from objects to the right, the left from objects to the left), the subject with a lesion of the optic chiasm is able to see straight ahead but not to either side. This is called bitemporal hemianopia.

Irritation of an occipital lobe causes the subject to see visions. If the lesion is far back in the lobe, the visions may be of unformed lights, colours, or shapes. However, the visions may be vivid and sharply defined pictures (visual hallucinations), as though a videotape of previous visual experiences were being replayed, if the lesion is farther forward and in the area where the parietal, temporal, and occipital lobes adjoin. This area of the cortex appears to be concerned with the analysis and storage of complex perceptions.

Pathologies

Many types of disease affect the nervous system. A short description of these types and an overview of representative disorders follows.

One pathology of the nervous system is genetic. Inherited neurological diseases are relatively common and may affect any site. Examples of such diseases are: Duchenne's and other muscular dystrophies; hereditary motor, sensory, or mixed neuropathies; spinocerebellar degenerations; disorders of closure of the fetal neural tube; numerous metabolic disorders; and maldevelopment or premature degeneration of parts of the nervous system, such as Huntington's disease and a form of Alzheimer's disease. A genetic component also determines a tendency to epileptic seizures.

Bacterial and viral infection

Inflammatory diseases are another neurological pathology. Although the blood–brain barrier plays its part in protecting the nervous system from microorganisms, it may be breached by bacteria, viruses, fungi, and many other organisms. When this occurs, the inherent resistance to infection of the nervous system is low. The major classes of disease are meningitis and encephalitis (infections of the meninges, or covering membranes, of the brain and of the brain itself, respectively) and abscess, which may be situated outside or just below the meninges or in the brain substance. Some viruses, such as the "slow" viruses, lie almost dormant within neural tissue for years before causing its destruction. The measles virus may do this, causing a chronic progressive encephalitis that is usually fatal.

Direct infections of muscles and of peripheral nerves are uncommon except in leprosy. Both the central and peripheral nervous systems may be severely damaged by reaction of the immune system after relatively trivial infections elsewhere in the body. Finally, in some infections such as diphtheria and botulism, a toxin is liberated by the infectious organism, which attacks the function of the nervous system.

Traumatic injury

Traumatic and mechanical injuries are a type that can affect all levels of the nervous system. Serious head injuries can lead to compression, laceration, or bruising of the brain inside the cranium. The compression is commonly due to a clot of blood inside the brain or formed outside or beneath the dura mater (extra- or subdural hematoma), but there is also inherent swelling of the brain tissue following trauma as fluid leaks from small blood vessel spaces into the extravascular space. This is called brain edema. Later consequences, such as seizures and alterations in mental process and personality, indicate the damage done to the brain by major or repeated minor head injuries. Less serious head injuries lead to concussion, a temporary loss of awareness.

Once destroyed, neurons are not replaced. Severed axons sprout growths from the cut end, but they do not form effective connections in the brain or spinal cord. Therefore, destructive injury of, for example, the spinal cord in the neck is followed by permanent loss of voluntary movement and of sensation below the level of injury.

In the peripheral nervous system, axons that have been cut or have degenerated because of disease can grow again. If the nerve remains in continuity, these sprouting axons may eventually reestablish effective connection with muscle fibres or sensory organs, but this reinnervation is often abnormal because of division and misdirection of growing axons.

Cancer

Neoplastic diseases are another pathological process. Both benign and primary and secondary malignant tumours attack the nervous system. The sites of both types include the meninges, the brain itself, and (more rarely) the spinal cord, its roots, and the peripheral nerves. In the latter sites the tumours are usually benign. The brain and spinal cord may also be compressed by masses arising in adjacent areas, such as the pituitary gland, the spinal column, or

the nasopharynx. Tumours declare themselves by destruction of the tissue in which they arise, by compression of neighbouring tissue, and by increasing intracranial pressure. Those arising outside the nervous system may lead to syndromes of brain, spinal-cord, nerve, end-plate, or muscle disease without direct infiltration of these tissues.

A fifth pathology comprises metabolic, toxic, and endocrine disorders. Numerous complications of disease of other organs affect the nervous system. The largest category (but not the most common) comprises the disorders of metabolism, many of which have a genetic basis. The most commonly occurring neural complications are those arising from the effects of exogenous toxic agents such as bacterial toxins, drugs, and other chemicals. Next in frequency are those representing the effects of disordered fluid, of mineral and electrolyte function, or of disease affecting other body systems, such as the endocrine glands (diabetes, thyroid disease), the kidneys, liver, and lung (organ failure), and the blood (anemia, leukemia).

Loss of blood supply

Vascular diseases, including stroke, are an important pathology. The central nervous system has a high metabolic rate and depends upon a liberal blood supply for nutrition and for clearance of metabolic end-products. In the event of the interruption of circulation, function quickly fails, and if circulation is not restored speedily, irreversible damage to the neurons results. (The area of dead nervous tissue is known as an infarct.) The peripheral nervous system is much more tolerant of loss of blood supply, called ischemia.

A further important vascular cause of brain damage is hemorrhage due to rupture of an artery.

Another pathological process includes diseases labeled demyelinating and degenerative. Demyelinating disease is characteristically scattered throughout the brain and spinal cord, with small foci where the myelin is attacked and replaced with glial scar tissue. Nerve fibres running through such areas may remain undamaged, but the lack of insulation normally provided by the myelin leads to a blocking of conduction of electrical impulses, so that the effect is as though the axons had been severed. Clinically, signs of damage to many sites in the nervous system are found, as in multiple sclerosis. In certain very rare diseases, known as leucodystrophies, large areas of demyelination occur in the white matter of the brain as a result of inherited metabolic disorders. Demyelination is also the result of immune attack upon the central nervous system, which may follow viral infections such as measles, and of immune deficiency states such as pernicious anemia.

In the peripheral nervous system the Schwann cells, which form the myelin investing the axons of peripheral nerves, may suffer immune or toxic attack, as in Guillain-Barré syndrome and diphtheria. This leads again to a blockage of electrical conduction. When an injury is primarily to the axons, the Schwann cells are also damaged, producing "secondary demyelination."

Under the label "degeneration" are grouped some nervous system diseases characterized by progressive destruction of neurons without evident cause. Such diseases are Alzheimer's disease, affecting maximally the cerebral cortex; Huntington's and Parkinson's diseases, affecting the basal ganglia and cortex; motor neuron disease, which attacks the corticospinal tracts and ventral-horn cells; spinocerebellar degenerations, involving long tracts in the spinal cord, the cerebellum and its connections, and sometimes peripheral nerves; and the hereditary neuropathies with no known metabolic basis, in which motor, sensory, or both classes of peripheral nerve degenerate and lose their function. Most such diseases develop after a variable period, during which that part of the nervous system subsequently affected apparently functions normally. As research progresses, the metabolic (and often genetic) bases of these diseases are being successively revealed.

Electrical pathologies present a unique problem of classification. Because the nervous system is a biologic electrochemical complex, it is possible to regard every aspect of its function as an electrical manifestation, but it is primarily the epilepsies that are regarded as expressions of disordered electrical activity. Seizures represent occasional, sudden, rapid, local, and excessive electrical discharges of the gray matter of the brain. There are two main classes, those with a focal origin anywhere within the gray matter and those in which no abnormal pathology is present but that manifest an abnormally low threshold for electrical activation. Although certain abnormal movements occasionally have their origin in spinal-cord disease, epilepsy is uniquely a brain disease (see below *Diseases and disorders: The cerebrum*). Narcolepsy, a disorder of sleep mechanisms, is not a variant of epilepsy.

Seizures

It is uncertain whether any diseases of the nervous system can properly be regarded as representing an allergic pathology in the strict sense of the term, but many conditions marked by inflammation of blood vessels, such as the auto-allergic collagen-vascular diseases, do have such a basis. These, through reduction of blood supply to parts of the nervous system, may well induce neurological symptoms.

Diseases and disorders

THE SKULL AND SPINE

Neural tube defects. The primitive neural tube normally closes by the end of the third week of fetal growth, but when it fails to close, severe deficits result. The worst of these is anencephaly, the absence of brain; a cyst replacing the cerebellum is a less severe form of the same problem. At lower levels the spinal canal or cord may also fail to close up. Such defects are known as spina bifida occulta when there is only X-ray evidence of this, meningocele when a meningeal pouch visibly projects through the skin, and meningomyelocele when such a pouch contains elements of the spinal cord or nerve roots. Depending on the level, function of the legs is often severely impaired. Bladder and bowel control is also lost in such cases, and the infants commonly have hydrocephalus as well.

Abnormal growth before birth

Hydrocephalus. This progressive enlargement of the head is caused by obstructed drainage of the cerebrospinal fluid, usually at the level of the aqueduct or fourth ventricular roof. Huge enlargement of the ventricles results at the expense of cerebral tissue; shunting of the fluid is required to prevent gross expansion of the skull and death through attrition of the brain.

Other congenital malformations in which the head size is abnormal include microcephaly and macrocephaly; in the latter case, expansion of the brain usually follows infiltration in metabolic diseases. In hypertelorism the eyes are set unusually far apart, and in craniostenosis the sutures of the skull do not develop, so that the skull grows abnormally along one or another diameter. In hemiatrophy, one-half of the skull and face may not develop as well as the other, in which case the brain also may be unusually small.

Occurring at the junction between skull and neck, platybasia, an abnormal shallowness of the posterior fossa of the skull, is a malformation that may be associated with projection of the vertebral column upward, indenting the base of the skull. (This condition may also occur in association with bony diseases such as osteomalacia and Paget's disease of bone in adult life.) In the Arnold-Chiari malformation, cerebellar or medullary tissue projects downward into the upper cervical spinal canal, causing signs of cerebellar dysfunction, hydrocephalus, or widening of the central canal of the spinal cord with damage to the surrounding fibre tracts. Fusion of the upper cervical vertebrae in the Klippel-Feil anomaly is another malformation, but it does not always produce symptoms.

Fractures. Fractures of the cranial vault are common, but, so long as they are linear and not depressed (and thus not liable to irritate the underlying brain), they usually require no treatment. Far more serious are the complications of extradural or subdural hematomas, or blood clots. Fractures crossing the middle ear and the nasal sinuses provide a portal for the entry of microorganisms into the cranial cavity and are therefore especially dangerous, while those at the base of the skull may damage cranial nerves crossing the fracture line.

Damage to the spinal cord

Fractures of the odontoid, the bony peg that forms a joint between the upper two vertebrae in the neck, may compress and severely damage the spinal cord; the odon-

toid process may also separate with the same consequences in rheumatoid arthritis. Fractures and dislocations of the spine occur most commonly in the neck, with consequent risk of spinal-cord damage; at lower levels the thoracic rib cage makes spinal-cord compression less likely. With compression fractures at lumbar levels, it is the cauda equina, the tail of nerve roots below the level of the spinal cord, that may be damaged, but the strength of the ligaments gives more solid fixation and complications are less common.

In addition to trauma, secondary malignant tumours, infections such as tuberculosis, and intrinsic bone diseases can damage the spine and spinal cord.

Tumours. Tumours of the skull base may compress the lowest cranial nerves or the medulla and upper cervical cord, with the consequences described above.

Vertebral disorders. The most common disorders affecting the spine are degenerative, most often following previous trauma such as heavy work or whiplash accidents or due to some intrinsic tendency of unknown cause. In spondylosis, small, bony spurs called osteophytes project from the vertebral margins, the ligaments hypertrophy, the bone becomes denser, and the disks degenerate and extrude both forward and backward—in the latter case narrowing the spinal canal, again with the risk of compromising the cord. More commonly, the backward protrusion of an intervertebral disk distorts the local ligaments and compresses an emerging nerve root, resulting in pain, weakness, and numbness in the area. Lumbar spinal stenosis is the condition of marked narrowing of the canal over a few segments when the bone, disk, and ligaments protrude into it, compressing the nerve roots of the cauda equina. Pain also occurs when misalignment of the vertebrae causes stretching of the many joint capsules at sites where the vertebrae are contiguous. Spondylolisthesis is a slipping forward of one vertebra onto another, occurring as a congenital deformity or due to trauma.

Prolapsed disk

Infections, tumours, and bone diseases are also responsible for vertebral disorders, causing pain and signs of damage to the roots and perhaps to the cord as well. Although direct infections of the cord are rare, pyogenic or tuberculous epidural spinal abscesses are important and treatable diseases. Tumours are usually secondary to such malignancies as lymphomas or carcinomas of the breast, prostate, or kidney. Benign tumours also occur. Paget's disease, osteomalacia, and osteoporosis may cause softening of the bone, which can then compress the cord or roots.

THE MENINGES AND CEREBROSPINAL FLUID

Obstruction of cerebrospinal fluid

Raised intracranial pressure. The circulation of the cerebrospinal fluid may be obstructed so that it accumulates behind the obstruction. Congenital stenosis, or narrowing, of the aqueduct, tumours encroaching on or blood accumulating within the ventricles, and fibrosis or occlusion of the roof foramina of the fourth ventricle are causes of obstructive hydrocephalus. They lead to massive enlargement of the ventricular system, with atrophy of the surrounding brain, and to a rise in intracranial pressure, with resulting long-tract motor signs, cranial-nerve palsies, visible swelling of the head of the optic nerve in the eye, headache, and vomiting.

In communicating hydrocephalus, the obstruction is to the flow of cerebrospinal fluid up over the convexity of the brain or to absorption at the sagittal venous sinus. Clinical features are similar to those of obstructive hydrocephalus but less severe. Sometimes following bouts of meningitis or blood in the fluid, the initially raised pressure falls (normal-pressure hydrocephalus), but brain damage persists. In such a condition dementia and gait disturbances are the major clinical features. Insertion of a shunt, or drain, may provide some relief.

Any mass lesion in the head (a blood clot, tumour, or abscess, for example) or external compression of the cerebrospinal-fluid pathway (such as the Arnold-Chiari malformation) raises the intracranial pressure, since the brain cannot shrink and compensation is only possible through a reduction in the amount of fluid present in the ventricles or of blood in the vessels. To the hydrocephalic signs mentioned above, then, must be added those of the causal lesion, affecting specific brain functions according to its site and nature. However, benign intracranial hypertension is a condition in which there is increased intracranial pressure in the absence of obstruction to fluid flow or any mass lesion. Instead, it is caused by various metabolic and endocrine diseases but is most commonly seen in people who are very obese.

Cerebral edema signifies the presence of excess fluid within either the cells or the extracellular tissues of the brain. This also causes brain swelling and a rise in intracranial pressure. Head injuries, encephalitis, abscesses, lack of oxygen, strokes, and toxic agents are the most common causes.

Drainage. Cerebrospinal fluid may leak through basal skull fractures, dripping out of the nose or ear, and it may also leak into the tissues when the needle is withdrawn after lumbar puncture (LP). As a result of the reduced pressure in the fluid, the brain is less well supported and pulls upon the meninges, causing what is called post-LP headache. In traumatic cases, patching of the hole in the meninges may be necessary.

Blood clot. Blood clots lying outside or just below the dura mater (called extradural or subdural hematomas) are other feared complications of trauma. Extradural hematomas usually complicate fractures of the temporal bone that rupture the middle meningeal artery. Arterial blood, shed under pressure, rips the dura off the underside of the skull bones, forming a rapidly expanding mass that raises intracranial pressure, compresses the brain, and may cause death unless evacuated surgically. Subdural hematomas are usually less acute, but they have similar characteristics and also require removal in most cases. Chronic subdural hematomas, however, expand very slowly and may only be discovered through the onset of seizures, focal neurological signs, or dementia.

Extradural and subdural hematomas

Meningitis. This is an inflammation of the meningeal coverings of the nervous system, with only secondary, mild involvement of the brain. A host of infectious microorganisms (bacteria, viruses, spirochetes, fungi, protozoa) and some chemical agents may be responsible. Organisms most often reach the meninges by way of the blood, but direct spread may occur if the usual barriers are broken—as is the case with skull fractures, middle-ear or nasal-sinus infection, or congenital defects of the meninges. Clinical features depend upon the organism, the acuteness of the disease, and the resistance and age of the patient, but they usually include lethargy and drowsiness, fever, headache, stiffness of the neck, vomiting, and (in smaller children) seizures.

Since treatment with the precisely correct antibiotic is essential, the most important diagnostic aid is lumbar puncture, whereby the infectious organism may be identified in the cerebrospinal fluid through microscopy and growth culture and its sensitivity to different antibiotics tested in the laboratory. Such indications in the fluid as the amount of protein, the number and type of cells, and the glucose level confirm the type of meningitis (*e.g.*, bacterial, viral).

Patients with nonbacterial, or aseptic, meningitis also have headache, fever, and other meningeal signs, but they are not so obviously ill. Viruses such as mumps, Coxsackie, and ECHO viruses, tuberculosis, fungi, spirochetes, and chemical substances are possible agents.

The prognosis in bacterial meningitis depends upon the type of organism, the general health of the patient, and the adequacy and speed of initiation of treatment, but there is still at least a 5 percent mortality rate. Residual consequences of the disease include cranial nerve palsies (especially loss of hearing), normal-pressure hydrocephalus, and damage to specific brain areas in a small number of cases.

Neoplasms. Tumours affecting the meninges are usually malignant, commonly spreading from cerebral tumours such as medulloblastoma, from distant tumours such as carcinoma of the lung or breast, and from lymphomas and leukemia. Both drugs and radiation therapy are used to slow the tumour's progression.

Benign tumours arising from the meninges are called meningiomas. These occur over the convexity of the brain and on the floor of the cranium, where they compress and damage brain areas or cranial nerves and may cause

Meningiomas

seizures. They seldom raise intracranial pressure, since their slow growth gives the brain time to compensate. Meningiomas show up clearly on radioisotope and CAT scans. They may be removed totally with an excellent prognosis.

THE PERIPHERAL SYSTEM

Neuropathies. Diseases of the peripheral nerves may be genetic or acquired, may progress quickly or slowly, may involve the motor, sensory, or autonomic fibres (or all three), and may affect all nerves symmetrically (usually at the extremities of the body) or just one or more nerves discretely. Thus, numerous classifications exist; the system used in this section takes as its basis the major pathological change taking place—namely, primary damage to the axon or to the surrounding Schwann cell (Figure 35).

Neuronal neuropathies. In the following diseases, the axon or cell body of the ventral-horn neuron or dorsal-root ganglion neuron is affected. Damage to the ventral-horn neurons leads to the typical signs of a lower motor neuron lesion: atrophy of the muscles supplied by the nerves, fasciculation in chronic disease, reduced muscle tone and power, and reduction or loss of reflexes with no change in sensation. Damage to the dorsal-root ganglion neurons also leads to reduced reflexes, in this case, because the afferent, or sensory, limb of the reflex arc is interrupted. Depending upon the size of afferent neuron that is primarily affected, loss of different sensations occurs: joint-position sense, discriminative light touch, and vibration with damage to the larger cells and skin pain, temperature, light touch, and scratch with smaller cell loss. Often all forms of sensation are impaired.

Polio-myelitis

Poliomyelitis is an acute viral infection. Initially it may cause only a brief, febrile illness, but groups of ventral-horn cells of the spinal cord may be destroyed by the virus. This later causes severe pain with further fever, occasional delirium and meningism (due to accompanying encephalitis), and a rapid onset of fasciculations, weakness, and atrophy of muscle groups that may be localized or diffuse, mild or profound, and that may endanger life if the respiratory or bulbar muscles are involved. Only supportive treatment is available for poliomyelitis, but some recovery occurs in those patients (the majority, in fact) who survive the acute stage of the illness. Since the advent of effective immunization programs this disease is now rare in the Western world.

Hereditary motor neuropathies (also known as spinal muscular atrophies and as Werdnig-Hoffman or Kugelberg-Welander diseases) are a diverse group of genetically determined disorders in which signs of ventral-horn disease occur in babies or young people. The usual features are muscle atrophy and weakness, which progress more slowly in the older age groups but which may be quickly lethal if the disorder strikes during the first year of life. Stricken babies show respiratory insufficiency, poor sucking, and severe limpness and weakness of all muscles except those of the face and eyes, but the muscles of the shoulder and pelvic girdles are most affected. At later stages normal motor development is delayed or absent. This muscular weakness and wasting has given such infants the name "floppy babies." Diagnosis of hereditary motor neuropathy must be confirmed by electromyography and muscle biopsy, as there are other possible causes, some responsive to treatment. There is no effective treatment of spinal muscular atrophy. When the disease begins at a later age (five to 15 years) the progress is slower; the disease may pass, leaving chronic mild weakness and secondary skeletal deformities such as scoliosis (rotation of the spine). Less commonly, similar weakness occurs in specific patterns—for example, involving only the facial, shoulder, or calf muscles—but in those cases the progress of the disease is much slower. In some of these cases specific enzyme deficiencies have been identified as the cause, but in most cases the etiological basis is unknown.

Amyo-trophic lateral sclerosis

Motor neuron disease is a lethal progressive disorder of older people, affecting not only neurons of the ventral horns and medullary motor nuclei but also of the corticospinal tracts. This combination gives rise to such diseases as amyotrophic lateral sclerosis (ALS), in which amyotrophy refers to the muscle wasting due to loss of the ventral-horn cells (the lower motor neurons), and lateral sclerosis is the loss of axons in the lateral columns of the spinal cord (the upper motor neurons of the corticospinal tracts). A combination of upper and lower motor neuron signs is found in these diseases, but weakness, atrophy, and fasciculations found in the muscles of two or more limbs is the hallmark. The mind, eyes, and sensory system are unaffected, prompting the comment that the disease allows the patient to observe his own dissolution. While a host of treatments are available for such symptoms as cramps, and while aids to daily living can be provided to help the patient maintain some self-care, the ultimate prognosis is death within a few years—or within one year when the muscles serving speech and swallowing are affected. Since the etiology is unknown, no cure is available.

Pure sensory neuronal neuropathies may be hereditary. A number of them are differentiated by their pattern of genetic transmission and the modalities of sensation mainly affected. Other causes include toxic drugs or other agents, diabetes, herpes zoster, and vitamin deficiency. They also occur in association with distant cancer. Mixed (sensorimotor) neuropathies have similar causes, in most acquired conditions representing a later stage of a sensory disease.

Injury

Nerve injuries function as neuronal neuropathies affecting the axon far from the cell body. Injuries are of three main grades of severity: in neurapraxia there is temporary blockage of impulse conduction, although the axons remain intact; more severe stretch or incision damage interrupts some axons (axonotmesis); and still worse injury actually cuts the nerve (neurotmesis), in which case microsurgery to rejoin the severed nerve ends is essential if any useful function is to be regained. Even this last is a slow process, since new nerve sprouts grow down the nerve framework at the rate of one to two millimetres per day at most.

Demyelinating neuropathies. The following diseases are those in which the Schwann cells, responsible for the formation of myelin, are primarily affected and migrate away from the nerve. This process leaves segments of the axons uncovered, and since the particular insulating property of the myelin is now lost, there is a block in conduction of nerve impulses down the axon.

Genetically acquired diseases include hereditary motor and sensory neuropathies, a group including Charcot-Marie-Tooth disease (also known as peroneal muscular atrophy because of the special involvement of shin muscles). High foot arches, distal motor weakness and atrophy, and reduced reflexes are the main features; sometimes the nerves are greatly thickened. Most of these conditions first appear in childhood, although they allow a normal life span.

Acquired demyelinating neuropathies may arise as com-

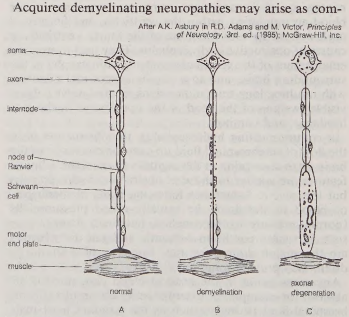

Figure 35: *Two major pathological changes in disease of the motor neuron.*
(A) Normal neuron with intact axon and myelin-forming Schwann cells. (B) Demyelination, or disintegration of the Schwann cells. (C) Axonal degeneration, or disintegration of the nerve fibre.

plications of diphtheria and diabetes, which, partly because of damage to the smallest blood vessels supplying the nerves, are sometimes accompanied by a variety of motor, sensory, autonomic, or mixed neuropathies. Some of these are extremely painful. When sensation is impaired, minor injuries lead to severely deformed, but quite painless, "Charcot" joints. Leprosy (probably still the most common cause of neuropathy in the world), metabolic diseases, cancer, and myeloma or other dysproteinemias also cause mixed demyelinating neuropathies.

Guillain-Barré syndrome

Acute inflammatory neuropathy (the Guillain-Barré syndrome) is another important demyelinating neuropathy. In this disease an autoimmune attack upon the myelin sheath of the motor nerves leads to progressive weakness and reflex loss with only slight sensory changes. The weakness may become so severe that the patient needs mechanical help in breathing, but as long as further complications do not occur, the disease remits spontaneously within weeks. In fact, many patients never develop this degree of weakness at all. In acute, severe cases, blood plasma exchange speeds recovery.

Ischemic neuropathies are those in which local or diffuse blood-vessel occlusion leads to damage of the Schwann cells. The most common example is external compression of a nerve, as when a person's foot "goes to sleep" after the legs have been crossed for too long. In such cases relief of the compression restores the blood supply, and the temporary dysfunction is relieved. Persistent compression, on the other hand, causes the Schwann cells to migrate. This narrows the nerve at the site of pressure, although the axon remains intact. Recovery may take months.

Carpal tunnel syndrome

Common nerve-compression syndromes include the carpal tunnel syndrome, in which the median nerve is compressed at the wrist. This causes pain, numbness, tingling, and weakness of the fingers and thumb, especially at night and on waking. The cubital tunnel syndrome is a similar problem affecting the ulnar nerve at the elbow. Compression of spinal nerve roots by, for example, prolapsed intervertebral disks, are further examples. Numerous nerve-compression syndromes can be diagnosed clinically and localized with the aid of electrodiagnostic studies, allowing precise surgical intervention to release the entrapped nerve. Ischemic neuropathies are also complications of a number of systemic diseases, such as diabetes mellitus and polyarteritis nodosa. In such cases the treatment is that of the underlying disorder.

Autonomic neuropathies may be hereditary, as in Riley-Day syndrome, or acquired, as in complications of partial nerve injuries, diabetes mellitus, tabes dorsalis, the Guillain-Barré syndrome, and other toxic or metabolic disorders (among which alcoholism and drug therapy are the most common). Damage to the sympathetic or parasympathetic pathways in the hypothalamus or brain stem may produce similar symptoms—for example, faintness due to disordered regulation of blood pressure and heart rate, disturbances of bladder and bowel control, impotence, and impaired visual accommodation. Some relief may be obtained from medications that replace a deficient neurotransmitter, expand the blood volume, or compress the limbs so that blood no longer pools in the veins.

Neuralgia is the pain caused by nerve disease. It is usually a severe, constant burning when following an attack of herpes zoster (shingles), but it may also be brief and stabbing in certain conditions affecting the cranial nerves (see below *The cranial nerves and brain stem: Trigeminal nerve*). The relatively common condition known as neuralgic amyotrophy consists of severe pain around the shoulders, followed by selective weakness and atrophy of muscles supplied by nerves of the brachial plexus. This form of neuritis may follow mild infections. The muscles eventually recover.

Myasthenia gravis

Disease of the neuromuscular junction. Myasthenia gravis is the most common disease of the neuromuscular junction. At this site the motor nerve impulse normally triggers the release of the neurotransmitter acetylcholine, which diffuses across the synaptic gap between the terminal of the nerve and the specialized end-plate region of the muscle-fibre membrane. (For discussions of synaptic transmission and neurotransmitter action, see above *Form and function of nervous systems: Transmission of information in the nervous system.*) In myasthenia, receptors in the end-plate region are partially coated with a specific antibody, so that the acetylcholine molecules are blocked, depolarization of the muscle fibre cannot occur, and the muscle does not contract. There is also a reduction in the amount of acetylcholine released from the nerve terminal. As a result, muscle contraction is possible after a period of rest, but sustained contractions quickly become weaker. This fatigability is especially present in the eye muscles, leading to drooping of the lids on looking upward and to imbalance of the ocular muscles, which causes diplopia (double vision). The muscles of the throat, limbs, and respiration may also become involved, creating a dangerous situation.

Diagnosis of myasthenia gravis is made by electrical studies of neuromuscular transmission, which show decreasing response, and by single-fibre electromyography (see above *Acquisition of data: Laboratory investigation*). Treatment involves the removal of the thymus gland (which may produce the antibody), drugs to augment the effect of acetylcholine, and suppression of the immune system. These treatments allow a prognosis of recovery in 60 percent of patients within five years.

Failure of neuromuscular transmission may also occur as a complication of certain drug therapies or of remote cancer, usually of the lung (as in the Lambert-Eaton syndrome). It may also be caused by the toxins of the botulism bacterium *Clostridium botulinus* and of certain species of ticks that attach themselves to the skin. Administration of antitoxin for botulism or removal of the tick, with full supportive hospital care in each case, are effective treatments.

Diseases of muscle. In primary muscle diseases the motor neurons supplying the muscles are not affected, the problem being of and in the muscles themselves. However, motor neuron diseases do cause secondary effects in the muscles.

Genetic dystrophies. The genetic dystrophies are diseases of muscle that progress at differing rates and affect different muscle groups. The best-known, most serious, and perhaps most common is Duchenne's muscular dystrophy (DMD), which ordinarily affects only males, although it is transmitted by females. By the age of three the boy begins to walk clumsily; thereafter, progressive failure to run, jump, and climb like his peers occurs, leading eventually to a loss of the ability to walk by the mid-teens and death in the early 20s. Because of the infiltration of degenerating muscles with fat, little atrophy may be noticed until late in the course of the disease, leading to the alternate term pseudo-hypertrophic muscular dystrophy. Diagnosis is confirmed by estimation of the blood-serum levels of creatine kinase, an enzyme released from degenerating muscle, and also by electromyography and muscle biopsy. The cause is unknown, and no specific treatment is available, but genetic probes and subsequent genetic counselling are used to determine whether a case represents a new mutation or has been transmitted by a carrier mother to her son. Intense rehabilitative efforts are also necessary, since boys with DMD have normal intelligence and can live a relatively full life, although for only a short time.

Duchenne's muscular dystrophy

Facioscapulohumeral dystrophy usually causes problems only in or after the early teens. It has a more benign prognosis, the weakness and wasting being predominantly of the face, shoulder girdle, and arms. Other conditions grouped under the heading limb-girdle dystrophies also show slower progression and may not declare themselves until adult life. Oculopharyngeal dystrophies first strike the eye muscles, causing drooping of the eyelids and weakness or paralysis of the muscles moving the eyes. Later involvement of the face, bulbar muscles, and limb girdles is common.

Myotonic dystrophy is characterized by weakness and wasting of the face and girdle muscles. In addition, there occurs a failure of muscles to relax after a strong contraction, so that, for example, the patient cannot easily let go after shaking hands. As with many of the conditions of dystrophy, involvement of other body systems is common.

Because the expression of the disease is so variable, some patients having minimal symptoms that pose no threat to life, its prevalence is higher than that of DMD. In myotonia congenita the same failure of relaxation occurs but without the wasting features of dystrophy. Indeed, patients with myotonia congenita have strong and well-developed muscles. Relaxation can be obtained with drugs such as diphenylhydantoin and quinine.

Myopathies

Other inherited muscle diseases. Congenital myopathies begin with weakness and poor muscle development in the early years of life, but generally they are not progressive. Diagnosis is achieved by microscopic examination of muscle biopsies. Lipid storage myopathies are associated with disorders of the metabolism of carnitine, a substance that muscle cells use to convert fatty acids into fuel. In these conditions variable severe weakness of the body musculature progresses slowly throughout life. Muscle biopsy specimens show accumulation of fat in the fibres. In the glycogen storage diseases it is glycogen that accumulates in muscle fibre, owing to a deficiency of an enzyme that helps degrade glycogen into lactic acid for the production of energy. Beginning in childhood, complaints of fatigue, aching, and occasional severe muscle cramps on exercise are usual. Diagnosis is confirmed by demonstrating that the exercising muscles do not produce lactic acid as they should.

Myoglobin is a substance that resembles the hemoglobin in blood and that performs a similar function as a repository of oxygen within the muscles. When muscles are damaged from any cause, myoglobin may spill into the blood and thence into the urine. This condition, called myoglobinuria, can also occur as an inherited metabolic defect, either on its own or in association with muscle disorders. Malignant hyperthermia is a dangerous metabolic muscle disease characterized by high fever and extreme rigidity of muscles, usually provoked by certain anesthetics or muscle-relaxant drugs given during surgery. It constitutes an extreme emergency; rapid cooling of the patient, correction of the accumulation of lactic acid in the blood (the result of intense muscle contraction), and administration of dantrolene sodium to relax the muscles are necessary.

In familial periodic paralyses episodes of weakness of variable duration and severity occur in association with abnormally high or low serum levels of potassium. Some attacks are precipitated by a period of rest following heavy exercise, others by carbohydrate or alcohol ingestion. Depending on the type of paralysis, potassium, glucose, and diuretics constitute the usual treatments.

Acquired diseases of muscle. Myoglobinuria may follow excessive exertion of healthy muscles, crush injury, or toxic damage from drugs or chemicals. It is also a feature of some of the inherited diseases mentioned above. With myoglobin present in urine, there is a danger that it may precipitate in the tubules of the kidney and cause renal failure. Muscle weakness and atrophy may also complicate the administration of many drugs (including cortisone and its derivatives), disease of the thyroid and parathyroid glands, and metabolic bone diseases. Primary tumours of muscle are rare.

Inflammatory muscle disease, called myositis, is seen in association with some viral infections, causing swelling, pain, and weakness, and in trichinosis and other tapeworm infestations, in which allergic skin rashes commonly accompany the same symptoms. Most serious is dermatomyositis, an autoimmune disease characterized by swelling, weakness, and tenderness of the proximal, facial, neck, and bulbar muscles in both children and adults. A skin rash is also present, mainly around the eyes but also on the face and extensor surfaces of the limbs. Diagnosis relies upon electromyography, serum enzyme levels, and sometimes muscle biopsy. Treatment with steroid and immunosuppressant drugs has markedly improved the prognosis for recovery. Closely related conditions without the rash are found in association with collagen-vascular diseases such as scleroderma and polyarteritis or with distant cancers. The response to treatment in these variants is less satisfactory.

Polymyalgia rheumatica is another autoimmune disease. It mainly affects women over the age of 55 years, who complain of severe muscle stiffness (especially after sleep) and of malaise, weight loss, muscle tenderness, and slight fever. In some cases frank inflammation of arteries, particularly of the branches of the carotids, is the most notable problem. Diagnosis is urgent, since blindness may follow if the ophthalmic arteries are involved—as is often the case. The blood sedimentation rate is much increased, and anemia is common. Treatment with steroid drugs produces excellent relief within a day, but it must be continued indefinitely.

THE SPINAL CORD

Spinocerebellar degenerations. These are genetically determined conditions in which evidence of dysfunction of the dorsal columns or the corticospinal and spinocerebellar tracts of the cord appears, usually in the first 20 years of life. They cause difficulty in position sensation, gait, limb power, balance, and coordination. (For further discussion, see below *The cerebellum: Genetic diseases.*)

Myelitis

Inflammation. Inflammation of the spinal cord, known as myelitis, is most commonly due to viral infection such as mononucleosis, mumps, and herpes zoster. It is rarely bacterial, although abscesses outside the dura mater (*e.g.*, tuberculosis) do occur. Severe pain in a girdle around the trunk, loss of motor, sensory, and bladder functions below the level of the attack, meningism, and fever are the main features. Myelitis may also be caused by autoimmune attack following such viral infections as measles and chicken pox or after such immunologic challenges as vaccination. Tabes dorsalis, now uncommon, is an infection of the dorsal-root ganglia by the spirochete bacterium that causes syphilis. Degeneration of the dorsal columns, severe girdle pains, and loss of position sense are the main features, though they often appear together with signs of spirochetal infection elsewhere in the central nervous system.

Paralysis

Trauma. Damage to the spinal cord occurs in association with spinal fractures and fracture-dislocations. The degree to which functions of the cord are affected varies with the severity of the injury. There may be only transient weakness and hyperactive reflexes due to damage to the corticospinal tracts, or there may be full-blown paraplegia with signs of damage to the motor and sensory fibres at the level of injury as well as loss of all sensation below the lesion. Accompanying paralysis, due to damage to descending motor tracts, is at first flaccid and later becomes spastic. After such an injury at high cervical levels, the diaphragm is paralyzed, and the resulting ventilatory failure is life-threatening. Since only minimal regeneration of neurons is possible in the central nervous system, the prognosis for recovery is hopeless and only supportive treatment is available.

Tumours. Tumours within the substance of the cord are labeled intrinsic, those outside but compressing it, extrinsic. Common intrinsic tumours include ependymomas and astrocytomas, which are malignant, and angiomas and cysts, which are benign. Extrinsic tumours include malignant secondary invasion by cancer of the breast, lung, kidney, or prostate gland as well as benign neurofibromas and meningiomas. Other tumours arising outside the dura include lymphomas, lipomas, and chordomas. All of these produce signs of spinal nerve root irritation, with pain and tingling, at the level of the tumour; signs of spinal cord involvement occur later. In all cases diagnosis is confirmed by myelography, usually with CAT or MRI scanning. Raised protein levels occur in the cerebrospinal fluid, but they are not specific to one type of cancer. Malignant cells themselves may be detected in the fluid, allowing precise diagnosis. Surgery and radiation therapy are the principal treatments.

Subacute combined degeneration of the cord. This is a condition resulting from deficiency of vitamin B_{12} from any cause, most often pernicious anemia. Its name indicates its insidious progression and the degeneration of two tracts, the corticospinal and the dorsal columns, which lose myelin and acquire a pale stain from dyes applied when the cord is examined post mortem. Much of the damage is to the large dorsal-root ganglion neurons; their peripheral processes (*i.e.*, the peripheral nerve fibres) are

also demyelinated, so that signs of peripheral neuropathy are superimposed onto the spinal symptoms. Replacement treatment with vitamin B_{12} often leads to improvement.

Vascular disease. Diseases of the blood vessels are surprisingly uncommon in the spinal cord, which contains long segments with a tenuous arterial supply, as in the mid-thoracic area. When blockages do occur, severe atherothrombotic disease of the aorta is a likely cause, as is previous aortic or thoracic surgery, with its risk of interruption of arteries supplying the cord. Compression of arteries by tumour tissue or a prolapsed disk is a rare cause; bleeding from an arteriovenous malformation is another.

Signs of acute, painful, and severe damage to the anterior three-quarters of the cord are usual, this being the area supplied by the single ventral spinal artery. Since the dorsal columns and the dorsal-root entry zone are supplied by three or more dorsal spinal arteries (an arrangement that confers some protection against ischemia) those regions usually escape damage.

Months or years after radiation therapy for such cancers as carcinoma of the breast, small-vessel disease may affect the cord. In this radiation myelopathy a slow but relentless deterioration of the roots and tracts at the irradiated level of the cord leads to spastic weakness of the legs and to less obvious sensory changes.

Syringomyelia. This condition frequently complicates obstructions of the roof foramina of the fourth ventricle. Pressure waves, transmitted through the cerebrospinal fluid down the central canal, enlarge the canal and ultimately lead to a cavity, or syrinx, branching out from the canal and enlarging over years. As a result, sensory fibres, running from the dorsal-root entry zone both to the opposite spinothalamic tract and to ventral-horn neurons at the same level, are interrupted. In addition, compression of the corticospinal tracts occurs. Interruption of the dorsal-root–ventral-horn connection, which mediates reflex activity, results in loss of stretch reflexes and atrophy of some muscles innervated at that level. Interruption of the spinothalamic fibres, which transmit sensory impulses from both sides of the body to the thalamus, leads to loss of the sensations of light touch, temperature, and skin pain, as well as signs of an upper motor neuron lesion below the level of the cavity. Despite the marked sensory changes, which may lead to the patient's burning himself without feeling any pain at all, some perception, such as position sense, is retained. This is an example of dissociated sensory loss, which is also found in some brain-stem lesions, transection of one-half of the spinal cord, and certain peripheral neuropathies.

Diagnosis of syringomyelia is best made by CAT scan combined with myelography or by MRI scanning (Figure 34), but since the cervical spinal canal is often widened in this condition, even a plain X ray of the cervical spine may be enough for diagnosis. Surgical therapy, aimed at draining the cavity and preventing pressure waves from distending it further, may lead to remarkable improvement in some cases, even after severe destruction of the cord.

Multiple sclerosis

Demyelinating disease. This condition frequently affects the spinal cord, and in older patients the cord may be the only clinically evident site of involvement in multiple sclerosis. The corticospinal tracts and dorsal columns are chiefly affected. In a variant of multiple sclerosis called Devic's disease, a band of spinal-cord inflammation and demyelination and optic-nerve involvement are the only features. In some patients with multiple sclerosis, clinical signs of disease of the cord are lacking, but measurement of somatosensory or motor-evoked potentials shows abnormalities indicating that disease is actually present.

Myoclonus. Brief, involuntary jerks of the whole trunk and of the limbs, or of one or two limbs alone, may occur in spinal myoclonus. Many diffuse, metabolic, or local structural causes are possible, but myoclonus more commonly originates in the brain stem or cerebral hemispheres.

THE CRANIAL NERVES AND BRAIN STEM

Olfactory nerve. The olfactory nerve is seldom disordered, but head injuries and pressure from tumours on the floor of the anterior cranial fossa may reduce smell sensitivity or cause complete loss. Patients complain of loss of taste, as all tastes except saltiness, sweetness, bitterness, and sourness are appreciated by the sense of smell.

Optic nerve. Visual-field deficits can occur with disease of the optic nerve or of the pathways traveling back to the occipital lobe. Optic neuritis is occasionally inherited, but it also occurs in some infections and particularly in demyelinating disease. Drug or chemical toxicity are rare causes, and in older people it may result from ischemia. Optic neuritis leads to total or partial loss of vision. Recovery may occur, depending upon the cause and its potential for treatment. It is often difficult to distinguish between compression of the nerve by a tumour or by an aneurysm. With any of these lesions, the nerve eventually loses myelin, causing optic atrophy, or pallor of the nerve head, which can be seen with the ophthalmoscope. Papilledema is a swelling of the nerve head with fluid as a result of raised intracranial pressure from any cause (Figure 36). Vascular diseases of the retina include occlusion of the retinal arteries and veins as well as temporary obstruction of a retinal arteriole by a blood clot from the arteries in the neck.

Lesions of the visual pathways are caused by upward pressure on the optic chiasm, by pituitary tumours or aneurysms and, farther back in the nerve pathway, by strokes or tumours.

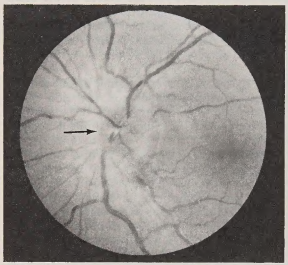

Figure 36: Photograph of the retina, showing (arrow) swelling of the head of the optic nerve. This swelling, called papilledema, is caused by raised pressure within the skull.

Oculomotor, trochlear, and abducens nerves. These nerves may be compressed by mass lesions anywhere along their course or by diabetes, vascular disease, head injury, local infection, and neuropathy. In the brain stem, multiple sclerosis, stroke, Wernicke's disease (see below *Brain stem*), and tumours are possible causes. Depending upon the nerve or nerves involved, various forms of double vision occur; if the oculomotor nerve is affected, the pupil will probably be enlarged as well. Muscle and end-plate diseases may mimic the appearance of discrete oculomotor nerve palsies. In Horner's syndrome interruption of the long sympathetic fibres passing from the brain stem to the pupil leads to drooping of the eyelid and a small pupil.

Horner's syndrome

Argyll Robertson pupils are small and irregular pupils that do not react to light but do constrict on accommodation to close vision. They have traditionally been associated with syphilis, but other brain-stem diseases may also be responsible. Adie's pupil constricts very slowly in light and also dilates slowly when the light is removed. It is not a sign of serious disease.

The two eyes may together fail to move in one or another direction. This gaze palsy may be quite fixed in progressive external ophthalmoplegia, a disorder of the central nervous mechanisms controlling gaze. Other neurological problems, such as parkinsonism, dementia, or neuropathy, may be associated with this condition. Local lesions of the brain stem may also cause paralysis of eye movement, as may severe myasthenia and myopathies affecting the eye muscles.

The jerky eye movements of nystagmus usually signify

brain-stem, vestibular, or cerebellar disease, but they may also be complications of very poor eyesight or may occur as a congenital defect.

Trigeminal nerve. Numbness in the face is commonly due to compression of this nerve, often by a tumour in the cranial cavity or nasopharynx, but it is also caused by brain-stem disorders. Neuralgia of the trigeminal nerve, called tic douloureux, is an intense, repetitive, irregular stabbing pain felt in the lower half of one side of the face. It occurs in elderly people. While the actual pathology of tic douloureux is in dispute, many patients are relieved by microsurgical removal of a loop of normal artery where it impinges upon the nerve at its exit from the brain stem. In most cases, however, drugs such as carbamazepine, diphenylhydantoin, or baclofen relieve the pain so well that no other treatment is needed.

Tic douloureux

Facial nerve. Bell's palsy is the most common lesion of the facial nerve. An abrupt weakness of all the facial muscles on one side, it is often accompanied by pain around the ear, unusual loudness of sounds heard in the ear on the same side, and loss of taste on the front of the tongue. Many patients believe that they have had a stroke, a conclusion corrected when it is seen that they cannot close the eye on the affected side.

The herpes simplex virus can be implicated in some cases of facial palsy. Other causes include lesions of the brain stem (see below) and of the angle between the cerebellum and pons; middle-ear infections; skull base fractures; and diseases affecting the parotid gland. In the Guillain-Barré syndrome, facial weakness on both sides is an important sign.

In hemifacial spasm repetitive twitching of one side of the face occurs. As with tic douloureux, irritation of the nerve as it leaves the brain stem appears to be a cause, and in many cases relief is obtained through surgical decompression.

Vestibulocochlear nerve. Deafness, if not caused by middle-ear disease, suggests damage to the cochlear portion of this nerve, while vertigo, an abnormal sensation of rotation, is a prominent symptom of vestibular-nerve disease. Compression of the nerve at the cerebello-pontine angle by, for example, a benign tumour of Schwann cells, an aneurysm, or meningioma, as well as certain systemic diseases, drug toxicity, small strokes, and Ménière's disease, are the more common neurological causes of hearing loss. In Ménière's disease accumulation of fluid in the inner ear produces increasing deafness and tinnitus, or ringing in the ears. Acute attacks bring intermittent bouts of vertigo. Both medical and surgical therapies are available.

Ménière's disease

The diffuse connections of fibres subserving hearing in the brain make central nervous causes of deafness rather uncommon. Any condition affecting the inner ear or cochlear nerve may give rise to tinnitus. Abnormally high blood flow in the region may do the same, but then the sound has a pulsating quality.

Benign postural vertigo is the term describing brief severe attacks of vertigo induced by movement, especially turning in bed. The condition is unpleasant but benign, occurring at any age and ceasing spontaneously after some months. It is less persistent than vestibular neuronitis, in which prostrating vertigo persists for some days, probably as a result of viral infection of the inner ear or vestibular nerve.

Bulbar nerves. (In this context, the term bulbar refers to the medulla oblongata, which looks like a swelling, or bulb, at the top of the spinal cord.) Diseases of the ninth through 12th nerves show themselves mainly through such motor dysfunctions as impairment of swallowing and speech and weakness of the neck muscles. Bulbar palsy is dangerous because inhalation of saliva or food may cause choking and asphyxia. A nasal tone to the voice and weakness of coughing are early signs. Causes of bulbar palsy include diseases of the brain stem (see below) and of the bulbar nerves themselves. The most important of these latter are motor neuropathies, such as diphtheria, poliomyelitis, and botulism, motor neuron diseases, and compression of the nerves by tumours. Myasthenia gravis and some muscle diseases cause similar signs.

Brain stem. Brain-stem lesions produce a multitude of syndromes according to the site and nature of the pathology. In Moebius' syndrome, the abducens and facial nerves, which originate in the brain stem, may not develop from birth. Encephalitis may affect the brain stem only, with consequent signs of damage to cranial nerves, to cerebellar connections, to the long ascending and descending tracts crowded together in the pons and medulla, and to the reticular activating system and short tracts within the brain stem that subserve the functions of consciousness and the coordination of eye movements. Brain-stem strokes frequently produce clear-cut syndromes that can be sharply localized. Malignant tumours such as gliomas also affect this region, and multiple sclerosis is another common cause of brain-stem dysfunction. In syringobulbia a cavity forms within the brain stem in association with syringomyelia (see above *The spinal cord*) and produces cranial-nerve palsies and both cerebellar and long-tract symptoms.

Wernicke's disease is caused by a deficiency of thiamine (vitamin B_1). It is seen most often in alcoholics who show such symptoms as ocular palsies, nystagmus, memory disturbance, and peripheral neuropathy. The eye symptoms are most readily corrected by the administration of thiamine. Wernicke's disease

Too-rapid correction of severe sodium depletion may lead to edema, or accumulation of fluid, in the central nervous system. Since many motor nerve fibres cross over and intertwine in the pons, the resulting swelling may lead to their compression and dysfunction, a condition known as central pontine myelinolysis because of the resulting demyelination. Depressed consciousness and spastic paralysis of the limbs are the chief manifestations; death frequently follows.

Disorders of sleep. The raphe nuclei of the pons and the locus ceruleus, which mediate sleep, are situated in the brain stem. Sleep consists of two rather different phases: rapid eye movement (REM) sleep and non-REM, or slow-wave, sleep. The latter phase is further divided into different stages during which the person progresses from drowsiness through deeper and deeper levels of relaxation, with decreasing ability to be aroused and with the appearance of progressively slower waveforms on an EEG. In REM sleep, periods of which punctuate slow-wave sleep during a normal night, dreaming occurs. Paradoxically, although the subject appears deeply asleep, there is much fast activity on the EEG, and numerous brief, small-amplitude movements are made by the eyes and the body musculature.

Narcolepsy is a disorder in which, with little warning, irresistible sleepiness overcomes a person during the day. In one form there are vivid hallucinations on awakening or going to sleep, temporary but profound sleep paralysis on awakening that does not affect breathing, and sudden, brief loss of muscle power in the limbs and trunk during emotional moments such as laughter (cataplexy). In this form of narcolepsy it is as though components of REM sleep were intruding into the daytime, waking hours. Narcolepsy is often hereditary. Treatment of the disorder with stimulants and tricyclic drugs is often remarkably effective. No structural disease of the brain has been detected in this condition. Narcolepsy

Other, even more common, sleep disorders include: insomnia, which is usually psychologically mediated but which, like hypersomnia, may also complicate hypothalamic disease; and sleepwalking and night terrors, which occur in the deepest sleep stages even though the person obviously has some awareness of his surroundings. The causes of these phenomena are poorly understood, but structural disease of the nervous system is not responsible.

Brain death. This is synonymous with brain-stem death, since the centres for the control of such essential body functions as consciousness, respiration, and blood pressure are situated within the brain stem. In many countries strict criteria for diagnosis of brain death have been established by common consent among neurological, neurosurgical, religious, ethical, and judicial experts. These include the presence of deep coma with an established cause, the absence of any brain-stem functions such as spontaneous respiration, pupillary reactions, eye movements, and gag and cough reflexes, and the exclusion of low body tem-

perature and drugs as relevant to the comatose state. The EEG is a useful (but not essential) confirmatory test. When such criteria are scrupulously applied and brain-stem death is confirmed, the heart always stops beating within a day or two, even when other vital functions are artificially maintained.

THE CEREBELLUM

The clinical features of cerebellar disorders are given above (see *Localization: Higher-level sites*).

Genetic diseases. Spinocerebellar degenerations are inherited atrophies of parts of the central nervous system and of peripheral nerves. They commonly affect the cerebellum and its connections, as well as the nuclei in the medulla known as the olives, the centres for control of eye movements, the optic nerves, the dorsal columns of the spinal cord, and the corticospinal tracts. Onset is usually in the first two decades of life, but there is great variability both in the age at onset and in the expression of any of the diseases. Some patients show only minimal signs, although most conditions are slowly progressive. Many syndromes are recognized according to the combination of signs produced. The prototype is Friedreich's ataxia, in which the optic nerves, dorsal columns, corticospinal tracts, and cerebellum are affected and in which a peripheral neuropathy is also found, along with skeletal deformities, high arched feet, and rotation of the spine.

Friedreich's ataxia

Inflammatory diseases. These comprise abscesses, which usually complicate chronic infections of the middle ear through the spread of infection along the veins draining back into the posterior fossa, cerebellitis, found in association with some viral infections in children, and tuberculomas, quiescent inflammatory masses acting as tumours by raising intracranial pressure and by creating symptoms of cerebellar dysfunction.

Vascular disorders. Cerebellar hemorrhage occurs in patients with high blood pressure, causing sudden headache, neck stiffness, and cerebellar signs, often with evidence of compression of the brain stem on the side of the bleeding. Prompt surgical evacuation of the blood clot may be life-saving, and the availability of CAT scanning has allowed this diagnosis to be made more accurately than before. Infarcts in the territory of the cerebellar arteries also involve part of the medulla or pons. The prognosis for functional recovery seems better with infarcts in the distribution area of the vertebrobasilar artery than in the carotid circulation.

Demyelinating disease. Demyelination frequently affects the cerebellum and its connections. Indeed, Jean-Martin Charcot, the French neurologist of the late 19th century, defined a triad of signs of cerebellar disease (nystagmus, ataxia, and scanning speech), which he considered diagnostic of multiple sclerosis. (For discussion of multiple sclerosis, see below *Unlocalized or multifocal disorders: Demyelinating diseases*.)

Metabolic diseases. Chronic alcoholism, toxicity of diphenylhydantoin (a drug used in epilepsy), thiamine and nicotinic acid deficiencies, and hypothyroidism, are all responsible for cerebellar dysfunction. In all of these, typical signs of truncal and limb incoordination, or ataxia, are detectable, and in most, treatment reverses the deficits more or less completely. Numerous inherited metabolic defects of metal, lipid, or amino acid metabolism (see below, *Unlocalized or multifocal disorders*) and some diseases marked by serum protein abnormalities also cause signs of cerebellar disease.

Neoplasms. Benign tumours, usually Schwannomas on the vestibular part of the vestibulocochlear nerve, may compress the cerebellar peduncles and lead to dysfunction on one side, but malignant astrocytomas and secondary deposits from distant cancers are more common. In children, medulloblastomas are fast-growing malignant tumours that destroy the central part of the cerebellum and cause severe gait ataxia as an early sign, while astrocytomas grow much more slowly and may be little more than a cyst that can be completely removed, leading to a relatively good prognosis.

Through an unknown mechanism, cancers located elsewhere may lead to degeneration of the cortex of the cerebellum without actually invading it.

THE BASAL GANGLIA

Parkinson's disease. This disease is caused by degeneration of the cells of the substantia nigra and locus ceruleus (both pigmented nuclei in the brain stem) and of their connections with the basal ganglia. The basal ganglia are nuclear masses situated above the brain stem and concerned with the initiation and patterning of voluntary movements. This motor control system employs both dopamine and acetylcholine as chemical transmitters of nerve impulses, and in parkinsonism there is a relative deficiency of the former as a result of the degeneration of neurons in the substantia nigra. This leads to inhibition of the activity within the basal ganglia. Slowness of movement, rigidity of the muscles of the body, stooped and flexed posture, and repetitive tremor of the limbs are the main clinical features of Parkinson's disease, but depression and loss of intellectual agility are also common. Most cases occur in late middle age. The cause is unknown, although encephalitis in early life, many drugs and toxic chemicals, brain trauma, cerebral anoxia, and other degenerative diseases of the nervous system (*e.g.*, progressive supranuclear palsy) cause similar or identical symptoms.

Treatment with levodopa

A tremendous advance in treatment of Parkinson's disease was the introduction in the 1970s of levodopa, or L-dopa, a precursor of dopamine that can be given orally and that crosses the blood–brain barrier into the brain, where it encourages the synthesis of the deficient transmitter. Other treatment approaches are to reduce the activity in the basal ganglia, through anticholinergic drugs, of acetylcholine (which is antagonistic to dopamine); to use such drugs as bromocriptine and pergolide to augment the responsiveness of the receptor sites where dopamine normally exerts its effect; to increase dopamine release using amantidine; and to block the action of the enzyme that breaks down dopamine by selective inhibitor drugs such as deprenyl. As a result of these approaches, the patient with Parkinson's disease can now expect many more years of functional activity than was thought possible in the 1960s, although progression of the disease cannot be halted. In severe cases the patient is eventually disabled by a combination of the disease and side effects of treatment.

Dystonias. These sustained muscular contractions, which produce abnormal postures of the face, head, trunk, and limbs, are caused by disease of the basal ganglia. Other abnormal involuntary movements, such as vocalizations, tremors, and body jerks, may also occur. The number and classification, and the biochemical and anatomical bases, of these movements are not clear. Diagnosis is difficult since many of the movements occur only intermittently and the influence of emotional states and normal activity upon them often leads to the incorrect diagnosis of hysteria. Both generalized dystonias affecting the limb and trunk muscles (*e.g.*, dystonia musculorum deformans) and focal dystonias (*e.g.*, writer's cramp, orofaciomandibular dystonia, torticollis) are seen. Generalized dystonia is an inherited condition in which persistent and often painful twisting and writhing movements of any muscle group occurs, usually in children. Their intensity may be so great as to make self-care impossible. While a number of drugs have been found effective in reducing the movements, none is consistent, and surgery on the thalamus is needed in the most severe cases. The surgical operation performed—destruction of the ventrolateral nucleus of the thalamus by local freezing—relieves muscle rigidity. It is also used to reduce tremors in severe Parkinson's disease and to incapacitate benign essential tremor. The ventrolateral nucleus has a modulating influence on the motor system, but it is not known precisely why surgery on the nucleus works in these situations.

Tics are related to dystonia, but they consist of brief, purposeless, stereotyped movements or utterances of unknown cause. At worst, sudden, explosive speech or movements occur repeatedly, as in children with the syndrome of Gilles de la Tourette. The range of drug therapy of potential value is as wide in this condition as with dystonias, and success is as uncommon.

Chorea. Brief, variable, small-amplitude, and involuntary dancelike movements are usually seen with disease of the caudate nuclei, which are part of the basal ganglia.

Huntington's disease

Huntington's disease is the most feared cause of chorea, since this inherited, dementing illness leads to early death but seldom declares itself until after the early procreative years. The discovery of the responsible chromosome has made possible effective genetic counseling and presymptomatic diagnosis. Early hallmarks of the disease are personality change, such as irritability and depression, and a liability to alcohol abuse. This is followed by intellectual deterioration with paranoid thinking and brief, involuntary, semi-purposive, jerky movements of the limbs and face—or, less commonly, to progressive rigidity of the body musculature. While treatment with phenothiazine or butyrophenone drugs is helpful for the movements, the mental symptoms progress inexorably.

Chorea also occurs in a nondementing, inherited form, as a complication of rheumatic fever in children (Sydenham's chorea) and of pregnancy (chorea gravidarum) in a few systemic diseases (*e.g.,* hyperthyroidism, lupus erythematosus), and as a toxic effect of drugs (*e.g.,* oral contraceptives and levodopa). In a more severe form called hemiballismus, caused by a small infarct of the subthalamic nucleus, wild, flinging movements of one side of the body exhaust the patient. Patients respond to drug therapy as in Huntington's disease.

Tardive dyskinesia is the name given to a syndrome of choreic movements affecting the face, eyes, tongue, and trunk, which usually appear after prolonged treatment with antipsychotic drugs such as the phenothiazines. Treatment with reserpine or amantidine may be partially successful.

Wilson's disease

Wilson's disease, an inherited condition, is characterized by cirrhosis of the liver and degeneration of the lenticular nuclei of the basal ganglia. The movement disorders produced by this condition include chorea, dystonia, athetosis (continuous, serpentine, writhing, and twisting movements around the long axes of the limbs), and tremor. Also, brown pigment is deposited around the edge of the cornea, and behavioral and intellectual disturbances are common. The disorder is due to the deposition of copper in the brain, corneas, and liver (urinary levels are also high)—all as a result of an inborn error of metabolism leading to failure of the liver to excrete copper normally. Treatment with d-penicillamine and a low-copper diet shows striking success in preventing progress and often reverses the course of the disease. Genetic counseling is another vital part of therapy.

Athetosis is also a complication of strokes, anoxia (particularly at birth), and hemolytic disease of the newborn (in which bilirubin derived from damaged red cells is deposited in the basal ganglia, causing the formation of glial scar tissue).

Essential tremor. In this common inherited disorder, which can occur at any age, movements are interrupted by a regular oscillation of the limbs, as during writing. The tremor is usually absent at rest and often affects the head and voice. It is frequently confused with parkinsonism, but the other features of that condition are not present. Alcohol reduces the problem, but β-adrenergic blocking drugs and primidone are more effective treatments.

THE CEREBRUM

Concussion

Craniocerebral trauma. The concussive and shearing stresses of head injury may cause concussion (a brief loss of consciousness without permanent consequences), contusion of the brain (most often of the tips of the frontal and temporal lobes, called contre-coup injury), or laceration of the brain tissue. In the last two cases, neurological deficits are detected at the time of injury, and with laceration (as in a depressed fracture of the skull) or bleeding into the brain, the eventual incidence of seizures is high. This is called posttraumatic epilepsy.

Complications of head injury include the development of extradural hematomas, often from tearing of the middle meningeal artery. Arterial blood, pumped into the space between the dura and the inside of the skull, acts as a fast-expanding mass lesion, compressing the brain downward through the tentorium or the foramen magnum. This is a lethal complication unless quickly relieved by surgical removal of the clot. Subdural hematomas are usually slower in development and may sometimes take weeks to form; they follow the rupture of small veins bridging the gap between the surface of the brain and the meninges. While compressive symptoms similar to those of extradural hematomas can occur, in most of these cases they are subacute or chronic, producing headache, seizures, or intellectual decline. Removal of the clot is the usual treatment.

Other complications include cranial nerve palsies, subarachnoid hemorrhage, thrombosis of a carotid artery, and cerebrospinal fluid leakage, which may lead to intracranial infection. Focal deficits are also common with brain tissue damage. Later consequences include dementia, seizures, and the posttraumatic syndrome of irritability, fatigue, headaches, insomnia, loss of concentration, poor memory, and loss of energy. Repeated minor head injuries, as occurs in some boxers, may also lead to dementia and to a Parkinson's-like syndrome.

Cerebral palsy. This term encompasses all the conditions that damage the brain around or before the time of birth—other than obviously developmental causes. Approximately six cases occur in every 1,000 live births in the Western world. Hypoxia and asphyxia during a prolonged and difficult labour are the most common causes, but improvements in obstetrical care have reduced the incidence of the condition. It is manifest by a delay in the motor development of the infant, who shows such clinical evidence of damage to the motor systems as spasticity, weakness of the limbs, and athetosis or ataxia. Sensory, visual, and cognitive defects may be detected later. Mental retardation occurs in about half of these children.

Mental retardation. Retardation signifies incomplete or insufficient general development of mental capacity, encompassing a global delay in the normal development of motor, language, and social adaptive skills. It has numerous causes. Before birth, chromosomal and developmental diseases, genetic and other metabolic disorders, and intrauterine infections or toxicity are important causes, while at the time of birth, asphyxia and hemolytic disease are prominent. In the postnatal period, nutritional deficits, infections such as meningitis, encephalitis, and the postinfectious syndromes, trauma, and toxins are the most frequent causes. Apart from delays noted in early learning and, eventually, substandard school performance, behavioral abnormalities and impaired emotional control are also common. Continuing advances in the understanding and early diagnosis of genetic diseases and in obstetrical care may further reduce the incidence of mental retardation, but it still represents a severe economic and emotional burden both for the family and for society.

Down's syndrome

Down's syndrome is the best known of the chromosomal disorders producing mental retardation. More than one in every 1,000 live-born children in the West suffer from this condition. Clinical features include short stature, smallness of the head, obliquely slanted eyes, a flattened face, wide hands with a single transverse palmar crease, short digits, and floppy muscles. The degree of mental retardation is variable. The brain is slightly smaller than normal, and the appearance of the neurons and perhaps the myelin are also abnormal (Figure 37). After the age of 30, neuropathological features common in Alzheimer's disease are almost always detectable in Down's syndrome patients. Discovery of the abnormal chromosome causing the syndrome allows prenatal diagnosis by examination of the amniotic fluid.

Dementia. This decline in intellectual capacity is caused by organic disease of the brain. Single deficits such as aphasia, an inability to use language, are not sufficient for a diagnosis of dementia, which requires evidence of diffuse, bilateral brain involvement. Common early clinical features include rigidity and blunting of personality, loss of interests, impairment of attention and concentration, difficulty with comprehension, and difficulty in handling abstract concepts. Later, increasing impairment of the capacity to retain new information, social withdrawal, unnecessary repetition of words and actions, and volatile emotions are signs of the disintegration of the mind. As dementia progresses, language ability begins to fail, the patient neglects to care for himself appropriately, and neurological signs appear on clinical examination.

Alzheimer's disease

The most common cause of dementia is Alzheimer's disease, but the absence of a specific test for this condition (apart from the major procedure of brain biopsy) makes the diagnosis one of exclusion. Biopsy may reveal characteristic changes of neurons in the cerebral cortex. The entire cortex is affected, although the brunt of the disease falls on the frontal lobe. Other areas of the brain are also affected, such as the hippocampus and amygdala, the brain stem, and the basal forebrain (the basal nucleus of Meynert). Alzheimer's disease carries a slight familial tendency, but the etiology of the disease is not known. Research continues on many fronts, including intensive surveys of possible environmental causes. The disease is increasingly common with old age. There is no specific therapy for the condition. Augmentation of brain acetylcholine (the neurotransmitter concerned in memory processes) is not very effective.

Multi-infarct dementia is the next most common type. It is the result of numerous small strokes, the cumulative effects of which impair the function of so much of the brain that the patient has truly global intellectual impairment. Clinical diagnosis is confirmed by demonstration of the infarcted areas on CAT scanning.

The multitude of other causes of dementia can be separated into three groups. (1) General medical illnesses include states of vitamin deficiency, intoxications, endocrine disorders, and metabolic diseases. (2) Underlying neurological disorders, among whose features dementia may appear, include some genetic diseases, brain inflammation, trauma, primary and secondary tumours, degenerative diseases, severe multiple sclerosis, and, less commonly, widespread disease of the larger or smaller arteries. (3) In a final category are some conditions of uncertain cause; normal-pressure hydrocephalus, Pick's disease, and progressive supranuclear palsy are examples.

A major condition that must be distinguished from dementia in all cases is depressive illness. Since the two may coexist, correct diagnosis may be difficult.

Epilepsy. Epilepsy is a tendency toward recurrent seizures. One seizure alone is not sufficient for the diagnosis. (The nature of the condition is described above; see *Pathologies.*) Epilepsy is estimated to affect between 1 and 2 percent of the population. The most useful classification divides seizures between those of unknown cause without any detectable brain abnormality (idiopathic, or primary, epilepsy) and those caused by structural lesions in the brain (symptomatic, or secondary, epilepsy). Another system, the International Classification of the Epilepsies, defines two major categories: generalized seizures (roughly corresponding to primary epilepsy) and partial seizures (corresponding to secondary epilepsy). Numerous subcategories are also defined.

Primary epilepsy. In the primary group, onset is in the early years of life, and there is a genetic component in causation. One primary type is grand mal, or tonic-clonic, attacks, in which the subject loses consciousness without warning, falls, and stiffens, with all muscles contracting maximally. He then begins a series of rapid but slowing jerks of the whole body that cease in approximately a minute, leaving him limp and still unconscious. The person awakes a few minutes thereafter, usually sleeps for a while, and is then back to normal unless further seizures occur.

Grand mal attacks

A second form is petit mal epilepsy, also known as absence attacks, during which the subject is unaware of his surroundings for a few seconds. The person may show little abnormal behaviour, except that he usually stops whatever he is doing, and his eyelids flutter. Such attacks may occur hundreds of times daily in an uncontrolled case (Figure 33).

Myoclonic epilepsies constitute a third form of primary epilepsy. In these cases, single or repeated brief shocklike contractions of all body muscles occur.

Although genetic factors are important, any person could be made to have a seizure, usually of grand mal type. Sleep deprivation, extreme fatigue, drug toxicity, certain metabolic disturbances, and withdrawal from drugs or alcohol are potent precipitants of seizure, and, when they can be incriminated, neither underlying brain disease nor the need for drug treatment need be considered.

Secondary epilepsy. The secondary epilepsies have even more varied presentations, since, in these, spontaneous electrical activation of any brain area can be the basis of the seizure. Both the causative brain diseases and the clinical varieties of seizure are innumerable. In one group, consciousness is retained while abnormal sensations, visual hallucinations, or local muscle contractions occur. In another group, caused by lesions within the temporal or frontal lobes, there are distortions of memory leading to illusions, abnormal sensations, hallucinations of smell or hearing, limb jerking or abnormal posture, and psychological symptoms in any combination. Any of these attacks may lead to seizures resembling grand mal attacks.

Diagnosis and treatment. The task of the neurologist is to confirm that the symptoms of the patient are in fact caused by abnormal electrical discharges, to determine whether they represent primary or secondary epilepsies, and, if the latter, from where in the brain they arise and the nature of the causative pathology. In patients whose seizures begin in adult life, secondary epilepsies must be assumed until proved otherwise. After clinical assessment careful investigation is almost always required. This includes EEG (perhaps with television monitoring), CAT scanning, and often other tests for underlying infectious, metabolic, or cancerous conditions.

Drug therapy

Treatment of epilepsy depends upon the nature of the attacks, since some drugs that suppress one form of seizure may actually worsen another. For the primary generalized epilepsies, valproic acid, ethosuximide, clonazepam, diphenylhydantoin, and carbamazepine are the drugs of first choice. For the secondary epilepsies, carbamazepine, diphenylhydantoin, and primidone are preferred. These drugs have different modes of action. Some selectively block the high-frequency electrical discharges that lead to seizure activity, while others stimulate the inhibitory effect of the neurotransmitter gamma-aminobutyric acid (GABA).

In cases where control of seizures proves difficult, repeated estimations of the concentration of the drug in the serum are necessary as are appropriate blood tests to detect unwanted effects on the blood and other organs in the body, such as the liver. Surgical therapy is reserved for cases in which the seizures are uncontrolled by drugs and in which a single focal origin of the seizures

is demonstrated. There are few such cases, and over 80 percent of patients with seizures achieve excellent control through faithful adherence to a regime of drug therapy. When epilepsy complicates severe brain damage, however, control may be impossible.

Headache. Diagnosis of a type of headache can usually be achieved by a complete history and physical examination without laboratory tests. There are four major varieties of headache, each with its own type and severity of pain, temporal relationship, site and pattern of radiation toward other areas, nature of aggravating or relieving factors, and associated symptoms.

Vascular headaches. These include migraine and its variants as well as headaches due to abnormal stretching of the arterial walls in the cranium as a result of vessel-
Migraine wall disease. Migraine headaches recur periodically; often a family history of the ailment can be obtained. The pain is typically severe, throbbing or pounding, felt on one or both sides of the head, and made worse by activity, noise, or bright lights. In classic migraine, visual phenomena such as zigzag lights in the visual fields precede the onset of pain. In complicated migraine, visual loss, weakness of a limb or of one side of the body, speech disturbances, or confusion may accompany and outlast the headache. Nausea and vomiting, pallor, irritability, and prostration usually accompany migraines of any variety. In a variant called cluster headache, excruciatingly severe pain is felt in and around one eye, lasting an hour or so and frequently waking the patient from sleep in the early morning. Such attacks occur in clusters, the pain occurring 10 or 20 times over a month or so, with months of freedom until the next cluster begins.

The treatment of migraines involves a careful search for the factors that precipitate them. Foods such as cheese and chocolate, beer and red wine, and those containing nitrite or monosodium glutamate are the most frequent culprits; their removal from the diet may be sufficient to relieve the patient permanently, but total success is uncommon. Other factors include excessive or deficient sleep, physical and psychological stresses, oral contraceptives, and the menstrual cycle in many cases. Drug therapy (such as ergotamine, anti-emetic agents, or even inhaled oxygen, and pain-relieving agents) may be necessary in acute attacks. As preventive measures, tricyclic drugs, adrenergic blocking agents, lithium, and numerous other classes of drug are available. In elderly patients brief episodes of brain dysfunction resembling small strokes may occur, apparently due to arterial spasm during migraine; in younger patients with severe migraine such spasm may very rarely cause such a reduction of blood supply to parts of the brain that permanent deficits occur.

Vascular headaches may be complications of fever, hangover, lack of oxygen, low blood sugar, and ingestion of certain drugs; they are also typical of cranial arteritis, a variant of polymyalgia rheumatica. In all these conditions treatment is directed at the underlying cause.

Tension headaches. These are continuous and generalized pains felt from front to back or all around the head; they are generally less severe than migraines. While emotional stress and letdown after such stress are the most common causes, arthritis of the joints of the neck may also contribute. Tension headaches alone are often experienced by migraine sufferers, and a combined form of headache also exists. Treatment is of the psychological cause when detectable, but chronic tension headache may be self-perpetuating.

Traction headaches. These are caused by the distortion
Intracranial of intracranial pain-sensitive structures. They have a much
pressure more serious import, as intracranial bleeding or tumours, brain infections, obstruction to the flow of cerebrospinal fluid, and low pressure in the fluid due to leakage after lumbar puncture are typical causes.

Such headaches are moderately but increasingly severe, involve the whole head, may have a throbbing component, are worse with movement and coughing and on awakening, and improve as the day progresses but recur for hours daily. They are often accompanied by focal neurological signs and signs of raised intracranial pressure. Diagnosis demands a full investigation.

Referred headaches. Pain may also be referred to the head (*i.e.*, felt in the head even though the site of disease is elsewhere) by eye disorders such as glaucoma and refractive errors, infections or tumours of the nasal sinuses, dental infections, and arthritis of the neck.

Infections. *Encephalitis.* (Meningitis is considered above; see *The meninges and cerebrospinal fluid.*) The term encephalitis signifies infection of the substance of the brain. It may be caused by viruses, bacteria, rickettsias, fungi, protozoans, or metazoans. In the Western world, viral encephalitis is the most common; it is typically due to herpes simplex and less commonly to arboviruses, measles, mumps, polio, and influenza viruses, or to the group known as enteroviruses. Rabies is another rare cause.

Typical features of encephalitis include the onset, over hours or days, of headache, fever, stiffness of the neck, drowsiness, and malaise. Seizures, evidence of raised intracranial pressure, and signs of focal damage to the brain are found on examination. This combination of findings, however, can occur in many other conditions, so that further investigations are necessary, including CAT scanning of the head, EEG, and lumbar puncture in order to examine the cerebrospinal fluid for cells, organisms, and sugar levels.

The mortality of herpes simplex encephalitis has been reduced from more than 60 percent to less than 20 percent with the introduction of acyclovir or vidarabine therapy. Measures to reduce the intracranial pressure are also required in severe cases. Specific antiviral treatment is not available for other forms of viral encephalitis.

Abscess. Cerebral abscess is due to bacterial infection that may be introduced from the bloodstream in cases of generalized or distant infection or from contiguous infection following a skull fracture. The infection produces a pus-filled abscess, usually localized close to the site of the original infection. The clinical features are the same as with viral encephalitis, but removal of cerebrospinal fluid by lumbar puncture is dangerous because swelling may cause the brain to herniate downward, with fatal compression of the vital centres. In many cases, evidence of the source of the invading organisms—such as chronic lung suppuration, congenital heart disease, or sinus or ear infections—suggests the diagnosis. Efforts can then be made to localize and typify the infection by EEG and CAT scanning.

Infection travels along the course of the intracranial Cortical thrombo-
veins, which themselves are infected and which thrombose, or clot. Such cortical thrombophlebitis can occur in the venous channels of the dura mater, resulting in infarcts of the surrounding brain and damage to contiguous cranial nerves. This condition is seen especially in children suffering from malnutrition and dehydration, but it also complicates some blood diseases and may occur in pregnancy. The symptoms resemble those of cerebral abscess, but there is a greater likelihood of seizures. phlebitis

As treatment, antibiotics are chosen according to the nature of the organism likely to be responsible, and surgical removal can follow encapsulation of the abscess within scar tissue. Anticoagulants may be used in cortical thrombophlebitis.

Abscesses also occur both outside and just below the dural membranes enclosing the central nervous systems, usually arising by spread of local infection.

AIDS. The acquired immune deficiency syndrome, or AIDS, virus causes an infection that greatly diminishes the body's cell-mediated immune system, thus disposing it to infections that healthy people seldom contract. Many viral infections as well as tubercular, toxoplasmic, fungal, and spirochetal infections of the brain or meninges occur as a result. Neurological complications include encephalitis, due to these superadded infections, or progressive dementia, directly due to invasion of the brain by the AIDS virus.

Following common viral infections such as measles, during bacterial endocarditis (a bacterial infection of the heart valves), or after vaccination against such diseases as smallpox, an acute neurological illness with meningeal irritation, fever, reduction in consciousness, seizures, focal signs, and evidence of raised intracranial pressure may occur. This is known as acute toxic encephalopathy and

is thought to represent an acute allergic reaction of the immune system to the preceding infection. In Reye's syndrome, a variation occurring in children, the same features are found, along with persistent vomiting that accompanies an acute degenerative change in the liver. There is some evidence that aspirin may precipitate the condition.

In yet another related syndrome, acute allergic encephalomyelitis, a similar illness occurs, again in the second week after vaccination or viral infection. This illness appears with signs of encephalitis and inflammation of the spinal cord or nerve roots. Damage to the myelin sheaths in the central nervous system is the basis of the disorder. Treatment with steroid drugs (related to cortisone) is sometimes effective, but many patients die during the acute stages of the illness.

Syphilis. This disease follows infection with the spirochete *Treponema pallidum,* almost invariably as a result of sexual contact or infection of the fetus in utero. Primary syphilis produces a chancre, or sore, at the site of infection; weeks later, secondary syphilis develops with a skin rash and signs of mild meningitis, but, in the third stage, signs indicate that the spirochete has invaded the substance of the nervous system. One syndrome is tabes dorsalis, involving the spinal cord (see above *The spinal cord: Inflammation*). Another is general paresis of the insane, an outmoded term for chronic syphilitic encephalitis, which causes progressive dementia and signs of focal damage to many brain areas. These two conditions may coexist. Diagnosis is confirmed by serological tests in the blood and by examination of the cerebrospinal fluid. Treatment with penicillin stops the progress of the disease and may relieve some of the more florid signs.

Progressive dementia

Slow viruses. In 1957, an unusual disease called kuru was described in the Fore tribe of New Guinea. Its means of spread was traced to ritual cannibalism, and its features included abnormal involuntary movements, dementia, and serious disturbance of motor functions. The disease was invariably fatal. A transmissible agent with a very long incubation period of years was shown to be the cause. This and similar agents are known as slow viruses, although they have properties quite distinct from those of conventional viruses.

Creutzfeldt-Jakob disease is a rare cause of rapidly developing dementia in adults, with added signs of multifocal disturbance of the brain and spinal cord. This condition has been transmitted between humans through such means as a corneal transplant taken from a person who unknowingly had the infection. The disease is fatal, and no treatment is known to affect its course. The transmissible agent resembles that of kuru.

Subacute sclerosing panencephalitis is characterized by slowly increasing loss of mental abilities, brief, shocklike jerks of the body, weakness, and spastic muscles. It affects children and young people. The measles virus is the responsible agent, probably evoking an abnormal response of the patient's immune system.

Progressive multifocal leukoencephalopathy is another fatal disease of the brain occuring in patients whose immune system is suppressed by drugs or disease. Progressive loss of myelin occurs in the white matter of the brain, cerebellum, and spinal cord. A polyoma virus that does not normally cause disease in man is responsible.

Neoplasms and nonmetastatic syndromes. Tumours affect the brain directly and indirectly. Their direct effects are mediated through replacement or compression of tissue, in each case impairing the function of the compressed part and often first appearing through epileptic seizures. Indirect effects include raised intracranial pressure, which is particularly common in the case of tumours arising within or compressing the ventricular system. A useful classification separates the benign tumours, which do not spread within the brain or metastasize (seed themselves) to distant sites, from malignant tumours, which do have these characteristics.

Benign tumours. Benign intracranial tumours include neurofibromas (technically tumours of the myelin-forming Schwann cells), which grow on cranial nerves. The most common are tumours of the vestibulocochlear nerve, tumours of the skull, and meningiomas. Pituitary adenomas arise within the pituitary fossa. By compressing the underside of the optic chiasm, they cause deficits in the visual fields, and they raise the intracranial pressure through compression of the hypothalamus and third ventricle. In addition, many secrete hormones, which may stimulate such reactions as abnormal growth and lactation. These signs may be the first evidence of pituitary adenoma. Surgical removal, approaching through the nose or through craniotomy (opening up the cranial cavity), is often required and may lead to cure, but small tumours of the pituitary may be suppressed by the drug bromocriptine.

Pituitary adenoma

Craniopharyngiomas arise from a vestigial remnant of tissue in the roof of the mouth and extend upward to produce effects similar to those of pituitary tumours. Since they often contain calcium, they may be seen on plain skull X rays. Craniotomy is necessary for their removal. Colloid cysts are found within the ventricles. Although seldom causing symptoms, on account of their small size, they occasionally block the flow of cerebrospinal fluid, causing an acute rise in intracranial pressure that results in headache and loss of consciousness.

Other benign intracranial masses include parasitic cysts, granulomas, tuberculomas, and dermoid cysts. These may arise in any part of the brain or beside it, in which case there may also be involvement of the skull bones. Infective tumours are now uncommon in the Western world.

Malignant tumours. Malignant tumours of the brain are more common than benign ones; the most frequent of all are the gliomas, which arise from the neuroglial cells. They are of varying degrees of malignancy as judged by their speed of growth and tendency to spread. Astrocytomas arise anywhere; destroying the function of the tissues that they invade and replace, they also cause seizures and eventually signs of raised intracranial pressure. The prognosis for astrocytomas arising in the cerebellum and for the least malignant of the others is fair after surgical removal and radiation therapy, but in the case of the most malignant, the glioblastoma multiforme, life beyond a year after diagnosis is exceptional.

Astrocytoma

Medulloblastomas and ependymomas are other varieties of glioma arising, respectively, in the brain stem and in the walls of the ventricles. The former are described above (see *The cerebellum: Neoplasms*). The latter also grow in the posterior fossa in young people, but more slowly. Because of their site of origin, they tend to cause early increase in intracranial pressure, with signs of brain-stem and cerebellar dysfunction. Surgical removal is seldom complete, but radiation therapy is able to shrink the tumour and slow its growth.

Oligodendrogliomas occur anywhere in the cerebrum and are particularly liable to cause epileptic seizures. They often contain calcium, which may allow their detection in plain skull X rays. Teratomas and pinealomas are more common in young men; arising from the region of the pineal gland and damaging the hypothalamus and upper brain stem, they disturb the control of eye movement, obstruct the flow of cerebrospinal fluid, and cause cerebellar dysfunction. Their behaviour may resemble that of a benign or of a malignant tumour. Lymphomas such as Hodgkin's disease rarely invade the brain, though they may compress it; but reticulum cell sarcomas (microgliomas) do invade diffusely and cause headache, seizures, change in personality, and various focal signs.

In all such cases, whether benign or malignant, tumours are suspected from the history of headache, seizures, and focal neurological problems; diagnosis is then confirmed by CAT or radioisotope scanning. Surgery is usually necessary in order to confirm the nature of the tumour, to relieve increased pressure, and to remove all or part of the mass itself. In malignancies this at least makes subsequent radiation therapy more effective, but in the gliomas the prognosis is poor in most cases despite such treatments. The swelling surrounding these tumours can often be greatly reduced by a steroid drug with rapid but temporary relief of symptoms.

Malignant tumours arising elsewhere in the body may metastasize to the brain; common sites of origin of such secondary tumours are the lung, breast, thyroid, and kidney. These are usually multiple tumours, so that surgical

removal is usually fruitless, although radiation therapy may shrink them and slow their growth.

Nonmetastatic syndromes are constellations of clinical features reflecting damage to the nervous system as a result of cancer elsewhere in the body that has not actually spread to the brain or spinal cord. How this arises has not been fully elucidated. Dementia, a syndrome resembling encephalitis, cerebellar degeneration, signs of transverse damage to the spinal cord, peripheral neuropathy, disease of the end plate somewhat resembling myasthenia, and weakness and wasting of muscles are common presentations of these syndromes.

Stroke. *Anatomy and collateral supply.* Blood follows two avenues to the brain: the two internal carotid arteries, which divide intracranially into a number of branches (the largest being the anterior and middle cerebral arteries); and the vertebral arteries, which fuse at the base of the brain and then divide again to form the posterior cerebral arteries (Figure 38). There are many communications between vessels inside and outside the head, and, in some places, two arteries supply the same territory. Despite this generous blood supply the huge requirements of the brain for blood and the fact that the last branches of arteries anastomose, or join together, very little, if at all, make the supply quite precarious. To help smooth out the different rates of cerebral blood flow caused by variations in heartbeat, respiration, blood pressure, and posture, a system of autoregulation exists whereby the cerebral blood vessels vary their size in response to such changes.

The carotid and vertebral arteries

Yet, in diseased states, the blood supply to parts of the brain still often fails. The effects vary from minor, transient slowing of activity, due to slight reduction in local blood flow, to severe, permanent loss of function when blood supply is completely lost. These failures of blood supply are strokes.

Brodmann, "Feinere Anatomie des Grosshirns," in *Handbuch der Neurologie* (1910), Springer-Verlag, Berlin

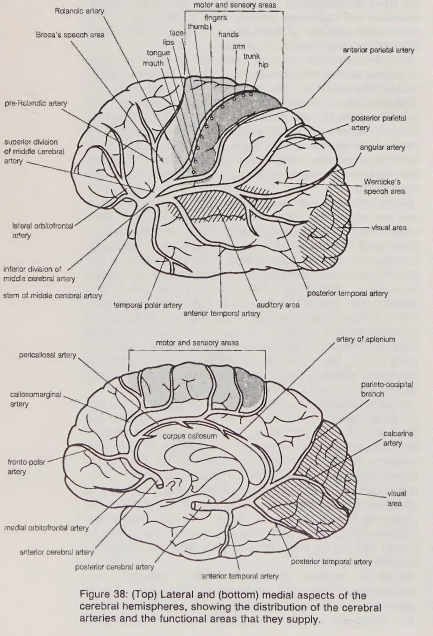

Figure 38: (Top) Lateral and (bottom) medial aspects of the cerebral hemispheres, showing the distribution of the cerebral arteries and the functional areas that they supply.

Pathogenesis and classification. The two main types of stroke are (1) those in which a blood vessel supplying a part of the brain is occluded briefly or permanently and (2) those in which the vessel bleeds as well, so that the loss of blood supplying the tissue is aggravated by a blood clot compressing it.

Occlusive strokes are further divided by clinicians into four groups: (1) Transient ischemic attacks (TIAs) are the mildest, the symptoms lasting only for minutes or hours. They are usually caused by small emboli, such as fragments composed of blood cells or cholesterol, that are swept into the brain's circulation from the arteries of the neck or elsewhere. (2) Reversible ischemic neurological deficits may have the same pathological basis, but the symptoms last for up to three weeks. (3) Evolving strokes show a stuttering or progressive deterioration. Blockage of the larger arteries in the brain or neck is usually responsible. (4) Completed strokes represent the final result not just of relative reduction in blood supply (ischemia) but of the death of brain tissue as a result of severe starvation of blood (infarction).

Transient ischemic attack

The most common pathological change causing stroke is atherosclerosis of the large- and medium-sized arteries in the neck and brain, which causes ulcers in the wall of the artery, narrowing of the lumen, or blockage of the vessel by a combination of these changes and blood clot. Small-vessel disease is the next most common, in which the thickening and degeneration of the walls of the arterioles are usually due to high blood pressure. Other vessel-wall diseases include inflammatory changes, as in collagen-vascular diseases or after deep X-ray treatment; spasm, as in severe migraine; splitting of the wall of the artery; and direct injury. Larger emboli causing more than just a TIA may arise in the larger arteries and from the valves or lining membrane of the heart.

Among other mechanisms for stroke are a severe global decrease in cerebral blood flow, as may occur with a severe hemorrhage or heart attack; diversion of blood to other arteries, as a result of a narrowing or blockage of a vertebral artery in the neck; cerebral anoxia, a severe reduction in the amount of oxygen in the blood; and abnormal viscosity of the blood due to excess numbers of cells or to increased protein concentration in the blood.

Hemorrhagic strokes are usually due to small-vessel disease in patients with high blood pressure. Such intracerebral hemorrhage occurs most often in the deep white matter of the brain, brain stem, and cerebellum. The incidence of such strokes has been reduced in part by the introduction of more effective treatments for hypertension. Bleeding also occurs when a defect in the wall of an artery, called an aneurysm, gives way. When this occurs at the sites of branching of the larger arteries inside the head, blood spills into the subarachnoid space, causing subarachnoid hemorrhage. Bleeding may also occur with malformations of arteries and veins, into an infarct, and with blood diseases that impair coagulation.

Hemorrhage

Clinical syndromes. The features of TIAs (and of any stroke syndrome) depend on which part of the brain has been affected. Transient loss of vision in one eye, like a graying-out or as if a curtain were being pulled over it, is one common manifestation of ischemia of the retina. Similar brief episodes of numbness or weakness of a limb or difficulty in speech suggests an attack in the carotid-artery territory, while brief reduction in consciousness, vertigo, slurred speech, impaired vision in both eyes, or imbalance point to ischemia in the vertebrobasilar circulation.

Infarction of the brain occurs most often during sleep, the patient awakening to find that he has lost the function of that part of his body supplied by the occluded vessel. The most common site of stroke is in the territory of the middle cerebral artery. The usual symptoms are aphasia and other disorders of higher cerebral functioning, hemiparesis (weakness of the face and arm more than of the leg on the other side of the body), and loss of sensation in the same areas. Blockage of the internal carotid artery in the neck produces a similar picture. Because there is extensive

Symptoms of stroke

communication between the anterior cerebral arteries on both sides, the area of the brain supplied by the anterior cerebral artery on the occluded side may escape damage. Anterior cerebral artery infarcts produce weakness and sensory change on the opposite side of the body, but the leg is more affected than the arm. Posterior cerebral infarcts cause loss of vision in the opposite half of the visual field and sometimes difficulty in the comprehension of speech (called receptive aphasia).

An infarct of the area of brain supplied by the basilar artery is usually fatal because of severe damage to the vital control centres in the brain stem.

Small, deep infarcts in the white matter also occur. The small cavities of damaged tissue, called lacunes, cause a number of syndromes in which the damage is restricted to, for example, pure weakness or pure sensory dysfunction on one side of the body.

Intracerebral hemorrhage most commonly occurs in the putamen and leads to sudden headache, severe hemiparesis, loss of consciousness, and deviation of the eyes to one side. Bleeding into the pons causes paresis of all limbs and loss of consciousness. Bleeding into the cerebellum produces typical signs of incoordination with headache and stiffness of the neck.

Massive cerebral infarction or hemorrhage, with swelling of the brain, is often fatal. With less severe brain damage a surprising degree of recovery occurs, so that a hemiplegic patient learns to walk again although use of the hand remains poor. The mechanism of this recovery process, which can continue for up to six months, is not well understood.

Subarachnoid hemorrhage (SAH) caused by rupture of an aneurysm, leads to a sudden, explosive headache, with a stiff neck, sometimes a seizure or loss of consciousness, and, depending on the damage done by the blood pumped out of the artery, focal signs of brain damage. Up to half the patients with SAH die within two months as a result of the initial or subsequent bleeding.

Diagnosis and treatment. The diagnosis of cerebrovascular disease is achieved by clinical evaluation, but it has been greatly improved by CAT scanning, which not only shows the site of the stroke but also allows determination of the amount of bleeding (if any) and thus indicates the nature of the stroke. Additional tests include angiography, for localizing an aneurysm or detecting the site and nature of disease in the arteries of the neck, and a battery of tests aimed at determining whether any underlying disease (*e.g.,* diabetes, blood cell or clotting disease, infections) might have led to the stroke.

The treatment of stroke patients is initially directed toward support of the cardiac and metabolic systems, no treatment being known to reverse the ill effects of ischemia. High blood pressure is controlled, acutely raised intracranial pressure lowered, and, in rare cases, anticoagulant drugs prescribed. Rehabilitative efforts start as soon as the patient's condition is stable. Risk factors such as smoking and diabetes are also tackled. Also appropriate in some cases, depending on the nature of the stroke, may be such specific treatments as the clipping or isolation of a cerebral aneurysm and, perhaps, surgical evacuation of a blood clot or clearing-out of the roughened lining of the major arteries in the neck.

Drugs such as aspirin, which inhibit the tendency of platelets to cause clotting in the bloodstream, have proved effective in the prevention of stroke and fatal heart attacks after TIAs in men.

UNLOCALIZED OR MULTIFOCAL DISORDERS

Many disorders of the nervous system cannot be localized to a single site, or they represent the distant effects of disease of other parts of the body.

Effects of systemic disease. *Endocrine diseases.* Disorders of the hypothalamus may lead to symptoms of autonomic dysfunction, sleep disturbance, and diabetes insipidus (in which large volumes of dilute urine are secreted). Pituitary adenomas may cause acromegaly, in which peripheral-nerve compression may also occur. Overactivity of the thyroid gland causes tremor, muscle weakness, and disturbances of eye movements, while underactivity leads to mental dulling, deafness, difficulty in relaxing muscles, and median-nerve compression. Muscle weakness is seen in overaction of the parathyroid gland; underactivity is associated with seizures. Muscle weakness is also one of the features of adrenal gland dysfunction (both Addison's and Cushing's diseases); both of these conditions also induce abnormal mental states.

Complications of diabetes mellitus

Diabetes mellitus causes many neurological complications, including peripheral neuropathy (with features of autonomic failure), painful nerve root lesions in the lumbosacral plexus, acceleration of the rate of atherosclerosis with an increased chance of stroke, and damage to the retinas. Hyperinsulinism reduces blood-sugar levels, which may cause coma. Use of oral contraceptives slightly increases the risk of stroke.

Organ failure. When the function of the liver, lung, heart, or kidney fails, the nervous system is affected. With liver failure the typical picture is of dementia or of a confused state, with aphasia, dysarthria, and a flapping tremor of the limbs progressing to coma in severe cases.

Kidney failure is often associated with high blood pressure, which may lead to acute brain edema (distension with fluid) with visual loss and coma. Chronic kidney failure is likely to produce peripheral neuropathy as well as symptoms similar to those of liver failure but with increased likelihood of epileptic seizures. Dementia is a complication of dialysis in areas where the aluminum content of the dialysis fluid is high.

Chronic respiratory failure is another cause of tremor, confusion, and raised intracranial pressure. Heart failure may also produce a confused state, and it may predispose an individual to stroke.

Blood diseases. Leukemia and polycythemia also affect the nervous system, the former mainly through infiltration of the meninges or brain and the latter by increasing the risk of stroke. Anemia due to deficiency of vitamin B_{12} is the cause of subacute combined degeneration of the spinal cord. Severe anemia may be associated with an increased risk of stroke.

Metabolic disease. Many biochemical disorders affect the nervous system, usually not in isolation. Most of them are genetically determined, and only a few are treatable. They can be classified into seven groups.

Phenylketonuria

Protein and amino acid disorders. Phenylketonuria is a disorder of the conversion of the amino acid phenylalanine (a building block of protein) into tyrosine. Among other neurological signs, it leads to a delay in mental and motor development. It can be diagnosed within days of birth by a simple urine test and treated with a diet low in phenylalanine, which may allow more normal intellectual development to proceed. Other so-called aminoacidurias, which cause psychomotor delay and a variety of neurological and musculoskeletal problems, include hyperglycinemia, hyperammonemia, Hartnup and Lowe's diseases, maple syrup urine disease (so called because of the distinctive smell of the urine), and homocystinuria (a condition that predisposes to strokes).

Disorders of fat and fatty acid metabolism. Many of the conditions mentioned in this and the next section are caused by a genetically determined enzyme failure within cells, which leads to the accumulation of substances that would normally be metabolized. They are called lysosomal diseases after the lysosome, the structure in the cell that contains these substances, and give rise to signs of neurological involvement at birth or, at latest, in the early years of childhood.

Sphingolipidoses are typical examples. They include gangliosidoses (of which the best known is Tay-Sachs disease), sulfatidoses (*e.g.,* metachromatic leucodystrophy), and such conditions as Krabbe's, Fabry's, Gaucher's, Farber's, and Nieman-Pick diseases. In these conditions psychomotor retardation and, variously, seizures, retinal abnormalities, peripheral neuropathies, and musculoskeletal deformities are prominent features. Sudanophilic leucodystrophies are characterized by defective formation of myelin (the insulating substance surrounding nerve fibres), with marked cerebellar and corticospinal-tract dysfunction. Adrenoleucodystrophy occurs only in males; it leads to blindness, motor weakness, spasticity, and signs

of adrenal-gland failure. In Refsum's syndrome peripheral neuropathy and retinal and cerebellar signs accompany a dry, scaly skin rash. This condition is of interest because restriction of dietary phytanic acid, a substance found in green vegetables, slows the progress of the disease.

Inherited deficiencies of blood lipoproteins are also associated with peripheral neuropathy, retinal degeneration, and other motor and skeletal deformities. In analphalipoproteinemia, the tonsils are swollen by accumulations of cholesterol, while in beta-lipoproteinemia, excessive fat in the stools suggests the diagnosis. Lipofuschinosis is a disorder in which lipids are stored in the retinas and nervous system, causing visual impairment, seizures, intellectual decline, and spastic weakness and ending in death.

Disorders of carbohydrate metabolism. Galactosemia develops when infants are unable to metabolize galactose, or milk sugar. Cataracts, floppiness of the limbs, and psychomotor delay occur unless substitutes for milk are given. In glycogen-storage diseases glycogen cannot be metabolized to yield lactic acid and energy, so that it accumulates within muscle, liver, and other tissues. In mucopolysaccharidoses and mucolipidoses (both lysosomal disorders), fatty and carbohydrate materials are deposited in the nervous system and in other tissues; severe mental retardation, motor and ocular signs, and skeletal abnormalities are prominent features within this group.

Vitamin deficiencies

Deficiency states. The effects of deficiency of vitamin A are mainly on the retina and skin, but components of the vitamin B group are essential for normal development and functioning of the nervous system. The Wernicke-Korsakoff syndrome (common in alcoholics) consists of disorders of eye movement, cerebellar incoordination, failure of the formation of new memories, and peripheral neuropathy, all due to deficiency of thiamine (vitamin B_1). Beriberi is the name given to the occurrence of the neuropathy alone. In each case, replacement of the vitamin may lead to substantial improvement. When other vitamins (niacin, pyridoxine, and so forth) are deficient, the symptoms are similar, and signs of spinal cord disease may occur.

Subacute necrotizing encephalopathy, also called Leigh's disease, is a lethal disorder of infancy marked by psychomotor delay, myoclonic jerks, paralyses of eye movements, and respiratory disorders. The precise biochemical defect is unknown, but thiamine metabolism is likely to be involved. Seizures in early childhood are the main feature of pyridoxine dependency, an inherited abnormal metabolic requirement for the vitamin.

Deficiency of vitamin D causes rickets, the bony softening of which may have secondary effects on the nervous system, and weakness of the proximal muscles.

Fluid, mineral, and electrolyte disorders. Inappropriate secretion of antidiuretic hormone from the pituitary gland leads to confused states and seizures; it may complicate almost any intracranial disease, especially subarachnoid hemorrhage. High or low levels of electrolytes such as sodium, potassium, calcium, and magnesium, as well as disorders of acid–base metabolism, also have neurological effects such as confusion, seizures, muscle weakness, tetany (spasm and irritability of muscles), and cramps.

Porphyria

Porphyria is a disorder of heme, the pigment in red blood cells. It occurs in a number of forms, the most important (acute intermittent porphyria) leading to attacks of acute abdominal or limb pains, marked weakness due to peripheral neuropathy, epileptic seizures, severely confused states, and increased pigmentation of the skin with abnormal sensitivity to sunlight. Attacks are sometimes precipitated by certain drugs, such as barbiturates and some antibiotics.

Among inherited disorders are: Menkes' disease, a familial disorder of copper metabolism presenting with seizures and the growth of abnormal hair; Hallervorden-Spatz disease, a condition marked by the deposition of iron in the basal ganglia that produces rigidity, weakness, and abnormal movements; the Lesch-Nyhan syndrome of raised levels of uric acid in the blood with abnormal movements, spastic weakness, mental retardation, and a tendency to self-mutilation; and familial hypoparathyroidism, in which the basal ganglia calcify, causing choreic movements.

Neurocutaneous syndromes. A number of genetically determined disorders of the ectoderm (the outside layer of cells in the embryo, from which the skin and the nervous system develop) are grouped together—slightly artificially—as the neurocutaneous syndromes. Five of these are mentioned below. (Down's syndrome is described above; see *The cerebrum: Mental retardation.*)

Neurofibromatosis

Neurofibromatosis (von Recklinghausen's disease) presents such features as café-au-lait spots on the skin, the formation of fibrous tumours on nerves and, in some cases, of various tumors in the brain, rotation of the spine, tumours of endocrine glands such as the adrenal gland, and other skeletal deformities. The Elephant Man, protected at the London Hospital in the 1880s, is thought by some to have suffered from this condition, his skin thickened by huge numbers of nerve and skin tumours. This disease is relatively common, but many patients have only minimal symptoms.

Ataxia-telangiectasia (the Louis-Bar syndrome) comprises cerebellar incoordination and choreic movements, overgrowth of blood vessels on the conjunctivas (eye membranes), and disorders of the immune system.

In von Hippel-Lindau disease, tumours of blood vessels grow in the brain, especially in the cerebellum and retina, and in other organs.

The Sturge-Weber syndrome is characterized by a large red ("port-wine") overgrowth of blood vessels in the skin over the upper face and by a growth of the underlying brain. The latter effect may cause seizures, spastic weakness, and visual-field deficits.

Tuberous sclerosis is characterized by epileptic seizures, a facial rash resembling acne, and the growth of many benign tumours in the lining membrane of the ventricles of the brain and in other organs.

Toxic effects of drugs, metals, and common poisons. Perhaps due to the complexity of the metabolic systems and to the rapid metabolic rate of the nervous system, the brain is highly susceptible to damage from chemical substances derived both internally and from the environment. Endogenous (internally derived) poisons are the products of organ failure and abnormal metabolism. Among the externally derived poisons are bacterial toxins, such as those in tetanus, which lead to increased excitability of the ventral-horn cells of the spinal cord, with muscular rigidity resulting; diphtheria, which produce severe loss of myelin from motor nerves, causing limp weakness of the throat and body muscles; and botulism and tick paralysis, which prevent normal transmission of impulses between nerve and muscle.

Heavy metals (such as arsenic, lead, thallium, gold, manganese, and mercury), synthetic chemicals (such as the organophosphates, gasoline, and toluene), the alcohols (especially ethyl and methyl alcohol), ionizing radiation, and a huge range of drugs can all be toxic to the nervous system. In addition, water overload can cause seizures, and oxygen, under high pressure, can induce depression of brain function.

The neurological syndromes that occur as a result of toxicity are remarkably varied. Toxic encephalopathy, characterized by reduced consciousness, seizures, and delirium, is seen in poisoning with alcohols, all sedatives, and many other chemicals and drugs—the last usually taken in overdose or for a prolonged period. Seizures, dementia, and drowsiness can also occur in isolation as drug and chemical toxicity, and the withdrawal from sedatives (including alcohol) may also be a cause of seizures. Syndromes of damage to the basal ganglia, including acute dystonias, chorea, and parkinsonism, occur with overdose or prolonged use of, or idiosyncrasy to, many drugs and as a result of poisoning by such heavy metals as mercury and manganese. Other agents selectively damage the cerebellum; diphenylhydantoin and ethyl alcohol are the best-known examples. Signs of damage to the spinal cord may appear following electric shock, deep X-ray treatments, or exposure to heavy metals and some drugs. Subacute combined degeneration of the spinal cord may be induced when drugs lead to a deficiency of vitamin B_{12}.

Drug overdose and withdrawal

Meningeal irritation often followed injection of air into the subarachnoid space when this was performed as a

diagnostic test; it also occurs with some drugs given by mouth or by subarachnoid injection. Fungal meningitis may complicate chronic suppression of the body's immune system. Raised intracranial pressure, due to an increase in the water content of the brain, occurs with cortisone-like drugs, and headaches of migraine type are frequently precipitated by foods and drugs.

The list of drugs and other agents capable of causing damage to cranial nerves or peripheral nerves is very long. It is of interest that some of these agents affect only one of the cranial nerves; thus, the birth control pill has been incriminated in Bell's palsy, a facial weakness caused by dysfunction of the facial nerve, but trichlorethylene (a solvent) and stilbamidine (a drug) cause numbness of the face by affecting the trigeminal nerve. The cochlear and vestibular portions of the vestibulocochlear nerve are also susceptible in different ways to toxicity from the group of aminoglycoside antibiotics.

In the peripheral nervous system the autonomic nerves may be damaged alone or in conjunction with other nerves. The transmission of impulses at the autonomic ganglia may also be blocked by many drugs used to reduce blood pressure. In part, this is a pharmacological response (in other words, it is the effect sought in the first place), but when this effect occurs with anticonvulsants, antidepressants, or sedatives, the effect is highly undesirable. A drop in blood pressure on standing up is the most common clinical effect.

Toxic symptoms affecting the muscles include cramps, weakness, and atrophy, or muscles may even degenerate acutely. The range of chemicals and drugs producing such effects is wide. Drugs may also reduce levels of potassium in the blood, resulting in secondary weakness of muscles. Blockade at the neuromuscular junction is an unwanted effect of some antibiotics and quinine.

Finally, within a miscellaneous group of problems, it should be mentioned that lymphomas may follow prolonged suppression of the immune system or treatment with diphenylhydantoin, that inflammation of the arteries (autoimmune vasculitis) arises as a complication of treatment with some drugs and as toxicity from chemical exposure, and that even drugs used normally can produce unusual effects in singular circumstances (for example, dangerously low blood sugar levels causing brain damage may occur in a diabetic patient taking his normal insulin dose but missing meals).

Demyelinating diseases. Demyelinating diseases must be differentiated from dysmyelinating diseases. In the former, normal myelin is damaged; in the latter group, the myelin is probably abnormal in the first place, as in leucodystrophies and other metabolic disorders involving fat or fatty acids (see above).

Demyelination can occur after trivial viral infections or vaccinations, but multiple sclerosis (MS) is the most important example and is discussed here.

Multiple sclerosis

Multiple sclerosis is a relatively common disease in temperate climates, with a prevalence of between 50 and 100 per 100,000 population in most areas where such figures have been gathered since 1970. Females are affected somewhat more often than males, and most patients develop the first signs within 10 years of their 30th birthday. Pathologically, multiple scattered areas of myelin breakdown, called plaques, are found within the white matter in the central (not peripheral) nervous system. The actual nerve fibres, the axons, remain intact but no longer conduct impulses adequately. The cause of this demyelination is not known, but people with certain genetically determined immunologic characteristics seem to be over-represented among the MS populations. Also, the influence of an outside agent is strongly suggested by variability between regions of the same geographic area and by the fact that people who migrate from an area of low MS prevalence to one of high prevalence before the age of 14 years take on, as it were, the higher risk of their new area. This increased risk does not occur if such a move is made after that age or if migration is in the other direction. The nature of the agent is unknown, epidemiological and clinical studies conflicting in suggestions that the virus of measles or of canine distemper is responsible.

Some typical clinical patterns of MS are:

1. Onset in young adult life, with inflammation of one optic nerve causing pain and diminished sight for a few days or weeks, followed by recovery. There is a transient appearance of scattered neurological signs in subsequent years.

2. The same as above, but with the initial signs suggesting lesions not only in the optic nerve but also in the spinal cord, cerebellum, or brain stem and in the deep cerebral white matter. A tendency to further relapses and remissions may leave more or less evidence of past attacks.

3. Severe and progressive involvement of any part of the nervous system, with further relapses and persistent deficits after subsequent attacks, leading to "chronic progressive multiple sclerosis."

4. The slower progression of signs mainly or only at spinal-cord level in patients who are usually over the age of 50.

Typical clinical features (varying with the site of the plaques) include eye pain and visual dimming (optic nerve); double vision, nystagmus, disturbances of speech, and facial numbness or pain (brain stem); incoordination of gait and of the limbs (cerebellum and cerebellar connections); spasticity, weakness, and increased deep tendon reflexes (corticospinal tracts at any level from the cerebral white matter down to the spinal cord); frequency and urgency of bladder emptying (corticospinal tracts); and alteration in sensation, especially involving the senses of joint position and discriminative touch (dorsal columns in the spinal cord or their upward connections in the brain stem or subcortical white matter). In severe cases, intellect and memory are impaired.

Diagnosis and treatment of MS

Diagnosis of multiple sclerosis depends upon the demonstration of physical signs that imply the presence of plaques in multiple areas of the central nervous system. When this cannot be done clinically, electrical survey of the nervous system, using evoked potential testing, may be useful. In the cerebrospinal fluid the detection of oligoclonal bands in the gamma-globulin fraction of the protein is also suggestive. Overall, the diagnosis is essentially clinical; if laboratory support is not forthcoming, observation of the patient's course over subsequent months or years may allow it to be made with confidence.

The outcome of the disease cannot be foretold from the initial symptoms. In some 20 percent of cases there is no disability 10 years after the onset, while other patients are rapidly disabled. Mean survival from onset is now well over 30 years.

Treatments of specific complaints, such as spasticity and cramping of the limbs, bladder symptoms, and facial pain, is relatively easy; the prevention of relapses or progression is extremely difficult. Measures that suppress the activity of the body's immune system, such as steroid (cortisone-like) drugs and specific immunosuppressants, are the mainstays of therapy. The chronicity of the disease and its potentially devastating effects during the relative youth of many of the patients has made multiple sclerosis a fertile field for scientifically unsupported claims. (W.E.M.P.-P.)

BIBLIOGRAPHY

Form and function of nervous systems. General physiological features are presented in JOHN P. SCHADÉ and DONALD H. FORD, *Basic Neurology: An Introduction to the Structure and Function of the Nervous System*, 2nd rev. ed. (1973); ERNEST GARDNER, *Fundamentals of Neurology: A Psychophysiological Approach*, 6th ed. (1975); ABEL LAJTHA (ed.), *Handbook of Neurochemistry*, 2nd ed., 10 vol. (1982–85); DAVID OTTOSON, *Physiology of the Nervous System* (1983); STEPHEN W. KUFFLER, JOHN G. NICHOLS, and A. ROBERT MARTIN, *From Neuron to Brain: A Cellular Approach to the Function of the Nervous System*, 2nd ed. (1984); MELVIN J. SWENSON (ed.), *Dukes' Physiology of Domestic Animals*, 10th ed. (1984); ERIC R. KANDEL, JAMES H. SCHWARTZ and THOMAS M. JESSELL (eds.), *Principles of Neural Science*, 3rd ed. (1991); *The Nervous System: Circuits of Communication* (1985), part of the series "The Human Body"; ARTHUR C. GUYTON, *Textbook of Medical Physiology*, 8th ed. (1991); and GORDON M. SHEPHERD, *Neurobiology*, 2nd ed. (1988). *Handbook of Physiology*, rev. ed., sect. 1, *The Nervous System*, 5 vol. in 9 (1977–87), examines the cellular biology of neurons, motor control, sensory processes, and regulatory systems and higher functions of the brain. See also D.M. GUTHRIE, *Neuroethology: An Introduction* (1980), a psychology of animal behaviour,

including that of humans. Studies of the nerve cells include ALAN PETERS, SANFORD L. PALAY, and HENRY DEF. WEBSTER, *The Fine Structure of the Nervous System: Neurons and Their Supporting Cells,* 3rd ed. (1991), a description of nerve cells based on numerous electron micrographs; and H. HYDÉN, "The Neuron," ch. 5 in JEAN BRACHET and ALFRED F. MIRSKY (eds.), *The Cell: Biochemistry, Physiology, Morphology,* vol. 4, part 1, *Specialized Cells* (1960), pp. 215–323. The effects of drugs on the central nervous system are detailed in JACK R. COOPER, FLOYD E. BLOOM, and ROBERT H. ROTH, *The Biochemical Basis of Neuropharmacology,* 6th ed. (1991).

The transmission of information in the nervous system via electrical signals is analyzed in three works of historical interest: KEITH LUCAS, *The Conduction of the Nervous Impulse,* rev. by E.D. ADRIAN (1917); E.D. ADRIAN, *The Mechanism of Nervous Action: Electrical Studies of the Neurone* (1932, reprinted 1959); and JOSEPH ERLANGER and HERBERT S. GASSER, *Electrical Signs of Nervous Activity* (1937, reprinted 1968), including bibliographies of the works of both authors. More recent works include ICHII TASAKI, *Nervous Transmission* (1953), and "Conduction of the Nerve Impulse," ch. 3 in *Handbook of Physiology,* sect. 1, *Neurophysiology,* vol. 1. (1959); JOHN C. ECCLES, *The Physiology of Nerve Cells* (1957, reprinted 1968), written by a co-recipient of the 1963 Nobel Prize for Physiology or Medicine; A.L. HODGKIN, *The Conduction of the Nervous Impulse* (1964, reissued 1971), a brief but lucid exposition; MARY A.B. BRAZIER, *Electrical Activity of the Nervous System,* 4th ed. (1977), a college-level survey; and BERTIL HILLE and WILLIAM A. CATTERALL, "Electrical Excitability and Ionic Channels," in GEORGE J. SIEGEL (ed.), *Basic Neurochemistry,* 4th ed. (1989), pp. 71–90. Other methods of transmission are described by A.V. HILL, *Chemical Wave Transmission in Nerve* (1932); JOHN C. ECCLES, *The Physiology of Synapses* (1964); M. GABE, *Neurosecretion,* trans. from French (1966), an account of neurosecretion in invertebrates and vertebrates; and BERNARD KATZ, *The Release of Neural Transmitter Substances* (1969).

The evolution and development of the nervous system is explored by C.U. ARIËNS KAPPERS, G. CARL HUBER, and ELIZABETH C. CROSBY, *The Comparative Anatomy of the Nervous System of Vertebrates, Including Man,* 2 vol. (1936, reprinted in 3 vol., 1967); THEODORE HOLMES BULLOCK and G. ADRIAN HORRIDGE, *Structure and Function in the Nervous Systems of Invertebrates,* 2 vol. (1965), a monumental, well-illustrated work containing comprehensive bibliographies that cover the available knowledge of the nervous systems of all the invertebrate groups; HARTWIG KUHLENBECK, *The Central Nervous System of Vertebrates: A General Survey of Its Comparative Anatomy to the Pertinent Fundamental Biologic and Logical Concepts,* 5 vol. in 7 (1967–78), including basic concepts and a general survey of the nervous systems of both invertebrates and vertebrates; THOMAS L. LENTZ, *Primitive Nervous Systems* (1968), an account of the neural organization of sponges, hydras, and planarias, including a hypothesis on the evolutionary origin of the nervous system; I.E. BAYLISS, *Principles of General Physiology,* 5th ed., vol. 2, pp. 492–533 (1960), a clear description, particularly concerned with the properties of the neuron, spinal reflexes, nerve excitation and inhibition, and reciprocal innervation; and HARVEY B. SARNAT and MARTIN G. NETSKY, *Evolution of the Nervous System,* 2nd ed. (1981), a comparative study of nervous systems. (T.L.L./C.R.N./S.D.E.)

Anatomy of the human nervous system. General overviews are provided by JAY B. ANGEVINE, JR. and CARL W. COTMAN, *Principles of Neuroanatomy* (1981), a short, concise description of anatomical and functional concepts; A. BRODAL, *Neurological Anatomy in Relation to Clinical Medicine,* 3rd ed. (1981), a scholarly source of detailed anatomical information, beautifully presented; MALCOLM B. CARPENTER, *Core Text of Neuroanatomy,* 4th ed. (1991), a popular medical-student text with excellent drawings, photographs, and teaching diagrams; MALCOLM B. CARPENTER and JEROME SUTIN, *Human Neuroanatomy,* 8th ed. (1983), a complete, well-documented source book with coloured atlas; and a work that contributes greatly to three-dimensional concepts, FRANK H. NETTER (comp.), *The Ciba Collection of Medical Illustrations,* vol. 1, *Nervous System,* new ed. (1983), a superb collection of instructive, authoritative colour drawings of the central, peripheral, and autonomic nervous systems as well as diseases of the brain and spinal cord.

The development of the human nervous system is discussed by RITA LEVI-MONTALCINI, "The Nerve Growth Factor 35 Years Later," *Science,* 237(4819):1154–1162 (Sept. 4, 1987), an interesting review of studies of the nerve growth factor by a Nobel Laureate; KEITH L. MOORE, *The Developing Human: Clinically Oriented Embryology,* 4th ed. (1988), a popular standard book presenting a synopsis of the embryonic development of the nervous system along with relevant clinical information and congenital malformations; CHARLES R. NOBACK, NORMAN L. STROMINGER, and ROBERT J. DEMAREST, *The Human Nervous System: Introduction and Review,* 4th ed. (1991), a general account of the development of the nervous system from its inception through old age, augmented with clinically significant information and appropriate illustrations; and JAN LANGMAN, *Langman's Medical Embryology,* 6th ed. by T.W. SADLER (1990), a well-known work on human embryology with concise text, excellent illustrations and charts, and numerous points of clinical significance.

Explorations of the central nervous system include STEPHEN J. DEARMOND, MADELINE M. FUSCO, and MAYNARD M. DEWEY, *Structure of the Human Brain,* 3rd ed. (1989), a photographic atlas of brain sections; DUANE E. HAINES, *Neuroanatomy: An Atlas of Structures, Sections, and Systems,* 3rd ed. (1991), an atlas of brain photographs and vascular supply, with teaching diagrams; and R. NIEUWENHUYS, J. VOOGD, and CHR. VAN HUIJZEN, *The Human Central Nervous System: A Synopsis and Atlas,* 2nd rev. ed. (1981), a well-illustrated, readable text.

Descriptions of the peripheral nervous system—the spinal and cranial nerves—are included in the work by Haines and in the general overviews cited above; and in a standard anatomy reference work available in 2 editions: HENRY GRAY, *Anatomy of the Human Body,* 30th American ed. edited by CARMINE D. CLEMENTE (1985), and *Gray's Anatomy,* 37th British ed. edited by PETER L. WILLIAMS *et al.* (1989).

The anatomy of the autonomic nervous system is dealt with in D.J. CUNNINGHAM, *Cunningham's Textbook of Anatomy,* 12th ed. edited by G.J. ROMANES (1981), a complete description; and in *Goodman and Gilman's The Pharmacological Basis of Therapeutics,* 9th ed. by JOEL G. HARDMAN and LEE E. LIMBIRD (1996), a summary of neurotransmission in the autonomic nervous system. (C.R.N./D.E.H./A.D.L./Ed.)

Functions of the human nervous system. General summaries are provided by DAVID JENSEN, *The Human Nervous System* (1980); and PETER NATHAN, *The Nervous System,* 3rd ed. (1988), a complete account of the anatomy, physiology, and psychology of the nervous system of humans and other animals, written for readers without an extensive background in biology. Information on sensory receptors can be found in WILFRED M. COPENHAVER, DOUGLAS E. KELLY, and RICHARD F. WOOD, *Bailey's Textbook of Histology,* 17th ed. (1978); ARTHUR C. GUYTON, *Basic Human Neurophysiology,* 3rd ed. (1981), an account of functional aspects of sensory receptors; and DON W. FAWCETT, *A Textbook of Histology,* 11th ed. (1986). G.H. PARKER, *The Elementary Nervous System* (1919), is a classic book on the origin of the basic receptor-adjustor-effector system of neural function. CHARLES S. SHERRINGTON, *The Integrative Action of the Nervous System,* 2nd ed. (1948, reprinted 1973), is a classic on the physiology of reflex mechanisms, by one of the important workers on the subject. (T.L.L./C.R.N./P.W.N.)

Discussions on the regulation of muscular contraction include BERNARD KATZ, *Nerve, Muscle, and Synapse* (1966), a clearly written work; PETER B.C. MATTHEWS, *Mammalian Muscle Receptors and Their Central Actions* (1972), a wide-ranging work dealing with the subject historically, and an article updating this, "Evolving Views on the Internal Operation and Functional Role of the Muscle Spindle," *The Journal of Physiology,* 320:1–30 (1981); and I.A. BOYD and M.H. GLADDEN (eds.), *The Muscle Spindle* (1985), an account of a specialized symposium with brief review articles interspersed. (P.B.C.M.)

The vestibular system and its functions are the subject of VICTOR J. WILSON and GEOFFREY MELVIL JONES, *Mammalian Vestibular Physiology* (1979), an account of the mammalian vestibular system, including anatomy, biophysics, and physiology, that assumes some physiological knowledge; ROBERT W. BALOH and VINCENTE HONRUBIA, *Clinical Neurophysiology of the Vestibular System,* 2nd ed. (1990), a review of the vestibular system in relation to disease states; and PETER RUDGE, *Clinical Neuro-Otology* (1983), which outlines from a clinical point of view the vestibular system and which deals with anatomy, physiology, and clinical conditions affecting this system, including an account of the auditory pathways. (P.Ru.)

Discussions of various aspects of the autonomic nervous system include R.F. SCHMIDT and G. THEWS (eds.), *Human Physiology,* 2nd rev. ed. (1989; originally published in German, 23rd ed., 1987), which contains a general account of the basic physiology of the autonomic nervous system; ARTHUR D. LOEWY and K. MICHAEL SPYER (eds.), *Central Regulation of Autonomic Functions* (1990), a review of the brain mechanisms involved in regulating the autonomic nervous system; LEONARD R. JOHNSON (ed.), *Physiology of the Gastrointestinal Tract,* 2nd ed., 2 vol. (1987), a series of comprehensive reviews on the tract's anatomy, physiology, and pathophysiology; and JAN M. LUNDBERG and TOMAS HÖKFELT, "Multiple Co-existence of Peptides and Classical Transmitters in Peripheral Autonomic and Sensory Neurons—Functional and Pharmacological Implications," *Progress in Brain Research,* 68:241–262 (1986), a discussion of the role neuropeptides play in neurotransmission in the autonomic nervous system. (A.D.L.)

The following works deal with other functions of the human nervous system: on pain, RONALD MELZACK, *The Puzzle of Pain* (1973); on vision, RICHARD L. GREGORY, *Eye and Brain: The Psychology of Seeing*, 4th ed. (1990); and on emotion and behaviour, LLOYD S. WOODBURNE, *The Neural Basis of Behavior* (1967), a useful review of the anatomy and physiology of the nervous system for the beginning student in biology, medicine, or psychology. See also RICHARD L. GREGORY and O.L. ZANGWILL (eds.), *The Oxford Companion to the Mind* (1987). (P.W.N.)

Cerebral functions are described in ALEKSANDR ROMANOVICH LURIA, *Higher Cortical Functions in Man*, 2nd ed. rev. and expanded (1980; originally published in Russian, 1962); ALAN BADDELEY, *Your Memory: A User's Guide* (1982); ENNIO DE RENZI, *Disorders of Space Exploration and Cognition* (1982); ANDREW W. ELLIS, *Normality and Pathology in Cognitive Function* (1982); MURIEL DEUTSCH LEZAK, *Neuropsychological Assessment*, 2nd ed. (1983); KENNETH M. HEILMAN and EDWARD VALENSTEIN, *Clinical Neuropsychology*, 2nd ed. (1985); BRYAN KOLB and IAN Q. WHISHAW, *Fundamentals of Human Neuropsychology*, 3rd ed. (1990); SALLY P. SPRINGER and GEORG DEUTSCH, *Left Brain, Right Brain*, 3rd ed. (1989); and KEVIN WALSH, *Neuropsychology: A Clinical Approach*, 2nd ed. (1987). I.P. PAVLOV, *Conditioned Reflexes: An Investigation of the Physiological Activity of the Cerebral Cortex* (1927, reprinted 1960; originally published in Russian, 1923), describes the classic experiments and studies of cerebral function in response to signals and reflex behaviour as carried out in dogs and their application to humans. (G.Ra.)

Nervous system diseases and disorders. Texts on the pathology, diagnosis, and treatment of nervous diseases and disorders include W.R. GOWERS, *A Manual of Diseases of the Nervous System*, 2nd ed. rev. and enlarged, 2 vol. (1892–93, reprinted 1970); WEBB HAYMAKER and BARNES WOODHALL, *Peripheral Nerve Injuries: Principles of Diagnosis*, 2nd ed. (1953, reprinted 1967); A.B. BAKER (ed.), *Clinical Neurology* (1955–), with annual revisions published for loose-leaf update; E. STEPHENS GURDJIAN and L. MURRAY THOMAS, *Operative Neurosurgery*, 3rd ed. (1970); ALEXANDER G. The Netherlands

One of the smaller countries of Europe, the Kingdom of The Netherlands (Dutch: Koninkrijk der Nederlanden) is a parliamentary democracy under a constitutional monarch. The Netherlands has often been known abroad as Holland (from Houtland, or "Wooded Land"). This name was originally given to one of the medieval cores of what later became the state and is still used for 2 of its 12 provinces (Noord-Holland and Zuid-Holland). The irregular outline of The Netherlands, not unlike a piece of a jigsaw puzzle, encloses some 16,164 square miles (41,864 square kilometres) of mostly flat land, which lies between the North Sea on the north and west, Germany on the east, and Belgium to the south. Large parts of the total area consist of water. Excluding the territorial waters, the land area amounts to about 13,255 square miles. The kingdom includes the former colonies of the Netherlands Antilles and Aruba.

Some 2,500 square miles of this country consist of reclaimed land, the result of a process of careful water management dating back to medieval times. Along the coasts, land was reclaimed from the sea, and, in the interior, lakes and marshes were drained. The reclaimed tracts, known as polders, are usually surrounded by dikes. Initially, manpower and horsepower were used to drain the land and were replaced later by windmills. The largest schemes were carried out in the second half of the 19th century and in the 20th century, when steam pumps and, later, electric or diesel pumps came into use.

The Netherlands is today one of the world's most densely populated nations. Even so, it continues to attract immigrants, who, with their families, constitute about one-tenth of all Netherlanders. More than one-third of the population is crowded into the Randstad ("Rim City"), a U-shaped urban belt near the western coast that includes Amsterdam, The Hague, and Rotterdam. The country has developed a reputation for social and cultural experimentation and liberal social policies. This independence of outlook has strong roots in the 16th and 17th centuries, when Dutch merchant ships sailed the world and helped lay the foundations of a great trading nation characterized by a vigorous spirit of enterprise. In later centuries, burgeoning trade and commercial growth further stimulated development of the country.

With Belgium and Luxembourg, The Netherlands is a member of the economic union known as Benelux, in which capital, goods, and people can freely circulate. This union, in fact, served as a model for the larger European Union (EU), of which the Benelux nations are members. The country is also a member of the North Atlantic Treaty Organization (NATO) and the Organisation for Economic Co-operation and Development (OECD).

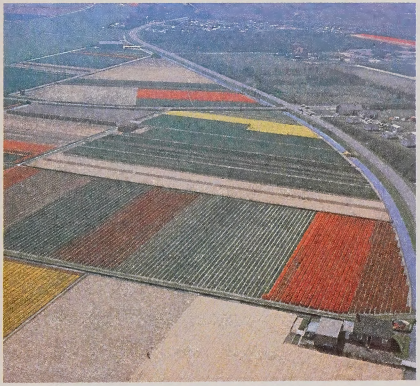
Physical and human geography

THE LAND



Relief. If The Netherlands were to lose the protection of its dunes and dikes, the most densely populated part of the country would be inundated (largely by the sea, but also in part by the rivers). This highly developed part of The Netherlands, which generally does not lie higher than about three feet (one metre) above sea level, covers more than half the total area of the country. About half of this area (some 27 percent of the total area of the country) actually lies below sea level. The Dutch refer to this area in the north and west as the Low Netherlands, while the area covering the south and east is termed the High Netherlands.

The Low Netherlands consists mainly of polders, where the landscape not only lies at a very low altitude but is also very flat in appearance. On such land, building is possible only after concrete piles, sometimes as long as 65 feet, have been driven into the sand layer.

The Zuiderzee project

The Zuiderzee was originally an estuary of the Rhine. By natural action it then became a shallow inland sea, biting deep into the land, and eventually it was hollowed into an almost circular shape by the action of winds and tides. In 1920 work was begun on the Zuiderzee project, of which the IJsselmeer Dam (Afsluitdijk), begun in 1927, was a part. This 19-mile-long dam, or dike, running northeastward to connect the provinces of Noord-Holland and Friesland, was completed in 1932 to finally seal off the Zuiderzee from the Waddenzee and the North Sea. In the IJsselmeer, or IJssel Lake, formed from the southern part of the Zuiderzee, four large polders with a total area of about 650 square miles were constructed around a freshwater basin fed by the IJssel and other rivers and linked with the sea by sluices and locks in the barrier dam.

Russ Kinne/Comstock

Flower cultivation in the polders of South Holland near the border with North Holland in The Netherlands.

The first two polders created—Wieringermeer and North East (Noordoost) Polder, drained before and during World War II—are used mostly for agriculture. The two polders reclaimed in the 1950s and '60s—South Flevoland Polder (Zuidelijk) and East Flevoland Polder (Oostelijk)—are used for residential, industrial, and recreational purposes. Among the cities that have developed there are Lelystad and Almere; the former is the capital of the new province of Flevoland, created in 1986 from the two Flevoland polders and North East Polder.

In the southwest, the disastrous gales and spring tide of Feb. 1, 1953, which flooded 400,000 acres (162,000 hectares) of land and killed 1,800 people, accelerated the implementation of the Delta Plan, which aims to close the sea inlets of the southwestern delta, mostly in the province of Zeeland. These delta works were designed to shorten the coastline by 450 miles, combat the salination of the soil, and allow the development of the islands of the area through roads that were constructed over 10 dams and two bridges built between 1960 and 1987. The largest of these dams, crossing the five-mile-wide East Schelde (Oosterschelde) estuary, has been built in the form of a storm-surge barrier incorporating 61 openings that can be closed in the event of flood. The barrier is normally open, allowing salt water to enter the estuary and about 75 percent of the tidal movement to be maintained, limiting damage to the natural environment in the East Schelde. In the interests of the commerce of the ports of Rotterdam and Antwerp, no dams were constructed in the New Waterway, which links Rotterdam to the North Sea, or the West Schelde, an approach to Antwerp, Belg. The dikes along these waterways consequently had to be strengthened.

The New Waterway

A region with a very specific character has been formed by the great rivers—Rhine, Lek, Waal, and Maas (Meuse)—which flow from east to west through the central part of the country. The landscape in this area is characterized by high dikes along wide rivers, orchards along the levees formed by the rivers, and numerous large bridges over which pass the roads and railways that connect the central Netherlands with the southern provinces.

In the High Netherlands, the layers of sand and gravel in the eastern part of the country were pushed sideways and upward in some places by ice tongues of the Saale Glacial Stage, forming elongated ridges, which may reach a height of more than 330 feet. These form a recreational area, Veluwe, which is of national significance. The southern part of Limburg province, in the border zone of the Ardennes, is the only part of the country where altitudes well over 350 feet occur. The Netherlands' highest point, the Vaalserberg, in the extreme southeastern corner, rises to 1,053 feet.

Soils. Only in the last Pleistocene Ice Age did the Scandinavian ice sheet cover the northern half of The Netherlands. After this period (about 10,000 years ago), a large area in the north of what is now The Netherlands was left covered by moraine (glacial accumulation of earth and rock debris). In the centre and south, the Rhine and Maas unloaded thick layers of sand and gravel transported from the European mountain chains. Later, during the Holocene Epoch, clay was deposited in the sheltered lagoons behind the coastal dunes, and peat soil often subsequently developed in these areas. If the peat soil was washed away by the sea or dug away by humans (for the production of fuel and salt), lakes were created. Many of these were reclaimed in later centuries (as mentioned above), while others now form highly valued outdoor recreational areas.

Climate. The climate is temperate, with gentle winters, cool summers, and rainfall in every season. Southerly and westerly winds predominate, and the sea moderates the climate through onshore winds and the effect of the Gulf Stream.

The position of The Netherlands—between the area of high-pressure air masses centred on the Azores and the low-pressure region centred on Iceland—makes the country an area of collision between warm and polar air masses, thus creating unsettled weather. Winds meet with little resistance over the flat country, though the hills in the south diminish by more than half the 13-mile-per-hour wind velocity that prevails along the coast. On average, frost occurs 60 days per year. July temperatures average about 63° F (17° C), and those of January average 35° F (2° C). The rainfall averages 31 inches (790 millimetres), with only about 25 clear days per year. The average rainfall is highest in summer (August) and autumn and lowest in springtime. The country is known—not least through the magnificent landscapes of Dutch painters—for its heavy clouds, and on an average day three-fifths of the sky is clouded.

Average temperatures and rainfall

Plant and animal life. Most wild Dutch plant species are of the Atlantic district within the Euro-Siberian phytogeo-

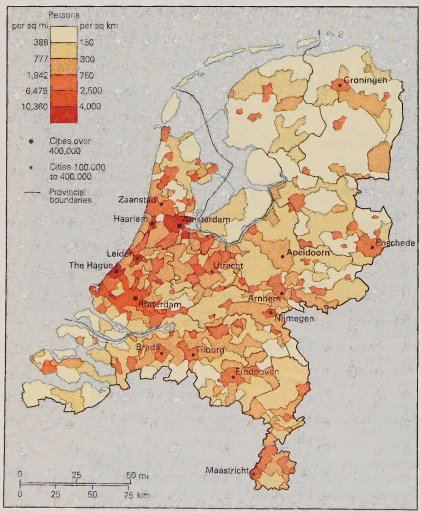
graphic region. Gradients of salt and winter temperature variations cause relatively minor zonal differences in both wild and garden plants from the coast to more continental regions. The effects of altitude are negligible. Vegetation from coastal sand dunes, muddy coastal areas, slightly brackish lakes, and river deltas is especially scarce in the surrounding countries. Lakes, marshes, peatland, woods, heaths, and agricultural areas determine the general floral species. Clay, peat, and sand are important soil factors for the inland vegetation regions.



Animal life is relegated by region according to vegetation. Seabirds and other sea life, such as mollusks, are found especially in the muddy Waddenzee area and in Zeeland. Migrating birds pass in huge numbers through The Netherlands or remain for a summer or winter stay. Species of water, marsh, and pasture birds are numerous. Larger mammals, such as roe deer, red deer, fox, and badger, are mostly restricted to nature reserves. Some species like boar, beaver, fallow deer, mouflon, and muskrat have been introduced locally or reintroduced. Reptiles and amphibians are endangered. Numerous species of river fish and river lobsters have become scarce because of water pollution. There is a diversity of brackish and freshwater animals inhabiting the many lakes, canals, and drainage ditches, but the vulnerable species of the nutritionally deficient waters have become rare.

Nature reserves have been formed by governmental and private organizations. Well-known reserves include the Naardermeer of Amsterdam, the Hoge Veluwe National Park, and the Oostvaardersplassen in South Flevoland. Some endangered species are protected by law.

Settlement patterns. Modern urbanization in The Netherlands has taken place mainly in the 20th century. In 1900 more than half the population was still living in villages or towns of fewer than 10,000 inhabitants. By the late 20th century this figure had decreased to about 13 percent. There has, nevertheless, been a decrease in the city proper population of the large metropolitan centres. These city regions are now becoming economic and cultural centres, their populations having spread outward in search of newer housing and greater living space in suburbs, new residential quarters of rural settlements, and new towns. In the 1960s and '70s the authorities stimulated this development by subsidizing house building in a number of so-called growth nuclei and by moving several groupings of public offices from the western core area to more rural areas in the north, east, and south of the country. More recently, however, government planning policy has aimed at again concentrating the population in and around the existing cities, especially in the western provinces.

The growth of urban centres

In this part of the country the bulk of the Dutch population is concentrated in the urban core known as the Randstad Holland, comprising such cities as Rotterdam, The Hague, Leiden, Haarlem, Amsterdam, Hilversum, and Utrecht. Extensions of the Randstad stretch toward the east (Arnhem, Nijmegen) and the south (Breda, Tilburg, Eindhoven), thus forming the so-called Central Netherlands Urban Ring. Other urban centres are Groningen in the northeast, Enschede and Hengelo in the east, and Maastricht and Heerlen in the southeast. It is government policy to keep traditional towns and cities separated by strips of agricultural or recreational land.

Population density of The Netherlands.

THE PEOPLE

Ethnic composition. Popular belief holds that the Dutch are a mixture of Frisians, Saxons, and Franks. In fact, research has made plausible the contention that the autochthonous inhabitants of the region were a mixture of pre-Germanic and Germanic population groups who in the course of time had converged on the main deltaic region of western Europe. There emerged from these groups in the 7th and 8th centuries some major polities based on certain ethnic and cultural unities that then came to be identified as Frisians, Saxons, and Franks.

The Dutch Republic originated from medieval statelets, and its legal successor, The Kingdom of The Netherlands, has attracted countless immigrants through the centuries. A strong impetus was the principle of freedom of thought, which engendered the tolerance that developed in the 16th and 17th centuries. These sentiments were—and are—most manifest in the prosperous commercial and industrial centres in the western provinces, which attracted many members of persecuted religious or political minorities. Among these were southern lowlanders, French Huguenots, and Portuguese Jews, along with many people who sought to improve their economic situation, such as Germans and non-Iberian Jews. In the 20th century, immigrants from the former Dutch overseas colonies added to the influx; they include Indonesians and peoples from the Moluccas and from Suriname on the northeast coast of South America.

Tradition of tolerance

The heritage of Dutch humanism. The considerable hospitality exhibited by the Dutch is to a large extent rooted in the spirit of humanism that was typical of the Dutch Republic of the 16th to the 18th centuries. Figures such as Erasmus in the 16th century and Hugo Grotius in the 17th century epitomize that spirit. It can be characterized as an amalgam of religious piety tempered by an awareness of scientific progress. It resulted in a rather pragmatic mode of thinking that has dominated Dutch bourgeois culture from the 16th century onward, coexisting with growing commercial acumen. Evolving Dutch society came to encompass a diversity of religious traditions, from rigid Calvinism and a more tolerant Protestantism to conformist Roman Catholicism.

Roughly speaking, the present Dutch population can be divided into three almost equal groups relative to religion: Roman Catholics (predominantly in the provinces of Noord-Brabant and Limburg), Protestants (particularly the Dutch Reformed Church), and the nonreligious. Although religious ardour and church attendance have slackened notably since about 1900, the educational institutions and political parties that evolved in the late 19th and early 20th centuries along denominational lines still play a considerable role vis-à-vis the more or less secularized parties and institutions that sprang from socialist, liberal, and conservative movements. The most constant factor in the body politic has for years been the so-called Christian Democrats—comprising Roman Catholics as well as Protestants—who traditionally dominate the centre of the parliamentary spectrum.

These more or less converging societal groupings have not completely obliterated a range of age-old regional cultural distinctions. They are sometimes vividly preserved, as in the case of the northern province of Friesland, which proudly conserves the ancient Frisian culture. With more recent immigration new cultural groups are becoming significant.

Linguistic composition. The language in the whole of the country is Dutch, or Nederlands, a Germanic language that is also spoken by the inhabitants of northern Belgium

(there called Flemish). Afrikaans, an official language of South Africa, is a variant of the Dutch spoken by 17th-century emigrants from Holland and Zeeland. Apart from Dutch, the inhabitants of the northern province of Friesland also speak their own language, which is closer to English than to either Dutch or German. In the major cities especially, many people are fluent in several languages, reflecting the nation's geographic position, its history of occupation, and its attraction for tourists. English, French, and German are among the languages commonly heard.

Dutch fluency in languages

Demographic trends. Although The Netherlands is one of the world's most densely populated countries, its growth rate has been slight in the 20th century. Birth and death rates are both among the world's lowest, causing a somewhat older society, and most population increase results from immigration. As a result of the postwar government policy mentioned above, however, emigrants had exceeded immigrants by an average of almost 20,000 each year from 1947 to 1954. Thereafter the economy and labour potential of the more industrialized European countries attracted an increasing number of Spaniards, Yugoslavs, Turks, and Moroccans, so that the balance remained more or less static. Since 1970 there has been a continuous immigrant surplus, with a peak in 1975 as a result of a large number of arrivals from Suriname (just before its independence). In the early 1990s more than 4 percent of The Netherlands' population was made up of foreign residents (excluding the tens of thousands of persons of Dutch nationality originating from former colonies). Muslims made up more than 2.5 percent of the population and Hindus and Buddhists another .5 percent.

For many years prior to 1970, internal migration showed a constant flow from the more rural provinces in the north, east, and south toward the more strongly urbanized western part of the country. After 1970, however, the trend toward migration to the west was reversed. Subsequent emigration was mainly from Zuid-Holland and Noord-Holland (the most heavily populated provinces) toward Utrecht and the less densely populated provinces, where the government has stimulated industrial growth—Groningen, Friesland, Drenthe, Gelderland, and Zeeland.

THE ECONOMY

Since World War II The Netherlands has become a highly industrialized nation occupying a central position in the economic life of western Europe. Although agriculture accounts for a small percentage of the national income and labour force, it remains a highly specialized contributor to Dutch exports. Because of the scarcity of mineral resources—with the important exception of natural gas—the country is dependent on large imports of basic materials.

State role in the economy

The Netherlands has a market economy, but the state is a major participant in such corporations as The Netherlands Railways, the Dutch State Mines, The Royal Netherlands Blast Furnaces and Steel Works, KLM Royal Dutch Airlines, and The Netherlands Natural Gas Company. The state thus has a direct, continuous influence on the management of some sectors of the economy and especially on investment policy. The government also employs a substantial percentage of the total labour force.

The Dutch economy nevertheless remains basically in private hands. Postwar industrial development has been consciously stimulated by government policy, and state subsidies have been granted to attract industry toward the relatively underdeveloped northern provinces, as well as Limburg and certain other pockets of economic stagnation. Despite these subsidies, the western provinces remain the centre of new industry, especially in the services sector.

Dutch employers are organized mainly in separate but closely cooperating organizations: one Roman Catholic and Protestant and one nondenominational. The labour force had a tripartite organization before the Socialist and Roman Catholic unions merged, leaving the Protestant union and a few small independent organizations far behind in membership. Employer organizations and labour unions are represented on the Joint Industrial Labour Council, established in 1945 for collective bargaining, and on the Socio-Economic Council, which serves mainly to advise the government.

Energy. With the increasing use of oil and natural gas, coal mining (concentrated in southern Limburg) was discontinued in 1974 because of the rising cost of production. The Netherlands imports several million tons of coal annually to meet domestic and industrial needs, including those of such industrial installations as the steel works of IJmuiden at the mouth of the North Sea Canal.

The production of crude oil, of which there are minimal deposits, covers only a small part of Dutch requirements. The wells are located in southeastern Drenthe, near Schoonebeek, and in Zuid-Holland. Large amounts of crude oil are imported for refining in The Netherlands, and much of the refined petroleum is exported.

The discovery of natural gas in 1959 had a tremendous influence on the development of the Dutch economy. The gas fields are in the northeastern Netherlands—with the largest field at Slochteren in the province of Groningen—and beneath the Dutch sector of the North Sea. Under the Geneva Convention of 1958, The Netherlands was allocated a 22,000-square-mile block of the continental shelf of the North Sea, an area larger than the country itself. Almost half of the natural gas produced is exported to Germany, Belgium, France, Switzerland, and Italy, helping to improve the balance of payments in the economic sector in which The Netherlands has usually had its largest deficit. The natural gas finds began a trend of Dutch industries toward using the fuel, among them the aluminium smelter at Delfzijl in Groningen. Purchase, transport, and sale of the gas are in the hands of The Netherlands Natural Gas Company, a limited company in which shares are held by Dutch and American firms and the Dutch state. Since it is the government's policy to reserve as much natural gas as possible for domestic use in future decades, the amount of imported coal again increased in the 1980s.

Agriculture. The country's agricultural land is divided into grassland, arable farmland, and horticultural land. Dutch dairy farming is highly developed: the milk yield per acre of grassland and the yield per cow are among the highest in the world. A good percentage of the total milk production is exported after being processed into such dairy products as butter, cheese, and condensed milk. Meat and eggs are produced in intensively farmed livestock holdings where enormous numbers of pigs, calves, and poultry are kept in large sheds and fed mainly on imported fodder. Most cereals for human consumption as well as fodder are imported.

Intense development of dairying and horticulture

Horticulture carried on under glass is of special importance. The export of hothouse tomatoes, cucumbers, lettuce, cut flowers, and house plants has greatly increased, and The Netherlands now contains almost half of the total European horticultural area under glass. Open-air horticulture also produces fruit, vegetables, cut flowers, and bulbs, the latter from the world-famous colourful bulb fields. Fishing is of minimal importance.

Industry. Dutch industrial development began relatively late, about 1870, and production rose even during the depression of the 1930s. Further development became a priority after World War II, when ascending population figures and growing farm-labour surpluses necessitated tens of thousands of additional jobs each year. Manufacturing industries accounted for about 20 percent of the labour force in the early 1990s, with the metal industry as the largest employer. The food, beverage, and tobacco manufacturing industries, based as they are on the highly productive agriculture sector, ranked second in employment but first in production value. Other important producers included the chemical, petroleum products, and electrical and electronics industries. Dutch industry has been able to redevelop commercial aircraft since World War II, and automobile manufacturing has been expanded. In contrast, employment in textile manufacturing and shipbuilding has decreased. The government has encouraged new industrial development in the fields of microelectronics, aerospace, and biotechnology.

Finance and trade. Commercial banking in The Netherlands is in the hands of a few large concerns, and there has been a trend toward mergers of banks and insurance companies. The General Netherlands Bank and the Amsterdam-Rotterdam Bank handle the majority of Dutch

Banking

financial business between them; these two institutions merged in 1990. A second large bank was created through the consolidation of the Postbank and the Netherlands Traders' Bank. The state-owned Netherlands Central Bank supervises the banking system. The Amsterdam Stock Exchange, one of the oldest in the world, was founded in the early 1600s.

Trade is conducted mainly with Europe and North America. The European Community (EC; also called the Common Market) is, of course, the dominant factor in foreign trade. In 1958 (just before the Common Market was established) some 40 percent of Dutch exports went to West Germany, Belgium, Luxembourg, France, and Italy, but by the late 20th century these nations and the EC as a whole accounted for about 75 percent of exports. The largest import source was Germany, followed by other EC countries and the United States.

Transportation. In The Netherlands transportation is of special importance because the country functions as a gateway for the traffic of goods between western Europe and the rest of the world. Trade flows through Dutch harbours, continuing its passage by river vessel, train, truck, and pipeline. Maritime traffic accounts for more than half of the total amount of goods loaded and unloaded in The Netherlands, and, indeed, the whole southern part of the North Sea may be likened to an immense traffic square, fed as it is by the Thames, Rhine, Maas, and Schelde rivers, with links into the hinterland of the continent that make it one of the greatest commercial arteries of the world. Rotterdam has the country's best-equipped modern harbour.

Europoort

Europoort, the region between Rotterdam and the North Sea, can easily be reached by the biggest oceangoing ships; it serves as an approach via the New Waterway to Rotterdam harbour, which handles more tonnage than any other harbour in the world. In petroleum processing, too, Rotterdam is one of the world's leading centres. A trench about 4,000 feet wide at a depth of 74 feet extends 27 miles into the North Sea to facilitate the entry of supertankers with 350,000-ton capacities. The number of rivercraft is probably unsurpassed by any other country.

Other important ports, though dwarfed by Rotterdam-Europoort, are Amsterdam, and, on the Western Schelde, Flushing and Terneuzen. KLM Royal Dutch Airlines initiated scheduled service between Amsterdam and London in 1920 and now has a worldwide network. Amsterdam Airport (Schiphol)—on the site of the former Haarlem Lake at about 13 feet below sea level—is one of Europe's largest airports. Smaller airports of international importance are Rotterdam Airport (Zestienhoven) and, in southern Limburg, Maastricht Airport (Beek).

In internal traffic the motor vehicle, accommodated by a comprehensive road network, dominates both passenger and goods transport, despite the fact that there is a dense and modern railway network. The length of the railroad track, however, is even surpassed by a network of inland waterways made up of some 3,000 miles of rivers and canals and linked with Belgian, French, and German systems. Besides such natural waterways as the Rhine, Lek, Waal, and Maas, many artificial waterways—the Juliana Canal (in southern Limburg), the Amsterdam-Rhine River Canal (between Amsterdam and Tiel), the Maas-Waal Canal (west of Nijmegen), and others—connect the major ports on the coast with the hinterland.

ADMINISTRATION AND SOCIAL CONDITIONS

The Kingdom of The Netherlands is a constitutional monarchy. The monarchy is hereditary in both the male and female lines.

Government. The constitution, which dates from 1814, declares that the head of state, the monarch, is inviolable and thereby embodies the concept of ministerial responsibility. It further provides that no government may remain in power against the will of Parliament. The States-General (Staten-Generaal), as Parliament is officially known, consists of two houses, a First Chamber, whose 75 members are elected by the members of the councils of the provinces, and a directly elected Second Chamber of 150 members. Both houses share legislative power with the government, officially known as the Crown (Kroon), defined as the head of state acting in conjunction with the ministers. The two houses control government policy. The First Chamber can only approve or reject legislation but does not have the power to propose or amend it.

Every four years, after elections to the Second Chamber have been held, the government resigns, and a process of bargaining starts between elected party leaders aspiring to form a government that will be assured of the support of a parliamentary majority. It usually takes a few months of maneuvering before a *formateur,* as the main architect of such a coalition is known, is ready to accept a royal invitation to form a government. The head of state then formally appoints the ministers. In the event of political crises resulting in the fall of the government before the end of a four-year period, the same process of bargaining takes place. The monarch, acting on the advice of the ministries, has the right to dissolve one or both chambers, at which time new elections are held.

Formation of the government

In local government, the most important institutions are the municipalities (*gemeenten*). Since World War II their number has been reduced to about 635 as a result of redivisions. Each municipality is run by a directly elected council of from 7 to 45 members, depending on the size of the population. This council is presided over by a *burgemeester* (mayor), who is appointed by the government and serves as chairman of the executive, the members of which are elected by and from the council. In those areas to which the councils' own ordinances are applicable, the municipalities are autonomous. In many instances, national legislation or provincial ordinances provide for the cooperation of municipal authorities.

The country is divided into 12 provinces: Groningen, Friesland, Drenthe, Overijssel, Flevoland, Gelderland, Utrecht, Noord-Holland, Zuid-Holland, Zeeland, Noord-Brabant, and Limburg. Their administrative system has the same structure as the municipal one: directly elected councils (*staten*) which elect the members of the executive, except for the chairman, who is appointed by the government. The main functions of the provinces include controlling the municipalities within their borders and controlling the district water-control boards (*waterschappen*).

Political life. The Second Chamber, the provincial councils, and the municipal councils are elected according to a system of proportional representation. In general elections for the Second Chamber, it can take as little as 0.66 percent of the overall vote to get one of the seats in the chamber. As a result, a large number of parties and political movements are represented in Parliament.

Justice. In The Netherlands the ordinary administration of justice is entrusted exclusively to judges appointed for life; there is no jury system. There are cantonal courts (*kantongerechten*), which exercise jurisdiction in a whole range of minor civil and criminal cases. More important cases are handled by one of the district courts (*rechtbanken*), which also can hear appeals from cantonal court decisions. Appeals against decisions from the district courts are heard by one of five courts of appeal (*gerechtshoven*). The Supreme Court (Hoge Raad) ensures a uniform application of the law, but it cannot determine constitutionality. In the legislative process itself, the government and Parliament together pass judgment on the constitutionality of a bill under consideration. Laws that are at variance with the nation's international agreements cannot be enforced by the courts.

The Supreme Court

Voting age and military obligation. The franchise is extended to all Dutch citizens who have reached the age of 18, except for a few special groups, such as the mentally impaired. The Dutch armed forces consist of an army, a navy, and an air force. All male citizens were liable for military service at the age of 18 until 1996, when conscription ended.

Education. All primary, secondary, and higher education is provided by either governmental (municipal or state) or private institutions. The latter are, with a few exceptions, run by Protestant and Roman Catholic organizations. All private schools are, when they conform to legally fixed standards, financed from governmental funds on an equal footing with their public (*openbare*) counterparts. Dutch secondary education consists of several

tracks. Among these are the five-year Higher General Education track, the mandatory preparation for institutions of higher education other than the university; and the six-year Preparatory Scientific Secondary Education track, which is mandatory for university admittance.

The system of higher education is a binary one. There are about 85 institutions for Higher Professional Education. These are called polytechnics, and they cover many professional fields complementary to the 13 universities. They are all publicly financed. Nine of them cover a general range of disciplines: the four state universities—of Leiden (founded 1575), Groningen (1614), Utrecht (1636), and Limburg at Maastricht (1976)—and the (former municipal) University of Amsterdam (1632), the Erasmus University at Rotterdam (1973), the (Protestant) Free University at Amsterdam (1880), and the Roman Catholic universities of Nijmegen (1923) and of Brabant at Tilburg (1927). The other governmental universities are more specialized: the universities of technology at Delft (1842), Eindhoven (1956), and Enschede (Twente University; 1961) and the Agricultural University at Wageningen (1918). In addition, the Open University established in 1984, provides for both university and vocational education through correspondence courses.

Health and welfare. Since World War II The Netherlands has developed an elaborate system of social security, providing all its citizens with universal health care and old age and unemployment benefits. All citizens are entitled to four national insurance schemes, including the General Old Age Pensions Act, the General Widows and Orphans Act, the Exceptional Medical Expenses Act, and General Disablement Benefits. There also are four employee insurance schemes, including the Sickness Benefits Act, the Disablement Insurance Act, the Compulsory Health Insurance Act, and the Unemployment Insurance Act. The system is supplemented by a number of social services, the most important ones being the General Family Allowance Act, which provides for family allowances for children up to age 17 and under certain circumstances for older children (including those not entitled to student grants), and the National Assistance Act, under which benefits are paid to claimants who have too little or no income.

National insurance schemes

Housing. A severe housing shortage began developing after the mid-20th century and became the source for political controversy. By the 1970s, in the face of continually growing demand, even an unprecedented boom of housing construction paled. Demographic changes led to a rapid increase in the number of households, and rising standards of living fueled the consumption of space per person. This crisis abated by the mid-1970s, only to be replaced by a financial one.

Rent controls, as well as alternative investment opportunities and the introduction of the social security of the welfare state, reduced the private rental sector from more than 60 percent in 1947 to less than 15 percent by the late 1980s. The expansion of the postwar housing stock was made possible only by massive investment in subsidized rental housing, which now accounts for more than 40 percent of the stock. Concurrently, the generously subsidized homeowner sector expanded to more than 45 percent.

Environmental control. In The Netherlands, as in all industrialized countries, the increasing pollution of both the natural and man-made environments is a major problem. Pollution in The Netherlands has certain specific aspects that are closely linked to the country's geography. For example, the maritime situation, together with the low-lying character of the coastlands, gives rise to a serious salination problem. The great European rivers, the Rhine, Maas, and Schelde, transport many waste products to The Netherlands and into the adjoining North Sea. High population density and its associated intensive land use also increase the concentration of all forms of pollution.

Government policy concentrates increasingly on combating negative environmental effects, preferably by tackling their source. Thus commuters are encouraged to travel by public transport, farmers are induced to reduce the use of pesticides and artificial fertilizers, and industries are regulated to promote cleaner production processes and to reduce emissions of pollutants into the air, water, and soil. Environmental control measures require costly sacrifices from both the individual taxpayer and industry.

CULTURAL LIFE

The cultural life in The Netherlands is varied and lively. Dutch painting and crafts are world-renowned, and Dutch painters are among the greatest the world has ever known. The Dutch themselves take great pride in their cultural heritage, and the government is heavily involved in subsidizing the arts, while not involving itself directly in artistic control of cultural enterprises. Indeed, the long-enduring tradition of Dutch freedom of expression has undoubtedly played a significant role in the flowering of Dutch culture through the ages.

Dutch tradition in the arts

The arts. *Painting and sculpture.* The history of Dutch painting offers such a deep, rich lode of names that only a few can be touched on here. Certainly among the most revered are those of Rembrandt and Vincent van Gogh. Rembrandt, painting in the 17th century, became a master of light and shadow, a technique reflected in his landscapes as well as such portraits as his monumental "The Night Watch." Van Gogh, born in the 19th century, was a powerful influence in the development of modern art.

Among other great painters of the Low Countries are Jan van Eyck, the founder of the Flemish school; the allegorical Hiëronymus Bosch; the portraitist Frans Hals and landscapists Aelbert Cuyp and Jacob van Ruisdael; still-life artists such as Jan Vermeer, Willem Heda, and Willem Kalf; and the geometrically inclined Piet Mondrian. For a broader discussion of Dutch painting, see PAINTING, THE HISTORY OF WESTERN.

Literature and the performing arts. Dutch literature, and theatre as well, has always been handicapped by the smallness of the proportion of the human race that speaks Dutch. Perhaps the greatest name of Dutch letters was that of the Renaissance humanist Erasmus. For more information, see DUTCH LITERATURE. The nation's performing arts are widely encouraged and supported. The National Ballet at Amsterdam and the Netherlands Dance Theatre at The Hague are internationally renowned. Theatre companies are all private foundations, though the state and the municipalities provide financial assistance. The Dutch film industry is not highly developed.

Ballet and theatre

Music. The Netherlands has not produced composers of the stature of some of its neighbouring countries, although it has built a fine reputation for performance. The Amsterdam Concertgebouw Orchestra is world-famous, and the Residentie Orchestra at The Hague and the Rotterdam Philharmonic Orchestra also have fine reputations. Various other towns have orchestras and choral groups, and there is a Dutch National Opera Company. Noted musical events include the World Music Festival at Kerkrade and the North Sea Jazz Festival at The Hague.

Cultural institutions. The Netherlands has a rich range of state-supported museums. The most famous is the Rijksmuseum at Amsterdam, noted for its collection of works by the great 17th-century Dutch masters (especially Rembrandt). Other major museums endowed by the state include the Mauritshuis at The Hague, Het Loo (the former royal palace) at Apeldoorn, and the Stedelijk Museum in Amsterdam, recognized for its collection of contemporary paintings. Two museums, the Rijksmuseum Vincent van Gogh in Amsterdam and the Rijksmuseum Kröller-Müller in Otterloo (Veluwe), are renowned for their collections of paintings by van Gogh. The most popular folk museums are the Openluchtmuseum (Open Air Museum) at Arnhem and the Zuiderzeemuseum at Enkhuizen.

Recreation. Favourite regions for open-air recreation are the sea coasts with their wide sandy beaches and the many interior lakes in the western and northern parts of the country. They are frequented by both Dutch and foreign visitors. The Dutch people also are attracted to hilly areas, such as the Veluwe and the southern part of Limburg province, while foreign visitors come in droves to the old cities in the western part of the country, with Amsterdam ranking as the most popular site. Favourite foreign vacation spots for the Dutch are the Mediterranean coasts during the summer holidays and the Alps during winter holidays.

Press and broadcasting. The constitution guarantees freedom of the press but does not allow journalists to protect their sources. The Dutch press has a long-standing reputation for high-quality reporting, newspapers having been printed in Amsterdam as early as 1618. One of the oldest newspapers in Europe is the *Oprechte Haerlemse Courant,* now called the *Haarlems Dagblad,* which was founded in 1656. By far the greatest circulation is enjoyed by *De Telegraaf* from Amsterdam (right of centre). The most widely read newspapers in political and intellectual circles are the *NRC Handelsblad* in Rotterdam (liberal) and *De Volkskrant* in Amsterdam (left of centre).

Radio and television

The majority of radio and television transmissions are produced by eight associations, all under private initiative. There are Roman Catholic, Protestant, Socialist, and independent broadcasting organizations, each of which publishes for its supporters a comprehensive weekly that lists all the Dutch and a fair number of foreign programs. All these stations operate within the framework of the Netherlands Broadcasting Corporation, which is responsible for the programming of unreserved airtime. Religious organizations, political parties, and small factional groups are granted some reserved broadcasting time. The government itself has no influence on the programs. Advertising is restricted and is controlled by a separate foundation. All broadcasting is financed by a licensing fee and by the yield from television and radio advertising. A commercial Dutch-owned television station, based in Luxembourg, can be received in most parts of the country thanks to the extremely dense Dutch cable television network.

For statistical data on the land and people of The Netherlands, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR. (M.W.H./H.Me.)

History of the Low Countries (to 1579)

For historical purposes, the name Low Countries is generally understood to include the territory of what is today the Kingdom of The Netherlands, Belgium, and Luxembourg, as well as parts of northern France. However, Belgium, although it was not constituted as an independent kingdom until 1831, became a distinct entity after 1585, when the southern provinces were definitively reconquered by Spain and separated from the northern sector. For a brief period, from 1814 to 1830, an attempt was made to unite the Low Countries into one kingdom again, but both regions by this time had developed cultures too different to form a single entity under a central government. Here, therefore, the history of the Low Countries will be surveyed as a whole to the late 16th century. The later individual histories of Belgium and Luxembourg are treated in the separate articles on those countries.

PREHISTORY

In most stages of the prehistory of the Low Countries the regions north of the lower courses of the Rhine and Meuse (Mass) rivers were part of a North European culture area, while those to the south had close relations to central and western Europe.

Lower and Middle Paleolithic (250,000–35,000 BP). The earliest well-dated remains of human habitation in the region are flint objects that reflect the Levalloisian stone-flaking technique. Found in the loess-covered Belvedere quarry near Maastricht on the Netherlands-Belgium border, these objects have been dated to about 250,000 years BP, correlating with an early interstadial period during the Saale Glacial Stage. The remains of human industry discovered in river deposits near Mons, Belg., may even be slightly older than the findings at the quarry. Hand axes from the late Saalian stage and other artifacts derived from ice-borne deposits have been recovered in the central and northern Netherlands and are characterized as late Acheulian.

The Mousterian culture (*c.* 80,000–35,000 BP) has been documented in the Ardennes caves in southern Belgium and in open excavation sites in The Netherlands' North Brabant and Belgian Limburg. Mousterian tool culture is associated with Neanderthal man, and the skeletal remains of that form have been found in several Belgian caves (at Spy near Namur and at Engis near Liège) in the 19th century.

Upper Paleolithic (35,000–10,000 BP). Aurignacian, Gravettien (upper Perigordian), and Magdalenian assemblages found in the Ardennes caves represent the northernmost fringes of the inhabited zone of Europe until about 13,000 BP. The open site of Maisières Canal in Hainaut province, Belg., is exceptional for its preservation of glacial fauna (from about 28,000 BP) in later river deposits. Several late Magdalenian sites (hunting stands) were discovered in southern (Belgian and Dutch) Limburg. A wide uninhabited area separated the Magdalenian sites from sites of the Hamburgian tradition (emanating from western Germany) in the northern Netherlands. The latter included reindeer-hunting peoples who were the first colonists of the North European Plain at the end of the last (Weichsel) ice age. Later cultural traditions (including the Federmesser, Creswellian, and Ahrensburgian) formed the basis for the cultures of the succeeding Mesolithic period.

Ardennes cave findings

Mesolithic (10,000 BP–4000 BC). (BC dates in this section are all based on radiocarbon measurements calibrated to real centuries before Christ). The distribution of hundreds of flint scatters often characterized by microliths (tiny blade tools) distinguish southern and northern cultural spheres, separated by the main rivers. Bone implements from the period have been dredged or fished up from locales in the North Sea and Rotterdam harbour. Outstanding among the relics of the period is a dugout pine canoe found at Pesse in Drenthe province; dating to 8500 BP, it is the oldest vessel known. Among the culture groups of the period were the Maglemesians of the northern cultural sphere. Their implements are often decorated with designs. Another culture group of the period, the Tardenoisian, occupied sandy regions and plateaus; their remains included arrowheads and other objects incorporating microliths.

Neolithic (4000–2900 BC). Farmers of the Linear Pottery culture, settling on the loess of Dutch Limburg and Belgium around 6500 BP, were among the first to bring Neolithic lifeways to the region. Large-scale excavations in Sittard, Geleen, Elsloo, and Stein in The Netherlands and at sites including Rosmeer and Darion in Belgium have rendered considerable remains from this early Neolithic group. This northwesternmost branch of the culture met with other communities that left, by contrast, few relics and are identified only by minimal scatters of their characteristic pottery, called Hoguette and Limburg. These early communities had widespread internal contacts, documented by remains that include adzes made of exotic stone, and external contacts with late Mesolithic communities to the north, especially along the Meuse River.

Other cultures briefly rose up (Blicquy in Belgium and Rössen in Germany) and in their turn were succeeded about 4100 BC by the northwesternmost branch of the Michelsberg culture in Belgium and, somewhat later, the Funnel-neck Beaker culture in The Netherlands. The evolution of these groups represents principally a transformation in the style of material culture of native communities. Among the most significant Michelsberg remains are the extensive fields of deep flint mines at Spiennes in Hainaut and Rijckholt in Dutch Limburg. Contacts by the Michelsberg with late Mesolithic hunter-gatherers north of the loess zone gave rise to semiagricultural communities, as evidenced by relics from about 4000 BC found in the Netherlands delta at Swifterbant in Flevoland and Hazendonkborn and Bergschenhoekborn in Zuid-Holland.

The late Neolithic (3300–2900 BC) is characterized in the eastern Netherlands, especially in Drenthe, by the Funnel-neck Beaker culture, which is particularly distinguished by megalithic burial monuments (the so-called *hunebedden*), the origins of which are still unknown. Composed of large stone blocks left behind by receding glaciers, these monuments mark collective tombs and may extend for up to 160 feet (about 50 metres) in length. In addition to the beakers for which the culture is named, the remains include collared flasks, buckets, and bowls—often decorated with horizontal and vertical grooves—and polished stone and flint tools. Southern Belgium was reached in this period by the northern fringes of the French Seine-Oise-

Funnel-neck Beaker culture

Marne culture. A third cultural entity has been identified in the Netherlands delta as the Vlaardingen group; it comprises fully agrarian as well as semiagrarian settlements.

Transitional between the Neolithic and Bronze ages is the beaker phase (2900–2000 BC). A distinguishing characteristic of the culture is its change to exclusively individual burial, in which specific grave goods (battle-axes, daggers, beakers) were included; the body, arranged in a flexed posture, was placed in an east-west orientation. This custom is assumed to indirectly reflect essential changes in society, possibly brought about by technological innovations, such as the plow, the wheel, and the cart, which might have caused a restructuring of the agrarian system.

The Bronze Age (2000–700 BC). The early Bronze Age in the region was characterized by a continuation of the beaker tradition, the beginnings of bronze imports (from central and northern Europe and the British Isles), and a modest local bronze industry. The origin of cremation and the burial of ashes in urns in the southern Netherlands and Belgium (Hilversum culture) can be related to close contacts with Wessex, in Britain.

Finds from the middle Bronze Age (1500–1100 BC) reflect the establishment of an essentially more advanced agricultural system: remains of some 80- to 130-foot-long farmhouses, including stable sections, provide evidence of true mixed farming, including manuring, care for winter fodder, and, presumably, the use of straw in stables. Cattle were by far the dominant livestock. This contrasts sharply with the Neolithic cultures, in which agricultural activities are presumed to have been less interrelated. Burial during the period was under barrows, now surrounded by post circles, with human remains either extended in coffins (common to the northern Netherlands) or cremated in urns (as in the south).

While settlement tradition continued, changes in burial custom took place around 1100 BC, with urn burial now taking place in small, individual barrows surrounded by ditches of various types. A northern sphere connected with Westphalia, a central sphere in Noord-Brabant/Limburg connected with the Rhineland, and a southern Flemish group are distinct examples of this type of burial. Modest native bronze industries have been identified in the north (Hunze-Eems industry) as well as along the Meuse in Limburg, while bronze weapons and implements were imported from Great Britain and various other sources.

The Iron Age (*c.* 700 BC to Roman times). The Iron Age in the Low Countries is characterized by Celtic and Germanic influences. In the south, Hallstatt (Celtic) and La Tène traditions can be traced through prestigious warrior chieftain graves at such sites as Court Saint Etienne (Hainaut, Belg.), Eigenbilzen (Belg.), and Oss (Neth.), which were stocked with chariots and harnesses, bronze weapons, implements, and even wine services. These traditions are also reflected in fortified hilltop settlements, in pottery styles, and in ornaments and other artifacts. On the sands to the north people had to cope with a deteriorating environment, especially impoverishment of the soils, podzolization, and wind erosion. They responded to these conditions with a more diversified agriculture and the more protective system of Celtic fields (small plots with low earthen banks formed around them). Other illustrations of renewed adaptability were demonstrated by the colonization of newly formed salt marshes and the building of artificial dwelling mounds called *terpen* in the north, the new settlement of creek and peat landscapes of the western river estuaries, salt production along the coast, and the breeding of horses elsewhere. (L.P.L.K.)

Celtic fields

ANCIENT AND EARLY MEDIEVAL TIMES

The Roman period. At the time of the Roman conquest (1st century BC), the Low Countries were inhabited by a number of Celtic tribes to the south and west of the Rhine and by a number of Germanic tribes to the north. Cultural and ethnic influences in both directions, however, make it difficult to draw the line between Celtic and Germanic peoples. On the coast of northern France and in Flanders lived the Morini; to the north of them, between the Schelde River and the sea, the Menapii; in Artois, the Nervii; between the Schelde and the Rhine, the Eburones and the Aduatuci; and, in what is now Luxembourg, the Treveri. North of the Rhine, the Frisii (Frisians) were the principal inhabitants, although the arrival of the Romans brought about a number of movements: the Batavi came to the area of the lower reaches of the Rhine, the Canninefates to the western coastal area of the mouth of the Rhine, the Marsaci to the islands of Zeeland, the Toxandri to the Campine (Kempenland), the Cugerni to the Xanten district, and the Tungri to part of the area originally inhabited by the Eburones.

The Roman conquest of Gaul, which was completed by Caesar in 59–52 BC, stopped short at the Rhine. The emperor Augustus' attempt to extend Roman military power over the Elbe failed, and the area occupied by the Frisians, north of the Rhine, was therefore never under Roman rule. In the Rhine delta and to the south and west of the Rhine, the Romans set up the same administrative organizations as those found in other parts of Gaul. The Low Countries formed part of the provinces of Belgica and Germania Inferior (later Belgica Secunda and Germania Secunda), which themselves were subdivided into *civitates:* in Belgica, those of the Morini, Menapii, Treveri, Tungri, and possibly the Toxandri; in Germania Inferior, those of the Batavi, Canninefates, and Cugerni. Because of the later adoption by the church of the division into *civitates,* a number of centres of the *civitates* have become the seats of bishoprics; among these are Thérouanne, Tournai, Tongeren (Tongres), and Trier (Trèves).

From the mid-1st to the mid-3rd century AD, the Gallo-Roman culture penetrated the northern provinces of the empire. The famous road network was constructed, and important garrisons were concentrated along the Rhine and also on the Waal at present-day Nijmegen. This affected a whole region: a more inland city such as Tongres became an important market for grain to be brought to Cologne. Along the great Cologne-Tongres-Bavai-Boulogne axis, relatively rich *villae* were located at regular distances. One of these, the city of Maastricht, profited from the river trade on the Meuse and had baths as early as the 1st century, while graves in the vicinity contained sarcophagi with bas-relief ornamentation, as well as splendid glass and sculptures of Mediterranean origin. The Gallo-Roman elite were concentrated along the main roads and especially on the richest lime soils. Some large industrial settlements producing iron works and clay tiles were located near the Schelde close to crossings of secondary roads to the north.

Decline of Roman power

In the mid-3rd century Roman power in the Low Countries began to weaken, and the forts were abandoned. This was the result not only of a resurgence of the Germanic tribes but also probably of the encroachment of the sea, which in all likelihood brought about a drastic change in the area's economy. A temporary recovery began at the end of the 3rd century. In particular, Julian, Caesar of Gaul, waged several wars in the Low Countries between 355 and 360 and was able to put new strength, for a time, into the Rhine border. A great invasion by Germanic tribes in 406–407, however, ended the Roman occupation of the Low Countries. The Romans had already tolerated the Germanic penetration of their territory and had given some tribes the task of protecting the borders of the empire. The Franks, who had settled in Toxandria, in Brabant, were given the job of defending the border areas, which they did until the mid-5th century.

Frankish rule. The Franks were probably influenced considerably by Roman culture, becoming familiar with the Roman world and way of life, although the expansion of their own race and their growing self-confidence were barriers to complete Romanization. About 450 they moved southward, founding a new Frankish kingdom in a region that was centred on the road from Tongres to Boulogne. The Gallo-Roman population had left the less-populated sandy areas in the north and withdrawn south of that road. The first king of the Merovingian Franks, Childeric I (d. 481/482), ruled the region around Tournai, while his son Clovis I (ruled 481/482–511) extended the kingdom, eliminating other Frankish leaders and becoming ruler of much of Gaul. During the 6th century, Salian Franks had settled in the region between the Loire River

in present-day France and the Coal Forest in the south of present-day Belgium. From the late 6th century, Ripuarian Franks pushed from the Rhineland westward to the Schelde. Their immigration strengthened the Germanic faction in that region, which had been almost completely evacuated by the Gallo-Romans. The Salian Franks, on the other hand, had penetrated a more densely Latinized area where they came under the strong influence of the dominant Roman culture.

Resistance to the Franks

The area occupied by the Frisians in the north was completely outside the Frankish sphere of influence, but the Rhine delta and even what is now Noord-Brabant also appear to have retained the virtually independent status they had possessed during the Roman era.

The Frisians were part of a North Sea culture that formed a distinct foil to Frankish power. The Frisians played an important role in trade, which sought routes along the Rhine and the Meuse and across the North Sea. Industrial products were imported from northern France, the Meuse plain, and the Rhineland, where Merovingian power was more firmly established and where centres of commerce (*e.g.,* Dinant, Namur, Huy, and Liège) developed. The more or less independent area on the North Sea coast, however, found itself threatened during the 7th century by the rise of the Frankish nobles. In particular, the family of the Pepins, who came from the centre of Austrasia (the Ardennes and upper Meuse), was able to secure land in Limburg. Moreover, encouraged by the Frankish king Dagobert (ruled 623–639), the Frankish church began an offensive that led to the foundation of the bishopric of Thérouanne (the *civitas* of the Morini).

This collaboration between church and nobles prepared the way for an expansion of political power to the north, which was carried out under the leadership of the Pepins, who as "mayors of the palace" in Austrasia had virtually taken over power from the weakened Merovingian kings. Charles Martel, a bastard son of Pepin II, who managed after several years' fighting (714–719) to grasp supreme power over the whole Frankish empire, succeeded in 734 in forcing his way through to the northern centres of the Frisians and gaining a victory near the Boorne River. His victory was later consolidated by Pepin III and his son Charlemagne (ruled 768–814). The whole area of the Low Countries thus effectively formed part of the Frankish empire, which was then ruled by the Pepin, or Carolingian, dynasty.

Life under the Franks

The Low Countries under the Carolingians. *Government.* The administrative organization of the Low Countries during this period was basically the same as that of the rest of the Frankish empire. Supreme authority was held by the king, who, aided by servants of the palace, toured the country incessantly. The Carolingian kings naturally made several visits to the Low Countries, where they had old palaces or built new ones (Herstal, Meerssen, Nijmegen, Aix-la-Chapelle) and where they also possessed extensive crown estates. Their authority (*bannus*) was delegated to counts who had control of counties, or *gauen* (*pagi*), some of which corresponded to Roman *civitates.* Among these counties in the Low Countries were the *pagus* Taruanensis (centred on Thérouanne), *pagus* Mempiscus, *pagus* Flandrensis (around Brugge), *pagus* Turnacensis (around Tournai), *pagus* Gandensis (Ghent), *pagus* Bracbatensis (between the Schelde and the Dijle rivers), *pagus* Toxandrie (modern Noord-Brabant), and, north of the great rivers, Marssum, Lake et Isla, Teisterbant, Circa oras Rheni, Kinnem, Westflinge, Texla, Salon, Hamaland, and Twente. In the north, however, it is frequently not possible to determine with certainty whether the word *gau* in fact denoted a region controlled by a count who exercised the king's authority or indicated simply a region of land without reference to its government. Smaller administrative units were the *centenae,* or hundreds, and districts called *ambachten.* These last were mainly in what are now the provinces of Vlaanderen, Zeeland, and Holland.

Religion. The conversion to Christianity of the southern Low Countries, which took place largely during the 7th century, led to the foundation of further bishoprics at Arras, Tournai, and Cambrai, which were part of the ecclesiastical province of Rheims (the former Roman province of Belgica Secunda). Germania Secunda contained the ecclesiastical province of Cologne, in which the *civitas* of Tongres seems to have had an uninterrupted existence as a bishopric since Roman times; the centre of this bishopric was moved for a time to Maastricht (6th and 7th centuries) until, about 720, Liège became the seat of the bishopric. Christianity was brought to the north of the Low Countries mainly by Anglo-Saxon preachers, by Frisians influenced by them, and by Franks. This Anglo-Saxon Christianity was particularly important in the missionary bishopric of Utrecht, which at first, because of its missionary character, had no precisely defined borders. True, the city of Utrecht had been named as the see of the bishopric, but, as in England, the monasteries played an important part in the missionary work; among these was the monastery of Echternach in Luxembourg and the two important Benedictine abbeys in and near Ghent, founded by St. Amand in the early 7th century. The country between the Meuse and the Waal rivers and the area around Nijmegen belonged to the bishopric of Cologne, while certain districts in the north and east were part of the bishopric of Münster (founded by Charlemagne).

Social classes. The social structure of the Low Countries in the Frankish era included a number of classes. At the top was an elite that probably already operated on a hereditary system and of which the members were bound to the king as vassals and rewarded by fiefs (*beneficia*). Next were the freemen (*liberi, ingenui*), bound to the king by an oath of allegiance and traditionally under an obligation to serve in the army and in the law courts. A freeman's *Wergeld*—the sum that had to be paid to his family if he was killed—was in principle 200 shillings (*solidi*); but the *ingenui Franci,* or *homines Franci* (found in the region of the great rivers; probably descended from native nobles who had early placed themselves in the service of the Franks in their policy of conquest), had a much higher *Wergeld.* At the bottom of the ladder were the bondsmen, who were closely dependent on a lord (often an important landowner), in whose service they stood, in most cases working on his estates. It may be supposed that the position of the bondsmen was relatively favourable in the coastal areas of Holland and Friesland, where there were no large estates and, moreover, where the struggle against the sea required as much manpower as the community was able to offer.

Economy. Economically, the structure of the Low Countries in the Frankish period was principally agrarian. Particularly in the south and east, it was common practice to exploit the land from a central farmhouse (*villa,* or *curtis*), using the services of dependent subjects (bondsmen), who were duty-bound to work on the domain of the lord and to this end received small farms from him. The nature of the land in the west and north, however, probably to a large extent precluded this classical type of exploitation of the domains; there was scattered, even fragmentary, ownership of land, and the *curtis* was no more than a gathering place to which the bondsmen had to take a part of their produce. In Holland and Friesland, fishing and the raising and selling of cattle were of importance. This Frisian trade, of which Dorestad was a centre, was greatly stimulated by absorption into the Frankish empire, and it reached its zenith under Charlemagne and Louis I the Pious (ruled 814–840). Moreover, by virtue of its becoming part of the Frankish empire, Friesland obtained an important hinterland in the southern regions of the Meuse and Rhine and was thus in a position to develop export and through trade to Denmark, Norway, and the Baltic countries. The importance of Frisian trade may be seen in the Carolingian coins found in Dorestad, where there was a toll and a royal mint. This trade was supplied by the southern Low Countries. Thus the cloths that were sold as Frisian cloths were produced in the area of the Schelde (later called Flanders). Quentovic, at the mouth of the Canche, was another trading centre; it too had a toll and a mint. Smaller trade settlements (*portus,* or *vicus*) emerged at Tournai, Ghent, Brugge, Antwerp, Dinant, Namur, Huy, Liège, and Maastricht—a clear indication of the commercial importance of the Schelde and the Meuse.

Decline of the Frankish empire. The great Carolingian

Partition of the empire

dynasty passed into a decline as early as the reign of Louis the Pious, and the process was accelerated after his death in 840. Repeated wars broke out under his sons, leading eventually to the partition of the empire. The dissolution of Carolingian power was further helped by Viking, Magyar, and Saracen attacks—the Viking attacks being of greatest import for the Low Countries. The attacks had begun immediately after the death of Charlemagne (814) in the form of plundering raids, the magnitude and danger of which soon increased. (Dorestad, for example, was destroyed four times between 834 and 837.) Churches and monasteries, with their rich treasures, were the principal targets for the Vikings, who soon took to spending the winter in the Low Countries. In order to ward off the danger, attempts were made to throw up walls around towns and monasteries or even to drive off the Vikings by fierce counterattacks—a procedure that enjoyed some success—so that the counts of Flanders, for example, were able to lay a firm foundation for their own power. Another method of defense was to admit the Vikings on the condition that they defend the areas given them against other Vikings. The danger diminished after 900.

THE DEVELOPMENT OF THE TERRITORIAL PRINCIPALITIES AND THE RISE OF THE TOWNS (925–c. 1350)

Politically speaking, the period between 925 and about 1350 is characterized by the emergence, growth, and eventual independence of secular and ecclesiastical territorial principalities. The rulers of these principalities—both secular and spiritual—had a feudal relationship with the German king (the Holy Roman emperor), with the exception of the count of Flanders, who held his land principally as the vassal of the French king, with only the eastern part of his county, Imperial Flanders, being held in fealty to the German king. While the secular principalities came into being as a result of individual initiative on the part of local rulers and of their taking the law into their own hands, to the detriment of the king's authority, the development of the spiritual princes' authority was systematically furthered and supported from above by the king himself. The secular principalities that arose in the Low Countries and whose borders were more or less fixed at the end of the 13th century were the counties of Flanders and Hainaut, the duchies of Brabant and Limburg (after 1288 joined in personal union), the county of Namur, the county of Loon (which was, however, to a large degree dependent on the bishopric of Liège and incorporated in it from 1366), the county of Holland and Zeeland, and the county (after 1339, duchy) of Guelders. The Frisian areas (approximately corresponding to the modern provinces of Friesland and Groningen, but excluding the city of Groningen) had no sovereign authority. The spiritual principalities were Liège, Utrecht, Tournai, and Cambrai. The secular authority of the bishop of Utrecht was exercised over two separate areas: the Nederstícht (now the province of Utrecht) and the Oversticht (now the provinces of Overijssel and Drenthe and the city of Groningen).

The spiritual principalities

It must be noted that, although these principalities displayed common characteristics in their economies, social structures, and cultures, it was the intrusion of the Burgundian dynasty that brought about a certain degree of political unity, which in turn furthered economic, social, and cultural unity and even led to the beginnings of a common national feeling (which was nevertheless too weak to prevent partition in the late 16th century).

The secular principalities. The secular princes consolidated their power in a number of ways. The count still exercised the rights that had for centuries been attached to the Carolingian office of count, denoted by the term *comitatus*. They included the administration of justice, various military powers, and the right to levy fines and tolls. To these rights fiefs were attached, which during the passage of time were expanded by the counts, who eventually owned such large estates that they were by far the greatest landowners in their territories. Soon the term *comitatus* covered not only the office, or duty, but also the whole area over which that office was exercised; thus it could be said that the count held his county in fief of the king. An important element of the count's authority was supervision over the county's religious foundations, especially the monasteries. In the 10th century, the counts sometimes even assumed the function of abbot (lay abbot); but they later contented themselves with the control of appointments to ecclesiastical offices, through which they often had great influence over the monasteries and profited from the income from monastic land. Thus, monasteries such as St. Vaast (near Arras), St. Amand (on the Scarpe), St. Bertin (near St. Omer), and St. Bavon and St. Peter (in Ghent) became centres of the power and authority of the counts of Flanders; Nivelles and Gembloux, of the dukes of Brabant; and Egmond and Rijnsburg, of the counts of Holland.

Expansion of counts' power

At the end of the 9th and in the 10th century, during the Viking attacks and while connections with the empire were loosening, the local counts built up their power by joining a number of *pagi* together and building forts to ensure their safety. The counts of Flanders amalgamated the *pagi* Flandrensis, Rodanensis, Gandensis, Curtracensis, Iserae, and Mempiscus, the whole being thenceforth called Flanders; they fortified this area of their power with new or surviving Roman citadels. In the northern coastal regions, the Viking Gerulf was granted in about 885 the rights over a number of counties between the Meuse and the Vlie (Masalant, Kinnem, Texla, Westflinge, and a district known as Circa oras Rheni, which was, as the name implies, on both sides of the Rhine); his descendants consolidated their power there as counts of west Frisia and, after 1100, took the title of counts of Holland. In Brabant and Guelders, the amalgamation of fragmentary and dispersed estates took place later than in Flanders and Holland.

During the 10th and 11th centuries, the German kings of the Saxon and Salian dynasties attempted to impose their authority on the increasingly powerful secular principalities by the appointment of dukes. In Lorraine, during the reign of Otto I (936–973), the king appointed his brother, Bruno, the archbishop of Cologne, to the position of duke. Bruno soon split Lorraine into two dukedoms—Upper and Lower Lorraine. In Lower Lorraine, the title of duke was given to the counts of Louvain and the counts of Limburg—the former at first called themselves dukes of Lorraine but soon assumed the title of dukes of Brabant; the latter were known as the dukes of Limburg.

Rise of bishops and abbots

The spiritual principalities. That the German kings failed to integrate Lorraine into the Holy Roman Empire as a duchy ruled by a viceroy may be attributed to the fact that the kings soon developed another way to strengthen their power, not only in Lorraine but throughout the empire, by systematically investing bishops and abbots with secular powers and making them pillars of authority. This procedure, developed by Otto I and reaching its summit under Henry III, was carried out in phases and led eventually to the establishment of the Imperial Church (Reichskirche), in which the spiritual and secular principalities played an important part. The most important ecclesiastical principalities in the Low Countries were the bishoprics of Liège, Utrecht, and, to a lesser degree, Cambrai, which, though within the Holy Roman Empire, belonged to the French church province of Rheims. The secular powers enjoyed by these bishops were based on the right of immunity that their churches exercised over their properties, and that meant that, within the areas of their properties, the counts and their subordinates had little or no opportunity to carry out their functions. The bishops' power was consolidated when the kings decided to transfer to the bishops the powers of counts in certain areas that were not covered by immunity.

Certain bishops, such as those of Liège and Utrecht, were able to combine their rights of immunity, certain jurisdictional powers, regalia, and ban-immunities into a unified secular authority, thus forming a secular principality called a *Sticht* (as distinct from the diocese) or—where the power structure was very large and complex, as in the case of the bishop of Liège—a prince-bishopric. As princes, the bishops were vassals of the king, having to fulfill military and advisory duties in the same way as their secular colleagues. The advantage of this system to the kings lay in the fact that the bishops could not start a

dynasty that might begin to work for its own ends, and its smooth running stood and fell with the authority of the kings to nominate their own bishops.

Thus the spiritual-territorial principalities of the bishops of Liège and Utrecht emerged—the prince-bishopric of Liège and the *Sticht* of Utrecht. In Liège this development was completed in 972–1008 under the guidance of Bishop Notger, appointed by Otto I. As early as 985 he was granted the rights of the count of Huy, and the German kings made use of the bishopric of Liège to try to strengthen their positions in Lorraine. Utrecht, which lay more on the periphery of the empire, developed somewhat later. It was principally the kings Henry II, Conrad II, and Henry III who strengthened the secular power of the bishops through privileges and gifts of land.

Struggle for independence. Thus, the Low Countries during the 10th and 11th centuries saw the development of the pattern of a number of more or less independent feudal states, both secular and ecclesiastical, each of which was struggling for more freedom from the king's authority, the enlargement of its sphere of influence, and the strengthening of its internal power. Flanders led the way. In the 10th and 11th centuries it needed to pay only scant attention to the weak French kings of the Capetian dynasty and was thus soon able to exercise its power farther south—in Artois—and was even able to play an important part in a political power struggle around the French crown. In 1066 the count of Flanders lent his support to the expedition to England of his son-in-law, William, duke of Normandy. The counts of Flanders built up a strong administrative apparatus—the *curia comitis,* based on central officials and on local rulers called burgraves, or castellans (*castellani*), who were in charge of districts known as castellanies, where they had extensive military and administrative powers. The reclamation of land from the sea and from marsh and wasteland in the coastal area, which began in the 11th century, enlarged the estates and the income of the counts and brought about the need for a rational administrative system. The nobles were a power to be reckoned with, but Count Robert I (ruled 1071–93) and his successors were able to find support and a balancing force in such developing towns as Brugge, Ghent, Ypres, Courtrai, and Cassel. The murder of the powerful and highly respected Count Charles the Good (ruled 1119–27), who was childless, plunged Flanders into a crisis that involved not only the nobles and the towns but also, for the first time, the French king.

Leadership of Flanders

About 1100 such other territories as Brabant, Hainaut, Namur, and Holland began to expand and form principalities, helped by the weakening of the German crown during the Investiture Contest (a struggle between civil and church rulers over the right to invest bishops and abbots). The Concordat of Worms (1122) ruled that bishops were to be chosen by the chapter of canons of the cathedral; thus, the German king was obliged to transfer the secular powers to an *electus,* who was then usually ordained bishop by the metropolitan. Although the king still exercised some influence over the elections, the local counts were able to make their voices heard the loudest in the chapter, so that Utrecht, for example, soon had bishops from the families of the counts of Holland and Guelders. This was the end of the strong influence that German imperial power exercised through the bishops in the Low Countries. Thenceforth, the spiritual and secular princes stood together, although the death of a bishop still tended to plunge the principality into a crisis.

End of German imperial power

French and English influence. As their power declined, the Holy Roman emperors could do little more than involve themselves almost incidentally in the affairs and many conflicts of the Low Countries. The German decline went hand in hand with the increasing influence of the French and English kings, particularly after 1200; this applied especially to French power in Flanders. A struggle for the throne that broke out in Germany at the death of Henry VI (1197) found the two powerful factions—the Ghibellines and Guelfs—on opposite sides; in the Low Countries, a game of political chance developed, in which the duke of Brabant (Henry I) played an important role, alternatively supporting both parties. The French king, Philip Augustus, and his opponent, King John of England, both interfered in the conflict, which polarized into Anglo-Guelf and Franco-Ghibelline coalitions, each looking for allies in the Low Countries. A victory won by the French king at the Battle of Bouvines, east of Lille (1214), put the count of Flanders at his mercy. The southern parts of the county were split off and incorporated into the county of Artois.

Throughout the 13th century, the French kings increased their influence in Flanders, which was joined to Hainaut by personal union. The power of the counts diminished during the reign of two countesses from 1205 to 1278 because of the increasing pressure of the kingdom and the growing power of the cities. The counts' efforts to control the urban elites (the patriciate) by controlling the cities' finances and the appointment of the magistrates (aldermen, or *schepenen*) failed because the French king supported the patricians. King Philip IV, who was successful in his territorial expansion in Champagne and Gascony, also tried to incorporate the county of Flanders by a military invasion, in which he was supported by his patrician partisans. By 1300 the annexation of Flanders was almost complete. Resistance by Count Guy, which was supported by the crafts in the towns, culminated in a resounding victory by the Flemish army (which consisted largely of citizens of the towns fighting on foot) over the French knights at Courtrai (the Battle of the Golden Spurs, 1302) and prevented total annexation.

French influence remained strong during the 14th century, however, as the counts saw themselves repeatedly opposed by a mighty coalition of subjects in revolt. An early case was the peasant revolt in the western part of the county, supported by Brugge and lasting from 1323 to 1328; it was provoked by heavy taxation as a consequence of the French-imposed peace conditions of 1305. Only the massive help of a French army enabled the count to impose his heavy repression. Then the outbreak of the Hundred Years' War about 1337 tempted the Flemish to take sides with the English, whose wool imports they needed for their large-scale textile industry. From 1338 until his death in 1346, Count Louis I of Nevers sought the protection of the French king, to whom he fled, leaving his county virtually in the hands of the three major cities of Ghent, Brugge, and Ypres, which had developed as city-states. Again in 1379–85 a new revolt of the major cities against the count's son, Louis II of Male, provoked French military intervention, which, however, did not resolve the situation. Louis of Male also fled to France, and peace with the Flemings could only be negotiated favourably for the cities by their new prince, Philip, duke of Burgundy, youngest son of the French king, John II.

Social and economic structure. To obtain some insight into the social structure of the Low Countries between 900 and 1350, it is important to realize that, although the territorial princes wielded supreme power, the people were in fact directly dependent on an elite that, by virtue of owning land and possessing certain powers of jurisdiction and administration, had formed seigneuries, in which they held considerable effective power. These lords could control their dependents by demanding agricultural services, exercising certain rights over dependents' inheritances, levying monies in return for granting permission to marry, and forcing them to make use of the lords' mills, ovens, breweries, and stud animals. In the main, the owners of these seigneuries were treated as nobles and were often, though not always, bound to the territorial prince by feudal ties. A separate class was formed by the knights, who in the 12th century were usually *ministeriales* (servants who had originally been bondsmen) and were used by their lords for cavalry service or for higher administrative duties, for which they received a fief. It was not until the 13th century and, in many places, even later that the feudal nobility and ministerial knights became unified in a single aristocracy. Apart from these nobles, there were also freemen who owned their own land (*allodium*), but little is known about them; they were present, however, in large numbers in the cattle-breeding regions of Flanders, Zeeland, Holland, and Friesland, where the numerous rivers and streams must have split up the land into many

Social classes

small farms. The descendants of noble families who were no longer able to live as richly as the nobles and who were known as *hommes de lignage* (in Brabant), *hommes de loi* (Namur), or *welgeborenen* (Holland), must have been very close in status to the freemen. In the agricultural areas of Hainaut, Brabant, Guelders, and the Oversticht were dependents whose legal status is difficult to determine, though they may be classed as bondsmen because of their being liable for various services and payments.

A factor of great, if not decisive, importance for social and economic relations, not only in the Low Countries but in all of western Europe, was the growth of the population. There is no direct statistical information but only a certain amount of indirect knowledge—after about 1050, it can be seen in the internal colonization (in the form of reclamation of such waste ground as woods and bogs), in the building of dikes and polders, in the expansion of agricultural land, and in the growth of the villages (new parishes) and towns.

Expansion of the land

The opening up of extensive areas of wood and heathland led to the foundation of new settlements (known in the French-speaking areas as *villes neuves*), to which colonists were attracted by offers of advantageous conditions—which were also intended to benefit the original estates. Many of these colonists were younger sons who had no share in the inheritance of their fathers' farms. The Cistercian and Premonstratensian monks, whose rules prescribed that they must work the land themselves, played an important part in this exploitation of new land. In the coastal regions of Flanders, Zeeland, and Friesland, they were very active in the struggle against the sea, building dikes both inland and on the coast itself. At first these dikes were purely defensive, but later they took on an offensive character and wrested considerable areas of land from the sea.

Especially important was the reclamation of marshland in the peat-bog areas of Holland and Utrecht and in the coastal regions of Flanders and Friesland. The Frisians had specialized in this work as early as the 11th century; Flemings and Hollanders soon adopted their methods, even applying them in the Elbe plain in Germany. The system, which consisted of digging drainage ditches, lowered the water table, leaving the ground dry enough for cattle grazing and, later, even for arable farming. The colonists, who were freemen, were given the right to cut drainage ditches as far back from the common watercourse as they wished. Certain restrictions were later imposed by the lords, however, who regarded themselves as the owners of these waste areas and demanded tribute money as compensation. Reclamation work was organized by a contractor (*locator*), who was responsible to the count and often carried out the function of local judge.

Thus, in the 12th and 13th centuries, a large area of land in the Holland-Utrecht peat-bog plain was made available for agriculture, facilitating the rise of nonagricultural communities (*i.e.,* the towns). In Flanders, Zeeland, Holland, and Utrecht this struggle against the sea and the inland water was particularly noteworthy in that it led to the foundation of water boards, which in the 13th and 14th centuries were amalgamated to form higher water authorities (the *hoogheemraadschappen*). Mastery over the water had to be carried out on a large scale and in an organized fashion; the building of dikes required a higher authority and coordinated labour. Thus, various organizations emerged, acting independently in the field of canal and dike building and maintenance and responsible only to the government itself. These were *communitates,* with their own servants and their own managements (dike reeves and *heemraden*) and empowered to take necessary measures to maintain the waterworks, administer justice, and issue proclamations. This included the levy of taxes for this purpose, under the exclusive control of the landholders, who had to contribute proportionally to the area they possessed. The need of absolute solidarity, imposed by geography, thus created a system of communal organization based on full participation and equality exceptional in European terms. In the core of Holland, three large *hoogheemraadschappen* controlled the whole territory. They were headed by dike reeves who also were the count's bailiffs and thus functioned as high judges and administrators. They were assisted by *heemraden* elected by the landholders.

Formation of water authorities

The increase in the population and the reclamation of land from the sea and marshes, as well as the fight to keep the sea out, all helped change the social and economic structures of the Low Countries. For centuries, the southern and eastern areas had been agricultural, often making use of the domain system. In the coastal areas, however, reduced labour requirements of cattle raising could be combined with fishing, weaving, and overseas trading. Dorestad, the centre of the Frisian trade, fell into decay not so much as a result of Viking raids (it was rebuilt after each one) as of a change in the course of the river upon whose banks the town was situated. Dorestad's leading position in trade was then taken over by Tiel, Deventer, Zaltbommel, Heerewaarden, and the city of Utrecht. Wheat was imported from the Rhine plain, salt from Friesland, and iron ore from Saxony, and, before long, wine, textiles, and metal goods were brought along the Meuse and Rhine from the south. The IJssel in Guelders also began to carry trading traffic through Deventer, Zutphen, and Kampen and, on the coast of the Zuiderzee (now IJsselmeer), through Harderwijk, Elburg, and Stavoren.

Growth of Flanders

In the south, commercial developments were concentrated in two areas: one was the Artois-Flanders region, which profited from the shipping facilities of a river system providing access to the sea and to the wide Schelde plains; the other was the Meuse corridor. For centuries, sheep farming on chalky soils and coastal marshlands had produced the wool needed in the cloth industry; but to meet an increased demand wool was imported from England, for which purpose merchants from various Flemish towns joined together in the Flemish Hanse, a trade association, in London. Flemish cloth produced in fast-growing cities such as Arras, Saint-Omer, Douai, Lille, Tournai, Ypres, Ghent, and Brugge found its buyers throughout Europe. Notary's registers in Genoa and Milan, preserved since about 1200, mention many transactions of different varieties of Flemish cloth and indicate the presence of Flemish and Artesian (from Artois) merchants. The fairs (markets) in the Champagne region linked northern Italy with northwestern Europe; in Flanders a series of similar fairs was set up to facilitate contacts and credit operations among merchants of different nationalities.

Flemish cloth market

To a large extent, the Flemish economy became dependent on the import of English wool, while its exports of finished cloth were directed mainly to the Rhineland, northern Italy, the French west coast, the northern Low Countries, and the Baltic. Flanders' early dominant position was possible owing to a favourable combination of geographic and economic factors. Because Flanders had the first large export industry in northern Europe, its production centres attained the highest levels of quality through specialization and diversification.

For the cloth industry itself, Ghent and Ypres were among the most important towns. In Ghent the production process was run by drapers (*drapiers*), who bought the raw material, had it treated by spinners, weavers, fullers, and dyers, and eventually sold the final product. A drop in wool imports from England could therefore cause immediate social and political upheavals in the city.

The area of the Meuse also carried on considerable trade and industry; merchants from Liège, Huy, Namur, and Dinant are named in 11th-century toll tariffs from London and Koblenz. This trade was supplied mainly by the textile industry of Maastricht, Huy, and Nivelles and by the metal industry of Liège and Dinant. Trade in Brabant, actively supported by the dukes, used the road, or system of tracks (medieval road systems were not advanced), that ran from Cologne through Aix-la-Chapelle, Maastricht, Tongres, Louvain, and Brussels to Ghent and Brugge. Four major trade routes thus developed before 1300 in the Low Countries, favouring the growth or even the emergence of cities; these were between the Rhine and the Zuiderzee, along the Meuse, along the land route from Cologne through Brabant to the sea, and through Flanders. Only the latter displayed a spectacular growth

during this period, taking advantage of its proximity to the sea to build up a massive export industry of labour-intensive, high-quality consumer products.

Since prehistoric times, fishing, particularly for herring, had been important in the coastal regions of Zeeland and Flanders. Since the 5th century BC, archaeological evidence shows that the people produced salt, important in fish preservation, by boiling seawater. In later centuries, a more sophisticated technique was devised by burning peat, from which salt could be refined. This industry was located along the coast and near Biervliet and Dordrecht on the major rivers. It evidently was established to support the fisheries. The fishing industry was given added stimulus by the shift of the herring shoals from the coast of Schonen (Sweden) to the North Sea. The ships, however, were increasingly placed at the disposal of general trade and, in particular, of the wool trade with England. The German merchants also turned their attention to Holland, where Dordrecht became the most important centre. Because of its central position in the rivers area, this town offered the counts the chance to raise tolls on all traffic in the neighbourhood; moreover, all cargoes had to be unloaded and offered for sale—wine, coal, millstones, metal products, fruit, spices, fish, salt, grain, and wood.

Importance of Dordrecht

The towns. The towns gave the Low Countries a special character of their own. Apart from some towns that had existed even in Roman times, such as Maastricht and Nijmegen, most towns arose in the 9th century; in the 11th and 12th centuries, they expanded and developed considerably. The emergence of the towns went hand in hand with the population increase and the extension of cultivable land, which made possible higher production. The population centres that emerged were not primarily agrarian but specialized in industry and trade.

The oldest towns were in the regions of the Schelde and Meuse. Near existing counts' castles or walled monasteries, merchants formed settlements (*portus,* or *vicus*). In some cases, like that of Ghent, for instance, the commercial *portus* was older than the count's castle and grew purely because of its advantageous location. The *portus* gradually merged with the original settlements to form units that both economically and in their constitutions took on their own characters with respect to the surrounding country—characters that were later manifested by defensive ramparts and walls. The cities in the Meuse valley (Dinant, Namur, Huy, Liège, and Maastricht) had already developed in the 10th century, owing to the heritage of this region as the core of the Carolingian empire. Maastricht in particular played a prominent role as one of the main seats of the German imperial church. In the Schelde valley a dense urban network had also developed. A later group (though not much later) was formed by the northern towns of Deventer and Tiel, while Utrecht had long been a town in the sense of a commercial centre. Zutphen, Zwolle, Kampen, Harderwijk, Elburg, and Stavoren are other examples of early towns. Much younger (13th-century) are the towns of Holland—Dordrecht, Leiden, Haarlem, Alkmaar, and Delft.

All the towns formed a new, nonfeudal element in the existing social structure, and from the beginning merchants played an important role. The merchants often formed guilds, organizations that grew out of merchant groups and banded together for mutual protection while traveling during this violent period, when attacks on merchant caravans were common. From a manuscript dated about 1020, it appears that the merchants of Tiel met regularly for a drinking bout, had a common treasury, and could clear themselves of a charge by the simple expedient of swearing an oath of innocence (a privilege they claimed to have been granted by the emperor). Thus, there and elsewhere, the merchants constituted a horizontal community formed by an oath of cooperation and with the maintenance of law and order as its goal.

Formation of guilds

In contrast, therefore, to the vertical bonds in the feudal world and within the manors, horizontal bonds emerged between individuals who were naturally aiming at independence and autonomy. The extent to which autonomy was achieved varied greatly and depended on the power exercised by the territorial prince. Autonomy often developed spontaneously, and its evolution might have been accepted either tacitly or orally by the prince, so that no documentary evidence of it remains. Sometimes, however, certain freedoms were granted in writing, such as that granted by the bishop of Liège to Huy as early as 1066. Such town charters often included the record of a ruling that had been the subject of demands or conflicts; they frequently dealt with a special form of criminal or contract law, the satisfactory regulation of which was of utmost importance to the town involved. Indeed, the first step a town took on the road to autonomy was to receive its own law and judicial system, dissociated from that of the surrounding countryside; a natural consequence of this was that the town then had its own governing authority and judiciary in the form of a board, whose members were called *schepenen* (*échevins*), headed by a *schout* (*écoutète*), or bailiff. As the towns grew, functionaries appeared who had to look after the town's finances and its fortifications. They were often called burgomasters (*burgemeesters*).

The development of a town's autonomy sometimes advanced somewhat spasmodically as a result of violent conflicts with the prince. The citizens then united, forming *conjurationes* (sometimes called communes)—fighting groups bound together by an oath—as happened during a Flemish crisis in 1127–28 in Ghent and Brugge and in Utrecht in 1159. The counts of Flanders from the house of Alsace (Thierry, ruled 1128–68, and Philip, 1168–91) kept careful watch, supporting and aiding the towns in their economic development but otherwise keeping the process in check.

Town opposition to the prince

In their struggle for autonomy, the towns had to fight for financial freedom, such as for the lessening or abolition of the taxes and tolls they had to pay to the prince but also and principally for the right to impose their own taxes, usually in the form of indirect taxation (*e.g.,* excise duties), in order to raise money for necessary public works. Especially important to them was the right to frame their own laws; this legislative right (the *keurrecht*) was in most towns originally restricted to the control of prices and standards in the markets and shops but was gradually extended to cover civil and criminal law. The extent of a man's obligation to serve in the prince's armed forces was often fixed or limited or both (sometimes by the provision for payment in lieu, sometimes by a legal definition of the number of foot soldiers or manned ships to be made available).

Thus, the town in the Low Countries became a *communitas* (sometimes called *corporatio* or *universitas*)—a community that was legally a corporate body, could enter into alliances and ratify them with its own seal, could sometimes even make commercial or military contracts with other towns, and could negotiate directly with the prince. Land within the town's boundaries usually became its property or its burghers' by redemption, and the town's inhabitants were usually exempt from any dependent relationship with outsiders.

A town's population usually had a distinct social structure. The merchants, the oldest and leading group, soon emerged as a separate class (the patriciate); they generally managed to gain control of the offices of *schepen* and burgomaster and thus controlled the town's finances. Sometimes the *homines novi,* a new class of up-and-coming merchants, tried to become part of the patriciate, as in Dordrecht and Utrecht. Beneath the patriciate a lower class formed, called the *gemeen* ("common," in the strict sense of the word), which embraced the artisans and organized into crafts such tradesmen as butchers, bakers, tailors, carpenters, masons, weavers, fullers, shearers, and coppersmiths. These crafts originally developed out of charitable organizations of people in the same profession and had to adhere to regulations laid down by the authorities. Gradually, however, they tried to obtain their independence, exercise influence in politics, cut themselves off from outsiders by means of compulsory membership, and introduce their own regulations regarding prices, working hours, quality of products, apprentices, journeymen, and masters. During the second half of the 13th century, class antagonism rose in the main industrial cities in Flanders. The political conflict between the count of Flanders, the

Class antagonism in Flanders

king of France, and the partriciate opened the way for the craftsmen to score a military victory in 1302. This led to the constitutional recognition of the crafts as autonomous organs with the right of considerable participation in the cities' administration. The achievements of the Flemish artisans inspired their colleagues in Brabant and Liège to revolt and raise similar demands; Flemish military incursions provoked the same reaction in Dordrecht and Utrecht. In Brabant, the concessions were only short-lived, but their effects were more durable in the other places, although never undisputed by the old elites.

In Flanders and in the bishopric of Liège, the towns rapidly attained such power that they constituted a threat to the territorial prince, a situation that often resulted in violent conflicts. In contrast to this, relations between the prince and the towns of Brabant were more harmonious; the political interests of the prince and the economic interests of the towns coincided for the most part during the 13th century, while John I, Duke of Brabant, sought expansion toward the Rhine valley, which offered protection for the growing trade that moved from Cologne overland through Brabant. Duke John II, however, left such formidable debts that Brabant merchants were arrested abroad, which made them claim control over the duke's finances during Duke John III's minority (1312–20). The fact that from 1248 to 1430 only two dynastic successions involved a direct adult male heir gave the cities (which had incurred massive debts) recurrent opportunities to intervene in the government and to impose their conditions on the successors in the form of public testaments called *joyeuse entrée* acts, which were delivered at all successions from 1312 until 1794. The acts, which also applied to Limburg, contained dozens of ad hoc regulations besides a few more general and abstract notions, such as the indivisibility of the territory, a nationality requirement for the officials, approval of the cities before embarking on a war, and the subjects' right of resistance in case of violation of any stipulation of the acts. In Holland the towns did not really develop until as late as the 13th century, when they were helped by the counts.

During this period, when foundations were being laid for the dominant role the towns would later play in the Low Countries, a decisive change also took place in the authority of the territorial prince. Originally he regarded his powers mainly as a means of increasing his income and of extending the area over which he could exercise power. He felt little duty toward his subjects or desire to further the welfare of the community as a whole. At best there were religious as well as material motives in his dealings with the churches and monasteries. There were no direct relations between the prince and all his subjects, for he was primarily lord of his vassals. The political, social, and economic developments discussed above, however, brought a change in this situation. In the first place, the prince's increasing independence meant that he himself began to behave like a king or sovereign lord. His authority was then referred to as *potestas publica* ("public authority"), and it was believed to be granted by God (*a Deo tradita*). The area over which he ruled was described as his *regnum* or *patria*. This implied not only the duty of a lord toward his vassals but also that of a prince (*princeps*) toward his subjects. This duty included as its first priority the maintenance of law and order (*defensio pacis*) by means of laws and their administration. He had further to protect the church (*defensio* or *advocatio ecclesiae*), while his involvement in land reclamation and in the building of dikes and with the development of the towns brought him into direct contact with the nonfeudal elements of the population, with whom his relations were no longer those of a lord toward his vassals but took on a more modern aspect—that of a sovereign toward his trusted subjects. He became, according to the 14th-century lawyer Philip of Leiden, the *procurator rei publicae* ("he who looks after the matters of the people"). Contact with his subjects was through the representatives of the *communitates* of the water boards and *heemraadschappen* and through the towns and nonurban communities, which were legally corporate bodies in dealings not only with outsiders but also with the prince. Sometimes the towns expressly placed themselves under the protection of the prince and declared themselves committed to loyalty to him. Such a town was Dordrecht, which, in a document dated 1266, expressed its loyalty and at the same time described the count of Holland as *dominus terrae* ("lord of the land"). These new notions point to a more modern conception of a state, to a growing awareness of territoriality, and to new possibilities of collaboration between prince and subjects.

Change in the prince's authority

CONSOLIDATION OF TERRITORIAL STATES (1384–1567)

Among the many territorial principalities of the Low Countries, Flanders, Brabant, Hainaut-Holland, and Gelderland (Guelders) in the mid-14th century had a dominating military and diplomatic position. Flanders had already arrested the course of French domination, and its feeling of territoriality was strengthened by this and by many minor wars between the principalities as well as by three major revolts of large segments of the population against the principality's count. This antagonism displayed some early expressions of Flemish nationalism against the count and the nobility, who were backed by France and were French-speaking. In Brabant, national feelings were similarly fostered by fears of foreign invasions in the 1330s. In many respects, Flanders was the real territorial leader during the late Middle Ages. Its population was by far the largest of the principalities, its economic development the strongest, and its institutions the most elaborate. The extraordinary size of the largest cities made it impossible to rule the county without their collaboration. Thus during the 13th century, the *scabini Flandriae*, uniting delegations from the governments of the main cities, intervened in various political matters of the principality, especially concerning economic policy. During the 14th century, the three largest cities, Brugge, Ghent, and Ypres, formed a nearly permanent consultation committee called the three members of Flanders on which was bestowed decisive powers in most political matters, including taxation, legislation, and justice; it wielded as well a strong influence in international relations. During the repeated periods of revolt or absence of the count, the three members automatically extended their functions to the overall exercise of power. This experience explains why in Flanders, in contrast to Brabant and Hainaut, a system of representation by three estates (clergy, nobility, and the burghers) did not develop spontaneously. The power of the cities proved so overwhelming that they did not have to share control with the clergy and the nobility. It was the duke of Burgundy who introduced assemblies of three estates from 1385 onward, as a means to contain the cities, just as he imposed the addition of a fourth member to the consultation committee, which provided rural representation. These moves, however, did not profoundly alter the balance of power, which remained intact until the prince expanded his territory during the 15th century.

The three members of Flanders

In the county of Holland, power relations were balanced between the count, the nobility, and the burghers; the clergy played almost no role, since there were few important abbeys. The cities were much smaller than those of Flanders; a group of the six largest cities (Dondrecht, Leiden, Haarlem, Amsterdam, Gouda, and Delft) wielded the greatest influence and power. From 1349 onward a deep cleavage among the Dutch nobility over the succession to the throne led to the formation of two parties, the Kabeljauwen (Cods) and the Hoeken (Hooks); most cities were also divided along these party lines. Feuds on a local basis took the shape of the party antagonisms, which during certain periods of crisis spread over the whole county and over neighbouring Zeeland and Utrecht as well. During the years after 1392, the periods from 1419 to 1427, 1440 to 1445, and again in the 1470s and '80s, there was a high degree of discord in which the prince and his high officials saw their prerogatives seriously challenged. The relatively small size of the cities, close links between noble and patrician families, a weak administrative organization, and dynastic rivalries for the throne contributed to the ongoing party strife until the end of the 15th century.

Gelderland was later in its development, partly because the powerful Duke William (ruled 1379–1402) of that principality had his own financial resources as a result of his

military activities in the service of the English and, later, French kings; under William's successors, however, the knights and the towns became more powerful and finally gained permanent representation as estates. In Utrecht, too, there was cooperation between the prince (the bishop) and the estates; and the clergy, particularly the collegiate churches of the town of Utrecht, played an important part: the Land Charter of Bishop Arnold in 1375 was inspired by the Joyeuse Entrée of Brabant. In the prince-bishopric of Liège, cooperation between prince and estates had to be won by violent conflicts between the towns and the bishop and, within the towns, between the patriciate and the crafts. It was mainly to these territorial estates that the princes had to turn for financial help, which was often voted to them only on limiting conditions.

Beginning of Burgundian infiltration

The Burgundians. In the second half of the 14th century, the dukes of Burgundy (princes of the French royal house of Valois) began to penetrate these territorial principalities in the Low Countries, whose feelings of territoriality made them regard the dukes of Burgundy with suspicion. The marriage in 1369 of Philip II the Bold of Burgundy to the heiress of the count of Flanders (Margaret) signified the beginning of this Burgundian infiltration, which was repeatedly furthered by marriages, wars, and such tricks of fate as inheritances.

Through his marriage Philip gained possession, after the death of his father-in-law in 1384, of the counties of Flanders, Artois, Rethel, Nevers, and the free county of Burgundy (Franche-Comté), the latter being within the Holy Roman Empire. He thus not only gained a large and powerful part of the Low Countries but was also able to extend his Burgundian property. Though it seemed at first that French power might again become the dominant force in the Low Countries, it soon became clear that the Burgundian dukes, while happy to continue taking part in French politics, were extremely independent and more interested in forging a single powerful empire out of the Low Countries and Burgundy. Duke John the Fearless succeeded to all his father's lands in 1404, while his younger brother Anthony was given Brabant, where the childless Duchess Joanna had named him as her successor, which was accepted by the estates. Anthony's branch of the Burgundians died out as early as 1430, so that Brabant fell to the other branch under Philip III the Good (ruled 1419–67), who also gained possession—through war, family relations, and purchase—of Hainaut-Holland, Namur, and Luxembourg. This Burgundian power structure was not a state but was founded on a personal union among the various principalities, each of which jealously guarded its own freedom and institutions. The Burgundian dukes did, however, attempt to set up central organizations to bridge the differences among the principalities and to keep the various regions under stricter control by appointing governors (stadtholders).

Regional courts and exchequers increasingly enforced the central government's control in administrative, political, and judicial fields. Some principalities, such as Brabant and Hainaut, claimed that their privileges disallowed any foreign interference in their territories; in Flanders and Holland, however, the dukes introduced officials from their Burgundian homeland. In the long term, this policy of bringing in foreign administrators raised serious resistance against the central government, especially because it tended to make French the only administrative language, while the majority of the population in the Low Countries was Dutch-speaking. To further central control, Duke Philip extended his court in order to incorporate regional nobilities, and in 1430 he created The Order of the Golden Fleece, to which he brought the highest nobles from his principalities. In addition, the judicial tasks of his Great Council were entrusted from 1435 to a special group of councillors who steadily increased the weight of the central jurisdiction over local and regional customs and privileges. The ambitions of the Burgundian dukes finally ran aground on the forced and overly hasty centralization and expansion of power carried out by Charles the Bold (ruled 1467–77), who was able, nevertheless, to annex Gelderland. Charles imposed increasingly high financial demands, which were put before the States-General—an assembly that united the delegates from the various states at meetings called by the duke and held at regular intervals; he tried to constitute a kingdom in the Low Countries with himself as regent, an endeavour that failed in 1473. Charles did manage, however, to elevate the central law court to the rank of the royal Parliament of Paris—an obvious defiance of the king of France's prerogatives. After his defeat and death in battle to French-supported forces, a movement for regional and local rights arose and won a series of privileges from his daughter Mary (ruled 1477–82) that halted the previous centralization movement. Moreover, the duchy of Burgundy itself was taken over by the French crown, so that the Burgundian union, as it was reformed by the States-General from 1477, became a union without Burgundy. The pressure of French incursions brought the members of the States-General into closer collaboration. While ensuring their loyalty to the Burgundian dynasty and organizing a defense against France, they obtained the first written constitution for the whole of the principalities in the Low Countries. It recognized extensive rights to the States-General, such as control over the waging of war, currency, taxation, and tolls; furthermore, it prescribed the use of the legal language to be used in the courts. This text remained for centuries a point of reference for the rights of the subjects, granting to individuals the right of resistance in cases where tenets of the document were seen to be violated.

Resistance to foreign administration

The Habsburgs. After Mary's position had become more firmly established by her marriage to Maximilian of Habsburg (the son and future successor to the Holy Roman emperor), the States-General, because of its internal particularism, proved unable to provide a lasting administration. Gradually, a restoration took place, at first under the regency of Maximilian after Mary's death in 1482. Maximilian, however, lacked the political skills to deal with the various social forces in the Low Countries. His political strategy was aimed simply at a thorough recovery of the territorial and institutional losses since 1477, but his policy of high taxation, debasement, warfare, and violation of privileges, during a period of deep general economic crisis, provoked opposition and revolt, first in Flanders but also later in Holland, Brabant, and Utrecht. His answer was, as it had been in the past, the brutal use of military force, which plunged these regions into 10 years of devastating internal war. When his and Mary's son Philip I the Handsome (ruled 1493–1506) took over the government, he smoothly resumed the centralization process by refounding the central law court (then known as the Great Council of Malines) and set up within the duke's council permanent commissions to discuss important political and financial questions.

Centralization

The fate of the Low Countries was already closely bound up with that of Austria by virtue of the Habsburg marriage; in 1504, this situation was intensified when Philip and his wife, Joan, inherited the Spanish crown. From then on, the Low Countries were merely a part of a greater whole, and their fate was principally decided by the struggle of this Spanish-Austrian empire for European hegemony. They repeatedly had to make sacrifices for the many wars waged against France, particularly under Emperor Charles V, who in 1519 had added the German imperial crown to his many possessions. The emperor, who was almost always out of the country, placed the Low Countries under the rule of governors-general—first his aunt Margaret and later his sister Mary, who retained control and worked toward further centralization even when he was in the country.

The States-General could do little more than offer passive resistance, principally through financial manipulations. As a meeting place for the regional deputies, the States-General did have a certain influence and, by its opposition, strengthened a sort of negative feeling of unity. That the emperor himself also saw the Low Countries as a unit can be seen in his incorporation of the territories in the north and east, including Groningen and Friesland (1522–28). A remarkable step was the imposition of temporal power over the bishop of Utrecht (1528); full power was also acquired over the duchy of Gelderland in 1543. Consequently, Charles took measures to separate his so-called

Seventeen Provinces of the Low Countries from the empire as "Burgundian Kreis" (1548) and in the Pragmatic Sanction (1549), which stated that succession would be regulated in identical fashion in all the regions of the Low Countries that he had included in his empire. The Low Countries were thus prevented from being split up.

The collateral councils

In the meantime, the process of centralization had reached a decisive phase with the foundation of the collateral councils (1531), which were separate from the Great Council. They were the Council of Finance, which had in effect already existed for some time; the Council of State, in which members of the high nobility could advise the governess; and the Secret Council, in which permanent officials dealt with everyday administration and composed ordinances without having to wait for advice. All the government organs, except for the central law court in Malines, were in Brussels, which from that time became the capital of the Low Countries. The States-General and territorial states were still a stumbling block in the acquisition of financial resources, so that Charles V was never able to provide himself with a standing army.

Under Charles's son Philip II, who in 1555–56 succeeded as king of Spain and prince of the Netherlands, the policy of centralization was continued. It culminated in the introduction of a new ecclesiastical hierarchy. The Low Countries, which formerly had been, ecclesiastically speaking, merely an extension of the archbishoprics of Cologne and Reims, became by virtue of a papal bull of 1559 a directly governed region of the church under three archbishops and 15 bishops. There was fierce resistance to this by the high nobles, who saw the high positions in the church slip from their grasp; by the abbots, who feared the incorporation of their monasteries for the maintenance of new bishoprics; and by a number of territories, which were afraid of greater inquisitorial activities under new bishops. The high nobles, who were often excluded from the activities of the Secret Council, led the resistance under the capable Prince William of Orange (1533–84) and the popular Count van Egmond. Resistance increased when the Burgundian Antoine Perrenot de Granvelle (bishop of Arras and virtually prime minister under the Netherlands' governor Margaret of Parma) was appointed archbishop of Malines and then cardinal of Malines and primate of the Netherlands. The government gave way, and Granvelle was forced to leave the country; yet the high nobles themselves hardly knew how to run affairs. The initiative was thus transferred to the low nobility, who in 1565 united by bond of oath in the so-called Compromise and in 1566 presented to the governor a petition requesting the relaxation of edicts and ordinances against the Calvinists and other Protestants. At the same time, they adopted the name Geuzen (*gueux*, "beggars"), originally a term of abuse.

As the resistance grew stronger, the Protestants became more confident, and fanatics started a violent campaign against churches—the "breaking of the images" (August 1566)—against which the governor took powerful measures but only in the first few months of 1567 managed to restore peace. King Philip II, however, whose information concerning these events was somewhat out of date because of slow communications and who was uneasy because of the "breaking of the images," decided to take stern measures. He sent his trusted general, Fernando Álvarez de Toledo, Duke de Alba, to the Netherlands. Alba's strict regime precipitated a revolt that eventually led to the partition of the Netherlands.

Economic structure. The economic structure of the Low Countries underwent far-reaching changes in the 14th–16th centuries. The growth in population, which in western Europe had begun in the 10th century, ceased with relative suddenness after 1300. The European famine of 1315–17 had dramatic effects in the cities; in Ypres 10 percent of the population that died and had to be picked up off the streets were buried by public means. Social tensions, insurrections, and internal wars also cost numerous lives during the 14th century, especially in the rebellious cities of Flanders and Liège. Many Flemish weavers and fullers fled to England, helping there to build up an English cloth industry, which came to compete with that of the Low Countries. The effects of recurrent plagues from 1349 onward, raging once in each decade until the early 15th century, must have been devastating as well. The global population was seriously diminished, but in the cities, where overpopulation had been developing since the late 13th century, the losses were replaced by rural surpluses, leaving somewhat easier living conditions in the cities for the survivors. Generally, the standard of living in the Low Countries improved in the second half of the 14th century.

The famine of 1315–17

In the 14th and 15th centuries, Brugge became the main international market of northwestern Europe. Colonies of foreign merchants installed their offices: Italians, Catalans and other Iberians, French and English, and above all the German Hanse, for whom Brugge was the most important *Kontor* (office). Southern and northern Europe met at Brugge, and their exchange networks were linked there. An intensive movement of bills of exchange converged there and helped to balance the region's export deficit with the Mediterranean states. The densely populated Low Countries evidently formed an important market for imported goods such as wine, Mediterranean fruits, and Eastern spices and silk; grain was also an important import. The relatively affluent population could afford expensive goods, but it also produced labour-intensive, high-quality objects, including fashionable clothing and various works of art and applied art, such as paintings, jewelry, woodcuts, and pottery. The trade network helped to spread these works throughout Europe.

On the other hand, the loss of some one-third of the European population, mostly to plague, had severely reduced the export markets, causing competition to intensify. The Brabantine cities had developed their own textile industry, competing internationally. Since the crafts held a firm grasp on wages and regulations from 1302 onward in Flanders, they raised the production costs higher than those in Brabant and much higher than those in England and Holland. The Flemish had to become reoriented toward ever more sophisticated methods and higher-quality products in that state's large, old cities. Improvements in linen and tapestry weaving exemplified new innovations. Entrepreneurs now shifted their production toward villages, unrestricted by craft regulations, where wages were lower and quality controls weaker. These rural manufacturers used cheaper wools from local areas and (from the 15th century) Spain, and they produced lighter, less refined cloth, which found a wide middle-class market.

Shift to rural cloth production

Holland became the site of marked economic change during the second half of the 14th century. The drainage of the peat bogs had made them gradually less suitable for the cultivation of bread grains, and cattle raising had become the major means of subsistence. That occupation's minimal labour requirements drove a large proportion of the rural population into the cities, where some found jobs in crafts and seafaring. Dairy products continued to be exported to the larger cities in Flanders and Brabant, but grain now had to be imported, largely from Artois and, increasingly from the 15th century, the Baltic region. The Dutch also learned the technique of preserving herring common to that region; the shift of the herring shoals to the North Sea had helped the Dutch take the lead in this trade. In addition, they developed a shipbuilding industry for which they again needed the import of wood, iron, tar, and pitch from the Flemish Hanse area. They succeeded in building a competitive fleet that could offer transportation at a lower cost than that of the Hanse. The Dutch then were able to penetrate the Baltic Sea region, not only to buy sorely needed raw materials but increasingly also to sell and transport. None of the Dutch products were exclusive to them, the goods being often of even lesser quality than those offered by their competitors; their price, however, was always more advantageous, thanks to their excellent cargo facilities. Apart from the herring industry, the Dutch competed in cloth and, even more effectively, in beer: their quality of barley, clear water, and hops enabled them to brew a product of distinctive character for which demand grew. The cities of Delft, Gouda, and Haarlem became major beer-exporting centres, shipping to the southern Netherlands and to the Baltic regions as

well. The Dutch also exported some bulk salt. The production of salt derived from peat having proved to be of insufficient quantity and quality for salting fish, the Dutch imported raw maritime salt from the French Atlantic coasts and refined it in their peat-fueled ovens. This was suitable for the fish industry and could also be exported to the Baltic area, the traditional production from Lüneburg, Ger., having slowed down.

While Holland thus laid the basis for its remarkable 17th-century prosperity, the southern Netherlands showed a shift of commercial leadership from Brugge to Antwerp.

Commercial ascendancy of Antwerp

During the 15th century, Antwerp developed strongly thanks to its free entrepreneurial climate and its two annual fairs, which were combined with two more in the nearby Schelde harbour city of Bergen-op-Zoom. At that time, the fairs still functioned as a corollary to the Brugge market, but they nevertheless attracted merchants from central and southern Germany. While Brugge lived through a deep political crisis in the 1480s, Antwerp attracted the new colonial trade, especially that of the Portuguese, and the important Augsburg, Frankfurt, and Nürnberg merchant and banking houses. They imported new textiles in return for copper, silver, and other metal products. The Italians soon left Brugge for Antwerp, belatedly followed by the increasingly regressing German Hanse. The fast expansion of the Antwerp market was supported by excellent relations with the monarchy which, in turn, could finance its hegemonistic policy through loans from Antwerp merchants. A special innovation was financial techniques developed at the Antwerp *beurs* (stock exchange), created in 1531. While Brugge remained a clearinghouse for international commercial debts, where exchange rates for bills were determined, the Antwerp exchange specialized in transferable, usually discounted, public debts.

Generally speaking, a commercial capitalism was developing that stimulated the entire economy of the Netherlands. Competition in the cloth industry was growing especially strong between urban and expanding rural manufacturers. The towns battled these rural clothmakers in vain, though in 1531 Holland issued an edict to restrict them throughout the county but with little success. Moreover, Holland itself had begun to play an increasingly important economic role; new industries were developing, but fishing, shipping, and trade remained its main means of support apart from arable farming and cattle breeding. Dordrecht, one of the major commercial centres of the Low Countries, was rivaled by Rotterdam and Gorinchem and, by the 16th century, was outstripped by Amsterdam, which cornered an increasing proportion of Baltic trade, as evidenced from the lists of the toll in the Sound (between Sweden and Denmark).

The regions along the Meuse and IJssel also maintained their commercial activity. In the bishopric of Liège there was even a metal industry with blast furnaces, paid for by capital raised by traders. Coal mining in the area between the Meuse and the Sambre was also organized according to modern capitalist methods.

The cultivation of commercially exploitable crops also developed in country areas—hemp for rope making, hops and barley for brewing, flax for the manufacture of linen.

Decline of grain farming

Yet all this was at the expense of wheat farming. Grain had to be imported in increasingly large quantities, and, whenever grain imports fell off, the people, particularly the lower classes, went hungry. The economic apparatus had become more versatile and brought greater prosperity, but at the same time, precisely because of this specialization, it had become more vulnerable. The distribution of prosperity was variable; the great mass of the people in the towns suffered the consequences and bore the main burden of the rise in prices occasioned by inflation.

Population growth. It is impossible to estimate the population of the Low Countries before about 1470, and even for that date complete data are not available. Figures are often not available for all areas at a given date in the Middle Ages. An acceptable figure for the Low Countries in the late 15th century might be about 2,400,000 inhabitants. Flanders was by far the most populated and most densely inhabited principality, with about 750,000 people and a density of 30 persons per square mile (77 per square kilometre). It was followed by Brabant with 413,000 people and about 15 persons per square mile (40 per square kilometre) and Holland with 268,000 people and 25 per square mile (66 per square kilometre), although the latter data are from the year 1514. The other principalities counted far fewer inhabitants—for example, 209,000 in Hainaut, 180,000 in Artois, and 140,000 in Gelderland, Liège, and Luxembourg.

After 1470 the population must have declined generally, owing to wars, bad harvests, and epidemics. From 1490 a new period of growth especially favoured Brabant and Holland. About 1570 the duchy of Brabant counted about 500,000 inhabitants, which was still less than the more densely populated Flanders. One-quarter of the Flemish peasants farmed plots of only 5 to 12 acres (2 to 5 hectares), and nearly half had even less than 5 acres. The level of urbanization was growing extremely fast in the Low Countries, especially in the largest principalities. In 1470, 36 percent of Flanders' population and 31 percent of Brabant's were city dwellers, while in Holland the proportion reached 45 percent in 1514. It should be noted, however, that the cities of Holland were still relatively small, the largest being Leiden with 14,000. In the southern Low Countries in the mid-14th century, Ghent and Brugge attained populations of 64,000 and 46,000, respectively, while Brussels counted 33,000 in 1482 and Malines (Mechelen) grew to 25,000 around 1540. Antwerp showed spectacular growth, from 15,000 in 1437 to nearly 40,000 around 1500, and more than 100,000 in 1560, its peak for this period.

Culture. The Low Countries played an important part in the artistic, scientific, and religious life of Europe. In the late Middle Ages, when prosperity was increasing and the princely houses, particularly that of the Burgundians, as well as the middle classes in the towns, were encouraging progress, the Low Countries began to make independent contributions to cultural life.

Artistic, scientific, and religious contributions

The most original of these were in the field of visual and applied arts. From the late 14th century the Low Countries produced sculptors like Claus Sluter, whose most famous works are the funerary monuments for the duke of Burgundy, Philip the Bold, and his wife at Dijon, Fr., and painters like Melchior Broederlam who also served the duke. In the 15th century, however, the cities in the southern Low Countries became the core of cultural activity, because the duke's court resided mostly in that region and because the local bourgeoisie, clergy, and noblemen profited from the Burgundian prosperity and could invest in works of art, which allowed them to share somewhat in the splendour of the court. The main centres were Ghent (Jan and Hubert van Eyck and Hugo van der Goes), Louvain (Dirck Bouts), Brussels (Rogier van der Weyden), and Brugge (Hans Memling, and Gerard David). Each of these masters stands for a school of followers. Miniature painting similarly was a most flourishing activity, reaching its first height in the northern Low Countries (Utrecht) about 1400, but rising also in the south through the 15th century. Tapestry weavers in Arras attained a unique quality, which was imitated in Tournai, Brussels, Oudenaarde, Brugge, Ghent, and elsewhere. Brabant was famous for its woodcut triptychs made in Louvain and Antwerp (then in Brabant). Brugge for its lace, jewelry, and fashionable clothing. All these extraordinary works were exported through Europe, where they won the appreciation of princes, aristocrats, and rich burghers.

In the southern Low Countries, mysticism reached its zenith in the 13th and 14th centuries in the poems of Sister Hadewych and the prose of the prior Joannes Ruusbroec (Jan van Ruysbroeck). Ruusbroec's writings were founded on a considerable knowledge of theology; it is not certain whether his work had a direct influence on the founding of the religious movement along the IJssel—the modern devotion (*devotio moderna*)—or whether mysticism merely created the intellectual climate in which the new school of thought could develop. The modern devotion was inspired by Geert Grote (Gerard Groote, 1340–84) of Deventer, who preached, as did many others, the ascetic and pious life and resistance to the secularization of the church. His

message was well received, and many lay people found in themselves a desire to live in communities devoted to the service of God; these were the Brethren and Sisters of the Common Life, who later organized themselves into the Windesheim monasteries and convents, which followed Augustinian rules. Their communities were extremely important for both education and religion; they were industrious copyists and brought a simple piety to the lower classes. Their work, like that of the mendicant orders, was a typical product of life in the towns. The movement reached its peak in Thomas à Kempis, from Zwolle, whose *Imitatio Christi* (*The Imitation of Christ*) became quite widely read, not least in Dutch versions.

Development of Dutch humanism

Within the modern devotion, where great importance was attached to good teaching, Dutch humanism was able to develop freely. Of importance was the foundation in 1425 of the University of Louvain; it received in 1517 the Collegium Trilingue where Latin, Greek, and Hebrew were taught. The greatest Dutch humanist was Erasmus (1469–1536), whose fame spread throughout the world and who had been taught in the schools of the Brethren of the Common Life. He drew his inspiration, as did many other humanists, from antiquity and was famed for his pure Latin. He was in touch with the greatest minds of his time, visited England (Cambridge) and Italy, and worked for some years in Basel and in Freiburg. Erasmus' greatest achievement was to turn the science of theology, which had degenerated into meaningless Neoscholastic disputes, back to the study of sources by philological criticism and by publishing a new edition of the Greek New Testament. Although he vociferously criticized the church and even the princes, he avoided out of conviction a break with the church and pleaded for religious tolerance.

The humanists were principally intellectuals, however, expressing themselves in literary and scientific treatises and having little impact on the broad masses of the people. Many of them, like Erasmus, desired no break with the church and did not accept that break when it became a fact by the appearance of Martin Luther. Instead, they wanted reformation within the church. It was otherwise for the reforming movements that brought turmoil to the Low Countries in the first half of the 16th century. Even Lutheranism had few followers, despite its early appearance (Luther's dogmas were condemned by the University of Louvain as early as 1520). There was a Lutheran community in Antwerp; but otherwise, support was limited to individual priests and intellectuals. It was precisely over the question of the Eucharist that the Sacramentarians differed with Luther; they denied the consubstantiation of Christ in the Eucharist, although their stance enjoyed little support from the people.

The Anabaptists

An uproar was caused by the Anabaptists (so called because they rejected the baptism of infants and therefore had themselves rebaptized as adults), who refused to swear the oath of allegiance to the prince or to serve in the armed forces or in government per se and who believed in a *lumen internum* ("inner light"). This baptist movement won great popularity in the Low Countries after 1530; from the very beginning there were two branches—the social revolutionaries and the "quiet baptists." The first of these was characterized by a lively enthusiasm and a willingness, once the external trappings of the church had been rejected, to organize itself into communities, which soon formed close ties with each other. Prophesies by the social-revolutionary branch of the imminent coming of Christ and of a New Jerusalem fascinated the masses, while their fanaticism and readiness to sacrifice themselves made a deep impression on a population suffering poverty and misery. In 1534 a section of the Anabaptists moved to Münster in Westphalia, where they supposed that the New Jerusalem would be built; and in 1535 an abortive attempt was made to take over the town hall in Amsterdam. After a long siege, the bishop of Münster succeeded in reconquering his town, and the Anabaptists suffered terrible vengeance. Only the "quiet baptists" were able to continue, under the leadership of the Frisian pastor Menno Simons (these Mennonites are even today strongly represented in the provinces of Groningen, Friesland, and Noord-Holland).

The future of the movement for reformation in the Netherlands was assured, however, not by the biblical humanists nor by the Anabaptists but by a movement less intellectual than the first and more realistic than the second—Calvinism.

The theology of John Calvin (1509–64) was radical, strict, logical, and consistent. Its central theme was the absolute might and greatness of God, which made man a sinful creature of no significance who hoped merely to win God's grace by honouring him in daily hard work. Calvinism found its way to the Netherlands by way of France, though there may have been some direct influence from Geneva, Calvin's town. Calvinist writings were known in Antwerp as early as 1545, while the first translation into Dutch of his *Christianae religionis institutio* is dated 1560, which was also the year in which support for him spread in the Netherlands, largely because the Calvinists preached their creed in public and held open-air services.

Calvinist teaching appealed not only to the lower classes but also to the intellectual and middle classes because of its glorification of work, its discipline, its organization into communities, and its communal singing of the psalms. The government saw the movement as a threat to its plans of unity and centralization, which were supported by the Roman Catholic church, and it took stern measures against Calvinism. Calvinists forcibly removed their coreligionists from prisons and occasionally even attacked monasteries. This group's rejection of icons, paintings, statues, and valuables in churches sometimes led them to remove them and hand them over to the town magistrates. But this idealism became corrupted, and the leaders were unable to retain control of the movement.

It should be noted that Calvinism and other forms of protestantism had spread rapidly among the urban middle classes after 1550 in defiance of rule by Roman Catholic Spain. From 1551 to 1565 the number of persons persecuted in the county of Flanders for heresy rose from 187 to 1322. In Antwerp, the largest city of the Low Countries, with some 100,000 inhabitants around 1565, one-third of the population openly declared for Calvinist, Lutheran, or other Protestant denominations; another third declared itself to be Roman Catholic, while the last third was undeclared. Similar proportions are assumed to have existed in the other main cities, while the rural textile area in southwest Flanders counted large numbers of Anabaptists and Calvinists. It was among these Calvinists that an iconoclast movement to desecrate churches and destroy church images began in August 1566, spreading within a week to more than 150 villages and towns in the southern principalities.

Persecution for heresy

The movement was weakened, however, when it lost the support of the nobility, and especially the lower nobility, which had been sympathetic to Calvinism. The government now besieged and captured the Calvinist centre, Valenciennes, by defeating a Calvinist army at Oosterweel, near Antwerp. The result was a great exodus of Calvinists. Nevertheless, Calvin's ideas had penetrated deeply, and his supporters, who had emigrated to England, East Friesland, and the Pfalz of Germany, were able to maintain their unity and support their coreligionists in the Low Countries. The Calvinists were to become the driving force behind the revolt against Spanish rule.

THE REVOLT AND THE FORMATION OF THE REPUBLIC (1567–79)

The forcible measures taken by the central government against the "breaking of the images" were followed by a brief period of peace. The Duke de Alba (who became governor after the departure of Margaret of Parma on the last day of 1567), introduced stern measures at the express command of the king. These provoked a resistance to the government (often referred to as the "revolt") that triggered the Eighty Years' War (1568–1648). The iconoclast movement itself, which had raged across the country like a storm, had already shown a deep-rooted resistance that had many causes and was brought to a head by Alba's measures.

Causes of the revolt. It is impossible to label any of the causes of the revolt as the decisive factor. An important

one, however, was a religious motive. Criticism of the structure of the church and the riches and worldly way of life of its prelates and the accompanying desire for reform had always been strong in the Low Countries; and Protestantism, through the teaching of Luther, the Sacramentarians, the Anabaptists, and, above all, the Calvinists, had gained a firm foothold. The measures taken against the resistance—harsh edicts, prison sentences, torture, and death sentences, carried out with great cruelty—fanned the flames all the more and among all classes. Social and economic causes, however, also lay behind the resistance, especially among the lower classes—the wars with France, the epidemics, poor harvests, hard winters, floods, and a frightening inflation and consequent rise in prices all combined to cause despair and misery among the masses and made them susceptible to radical ideas. At the same time, in the upper classes of the nobility and the urban patriciate, there was a sharply felt reaction against the absolutist policy of the king, who lived far away in Spain and yet whose wish was law in the Low Countries. Towns felt their privileges being threatened, and the nobles found their independent status being undermined by the ever-increasing activities of the secret council. The mercenaries, who were often stationed in a town as a garrison and acted as occupying forces, also aroused hostility. The fact that the resistance did not present a united front may be ascribed to the particularism among the territories—Holland, with its commercial interests, could hardly be expected to be enthusiastic on behalf of typically agrarian feudal provinces such as Hainaut or Artois.

Harsh reaction to the resistance

The main cleavage in the opposition groups, however, was social as well as religious: the high nobility and richest merchants mostly remained Roman Catholic, as did the peasants and the urban poor living on the church's alms. The lower nobility, the urban middle classes, and the rural textile workers massively opted for one or the other form of religious, political, and social protest against the prevailing order. This fundamentally explains the earlier accommodation of the rural provinces of Artois, Hainaut, Namur, and Luxembourg under Spanish rule, while opposition was fierce in the urbanized provinces of Flanders, Brabant, Holland, and Zeeland. The rural northeast also remained predominantly Roman Catholic until well into the 17th century.

It is clear, however, that the terror organized by Alba burst like a bombshell in this political, social, economic, and religious climate. William, the prince of Orange, with sharp political insight, had decided not to wait for Alba's arrival; he had managed to escape in time to his birthplace in Nassau-Dillenburg, leaving behind all his possessions, which were promptly confiscated. His son, Philip William, was taken prisoner to Spain. Alba sent his troops to the principal towns and set up the Council of Troubles (or Council of Blood), which imposed severe penalties, often including the death sentence or confiscation of property, sparing nothing and nobody, not even the most powerful—the counts of Egmond and Hoorne were publicly beheaded in Brussels in June 1568.

Alba also rushed through installation of the new ecclesiastical hierarchy, which had not been completed. Furthermore, he attempted to make the central government independent of the provincial states by means of new taxes on property, on the sale of land or building, and on the sale of goods. This met with violent resistance because the taxes were to be general and permanent, so that the separate states would no longer have the means to make conditions for the furnishing of taxes (although they themselves already levied taxes on the sale of goods) and, more important, because a permanent tax system would make the king independent of his subjects. The taxes were the final link in the policy of absolutism and centralization, which would lead to a unified state controlled by a prince with unlimited power.

New taxes

The severity with which Alba ruled was not able to prevent the immediate appearance of resistance. The Geuzen (guerrilla forces) conducted pillaging raids in the country and piracy at sea, for which they had "authority" in the form of letters of marque issued by William of Orange in his capacity as sovereign of the principality of Orange. Attacks took place as early as 1568. A small force led by Louis of Nassau, William's brother, enjoyed a modest victory over the Spaniards at Heiligerlee (in the province of Groningen), considered the beginning of the Eighty Years' War; but shortly afterward Louis was defeated near Jengum in East Friesland. A greater setback, however, was the complete failure, due to lack of funds, of a campaign led by William himself in Brabant. During the sombre years of 1568–72 the "Wilhelmus" was written—a song of faith, hope, and trust that was to become the Dutch national anthem. Other songs written by the Geuzen lifted the spirits of the people during this period and in later years.

During these years, William negotiated for help from Germany, England, and, above all, the French Huguenots. A large-scale attack was planned for the summer of 1572. Before William could carry it out, the Geuzen seized the port of Brielle (April 1, 1572), west of Rotterdam. This was a move of considerable strategic importance because the port controlled the mouth of both the Meuse and the Waal, and the prince immediately supported the movement. The Geuzen then took Flushing, Veere, and Enkhuizen, so that William had useful bases in Holland and Zeeland. The help that the Geuzen received from the Calvinists in these towns was striking—the Calvinists, a radical minority, were again and again able to force the more conservative town magistrates to either cooperate or resign. Oudewater, Gouda, Dordrecht, Leiden, Hoorn, and Haarlem followed, only Amsterdam keeping the Geuzen out. The purposeful activities of the Calvinists also led to their gaining churches, often the principal church of a town, for their services; they closed monasteries, and Roman Catholic services were soon forbidden.

The revolt was at first successful only in Holland because of its unique position. As a commercially oriented province, it had been more inclined to look after its own interests than to cooperate with other provinces. Trade had been seriously threatened by the Geuzen but was now free again. Moreover, the province lay in a strategically favourable position—difficult to reach from the central government in Brussels and almost inaccessible to the Spanish armies by virtue of its many rivers, lakes, drains, and bogs.

To give the revolt a legal basis, the fiction was invented that it had been a revolt not against the king but against his evil advisers, particularly the governor. By their own authority, in July 1572 the states of Holland gathered in Dordrecht, where William of Orange was proclaimed stadtholder of Holland and Zeeland. The prince himself went to Holland and, realizing that the Calvinists had been the driving force behind the revolt, became a member of the Calvinist church. But he repeatedly expressly avowed his ideal of the United Netherlands, in which there would be room for Catholics and Calvinists alike.

Legal basis of the revolt

Alba, disappointed by his failure to push through the tax reforms and about to return to Spain, learned of the fall of Brielle and decided to stay and start a counteroffensive. The south was immediately brought under control with the occupation and plundering of Malines; then Zutphen and Naarden in the north were taken and likewise plundered. This provoked stronger resistance, and Haarlem was retaken only after a long siege, which not only demoralized and decimated Alba's troops but also strengthened the other towns in their decision to offer resistance (1573). Thus, the Spaniards were unable to take Alkmaar, their fleet suffered a heavy defeat in the Zuiderzee, and a long siege of Leiden was relieved by flooding the surrounding country (1574). (As a reward, the town later was given a university, where Calvinistic theology was to be a principal subject for study.) Spanish troops never again forced their way into Holland—a heavy blow for the most powerful monarchy in the world.

Unification after Alba. Alba left on Dec. 18, 1573, and his successor, Don Luis de Requesens, was unable to prevent further secessions in the north. Even the south, which had been loyal to Spain until then but where active Calvinist movements existed (especially in Ghent), became amenable to William's ambition for a united resistance to the Spanish regime. Problems involved were consider-

able, with one of the most contentious points being the question of religion—the more radical north demanded the total abolition of Roman Catholicism in Holland and Zeeland and the acceptance of Calvinism by the southern provinces. William, however, was diplomatic enough not to make this demand. It was finally agreed that the States-General would deal with the question later, and until such time the Calvinists would be masters only of Holland and Zeeland. A new governor (Requesens died in March 1576) was to be accepted only if he approved the pacification and sent away the foreign troops, who, because they had received no pay, were beginning to mutiny and plunder and were becoming an increasing nuisance. Another condition of his acceptance was that he govern with native officials and in close consultation with the states. On this basis, delegates from all the provinces came to an agreement, and on Nov. 8, 1576, they signed the Pacification of Ghent. Their sense of unity was further strengthened by the news that on November 4 Antwerp had been invaded by mutinying Spanish troops, who had slaughtered 7,000 citizens in a massacre that came to be known as the "Spanish Fury."

The Pacification of Ghent

William's idealism, his desire for unity, and his tolerant ideas had apparently triumphed. Unity of thought, however, did not last long; and within three years signs of a split appeared between the urbanized and rural provinces (which later became a permanent split). It was immediately obvious that within the United Netherlands there were opposing powers of radicalism and reaction. For various reasons, they could not maintain equilibrium; the reactionaries tried to force their ideas on the country with the help of the new governor, Don Juan de Austria, a half-brother of the king, and the Calvinists continued their radical program to make theirs the official and only religion. In Ghent, Malines, and Brussels, radical Calvinists took over the city governments, while in Antwerp, the magistrate displayed a conspicuous tolerance toward the Protestants.

Many intractable factors underlay these conflicts—deep-running religious differences between regions; a deeply rooted particularism that hindered cooperation; and structural and economic differences between Holland and Zeeland on the one hand (commerce and industry) and Hainaut and Artois on the other (agrarian economy and feudal possession of land). It is impossible to point to any one factor that was of paramount importance. William did his utmost to save the pacification, and he found support for his ideas of tolerance among the rich burghers; yet he was unable to bridge the differences between rich and poor, Roman Catholics and Calvinists. Moreover, Don Juan died in 1578 and was succeeded by Alessandro Farnese (duke of Parma and son of the earlier governess Margaret), who was conspicuous for his military and diplomatic gifts, which made him a worthy opponent for William and who may be credited with removing Calvinist control in the south and with the return of loyalty to the king in the southern provinces.

Notable, too, was the appearance in the north and south of movements toward "closer unions," which within the whole of the United Netherlands were to bring about greater community of interests between certain provinces.

The Union of Arras

On Jan. 6, 1579, the Union of Arras (Artois) was formed in the south among Artois, Hainaut, and the town of Douay, based on the Pacification of Ghent but retaining the Roman Catholic religion, loyalty to the king, and the privileges of the estates. As a reaction to the accommodation of Artois and Hainaut, the Union of Utrecht was declared, at first including northern principalities but later drawing signees from the south. This unity was eventually broken by military force. (C.v.d.K./W.B.)

History of The Netherlands (1579 to the present)

The early history of the Low Countries, including the area now occupied by the Kingdom of The Netherlands, has been treated in the preceding section. Treated in the following section is the history of the modern state of The Netherlands, beginning with its establishment in 1579.

THE UNION OF UTRECHT

On Jan. 23, 1579, the agreement at Utrecht was concluded, forming a "closer union" within the larger union of the Low Countries led by the States-General sitting in Brussels. Included in the Union were the provinces and cities committed to carrying on resistance to Spanish rule: Holland, Zeeland, Utrecht, Gelderland (Guelders), and Zutphen (a part of Overijssel) as the first signatories, followed in the next year by the whole of Overijssel, most of Friesland, and Groningen, all in the north; and in the south by the cities of Antwerp and Breda in Brabant, and Ghent, Brugge, and Ypres in Flanders. Designed to establish a league for conduct of the war of independence and ultimately to strengthen the central government in Brussels, the Union of Utrecht became in fact the foundation of a separate state and a distinct nation in the northern Netherlands. The new state was named the United Provinces of the Netherlands, or, more briefly, the "Dutch Republic," and was known in the international community as the "States-General." The people of the northern Netherlands began to be distinguished from the inhabitants of the south (to whom the name of Flemings continued to cling) by the appellation Hollanders (French: Hollandais; Italian: Olandese; German: Holländer; and so forth), after their principal province. The English, however, came to apply exclusively to the Hollanders the term Dutch, which previously they had applied to all German speakers (from German Deutsch, Dutch Duits). The name Netherlanders, which remained in use in the Low Countries for the inhabitants of the United Provinces specifically and for all those, north or south, who spoke Dutch (Nederlands), passed out of currency in most foreign countries or came to be restricted to the northerners. The transformation had a price: the erosion of the bond of historical identity between northerners and southerners, Dutchmen and Belgians as they would be called in the 19th and 20th centuries.

The "Dutch Republic"

The treaty that formed the basis of the new northern union established a military league to resist the Spaniards but on a "perpetual" basis, and it provided for closer political arrangements among the provinces than those of "allies" in the ordinary sense. The provinces united "for all time as if they were a single province"; each remained sovereign in its internal affairs, but all acted as a body in foreign policy. Decisions on war and peace and on taxation could be made only unanimously. The union did not throw off the formal sovereignty of the king of Spain, but it confirmed the effective powers of the provincial stadtholders (formally the "lieutenants," or governors, of the king) as their political leaders (there was no "stadtholder of the United Provinces," as foreigners often assumed). The union moved away from the religious settlement embodied in the Pacification of Ghent of two years before (see above) and toward a predominance of the Calvinists and their monopoly of public practice of religion in the key provinces of Holland and Zeeland.

The immediate political significance of the union was that it dovetailed with the Union of Arras, concluded earlier in the month, which began the reconciliation of the southerners with King Philip II of Spain. The two "unions," parallel but opposite, thus undermined the policy of Prince William of Orange of collaboration between Roman Catholics and Calvinists throughout the Low Countries in resistance to the Spanish domination, which required mutual toleration among the religions. But it took some time before the "general union," with its base in the States-General at Brussels, fell apart irrevocably. For another half decade the prince struggled to keep intact the broader union and at the same time to assure its military and political support from abroad. Although Archduke Matthias of Habsburg, named governor-general by the States-General in 1577 after the deposition of Don Juan, remained the formal head of state until 1581, the prince continued to exercise his leadership. That the prince was the head and heart of the rebellion was recognized by Philip II in 1580 when he put him under the ban of outlawry. William's *Apology* in defense of his conduct was followed in 1581 by the Act of Abjuration (Akte van Afzwering) by which the States-General declared that

Declaration of independence

Philip had forfeited his sovereignty over the provinces by his persistent tyranny. This was a declaration of independence for the whole of the Low Countries, but the military and political events of the next decade limited its permanent effect to the northern provinces under the "closer union" of Utrecht.

FOREIGN INTERVENTION

Yet independence did not become William's objective even after the proclamation of the Act of Abjuration. Archduke Matthias returned home in 1581 after William turned to the duke d'Anjou, who agreed to take over the "lordship" of the Low Countries in 1580. The prince hoped for assistance from the duke's brother, King Henry III of France, and considered the "lordship" of Anjou as only a kind of limited, constitutional "sovereignty" like that which the rebels had hoped to impose on Philip II at the beginning of their rising. Anjou, however, saw the lordship as a means to total dominion over the Netherlands. Irritated by restraints upon his authority, he even attempted the seizure of power by military force, resulting in the so-called French Fury of Jan. 17, 1583, when his troops tried to capture Antwerp. The coup misfired, but William managed to keep Anjou (who returned to France) in his post despite the outraged feelings of the Netherlanders. Holland and Zeeland were on the verge of offering the title of count to William when he was assassinated on July 10, 1584, at Delft, by Balthasar Gérard, a fanatical young Roman Catholic from Franche-Comté, spurred by the promises of the ban of Philip II. William's death did not end the rebellion, as Philip had hoped, but it did result in the almost unnoticed disappearance of the central government in Brussels. The States-General, which now met at The Hague in Holland, represented only the provinces in the Union of Utrecht.

Leicester as governor-general

With the Spaniards steadily overrunning Flanders and Brabant, the Dutch in their plight did not immediately abandon William's policy of seeking foreign assistance. But after Henry III of France and Elizabeth I of England both refused sovereignty over the country, the States-General in 1586 named as governor-general Robert Dudley, earl of Leicester, whom Elizabeth had sent to command Dutch and English auxiliary forces against the Spaniards after the fall of Antwerp. Leicester, like Anjou before him, endeavoured to make himself absolute master of the country, relying on the support of popular Calvinism and of the outlying provinces that were jealous of Holland to create a strong centralized government under his authority. Holland thwarted Leicester's efforts, which culminated in an attempted invasion of Holland from Utrecht in 1587. With Leicester's departure, the United Provinces put aside all efforts to obtain a foreign protectorate and stood forth as an independent state.

THE FORMATION OF A NEW GOVERNMENT

Although derived from historical institutions, the government of the United Provinces was in practice largely a new set of institutions, not created, but confirmed, by the Union of Utrecht. Their primary force lay in the provinces, seven in number (Holland, Zeeland, Utrecht, Gelderland, Overijssel, Friesland, and Groningen), which were ruled by assemblies of provincial States representing the towns and the landed nobility. Although the stadtholders (who after a few years came to be drawn exclusively from the house of Orange) were elected by the States of the provinces, they at the same time possessed important prerogatives in the selection of members of the town governments from which the provincial assemblies ultimately derived their authority, and they were the acknowledged military leaders of the republic. Central government passed from the Council of State to the States-General, which was more explicitly subordinated to provincial authority. Although it conducted the military and diplomatic work of the republic, the States-General failed to obtain effective rights of direct taxation (except for import and export duties assigned to the admiralties), and its major decisions were taken under the rule of unanimity. In practice the province of Holland, by far the wealthiest province in the union and the contributor of more than half of the revenues of the central government, became the preponderant political force in the country, along with the stadtholders of the house of Orange. The relationship between Holland and the house of Orange governed the republic's politics for the two centuries of its existence. As collaborators, Holland and the princes of Orange could make the clumsy governmental system work with surprising effectiveness; as rivals, they imperiled its potency as a state, at least until one or the other emerged a temporary victor: but neither force was able to rule permanently without the other.

The decades immediately after 1587 were marked by close collaboration between Johan van Oldenbarnevelt, "advocate" of Holland (the legal and executive secretary of the provincial States), and Maurice of Nassau, William I the Silent's second son (the first, Philip William, became prince of Orange and remained loyal to Spain), who was named stadtholder of Holland and Zeeland and became the commander of the republic's armies. The result was a series of military triumphs over the Spanish forces under Parma. Maurice recaptured the Dutch territories north of the great rivers and extended them southward into much of Brabant and enough of Flanders to cut off Antwerp from the sea. These victories are recorded in the historical memory of the Dutch as "the closing of the garden," the territory that became the republic of the United Provinces and then (with a few additions) the modern Kingdom of The Netherlands. These victories were accompanied by the emergence of the States-General diplomatically recognized by England and France as an independent state.

ASCENDANCY OF THE DUTCH ECONOMY

Commercial domination of Amsterdam

The military prowess of the fledgling republic rested upon the wealth of Holland—which managed in wartime to maintain and extend its trade to all Europe and, after the turn of the century, even to East Asia. Amsterdam replaced Antwerp, the great port on the Schelde River, as the principal warehouse and trading centre for all Europe, even while Holland maintained the leadership in shipping it had already garnered during the 16th century. The foundation of Dutch economic prosperity lay in the fishing and shipping industries. Even during the period of Antwerp's ascendancy, ships from Holland and Zeeland had carried a large portion of the goods that passed through the Schelde, and now that Amsterdam had taken over from Antwerp, Dutch shipping only expanded its predominance. Dutch fishermen had harvested the North Sea for centuries, and the salted cargoes were sold widely through western and central Europe. Dutch trade benefited, as had that of Flanders, from the location of the country at the nexuses of the great north-south and east-west trade routes of Europe. To these were added the route to the East Indies early in the 17th century. Amsterdam and the lesser ports of Holland and Zeeland became the principal European suppliers of grain and naval stores from the Baltic, to which they shipped manufactured goods and wines from the south. Germany's principal exports were now shipped down the Rhine, as Dutch ports replaced the Hanseatic towns of northern Germany. The bulk of French exports were carried in Dutch ships, and even Spain and Portugal depended on the Dutch for grain and naval stores (thereby enabling the Dutch to finance their war of independence). During the 17th century the Dutch assumed a major role in supplying grain and other northern commodities to the countries of the Mediterranean and also became the principal importer of spices and other luxury goods from the East. Even England relied to a great extent upon Dutch shipping. The Dutch advantages lay not only in their situation but also in the efficient design of their bulky flyboats (*fluiten*), manned by small crews at less cost than any of their competitors. Modern banking institutions developed to meet the needs of the vastly expanding trade. Amsterdam's "exchange bank" was instituted in 1609 to provide monetary exchange at established rates, but it soon became a deposit bank for the safe settling of accounts. Unlike the Bank of England, established almost a century later, it neither managed the national currency nor acted as a lending institution (except to the government in emergencies). Private bankers met the need for credit, as well as acting as brokers in financial transactions. The need

Banking in Amsterdam

for commercial exports, as well as a growing population at home, spurred industry in many towns. Although the shipbuilders on the Zaan, northwest of Amsterdam, and the sugar refiners in particular developed large-scale operations, sometimes including machinery, Dutch industry generally remained at the level of handicraft production. Dutch agriculture also responded to the new needs. Grain production was encouraged in the inland provinces, while the polders of the delta islands and along the coast were drained and diked, providing pastureland for a flourishing dairy industry.

THE TWELVE YEARS' TRUCE

The Twelve Years' Truce that began in 1609 arose out of political controversies that were to dominate the republic for the next two centuries. The collaboration between the house of Orange and the leaders of the province of Holland, which had thwarted Spain in its reconquest of the Netherlands north of the great rivers, was replaced by an intermittent, but often fierce, rivalry between them, in which the other tensions of Dutch political life were reflected and incorporated: the jealousy among the lesser provinces of a Holland that they considered too wealthy, too mighty, and too arrogant but which they knew they needed for their own defense; the misunderstanding between maritime and landward provinces; the annoyance of landed nobles that they were dependent upon the goodwill of burghers in Holland (they preferred the prince of Orange, whom they saw as one of themselves); the resentment of the popular classes, men of small property and of none, toward the town regents (members of government) from whom they looked to the princes of Orange to protect them; and the antipathy of the Reformed clergy toward the regents, who obstructed their desire to make the state serve the church. The debate over whether or not to conclude a peace with Spain mingled these various interests with that of the house of Orange, partly because Maurice opposed peace, partly because it involved making some compromise with Spain, and partly because it would mean a reduction of his influence in the state; but the province of Holland in particular, under Oldenbarnevelt's leadership, felt that the independence and security of the United Provinces had been sufficiently assured to permit a reduction of the immense expenditures for the war. When Spain reduced its immediate proposal to a truce rather than permanent peace, agreed to treat the United Provinces as independent and sovereign, which was just short of outright recognition, and put aside efforts to win guarantees for Dutch Catholics, the pressure for conclusion of a truce could not be withstood.

The Twelve Years' Truce did not, however, end internal controversy within the republic. If anything, it only sharpened Maurice of Nassau's opposition to Holland and Oldenbarnevelt. The staunch Calvinists endeavoured to hold the Reformed church to the strict orthodoxy expounded by Franciscus Gomarus, a Leiden professor of theology, against the broader, less rigorous tenets upheld by his colleague Jacobus Arminius. The Gomarists demanded that the government uphold their principles because the Reformed church was the only true church, but they reserved for themselves the right to declare what the correct doctrines were; and they vigorously asserted that other religious groups, Catholic, Protestant, and Jewish alike, should be suppressed or at least penalized and restricted. On the other hand, the Arminians had the support of the leaders of Holland and a majority of its towns, who felt that what was in effect the state church had to be under the authority of the government. Both out of principle and out of a desire not to hamper trade with men of all religions, they favoured a broadly inclusive Reformed church and toleration for those outside its ranks.

Gomarists versus Arminians

The efforts of Gomarists to seize churches for their own use in defiance of town authorities led to incipient civil war. Maurice broke openly with the dominant party in Holland when it attempted to set up little provincial armies in Holland and Utrecht. In 1618 he acted under the authority of the States-General, in which the majority of provinces favoured the Gomarists (now called the Contra-Remonstrants because they had opposed an Arminian petition) over the Remonstrants (Arminians) to crush the resistance of Oldenbarnevelt's party. Oldenbarnevelt, together with two of his chief supporters in Holland (including the great jurist Hugo Grotius) and an ally in Utrecht, was arrested and tried for treason by a special court instituted by the States-General. The defendants affirmed that they were subject only to the authority of the sovereign province that they served. The sentence, which to foes of the house of Orange over the centuries became an act of judicial murder, sent Oldenbarnevelt, then 71 years old, with almost four decades of service as Holland's leader, to his death by beheading in May 1619. Grotius and another defendant (the third had committed suicide) were sentenced to life imprisonment, although Grotius escaped, sensationally, a few years later.

During these fateful months, the Reformed church held a national synod at Dordrecht. Dominated by the Contra-Remonstrants, the synod expelled the Remonstrants, reaffirmed the doctrines of the church along Gomarian lines, and ordered the preparation of a new translation of the Bible (the famous States Bible that consolidated the Dutch language much as the contemporary King James Version consolidated English). The triumph of Maurice and the Contra-Remonstrants meant that war with Spain would be a virtual certainty upon the expiration of the Twelve Years' Truce in 1621—all the more because the Spanish authorities in the southern Netherlands insisted upon including rights for Dutch Catholics in a permanent treaty and even sought an acknowledgment by the States-General of the nominal overlordship of the king of Spain. Maurice did not use his new uncontested power to reform the complicated incoherence of the Dutch constitution; the structure of government and the distribution of formal power remained the same. Maurice was not a politically minded ruler and was satisfied as long as he had his way in military matters. The United Provinces remained essentially republican in character.

WAR WITH SPAIN (1621–48)

The war resumed in 1621 under Maurice's leadership. But his touch of victory was gone, and the republic appeared in danger when the great fortress of Breda on the southern frontier fell to the Spaniards in 1625. Only a few weeks before, Maurice had died. The danger was all the greater because the Austrian Habsburgs, in alliance with their Spanish cousins, were waging a successful struggle against their Protestant foes in Germany in the first stages of the Thirty Years' War. But Maurice's half-brother, Frederick Henry, who succeeded him as prince of Orange, stadtholder, and commander in chief, resumed the course of victory. He completed the recapture of towns recently gained by the Spaniards and extended the territory under the States-General to the key fortress of Maastricht on the Maas (Meuse) well to the south. At the same time, the Dutch navy won a series of victories over the Spaniards, including Piet Heyn's celebrated capture of their silver fleet off the coast of Cuba (1628) and the destruction of a Spanish fleet in the Downs, off the English coast, by Maarten Tromp in 1639.

Victories under Frederick Henry

Frederick Henry turned out to be a more subtle and purposeful politician than Maurice. On the one hand, he ended the suppression of the Remonstrants, with whose religious views he sympathized, without exasperating the Contra-Remonstrants beyond repair. On the other hand, he established a firm grip over the policies of the republic, notably by establishing a close alliance with France aimed at the joint conquest of the Spanish Netherlands. Frederick Henry's political predominance within the republic was based upon his control of the lesser provinces, which had a majority in the States-General and which could outweigh the influence of Holland. Gradually Holland turned against him, especially after he arranged the marriage of his young son William to Princess Mary Stuart, daughter of Charles I of England, on the eve of the English Civil War (1642–51). This fateful dynastic bond tied the interests of the house of Orange to the royal families of England, first to the Stuarts and later to the Hanoverians. The position of the house of Orange, however, was elevated by the connection: the French monarchy granted

Frederick Henry the honorary address of "His Highness," normally restricted to royalty; and the debate over the function of the princes of Orange in Dutch politics began to be conducted as a controversy over monarchy. A quasi-royal court rose up around Frederick Henry, and this in turn only clarified and strengthened the republicanism of his opponents, especially in Holland, who feared that the political leadership of the princes of Orange would be turned into an explicit monarchy.

During the 1640s, however, Frederick Henry lost his physical and intellectual powers and was unable to prevent Holland from reasserting its predominance over the republic's policies. The States-General entered into peace negotiations with Spain at Münster in Westphalia. Frederick Henry died in 1647 before the conclusion of the talks, but his son, William II, could not prevent the signing and ratification of the treaty in January 1648. Spain now formally acknowledged the independence of the Dutch, and indeed even urged its friendship upon the United Provinces, warning of the threat to both the Dutch and the Spanish from the rising power of France.

Peace of Westphalia

Prince William was not ready to accept a permanent peace, and he negotiated secretly with the French for a resumption of the war, not only against Spain but also against republican England, which had executed his father-in-law, King Charles I, in January 1649. Needing a powerful army to wage the anticipated war, William bitterly fought the efforts of Holland to reduce the standing army and thereby to permit more rapid payment of the huge debt accumulated over the eighty years' struggle for independence. Efforts at compromise broke down during the spring of 1650, as the Hollanders and William each sought to compel the other to concede political inferiority. William decided to make use of his preponderance in the States-General, and he led a delegation from that body to the towns of Holland to seek a change of their vote in the States of Holland; such a delegation was a direct violation of what Holland saw as its provincial sovereignty. Rebuffed by a number of town governments, most importantly by those of Amsterdam and Dordrecht, William decided to cut through the resistance by force. At The Hague, on July 30, 1650, he arrested six of the States' deputies from the recalcitrant towns and sent them to the castle of Loevestein (where Grotius had been imprisoned) on charges of having resisted lawful orders of the States-General. At the same time he sent an army to seize Amsterdam, but it was thwarted by delays on its march and by the determined resistance of the municipal authorities, supported by the common people. Amsterdam, however, faced a siege that might gravely imperil its trade, while the besiegers themselves ran the danger of being drowned should Amsterdam open the dikes. A compromise was soon worked out whereby William's opponents were released but were required to withdraw from government. William had cleared the way for his policies but at the price of arousing deep fears among the Dutch people—most of all in the powerful province of Holland—of military dictatorship, monarchical rule, and renewed involvement of the nation in war. But before he could carry out his plans, William II died of smallpox in early November. A posthumous son, William III, was born a week later.

Death of William II

THE FIRST STADTHOLDERLESS PERIOD

Fate thus intervened to give Holland's leaders, now intensely distrustful of Orangist influence, a chance to take over the country from the leaderless party of their antagonists. They governed the country for a little more than two decades, during what is known as the "first stadtholderless period" (1650–72) because the five leading provinces did not appoint a successor to William II. (William II's cousin, William Frederick, of the junior branch of Orange-Nassau, continued to govern Friesland as well as Groningen, which also elected him as stadtholder.) During the early months of 1651, a "Great Assembly" of the States-General, with expanded delegations from all the provinces, met at The Hague to consider the new situation. Holland was satisfied to consolidate the leadership it had so unexpectedly regained and conciliated the lesser provinces by leaving undisturbed the religious settlement of 1619 and by granting amnesty to those who had supported William II in 1650. But Holland's fears of the increased powers of the central government had been so stiffened that it depended upon its own preponderance, rather than upon constitutional reforms, to achieve effective government.

Yet efficiency of rule, so difficult to obtain when the powers to make and apply policy were so widely scattered, became all the more necessary when the republic became embroiled in war with the English Commonwealth in 1652. That conflict arose out of a medley of causes: first, the English republicans, after their successes against the royalists, took up the cause of defending English commercial interests against the Dutch and passed the Navigation Act of 1651 forbidding Dutch shippers from acting as middlemen in English trade both in Europe and overseas; second, the English sought to bring the Dutch into a political union directed primarily against the Stuarts and their cousins of the house of Orange. But the Dutch, whatever resentment the Hollanders bore against the Orange dynasty, were unwilling either to court civil war or to abandon their dearly won independence in a union that would make them junior partners to the English. An accidental clash between the Dutch and English fleets led to full-scale war in which a greatly improved English navy won the upper hand. By 1654 the Dutch were compelled to accept peace on English terms, including a secret promise by Holland ("Act of Seclusion") to exclude forever the prince of Orange from the stadtholderate and the supreme command.

The decision to accept a humiliating peace as the only way to terminate a disastrous war had been taken at the insistence of the young Johan de Witt, who had taken office in 1653 as councillor pensionary of Holland (the same office once held by Oldenbarnevelt). With the return of peace, de Witt became the brilliant leader of the republic's foreign and domestic policy. He rebuilt the Dutch navy, reduced indebtedness, improved the financial condition of both the States-General and the States of Holland, and restored the republic's prestige in Europe. Carefully averting any renewal of strife with England, he was able not only to compel France to back down in a naval dispute but also to send a powerful Dutch fleet to save Denmark from Swedish conquest in the First Northern War (1657–60).

Leadership of de Witt

When the exiled English king, Charles II, was restored to his throne in 1660, de Witt continued his policy of staying on good terms with England no matter who ruled there; this policy, however, foundered on the same two issues—commercial rivalry and the status of the house of Orange—that had brought about the war of 1652–54. Charles not only accepted the renewal of the Navigation Act of 1651 but intensified the rivalry with the Dutch by demanding forcefully that they acknowledge his sovereignty over the adjacent seas, pay tribute for the right to fish in the North Sea, and open the Dutch East Indies to English traders. When naval warfare resumed in 1664 off Africa, followed by war in Europe the next year, Charles took up the cause of the young prince of Orange. By persuading the Orangists that his price for peace was restoration of William III to the offices of his forefathers, the English monarch built up a friendly party in the United Provinces that urged acceptance of his terms and even fostered a conspiracy to overthrow the government of de Witt and his friends. But de Witt managed to meet the new threat. An Orangist plot in Holland was uncovered and put down in 1666.

When Charles had demanded too high a price for Dutch friendship in 1660–62, de Witt had negotiated an alliance with the French, who feared that the restoration of the prince of Orange would create a hostile Anglo-Dutch coalition. Furthermore, the fighting at sea increasingly went to the newly rebuilt Dutch navy. In 1667 the Dutch fleet sailed up the Thames and the Medway to Chatham, destroying the English shipyards and burning the fleet at its moorings. In that same year, however, the French, under Louis XIV, who had only belatedly sent naval and land forces to aid the Dutch, began an invasion of the Spanish (southern) Netherlands in the War of Devolution. As French conquest of the southern Low Countries constituted a threat to both the Dutch Republic and Britain, those states came to terms in the stand-off Peace of Breda

(July 31, 1667), followed in January by an Anglo-Dutch alliance compelling France to make peace with Spain.

The Triple Alliance

This Triple Alliance (so called because Sweden became a third partner) proved to be de Witt's undoing, although he had no effective diplomatic strategy to put in its place. Louis XIV, balked in his aim of conquest, considered that the Dutch had betrayed their alliance and turned to Charles II with proposals for a joint war against the United Provinces. Charles, bitterly resentful over his humiliating defeat at Chatham, accepted the French offer of a richly subsidized alliance. Even as the threat from France emerged more clearly, the Orangists imagined that the Dutch could still win over Charles by the restoration of William III, but they were able to obtain only the prince's appointment as commander in chief early in 1672. Charles joined the French in open war in the spring of 1672, counting upon William to accept rule of a rump Dutch Republic after France and Britain had taken away important territories for themselves. But William, who was given full power, including the stadtholdership, during a storm of riots and near rebellion that swept the country in June and July after the French invasion penetrated to its heart, took over the leadership of the Dutch defense from de Witt, who was lynched by a mob in The Hague in August. With William's support, the States-General rejected the Anglo-French terms.

WILLIAM III

The tide of war now turned against the aggressors. The Dutch navy under Admiral Michiel Adriaanszoon de Ruyter repeatedly defeated the allied fleets off the coast of the republic, while the Dutch armies held on behind the flooded polders of the "water line." When other powers—Spain, at first as an auxiliary, then as a full participant, the German emperor, and Brandenburg—joined the Dutch side, the French armies withdrew from the republic. During six years of bitter war, William III was able to bring about the withdrawal of England (1674) and the defeat of all French war aims against the Dutch; yet his Grand Alliance was unable to bring Louis XIV to his knees, although Spain paid the price of a peace negotiated at Nijmegen in 1678. But during these years in which his political control of the republic, while strong, was not absolute, William was no more interested in constitutional reform than de Witt, his predecessor in the leadership of the country, had been. He was satisfied to expel adversaries from office and dominate the decisions taken by men who represented the same groups and the same social principles as those whom they replaced; but Holland, whose wealth ultimately was the basis for all Dutch power, political and military, slipped from under his thumb and asserted its autonomy of judgment and decision. The transformation of the republic, which had been from its origins an aristocracy dominated by mercantile wealth, into an oligarchy of inherited power, continued unimpeded by William: he had used the violence of the urban citizenry during the crisis of 1672 to unseat his opponents, including de Witt, but he was no more sympathetic than they had been to the vague democratic aspirations that were expressed here and there.

During the decade after the conclusion of the Peace of Nijmegen, the tension between William and Holland (particularly Amsterdam) worsened because the prince was fixed upon a policy of renewed resistance to Louis XIV, while the Hollanders preferred peace at any reasonable price. But the upsurge of the threat from France in the late 1680s—the French incursions into western Germany and the threat of French domination of England under James II, a stalwart Roman Catholic and a pensioner of Louis XIV—brought William and Holland into agreement upon the need to support the prince's expedition to England in 1688, which resulted in his acceptance of the English throne, jointly with his wife Mary Stuart, early the next year. William, as king-stadtholder, had to give primacy to English interests because England was the more powerful partner in the alliance. He therefore approved the arrangement whereby England concentrated her efforts against France on the sea, while the Dutch did so on land; the result was neglect of the Dutch navy. Ironically, the final triumph of the English over the Dutch in their commercial rivalry was a consequence of their alliance, not their enmity.

William accepts the English throne

The war begun in 1689 ended with a stalemate peace in 1697, followed by two treaties between the maritime powers and France for partition of the Spanish monarchy. In 1700, however, Louis XIV accepted the bequest of the Spanish throne for his grandson, Philippe d'Anjou (Philip V of Spain), and war was resumed the next year.

William died, childless, in 1702. When Holland again took the initiative for government without a stadtholder, it was followed by the other provinces with much greater alacrity than had been true in 1650–51. Resentment had built up against the harshness with which the prince had governed the country for three decades, and the absence of an adult heir meant that there was no effective opposition to the new course. Leadership of the Dutch state for the next 45 years came from the councillor pensionaries of Holland, who were often able men but either unwilling or unable to do more than conduct current business without attempting the delicate and explosive task of restructuring the government. On the contrary, constitutional rigidity became the credo not only of Dutch republicans but also of the Orangist party, with the only point in contention between them being whether or not the prince of Orange-Nassau, who was stadtholder of Friesland, should be elected to the same office in the other provinces. William IV, who followed his father in Friesland in 1711, was chosen stadtholder in Groningen in 1718 and in Gelderland (and the district of Drenthe) in 1722. Even without a stadtholder in the principal provinces, Dutch subordination to English interests remained intact during the War of the Spanish Succession (1701–13) and the succeeding years of peace.

DUTCH CIVILIZATION IN THE GOLDEN AGE (1609–1713)

The "Golden Age"

The century from the conclusion of the Twelve Years' Truce in 1609 until either the death of Prince William III in 1702 or the conclusion of the Peace of Utrecht in 1713 is known in Dutch history as the "Golden Age." It was a unique era of political, economic, and cultural greatness during which the little nation on the North Sea ranked among the most powerful and influential in Europe and the world.

The economy. It was a grandeur that rested upon the economic expansion that continued with scarcely an interruption until 1648, at the end of the Thirty Years' War. The half century that followed was marked by consolidation rather than continued expansion, under the impact of the revived competition from the other nations, notably England and France, whose policies of mercantilism were in large degree directed against the near monopoly of the Dutch over the trade and shipping of Europe. Although the Dutch tenaciously resisted the new competition, the long-distance trading system of Europe was transformed from one largely conducted through the Netherlands, with the Dutch as universal buyer-seller and shipper, to one of multiple routes and fierce competitiveness. Nonetheless, the wealth earned during a long century of prosperity made the United Provinces a land of great riches, with more capital by far than could find outlet in investment. Yet the economic burden of repeated wars caused the Dutch to become one of the most heavily taxed peoples in Europe. Because the role of agriculture was secondary, taxes were to some extent imposed on the transit trade in and out of the country. But as mercantile competition became stiffer, the rate of such taxation could not be safely increased, and the burden therefore fell increasingly on the consumer. Excise and other indirect taxes made the Dutch cost of living one of the highest in Europe.

Dutch prosperity was built not only upon the "mother trades"—to the Baltic and to France and the Iberian lands—but also upon the overseas trades with Africa, Asia, and America. The attempt of the Spanish monarchs (who also ruled Portugal and its possessions from 1580 to 1640) to exclude Dutch merchants and shippers from the lucrative colonial commerce with East Asia led the Dutch to trade directly with the East Indies. Individual companies were organized for each venture, but the companies were

The Dutch East India Company

united by command of the States-General in 1602 in order to reduce the costs and increase the security of such perilous and complex undertakings; the resulting United East India Company established bases throughout the Indian Ocean, notably in Ceylon (Sri Lanka), mainland India, and the Indonesian archipelago. The Dutch East India Company, like its rival English counterpart, was a trading company granted quasi-sovereign powers in the lands under its dominion. Although the East India fleets that returned annually with cargoes of spices and other valuables provided huge profits for the shareholders, the East India trade of the 17th and 18th centuries never provided more than a modest fraction of Dutch earnings from European trade. The West India Company, established in 1621, was built upon shakier economic foundations; trade in commodities was less important than the trade in slaves, in which the Dutch were preeminent in the 17th century, and privateering, which operated primarily out of Zeeland ports and preyed upon Spanish (and other) shipping. The West India Company had to be reorganized several times during its precarious existence, while the East India Company survived until the end of the 18th century.

Society. The social structure that evolved with the economic transformation of Dutch life was complex and marked by the predominance of the business classes that later centuries called the bourgeoisie, although with some significant differences. It was an unabashedly "aristocratic" country, socially and politically. The social "betters" of Dutch aristocracy were only to a limited extent landed nobles, most of whom lived in the economically less advanced inland provinces. Most of the Dutch elite were wealthy townsmen whose fortunes were made as merchants and financiers, but they frequently shifted their activities to government, becoming what the Dutch called regents, members of the ruling bodies of town and province, and drawing most of their incomes from these posts and from investments in government bonds and real estate. The common people comprised both a numerous class of artisans and small businessmen whose prosperity provided the base for the generally high Dutch standard of living and a very large class of sailors, shipbuilders, fishermen, and other workers. Dutch workers were in general well paid, but they were also burdened by unusually high taxes. The farmers, producing chiefly cash crops, prospered in a country that needed large amounts of food and raw materials for its urban (and seagoing) population. The quality of life was marked by less disparity between classes than prevailed elsewhere, although the difference between a great merchant's home on the Herengracht in Amsterdam and a dockworker's hovel was all too obvious. What was striking was the comparative simplicity even of the wealthy classes and the sense of status and dignity among the ordinary people, although the exuberance that had earlier marked the society was toned down or even eliminated by the strict Calvinist morality preached and to some extent enforced by the official church. There was, too, a good deal of mingling between the burgher regents who possessed great wealth and political power and the landed gentry and lesser nobility who formed the traditional elite.

Religious "pillars"

Religion. One of the characteristic aspects of modern Dutch society began to evolve in this period—the vertical separation of society into "pillars" (*zuilen*) identified with the different Dutch religions. Calvinist Protestantism became the officially recognized religion of the country, politically favoured and economically supported by government. But the Reformed preachers were thwarted in their efforts to oppress or drive out other religions, to which a far-reaching toleration was extended. Mass conversion to Calvinism had been confined mainly to the earlier decades of the Eighty Years' War, when Roman Catholics still frequently bore the burden of their preference for the rule of the Catholic monarchs in the southern Netherlands. Sizable islands of Roman Catholicism remained in most of the United Provinces except Zeeland, while Gelderland and the northern parts of Brabant and Flanders conquered by the States-General were overwhelmingly Roman Catholic, as they remain today. Although public practice of Catholicism was forbidden, interference with private worship was rare, even if Catholics sometimes bought their security with bribes to local Protestant authorities. Catholics lost the traditional form of church government by bishops, whose place was taken by a papal vicar directly dependent upon Rome and supervising what was in effect a mission; the political authorities were generally tolerant of secular priests but not of Jesuits, who were vigorous proselytizers and linked to Spanish interests. Protestants included, along with the predominant Calvinists of the Reformed church, both Lutherans in small numbers and Mennonites (Anabaptists), who were politically passive but often prospered in business. In addition, the Remonstrants, who were driven out of the Reformed church after the Synod of Dort (Dordrecht; 1618–19), continued as a small sect with considerable influence among the regents.

There were also other sects emphasizing mystical experiences or rationalist theologies, notably the Collegiants among the latter. Jews settled in the Netherlands to escape persecution; the Sephardic Jews from Spain and Portugal were more influential in economic, social, and intellectual life, while the Ashkenazim from eastern Europe formed a stratum of impoverished workers, especially in Amsterdam. Despite unusually open contacts with the Christian society around them, Dutch Jews continued to live in their own communities under their own laws and rabbinic leadership. Successful though some Jews were in business, they were by no means the central force in the rise and expansion of Dutch capitalism. Indeed, no clear pattern can be detected of religious affiliation affecting the growth of the Dutch business community; if anything, it was the official Dutch Reformed Church that fulminated most angrily against capitalist attitudes and practices, while the merely tolerated faiths often saw their adherents, to whom economic but not political careers were open, prospering and even amassing fortunes.

Culture. The economic prosperity of the Dutch Republic in this "golden century" was matched by an extraordinary flowering of cultural achievement, which drew from the nation's prosperity not only the direct resources of financial nourishment but also a driving and sustaining sense of purpose and vigour. This was reflected in the first instance by a notable series of historical works: the contemporary chronicles of the revolt by Pieter Bor and Emanuel van Meteren; the highly polished account by Pieter Corneliszoon Hooft, a masterpiece of narration and judgment in the spirit of Tacitus; the heavily factual chronicle of Lieuwe van Aitzema, with its interspersed commentary of skeptical wisdom; Abraham de Wicquefort's history of the republic (principally under the first stadtholderless administration); and the histories and biographies by Geeraert Brandt. These were works in which a proud new nation took account of its birth pangs and its growth to greatness. Only in the latter part of the century did Dutch historians begin to express a sense that political grandeur might be transient.

Flowering of historical works

Political theorists shared the same concerns, although the effort to fit new experience and ideas into the traditional categories derived from Aristotle and Roman law created an air of unreality about their work, perhaps even more than was true of political thinkers elsewhere in Europe. Theorists such as the Gouda official Vrancken in the days of the foundation of the republic and Grotius in the early 17th century portrayed the republic as essentially unchanged since the early Middle Ages or even since antiquity—a country where sovereignty resided in provincial and town assemblies, which had partly lost their control to counts and kings before regaining it in the revolt against Philip II. The next surge of political debate came after mid-century, when for a little more than two decades the country was governed without a prince of Orange as stadtholder.

The controversy over whether the young Prince William had any right by birth to the offices of his forefathers probed the fundamental character of the republic, for even a quasi-hereditary stadtholdership created an incipient monarchy within the traditional structure of aristocratic republicanism. The debate involved the issue not so much of centralization versus provincialism as where the leadership of the republic properly lay, whether in the house

of Orange or in the province of Holland and notably its greatest city, Amsterdam. Only the celebrated philosopher Benedict de Spinoza, an outsider by origin and character (a Jew by birth and upbringing), elevated these political questions to the level of universality.

Another great philosopher of the 17th century who resided in the Dutch Republic was the Frenchman René Descartes. Though an outsider, Descartes found in the Netherlands a freedom from intellectual inquisitions and personal involvements. He lived there for two decades while engaged in the studies that helped transform modern thought.

Scientific achievements

Scientific activity in the United Provinces also reached a high level. The physicist Christiaan Huygens approached Newton himself in power of mind and importance of scientific contribution. The engineer and mathematician Simon Stevin and the microscopists Antonie van Leeuwenhoek and Jan Swammerdam rank in the front of their fields.

Dutch literature, which knew great creativity during the "golden age," remained the possession of the relatively small number of those who spoke and read Dutch. Figures like the historian P.C. Hooft or the poets Constantijn Huygens and Joost van den Vondel, who was also a distinguished playwright, wrote with a power and a purity worthy of the best that France and England produced at that time. Music was hampered by the Calvinists' antipathy to what they saw as frivolity. Organ music was barred from services in Reformed churches, although town authorities frequently continued its performance at other times. The great organist-composer J.P. Sweelinck was more influential in encouraging the creative wave in Germany than among his own countrymen. The art whose achievements rank at the very top was painting, which rested upon the broad patronage of a prosperous population. Group portraits of regents and other influential citizens adorned town halls and charitable establishments, while still lifes and anecdotal paintings of popular life hung in profusion in private homes. Some of the greatest work, from the brushes of such painters as Frans Hals, Jan Steen, and Jan Vermeer, were painted for these markets, but the greatest of Dutch painters, Rembrandt, broke through the boundaries of the group portrait to create works with his own extraordinary mood and inward meaning. The landscape painters, notably Jacob van Ruisdael, captured the distinctive Dutch flat land, broad skies with massed clouds, and muted light. Architecture remained at a lesser level, merging with some success the native traditions of brick buildings and gable roofs and fashionable Renaissance styles. Sculpture remained a largely foreign art.

THE 18TH CENTURY

Economic and political stagnation. Once the Dutch fleet had declined, Dutch mercantile interests became heavily dependent on English goodwill; yet the rulers of the country were more concerned with reducing the monumental debt that weighed heavily upon the country. During the 18th century Dutch trade and shipping were able to maintain the level of activity reached at the end of the 17th century, but they did not match the dramatic expansion of French and especially English competitors. The Dutch near-monopoly was now only a memory. Holland remained rich in accumulated capital, although much of it could find no outlet for investment in business. Some went into the purchase of landed estates, but a great deal was used to buy bonds of foreign governments; the bankers of Amsterdam were among the most important in Europe, rivaling those of London and Geneva. Dutch culture failed to hold its eminence; a medical scientist like Hermann Boerhaave or a jurist like Cornelis van Bynkershoek was highly respected, but they were not the shapers and shakers of European thought. Dutch artists were no longer of the first order, and literature largely followed English or French models without matching their achievements. The quality of life changed: instead of the seething activity of the 17th century, the 18th century was one of calm and easeful pleasantness, at least for men of property. The middling classes in town and countryside also knew continuing prosperity; conditions for the labouring classes continued to be hard, although foreign visitors thought the workers lived better than elsewhere. The poor as such were not labourers but a residual class of unemployed who subsisted on the charity of town governments and private foundations. Religious life was more relaxed, particularly among Protestants. Roman Catholics, still without political rights but facing milder restrictions, fell into a quarrel between adherents of Jansenism, which denied free will, and supporters of Rome; the former split off to form the Old Catholic Church, a small denomination that still exists. The educated classes widely accepted the principles and attitudes of the Enlightenment although without the sharp hostility to religion that characterized the French philosophes.

Decline of Dutch commerce and culture

During the second stadtholderless period of Dutch government (1702–47), the republican system became an immobile oligarchy. The "liberty" defended by the regents as soundly republican was in practice the rule of hereditary patricians, responsible to neither the citizenry below nor a stadtholder above. Although William IV yearned for restoration to the offices held by the princes of Orange before him in the provinces to the south, he accepted, with no less admiration and commitment than the regents, the perfection and immutability of the Dutch constitutional system, with the single difference that he envisioned it including the stadtholderate for all the provinces. It was not until the War of the Austrian Succession (1740–48) that the power of the regents began to crumble. As in 1672, disaster on the battlefield proved the Achilles' heel of a regime that had not built up a broad popular political base. The regents had not been able to overcome the traditional commitment of the people to the house of Orange as their natural leader and saviour. French and Prussian armies swarmed over the Austrian (formerly Spanish) Netherlands and were poised for invasion of the United Provinces, which were linked by alliance with England, although they had remained formally neutral. When the French forces crossed into Dutch territory, rioting reminiscent of 1672, although less widespread and violent, led to the fall of the second purely republican government and the election of William IV as hereditary stadtholder of all the provinces. Otherwise there was little change; some regents were compelled to step down from their posts, and leadership in the hands of the prince of Orange was uncontested. William rebuffed the efforts of burghers in Amsterdam and other towns who had supported his restoration in order to achieve democratic reforms, in which participation in government would be extended to men of modest property who had been completely disfranchised (although not to wageworkers or to paupers).

Reaction to French incursion

The Patriot movement. During the next decades, in the face of the rigid conservatism of the princes of Orange (William V succeeded his father in 1751 and assumed personal government in 1759) and under the influence of the French Enlightenment, an essentially new political force began to take shape. Known as the Patriot movement after an old party term used by both republicans and Orangists, it applied fundamental criticism to the established government. Although the Patriot movement was representative of the new democratic and Enlightenment ideals, it had strong roots in native Dutch traditions. From the beginning, the United Provinces had rejected specifically democratic institutions in favour of frankly aristocratic government (in the Aristotelian sense), but the notion that the regents had a duty to serve not their own private interests but those of the country and the people had persisted in theory and in mood. When the aristocracy ceased to recruit new members from below and thus became an enclosed caste, the discrepancy between its claim of service to the general welfare and the reality of its practice became evident. The Patriot movement took in a wide range of supporters: discontented noblemen like the Gelderland baron Joan van der Capellen tot den Pol; wealthy bankers and businessmen without a voice in government; artisans and shopkeepers, traditionally Orangist in sympathy, who were dismayed to find their claims to an effective role in the politics of their towns rebuffed by the princes; and intellectuals committed to the new Enlightenment rejection of arbitrary power. The Patriots included in their ranks many Protestant dissenters and

Roman Catholics, but the Jews continued to look to the prince of Orange as their protector. Some regents, holding firm to the republicanism of their ancestors and resenting the return of the stadtholderate, found a new base for their ideas in the Patriot movement. Most regents, however, saw more peril in the new movement for broader popular government than in the stolid conservatism of the princes of Orange; a reconciliation between the camps of the patrician republicans and the Orangists began to take shape under the impact of a common threat from below.

Causes of Dutch-British hostility

Again the events of war imperiled the established regime. Although the diplomacy of William V was firmly based upon the alliance with England, London became exasperated with the Dutch during the American War of Independence (1775–83), when they attempted to continue and expand their profitable trade with the new American nation as well as with France. Dutch flirtations with the Russian-sponsored League of Armed Neutrality, resisting British searches of neutral vessels, and indications of Dutch negotiations for an alliance with the Americans only worsened relations. Finally open hostilities erupted in the fourth Anglo-Dutch War (1780–84). The Dutch navy, sorely neglected for more than a half century, was utterly unprepared to battle the powerful British fleet, and the Dutch fleet's attempts to convoy their merchantmen brought only disaster.

The onus of defeat fell upon the stadtholder. He was unable to stand firm against the increased agitation of the Patriots, who forced their way into governments of town after town in Holland and other provinces. Holland began organizing its own army, distinct from that under the prince's command, and civil war seemed in the offing. William V fled to Gelderland with his wife, Wilhelmina, the sister of the Prussian King Frederick II. Holland declared him deposed.

It was the strong-willed Wilhelmina, rather than her hesitant and rather docile husband, who took the lead in the restoration of the stadtholderate. Dutch politics had now become a concern of the great powers. France sided with the Patriots, not out of sympathy with their principles but because they opposed the stadtholder, who had fallen back into dependence upon English and Prussian support. As long as Frederick II ruled in Prussia, Wilhelmina's pleas for armed intervention fell on deaf ears, but when the throne passed to his nephew Frederick William II in 1786, the way opened for action. The Patriots counted upon the support of the French, but the government at Versailles, then entering the final financial and political crisis of the monarchy that erupted in the Revolution of 1789, could give no more than verbal encouragement. Wilhelmina, working closely with the English ambassador, arranged to create a crisis by seeking to return to Holland; her detention at the provincial border was taken by Prussia as justification to send an army into the United Provinces. The Prussians quickly swept away the makeshift militias of Holland and Utrecht and restored the stadtholder, William V, to his offices. A period of repression of Patriots followed; many went into exile, first in the Austrian Netherlands and then in France. The outbreak of the French Revolution in 1789 gave new hope to the exiles and their friends at home. They looked now for more effective French assistance and at the same time found in the French revolutionary experience practical ideas for the reorganization of the government at home, notably the principle of a single, indivisible republic. The Patriots' hopes rose when the armies of the French Revolution swept over the Austrian Netherlands (which had had a brief interlude of independence in 1789–90) in 1792, but the French forces retreated the next year. It was not until 1794 that they returned to Belgium (as it now became customary to call the southern Netherlands), driving up to and then across the frontier of the United Provinces. The moment for which the Dutch Patriots had long been waiting was at hand: French power would more than overweigh the English and Prussian strength upon which the stadtholder relied (Prussia made a separate peace with France in 1795), and a democratic revolution, thwarted in 1787, would be possible. The freezing of the great rivers during the winter permitted the French forces to cross into the Dutch heartland, but even before they arrived the Patriots seized the reins of state from helpless William V, who abandoned office and fled to England.

Impact of the French Revolution

THE PERIOD OF FRENCH RULE (1795–1813)

The old republic was replaced by the Batavian Republic, and the political modernization of the Netherlands began—a process that would take more than half a century and pass through many vicissitudes; yet it was one marked by an extraordinary lack of violence. For all its flaws and inconsistencies, the old regime of the United Provinces had enjoyed many of the institutions and practices that other countries had to create in the fire of revolution: the sovereignty of parliamentary assemblies; wide-ranging political and religious toleration; equality of all citizens before the law; and an unusually broad distribution of the benefits of economic prosperity, however far the social system was from equality. Even the sense of nationhood had put down deep roots, although the awareness of differences of religion remained powerful. In a word, the Dutch had already achieved a large measure of the "liberty, equality, and fraternity" that had become the slogan of the French Revolution. The task that confronted the Batavian and the successor regimes was to adapt old institutions and create new ones that could meet the needs of a new era. But the Dutch statesmen had to operate within the confines of a small power shorn of most of its military and naval strength and yet more dependent than most other countries upon its trading and shipping.

The Batavian Republic (1795–1806). The Batavian Republic lasted 11 years, during which it proclaimed the sovereignty of the people but was in fact a protectorate of France. The organization of government had to be approved not only by the Dutch people but also by whatever government happened to be in control in France. The constitutions therefore reflected not only Dutch conditions and ideas but also the arrangements in effect in Paris; nonetheless, they did create a political system of the new type, a new regime, in the Netherlands. After much debate, the ancient historic provinces—so unequal in wealth, population, and influence—were replaced by a unitary republic divided into departments and electoral constituencies that were roughly equal in population, if not in wealth. The representatives elected to the National Assembly (which replaced the historic States-General) were not delegates of provincial assemblies by whose decisions they were bound but deputies with full independence of judgment. The ancient system of government, with its medley of assemblies and boards with imperfectly differentiated functions, was replaced by a modern system of separate and explicitly defined legislative, executive, and judicial branches; functionally organized ministries directed the work of foreign affairs, internal affairs, war, and navy. The full legal equality of all citizens in all parts of the country was proclaimed; the residents of North Brabant, Zeeland-Flanders, Limburg, and Drenthe gained the same rights as all other citizens of the republic, just as their districts, once excluded from the States-General, now participated in the national government equally with all others. The Reformed church lost its standing as the sole official, protected church, supported out of state revenues; equal status was accorded to all religious denominations, including Roman Catholics and Jews. Yet full separation of church and state was not proclaimed, and their relationship was to continue as one of the central factors in Dutch politics for more than a century. The historic privileges of class and locality were abolished; the liberty of each and all under the law and before the courts replaced the diverse "liberties" of town and province, noble and regent. Where, before, town governments had co-opted their members, deputies to the National Assembly were now elected; but the franchise was limited to property holders, and these did not choose their representatives directly but through electors named by primary assemblies. Most of these institutional changes were permanent, though the republican form of government was replaced by a kingdom in 1806 and never reestablished.

Reorganization of the provinces

While these momentous changes were being debated and adopted, the ordinary work of state and nation had to con-

tinue amid conditions of almost unprecedented difficulty. England reacted to the French occupation of the Netherlands and the flight and overthrow of the stadtholder by a declaration of war and a blockade. Dutch overseas trade and fishing, the country's most essential occupations, were brought to a near standstill, while most of the Dutch colonies were seized by the English on behalf of William V. The French, however, remained relentless in their own exploitation of the occupied "fraternal republic." The Dutch government, which took over the whole accumulated burden of national and provincial indebtedness, had also to bear the costs of the French occupying forces and to pay immense sums in tribute to the Paris government; indeed, the forced circulation of vastly inflated French assignats (paper currency) at face value was a scarcely disguised and very effective form of French taxation directly upon the Dutch people. Nor did the successive French governments—republican, consular, or imperial—grant the Dutch any greater freedom of trade with France or other countries under its control in compensation for the lost overseas business.

Shift toward agriculture

As trade declined and industry languished, the Netherlands began to change in economic character toward a primarily agricultural country. The venturesome spirit for which Dutch businessmen had been so famed a century or two before seemed to be lost, replaced by what the Dutch themselves called a "jansalie" (stick-in-the-mud) attitude; once-bustling cities dwindled to mere market towns; even Amsterdam lost much of its population. As a result, it became difficult to consolidate the new government. A multiple executive modeled on the French Directory and lacking a firm base in established political institutions and practices reflected the intrigues of individuals rather than the programs of clearly delineated parties. The victors quarreled among themselves and looked to Paris to decide among them, or at least passively accepted its dictum, given by coups d'état organized or approved by the French army command. In 1805, Napoleon gave quasi-dictatorial powers to R.J. Schimmelpenninck. Schimmelpenninck, called councillor pensionary after the fashion of the old provincial leaders, was actually an uncrowned and nearly absolute monarch (although, ultimately, power continued in Napoleon's hands); he nonetheless carried into practice many of the reforms that had been proposed but not adopted. Napoleon, however, decided the next year to incorporate the Dutch state directly into his "Grand Empire" of vassal states.

The Kingdom of Holland and the French Empire (1806–13). Renamed the Kingdom of Holland, the Netherlands received as its monarch Napoleon's younger brother Louis. The four years of his kingship were one of the strangest episodes in Dutch history. Louis Bonaparte was a stranger in the land, yet he took its interests to heart, evading his brother's commands and winning the respect, if not quite the affection, of his subjects. The reconciliation of former Orangists, republicans, and Patriots began under his rule, for, in the face of the apparent permanence of the Napoleonic empire, they entered his government and worked together. Nonetheless, the brute fact remained that, for Napoleon, Holland was the kingpin of the "continental system," which he hoped would bring England to its knees by cutting off its continental exports. French officials enforced the vigorous suppression of the smuggling of English and colonial goods to the Continent through Holland that had sprung up over the past decade with London's connivance. King Louis's resistance to his brother's efforts and his refusal to put French interests ahead of Dutch led to the emperor's decision to oust his brother from his throne in 1810 and to incorporate Holland into the French Empire.

Ouster of King Louis

Little changed, however; the same officials—some Dutch, some French—continued to do the work of government in the country, which remained outside the French tariff system. As long as the Napoleonic empire seemed firmly based and permanent, Dutchmen served the new sovereign as they had King Louis, all the more readily because the exiled prince of Orange gave permission for such collaboration. Dutch soldiers continued to fight in Napoleon's campaigns, losing heavily in the Russian invasion of 1812. But as it became increasingly obvious, after the failure of the Russian and Spanish campaigns, that the Napoleonic empire was collapsing, influential Dutchmen began to prepare for the creation of a new and independent regime; it was taken for granted that its head would be the prince of Orange—the son of William V, who had died in 1806—and that it was desirable that it be established by the Dutch people rather than imposed by the eventual allied victors. The movement for restoration was led by a remarkable figure, Gijsbert Karel van Hogendorp, a man of firm political principle who had refused to serve any of the governments that ruled in Holland after 1795, yet accepted the necessity for a reestablished prince of Orange to govern the country as a limited constitutional sovereign.

During the autumn of 1813, Hogendorp secretly planned a takeover of government from the French, which became possible without bloodshed during November as French troops withdrew to their homeland. On November 30, the hereditary stadtholder, at the invitation of Hogendorp's provisional authority, returned from England to proclaim his reign as hereditary prince. In 1814, he granted a charter establishing a constitutional monarchy, with restricted powers for a Parliament elected by a narrow property suffrage. At the insistence of the victorious powers meeting at the Congress of Vienna, he took the title of king of The Netherlands and was given sovereignty over the southern Netherlands, which included both Belgium and Luxembourg. During the campaign against Napoleon after his return from Elba in 1815, Dutch troops played a major role in his defeat at Waterloo.

THE KINGDOM OF THE NETHERLANDS (1814–1918)

King William I. The reign of King William I, as the restored prince of Orange was now called, was one of the most critical periods in the history of The Netherlands. During this quarter-century the adaptation of the country to the conditions and requirements of modernity moved in a complex and even contradictory way, guided by a monarch who in his economic policy was far more forward-looking than most of his countrymen but who in politics resisted the expansion of Parliament and the introduction of liberal principles. He was a 19th-century version of the "enlightened despot," a man intent upon power, although not so much for its own sake as in order to serve the welfare of his country as he saw it. The role of the States-General—which continued to represent a general electorate of tax-paying citizenry—was strictly limited to the enactment of laws proposed by the government and to approval of a long-term budget; it was in no sense the representative of a sovereign people. The ministers of state were the agents of the king and responsible to him, not to the States-General. Yet the basic structure of modern government had been created in The Netherlands; constitutional debate would be concerned with redistributing powers and responsibilities among existing institutions.

Role as the "enlightened despot"

William I was at his best in confronting the problem of reviving the economic life of the country after the shattering impact of the long French occupation. He put the support of both the government and his own private fortune behind encouragement of commerce and, to a lesser extent, of industry. He sponsored the formation of The Netherlands Trading Society, a nominally private firm that undertook the important but costly and risky enterprise of reorganizing Dutch long-distance trade and shipping, particularly to the Netherlands East Indies, which were returned to Dutch sovereignty by England as part of the peace settlement. With the reopening of trade between the European continent and the wider world, the advantages of the Dutch position at the mouth of the great rivers favoured the revival of the traditional branches of Dutch enterprise; but competition from the ports of other countries, notably from Hamburg and Bremen, as well as from Britain, remained strong. Only in the Netherlands East Indies did the Dutch have a clear advantage over their rivals, despite the abandonment of the monopoly formerly maintained under the East India Company.

The most difficult problem faced by the new regime in The Netherlands was the relations between Holland (which now became the everyday name for all the north-

ern Netherlands, in Dutch as well as foreign usage) and Belgium. The king was passionately devoted to the preservation of a single state encompassing all the Low Countries, a unity lost in the revolt against Spain more than two centuries before; but the sense of common nationhood, cultural and political, was quite weak among the people. The Belgians resented assuming a share of the burden of debt inherited by Holland; they were oriented toward industry, Hollanders toward trade. French was the language of the leading classes in the south, and the use of Dutch as the official language was bitterly opposed even by Flemings, who resented the Dutch version of the common Dutch-Flemish language. Most Flemings, as devout Roman Catholics, were hostile to the predominantly Protestant Hollanders. William's efforts to assume the control that Napoleon had possessed over the Belgian Catholic church met fierce resistance. At the same time the authoritarian character of William's government, particularly the sharp censorship of the press in Belgium, aroused the antipathy of liberals to the regime. The result was the outbreak of the Belgian Revolution of 1830 and the proclamation of Belgian independence. William, supported by a majority of Dutchmen, who were angered by what they saw as Belgian ingratitude, was able to defeat the hastily organized Belgian army; but the European powers intervened to secure Belgian independence, although it was not until 1839 that a final settlement was reached and the last Dutch troops withdrew from Belgian soil. William, deeply despondent, abdicated the next year, leaving to his son, King William II, the task of coming to terms with the new situation.

The Belgian Revolution of 1830

William II and William III. The new king was not a man of clear ideas or strong will, but he was able to do what his father dared not even envisage—to oversee the transformation of The Netherlands into a parliamentary, liberal state. When the crisis of the 1848 revolutions broke, first in France and then in central Europe, William II turned to the leading liberal thinker, J.R. Thorbecke, to guide the change. A new constitution was written, largely modeled on the British (and Belgian) pattern, which gave effective supremacy to the States-General and made the monarch a servant and not the master of government. The king died the next year, and the work of transformation continued under his son, William III (1849–90), who named Thorbecke prime minister. The constitutional monarchy was consolidated, even though Thorbecke stepped down in 1853 because of Protestant rioting against the reestablishment of a Roman Catholic archbishop at Utrecht. Gradually, over the next century, the scope of Dutch democracy was extended to include ever broader sections of the Dutch population in the franchise; universal male suffrage was achieved during World War I, and suffrage was extended to women after World War II. During this period, political parties of the modern type took shape, organized along religious and ideological lines; to the original Liberal, Protestant, and Catholic parties were eventually added Socialist, Conservative-Protestant, Communist, and minor parties. As no single party was able to emerge with a majority, coalition politics became inevitable. The central issue of political controversy became the "school conflict" (*schoolstrijd*), which pitted the liberal (and later socialist) advocates of public schools against the combined Protestant and Catholic parties, which demanded that the state support private ("special") schools equally with the public schools. For several decades, the liberals remained generally in control and made few concessions on the school issue. But when the Protestant leader Abraham Kuyper formed a coalition with the Catholics in 1888, the religious parties were able to gain power and to favour the special over the public schools. Their policy was assailed by the secular parties, the traditional liberals, the progressives, and the socialists. The liberals, however, were at odds with the other anticlerical parties on other issues, notably economic policies and the extension of the suffrage. The liberals tended to be the most conservative party on economic issues and favoured a restricted electorate; the progressives were vigorously democratic in outlook, as were the socialists, who also favoured universal suffrage, protection of the right to strike, labour legislation, and other welfare measures. The other major issue of the latter half of the 19th century was the role of the Dutch East Indies. The income received by the Dutch treasury from Indonesian taxes helped balance the national budget; yet the revelations of harsh conditions in the distant archipelago made it impossible to maintain the "culture system," which had been introduced to force the production of certain crops for export, while the long Achinese War drained the treasury.

Issue of the Dutch East Indies

Queen Wilhelmina and World War I. During the first half of the reign of Queen Wilhelmina (1890–1948), the political situation remained fundamentally unchanged. The major parties came to recognize that the school struggle interfered with the solution of other problems. An agreement in principle was reached on the eve of World War I, by which the secular parties accepted state support for religious schools on a basis of equal funds in exchange for enactment of universal male suffrage. When war broke out in 1914, Holland, which had declared its neutrality, put aside the proposed reforms in order to concentrate on the immediate problem of maintaining the country's livelihood in the face of blockades. The "Pacification," as the compromise was called, was adopted in 1917 and put into effect after the return of peace. The war years saw almost all political controversies set aside, while the government took unprecedented action in maintaining trade and guiding economic life. Although spared the horrors of combat, the Dutch had to maintain a large standing army, and mutinies broke out among the soldiers in 1918.

The century from the restoration of Dutch independence in 1813 until World War I saw fundamental transformations of Dutch life. The economic base was modernized; the role of agriculture fell off, with most Dutch farmers producing dairy and meat products for the market; trade and shipping were revived in the face of fiercely competitive conditions. But most important was the rise of industry—first textiles in the eastern provinces, then coal in the southeast in Limburg, and finally modern manufactures, notably the great Philips electrical products factories at Eindhoven. Rotterdam became one of the world's busiest ports and the centre of chemical and other industries. These changes were paralleled in society by the gradual extinction of pauperism, the domination of the middle-class business and professional men, and the improvement of the conditions of working people and farmers, especially after the mid-19th century.

Changes in Dutch society

Although religious freedom in the Netherlands was generally as great as anywhere in Europe, Protestant conservatives faced major difficulties, especially during the first half of the 20th century, when they protested the modernizing ideas of the Reformed (Hervormde) church; their efforts to create independent religious communities met with sharp resistance from the government, which, it should be noted, did not interfere in non-Protestant religions. Some of the Gereformeerden (the older name for "Reformed" used by the conservatives) emigrated, many of them to the United States; but, by the latter half of the century, persecution ceased.

The cultural life of Holland remained very largely confined within national boundaries; Dutch thinkers, writers, and artists responded strongly to influences from Germany, France, and England but themselves had little impact abroad. Dutch scientists maintained a respected position for their country; Hugo de Vries was one of the principal founders of the science of genetics, while the physicist Hendrik Antoon Lorentz contributed greatly to Einstein's theories of relativity. Dutch artists were generally imitative, although the Hague school of Impressionists displayed great gifts; only van Gogh, who spent most of his active life in France, achieved world reputation. Dutch literature ran parallel to main currents abroad; the Réveil early in the century was a movement of intensely religious romanticism with strongly conservative ideas, while Eduard Douwes Dekker (pseudonym Multatuli) in mid-century expressed the moods of social criticism with great power; the movement of "Men of the 'Eighties" (Tachtigers) brought to the fore an emphasis on aesthetic values and spirituality; and early in the 20th century a literature of social protest reemerged.

THE NETHERLANDS SINCE 1918

The modernization of The Netherlands accelerated after 1918. Although the country became a member of the League of Nations, it reaffirmed its neutrality, which was symbolized by the presence of the International Court of Justice at The Hague. There were troubled relations with Belgium, which not only abandoned its neutrality for a close alliance with France but demanded territorial cessions from Holland. The Dutch government successfully resisted any amputation of its territory. The Dutch, for their part, refrained from giving any official support to the Flemish nationalist movement in Belgium, although a Great Netherlands movement, principally among intellectuals, emphasized the underlying unity of the Dutch and Flemings. Domestic politics followed the same course, with the Protestant political parties continuing to back generally conservative policies, especially after the onset of the world depression in the 1930s.

Dutch resistance to Belgian demands

World War II. At the outbreak of World War II in 1939, the Dutch sedulously maintained their neutrality, although their sympathies lay overwhelmingly with the Allied powers. Nonetheless, when Nazi Germany undertook the campaign against France in the spring of 1940, its forces attacked not only Belgium in order to outflank the French defenses but also Holland. The Dutch armies were overwhelmed in less than a week, and the government, accompanied by Queen Wilhelmina and the royal family, withdrew to England and formed a government in exile.

Under German occupation, public administration remained the responsibility of the Dutch bureaucracy, which made some effort to buffer German political repression, deportation of Jews, and forced employment of Dutch labour in Germany. A resistance movement sprang up, which, with the exception of a few Dutch Nazi collaborators, spanned all groups from the conservatives to the communists. The Germans retaliated by executing Dutch hostages for such measures of resistance as the strike of Amsterdam dockworkers against the seizure and deportation of Dutch Jews to extermination camps in Germany. Some Jews were able to go into hiding with the assistance of friends, but the large majority were taken away to their death. In the final phases of the war, the Dutch faced severe food shortages, and, during the last months before liberation (May 1945), they were near famine.

The postwar period. After World War II Dutch life changed dramatically. Wilhelmina and her government returned from exile to reestablish a government more strongly democratic than ever, with both universal suffrage and proportional representation in elections. Anticipating the difficulty of postwar reconstruction, the government, industry, and labour agreed on a plan for industrial and commercial expansion that avoided a rapid expansion of prices or wages. The plan worked effectively for more than two decades, so that the Dutch were able to avoid serious inflation until the breakdown of the consensus between industry and labour in the late 1960s.

Dutch industrialization moved forward with speed and depth, expanding to include the large-scale production of steel, electronics, and petrochemicals. Holland, putting aside the policy of neutrality as a failure, entered vigorously into the postwar Western alliances, including the Benelux economic union with Belgium and Luxembourg and the North Atlantic Treaty Organization (NATO). It also was one of the founding members of the European Economic Community (1957), now part of the European Union (EU), but, as a relatively small country, it has had limited influence. In Indonesia, after wartime occupation by Japanese forces, a nationalist rebellion forced the Dutch to grant the country full independence in 1948. The Netherlands Antilles remained part of the Dutch kingdom, although no longer under the authority of the government at The Hague; Surinam became independent in 1975 and was renamed the Republic of Suriname in 1978.

Abandonment of neutrality

Dutch political alignments since the mid-20th century have evolved slowly. The first postwar governments were dominated by an alliance of the Labour and Catholic parties, which continued until the Labour Party went into opposition in 1958. From 1958 until 1973, centre-right coalitions ruled the country, and from 1973 to 1977, a left coalition controlled the government. Since the 1970s, governing coalitions have included at least two of the three main parties (Christian Democrats, Liberals, and Labour) in various combinations. During the 1990s, support for the Christian Democrats declined, and most governments were Liberal-Labour coalitions.

During the 1960s the postwar social consensus broke down, and protests by youth and labour erupted into riots, especially in Amsterdam. The royal family was the subject of controversy, particularly after the marriage in 1966 of Queen Juliana (who had succeeded Wilhelmina in 1948) to a German diplomat. The queen's husband and consort, Prince Bernhard, was involved in a bribery scandal and resigned his public offices. Juliana abdicated in 1980 and was succeeded as queen by Beatrix. Meanwhile, The Netherlands faced a series of economic recessions during the 1970s and '80s, as well as a controversy during the 1980s over the siting of U.S. nuclear missiles in the country.

By the 1970s Dutch politics, like Dutch society in general, had largely ceased to practice what was called pillarization (*verzuiling*)—the organization of political parties, schools, labour unions, businessmen's organizations, social and sport clubs, and many professional groups on the basis of membership in a religious-ideological "pillar," either Roman Catholic, Protestant, or humanist (the latter including liberals and socialists). Pillarization had received official confirmation in the Pacification of 1917 and removed most of the tinder from Dutch politics, but it also kept ordinary Dutch people socially separated to a greater degree than in most other Western countries. Some 25 years after the end of World War II, the system began to disintegrate. New political parties were formed, most importantly the Christian Democratic Appeal (CDA), inclusive of all major Christian factions. The Labour Party (Partij van de Arbeid), keeping its distance from the more extreme leftist groups, joined with the CDA in forming a coalition government in 1989. In 1990 left-wing groups formed a new party called Green-Left. (H.Ro./Ed.)

Discontinued pillarization

During the 1990s, while the economy prospered, environmental concerns increased, not only because of the country's vulnerability to rising sea levels, river flooding, and the effects of pollution but also because Dutch industry and agriculture are themselves major sources of pollution.

By the turn of the 21st century, The Netherlands had developed a reputation for liberal policies, such as toleration of prostitution and of the limited use and sale of marijuana and hashish. Same-sex marriages and euthanasia were legalized, and penal sentences were relatively light. However, The Netherlands also was one of the most heavily planned and regulated Western societies: the state had a role in most matters, despite attempts to reduce its intervention in the 1980s and '90s. In general, the Dutch tradition of tolerance extended to its immigrant population, but anti-immigrant politician Pim Fortuyn was able to tap into increasing Dutch uneasiness in 2002. Just nine days before that year's election, Fortuyn was assassinated—the country's first modern political killing. Nevertheless, his party gained enough support to become part of a centre-right governing coalition. Because of disputes within Fortuyn's party, however, the government resigned after only three months in office. (M.J.W./Ed.)

For later developments in the history of The Netherlands, see the BRITANNICA BOOK OF THE YEAR.

BIBLIOGRAPHY

General works. An extensive source is *The Kingdom of The Netherlands,* a collection of 17 short booklets published by the Ministry of Foreign Affairs. Further resources may be found in PETER KING and MICHAEL WINTLE (comps.), *The Netherlands* (1988), an annotated bibliography.

Physical and human geography. H. MEIJER, *Compact Geography of The Netherlands,* 5th rev. ed. (1985), is a brief survey of geographic conditions. Informative atlases include R. TAMSMA, *The Netherlands in Fifty Maps* (1988); and *Atlas of the Netherlands* (1963–77). AUDREY M. LAMBERT, *The Making of the Dutch Landscape,* 2nd ed. (1985), provides a historical geography. Modern Dutch society is explored in JOHAN GOUDSBLOM,

Dutch Society (1967); GERALD NEWTON, *The Netherlands: An Historical and Cultural Survey, 1795–1977* (1978); HANS VAN AMERSFOORT (J.M.M. VAN AMERSFOORT), *Immigration and the Formation of Minority Groups: The Dutch Experience, 1945–1975* (1982, originally published in Dutch, 1974); and WILLIAM Z. SHETTER, *The Netherlands in Perspective: The Organizations of Society and Environment* (1987). Dutch economic history and conditions are addressed by MARC DE SMIDT and EGBERT WEVER (eds.), *A Profile of Dutch Economic Geography* (1984); RICHARD T. GRIFFITHS (ed.), *The Economy and Politics of the Netherlands since 1945* (1980); and HERMAN VAN DER WEE and EDDY VAN CAUWENBERGHE (eds.), *Productivity of Land and Agricultural Innovation in the Low Countries, 1250–1800* (1978).

History. *General works:* PETRUS JOHANNES BLOK, *History of the People of the Netherlands,* 5 vol. (1898–1912, reprinted 1970; originally published in Dutch, 8 vol., 1892–1908), is a classic history of the northern territories, although now outdated, particularly so on the history of the Middle Ages. HENRI PIRENNE, *Histoire de Belgique,* 7 vol. (1900–32), a brilliantly written history extending to 1914 by the famous Belgian historian, covers for the period of the Middle Ages the northern as well as the southern parts of the Low Countries, although emphasis is on the south (the post-Revolt period is covered only for the south). GEORGE EDMUNDSON, *History of Holland* (1922), is an excellent general work, although better for the republican than the modern period. IVO SCHÖFFER, *A Short History of the Netherlands,* 2nd rev. ed. (1973), provides a useful history of the northern Netherlands. An excellent general synthesis written by expert authors is J.A. BORNEWASSER *et al.* (eds.), *Winkler Prins Geschiedenis der Nederlanden,* 3 vol. (1977–78). PIETER GEYL, *Geschiedenis van de Nederlandsche stam,* rev. ed., 3 vol. (1948–58), is a monumental work in which the linguistic-ethnic unity of the Dutch-speaking Low Countries is emphasized. D.P. BLOK *et al.* (eds.), *Algemene Geschiedenis der Nederlanden,* 15 vol. (1977–83), is an extensive history of both the northern and southern Low Countries from Roman times to the present day, with detailed bibliographies. The Dutch-speaking part of actual Belgium is considered in MAX LAMBERTY *et al.* (eds.), *Twintig Eeuwen Vlaanderen,* 15 vol. (1972–79). Other works concerning the same area include RENÉE DOEHAERD *et al.* (eds.), *Histoire de Flandre: des origines à nos jours* (1983), an excellent and up-to-date general synthesis; and A.G.H.A. BAART and J. LOUAGE (eds.), *Culturele geschiedenis van Vlaanderen,* 10 vol. (1982–83), a more popular version by good scholars of the general history of art, literature, and daily life. The French-speaking regions have been competently dealt with by ÉMILE COORNAERT, *La Flandre française de langue flamande* (1970); LOUIS TRENARD (ed.), *Histoire des Pays-Bas français* (1972, reissued 1984); and HERVÉ HASQUIN *et al.* (eds.), *La Wallonie: le pays et les hommes,* 6 vol. (1975–81).

History of the Low Countries to 1579: The prehistory of the Low Countries is presented by SIEGFRID J. DE LAET, *The Low Countries* (1958), the only general survey in English on the topic, but now out of date in many respects; L.P. LOUWE KOOIJMANS, *The Rhine/Meuse Delta* (1974), on prehistory and Holocene geology in the Dutch coastal wetlands; H.T. WATERBOLK, "Archaeology in the Netherlands: Delta Archaeology," *World Archaeology,* 13(2):240–54 (1981), a short evaluation of Dutch archaeology in the last decades; and J.H.F. BLOEMERS, L.P. LOUWE KOOIJMANS, and H. SARFATIJ, *Verleden Land: Archeologische opgravingen in Nederland* (1981), a full-colour presentation of modern-day archaeology in the Netherlands, from the Middle Paleolithic up to post-medieval times. W. JAPPE ALBERTS, H.P.H. JANSEN, and J.F. NIERMEYER, *Welvaart in wording: sociaal-economische geschiedenis van Nederland van de vroegste tijden tot het einde van de Middeleeuwen,* 2nd enlarged ed. (1977), presents a social and economic history of the northern Netherlands during the Middle Ages, with emphasis on the economic aspects. É. DE MOREAU, *Histoire de l'Église en Belgique,* 5 vol. (1945–52), with exhaustive bibliographies, and a supplemental vol. containing maps (1948); and R.R. POST, *Kerkgeschiedenis van Nederland in de Middeleeuwen,* 2 vol. (1957), are extensive handbooks of the church history of, respectively, the southern and the northern Netherlands. D.P. BLOK, *De Franken in Nederland,* 3rd ed. (1979), offers a brilliant portrayal of the early history of the northern Netherlands. P.C.J.A. BOELES, *Friesland tot de elfde eeuw: zijn vóór- en vroege geschiedenis,* 2nd ed. (1951), is an authoritative work on early Frisian history, with a lengthy English summary. FRANÇOIS-L. GANSHOF, *La Flandre sous les premiers comtes,* 3rd ed. rev. (1949), recounts the history of the important principality of Flanders, tracing its origins and ending with the eventful crisis of 1127–28. HENRY STEPHEN LUCAS, *The Low Countries and the Hundred Years' War, 1326–1347* (1929, reprinted 1976), is a reliable and richly documented account of political events. A series of books by RICHARD VAUGHAN, *Philip the Bold: The Formation of the Burgundian State,* rev. ed. (1979), *John the Fearless: The Growth of Burgundian Power,* rev. ed. (1979), *Philip the Good: The Apogee of Burgundy* (1970), and *Charles the Bold: The Last Valois Duke of Burgundy* (1973), are well-documented studies of the Burgundian dukes and the growth of their political power. J. HUIZINGA, *The Waning of the Middle Ages: A Study of the Forms of Life, Thought, and Art in France and the Netherlands in the XIVth and XVth Centuries* (1924, reprinted 1985; originally published in Dutch, 1919), is a classic work. WALTER PREVENIER and WIM BLOCKMANS, *The Burgundian Netherlands* (1986; originally published in Dutch, 1983), is a magnificently illustrated scholarly general synthesis concerning the period 1380–1530. GEOFFREY PARKER, *The Dutch Revolt* (1977), analyzes the period 1565–1659.

History of The Netherlands, 1579 to the present: PIETER GEYL, *The Revolt of the Netherlands, 1555–1609,* 2nd ed. (1958, reissued 1980), and *The Netherlands in the Seventeenth Century,* 2nd ed., 2 vol. (1961–64), are complementary works. J. HUIZINGA, *Dutch Civilisation in the Seventeenth Century, and Other Essays,* comp. by PIETER GEYL and F.W.N. HUGENHOLTZ (1968), is a masterpiece of condensation. C.R. BOXER, *The Dutch Seaborne Empire, 1600–1800* (1965, reissued 1977), is a vigorously written and well-informed account. CHARLES WILSON, *The Dutch Republic and the Civilisation of the Seventeenth Century* (1968), is written by an outstanding English historian of The Netherlands. HERBERT H. ROWEN, *The Princes of Orange: The Stadholders in the Dutch Republic* (1988), surveys the period of the house of Orange. SIMON SCHAMA, *The Embarrassment of Riches: An Interpretation of Dutch Culture in the Golden Age* (1987), and *Patriots and Liberators: Revolution in the Netherlands, 1780–1813* (1977), are brilliant, innovative studies. E.H. KOSSMANN, *The Low Countries, 1780–1940* (1978), offers a penetrating comparison of the history of Holland and Belgium. HENRI GRIMAL, *Decolonization: The British, French, Dutch, and Belgian Empires, 1919–1963* (1978; originally published in French, 3rd ed., 1975), includes useful documents, maps, and case studies. AREND LIJPHART, *The Politics of Accommodation: Pluralism and Democracy in the Netherlands,* 2nd ed., rev. (1975), provides a sociological study of "pillarization," fundamental for the contemporary period.

New Orleans

Unquestionably one of the most distinctive cities of the New World, New Orleans was established at great cost in an environment of conflict. Its strategic position, commanding the mouth of the great Mississippi–Missouri river system, which drains the rich interior of North America, made it a pawn in the struggles of Europeans for the control of North America. As a result, the peoples of New Orleans evolved a unique culture and society, while at the same time blending many heritages. Its citizens of African descent have provided a special contribution in making New Orleans the birthplace of jazz. New Orleans is a city of paradox and contrast: while it shares the urban problems afflicting other U.S. cities, it has nevertheless preserved the exuberant and uninhibited spirit exemplified by its carnival season, which culminates in the famous annual Mardi Gras, when more than 1,000,000 people throng the streets. The city also has a solid economic base: it is the largest city in Louisiana, the second port of the United States in tonnage handled, a major tourist resort, and a medical, industrial, and educational centre.

Physical and human geography

THE LANDSCAPE

The city layout. The city of New Orleans and Orleans Parish (county) are coextensive, covering an area of 199 square miles (518 square kilometres). The boundaries are formed by the Mississippi River and Jefferson Parish to the west and Lake Pontchartrain to the north. Lake Pontchartrain is connected by the Rigolets Channel to Lake Borgne on the east, and the southern boundary of New Orleans is made up of St. Bernard Parish and, again, the Mississippi River. The city is divided by the Mississippi, with the principal settlement on the east bank. The west bank, known as Algiers, has grown rapidly. It is connected to eastern New Orleans by the Greater New Orleans Bridge. The bridge, completed in 1958, proved to be a bottleneck to the city's traffic; a second, adjacent bridge designed to alleviate the problem was completed in September 1988.

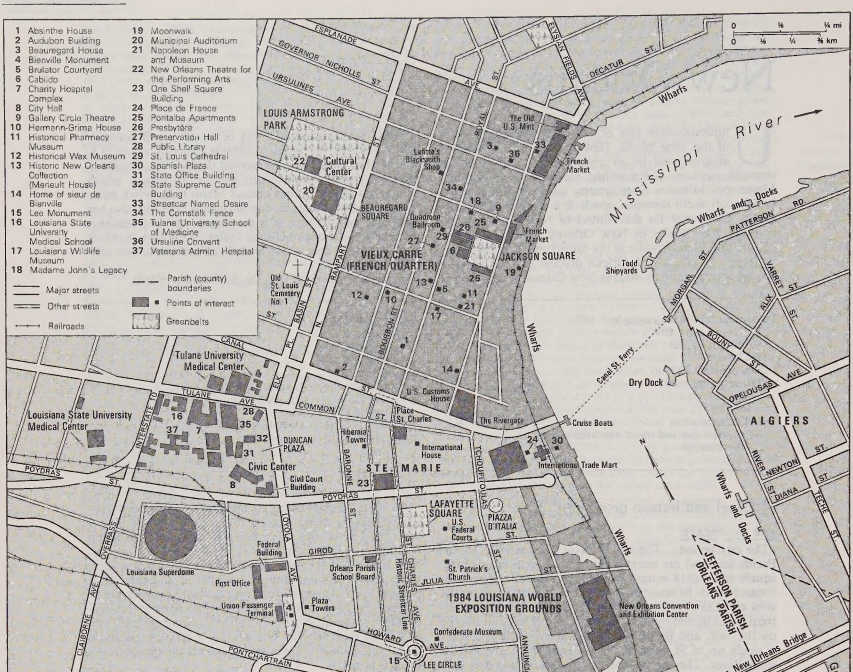
The early city was located on the east bank along a sharp bend in the Mississippi, from which its popular name, "Crescent City," is derived. The modern metropolis has spread far beyond this original location. Because its saucer-shaped terrain lies as low as five feet (1.5 metres) below sea level and has an average rainfall of 57 inches (1,425 millimetres), a levee, or embankment, system and proper drainage have always been of prime importance to the city.

Climate. New Orleans has a moderate climate; the average daily temperature from October through March is 60° F (16° C), and from April through September the daily average is 77° F (25° C). Freezing weather is rare, and the temperature rises above 95° F (35° C) only about six days a year.

THE PEOPLE

The population of New Orleans has been declining. Whites account for less than half of the total, whereas in 1960 they made up almost two-thirds. In contrast to the population decline in Orleans Parish, the adjacent parishes of St. Bernard, Jefferson, and St. Tammany—which, together with Orleans, compose one of the national Standard Metropolitan Statistical Areas (SMSA)—have shown steady increases. Since the black population in these three parishes is quite small, these figures indicate a white move to the suburbs, a trend common to major U.S. cities.

The shift in population to the suburbs has been motivated less by racial tension (although this may play a part) than by desires for better and more modern living facilities. The fact that a large segment of the black population resides in declining neighbourhoods (some segregated, some integrated) has spurred both black and interracial political, social, and religious organizations to work either independently or with city and federal agencies on projects to improve the quality of life for low-income citizens. The additional fact that New Orleans has an upper-class and a middle-class black population has been a significant factor in such projects.



THE ECONOMY

The port. New Orleans has always been primarily a commercial centre, with manufacturing playing a secondary role in its economic life. The busy harbour, besides adding to the city's cosmopolitan atmosphere, is the foundation of the metropolitan economy, influencing many aspects of urban life.

The era of the modern Port of New Orleans began in 1879 with the construction of jetties in South Pass, one of three passes that flow from the river into the Gulf. Sandbars had formed at intervals in these passes and had hindered ships entering the river since the city's founding. The jetties narrowed South Pass, forcing the river to cut a deeper channel to a depth of 30 feet. Later, a second channel, Southwest Pass, was deepened to 40 feet by installing jetties; it is now the main pass used by seagoing vessels entering and leaving the river. The distance from New Orleans to the Gulf is about 110 miles (180 kilometres).

Another major step forward for the port was taken in 1896, when the state legislature removed wharf facilities from the control of private contractors and created the Board of Commissioners of the Port of New Orleans (the Dock Board), a body charged with administering the public wharves. In 1908 the Dock Board was authorized to issue negotiable bonds for the improvement of port facilities. The projects subsequently accomplished included the rebuilding and expansion of public wharves and the construction (in partnership with the Board of Levee Commissioners of the Orleans Levee District) of the five-and-a-half-mile Industrial Canal, which links the river to Lake Pontchartrain, the Intracoastal Waterway, and the Mississippi River–Gulf Outlet. In 1963 the Mississippi River–

Legislative control of the port

Central New Orleans.

Gulf Outlet, a ship channel shortening the passage to the Gulf by 40 miles, was opened to maritime traffic.

The Dock Board has formulated a plan called Centroport U.S.A., by which much of the port's activities will be switched from the Mississippi River to wharves and industrial complexes along the Gulf Outlet. The river frontage thus retired from maritime use will be diverted to such projects as high-rise apartments and public recreation areas. The Julia, Erato, and upper Poydras wharves were developed as the site of the 1984 Louisiana World Exposition. Permanent structures enhancing this area are the New Orleans Convention and Exhibition Center and the International Pavilion.

New Orleans is a major grain port both in the United States and worldwide; other exports include raw and processed agricultural products, fabricated metals, chemicals, textiles, oils, petroleum and petroleum products, tobacco, and paperboard. There has been substantial growth in bulk exports since the early 1980s, which has made New Orleans the lighter aboard ship (LASH) cargo and Seabee barge capital of the world. Grain, coal, and animal feed make up a major portion of LASH and Seabee trade. In international commerce about 5,000 oceangoing vessels dock at New Orleans annually, and more than 40 nations have consular offices in the city.

Industry. Greater New Orleans is a major industrial area. A concentration of petrochemical plants has sprung up along the Mississippi River above New Orleans. The National Aeronautics and Space Administration established the Michoud Assembly Facility in New Orleans in 1961 to produce the giant Saturn rocket boosters used in flights to the Moon. The major goods manufactured in the Greater New Orleans area are food products, clothing and related items, stone, clay and glass articles, primary metal and fabricated metal items, and transportation equipment. Tourism is a major industry.

Petrochemical industries along the Mississippi above New Orleans and offshore oil rigs in the Gulf have become serious polluters, however, through oil-rig fires and oil slicks and discharges of mercury, arsenic, and lead, threatening the city's drinking water, ruining the taste of river fish, and endangering the ecology of the Gulf. Despite federal actions against the offending industries, much remains to be done.

Transportation. The transportation facilities of New Orleans include three airports: New Orleans International Airport, to the west of the city; New Orleans Airport, on Lake Pontchartrain, devoted to private and corporate use; and the U.S. Naval Air Station, serving air reserve units of the various armed services. Several railroads operate out of New Orleans, and passenger bus, truck, and barge lines transport people and cargo to and from the city. Regular express sailings by steamship lines also offer passenger- and cargo-carrying service. The major access bridges serving

the Greater New Orleans area, in addition to the Greater New Orleans Bridge (also known as the Crescent City Connection), are the Huey P. Long Bridge, which crosses the river above the city, and the Lake Pontchartrain Causeway, a twin span that is among the world's longest bridges, stretching more than 23 miles.

ADMINISTRATIVE AND SOCIAL CONDITIONS

Government. Both the political life and the municipal government of New Orleans have been dominated by factions of the Democratic Party. The question of state interference in city affairs versus home rule is one of the major issues. In 1954 New Orleans finally received a strong home rule charter, which substituted a mayor–council form of government for the mayor–commission form that had existed since 1912.

Municipal management

In addition to the mayor and seven council members—five elected from districts and two at large—who serve four-year terms, the position of chief administrative officer to the mayor was created. The mayor is the top administrator over the 14 municipal departments and oversees the affairs of various commissions and boards. The chief administrative officer, appointed by the mayor, is charged with supervision of city departments, the preparation of the annual budgets, and the coordination of city relations with state and federal agencies. The council is strictly a legislative body.

Political issues have changed. Gone is the antagonism between city and state governments that spanned the era from governors Huey Long in the 1920s through Earl Long in the 1940s. Political corruption is no longer an issue in city politics, and blacks have become more politically articulate since they emerged as the majority of the city's population. There has been an increase in voter registration among blacks, and black political groups now play an effective role in municipal politics. The city's first African-American mayor, Ernest N. Morial, was elected in 1978 and reelected in 1982. His son, Marc H. Morial, was elected mayor in 1994 and 1998.

Although most city and parish government has been consolidated in New Orleans, Orleans Parish officials continue to play an important role. These officials include the district attorney, the board of assessors, and the Orleans Parish School Board, which supervises public education under the state department of education.

Municipal services. Expansion of new residential areas in New Orleans, combined with the spiraling cost of services, has caused the operating budget for municipal services to rise considerably. The municipal government has been hampered by a lack of funds necessary to carry out its work effectively and to provide an appropriate income for the employees of its various departments. One of the major problems is the low assessment of taxes on both residential and industrial property and the loss of taxpayers to the suburban parishes.

Drainage has always been the main problem among municipal services. The city is virtually surrounded by levees—25 feet high on the Mississippi River and nearly 20 feet high on Lake Pontchartrain—and has some two dozen major drainage pumping stations. The drainage machinery used at these stations is among the largest found in the world. Following the disaster of 1965, when Hurricane Betsy flooded the city's lower Ninth Ward, the Sewerage and Water Board operating the pumping stations drafted a plan to make these facilities hurricane-safe. Further improvements in drainage canals and pumping equipment in the older sections of the city were also made.

Drainage and flood-control systems

Flood control along the river, Lake Pontchartrain, and secondary waterways in the city is under the direction of the Board of Commissioners of the Orleans Levee District. In addition to its primary job of flood control, the board has, since the 1920s, reclaimed hundreds of acres of Lake Pontchartrain bottomland and developed it into one of the most scenic lakefront areas in the United States. A majority of the land is dedicated to public facilities, which include sandy beaches, a marina, a cement seawall from which fishing can be enjoyed, picnic grounds, parkways with flower beds, fountains, and shelter houses. The remainder of this reclaimed land has been turned into residential subdivisions, which are among the finest in the city.

In the fight against the steadily rising crime rate in the city, the police department has, since 1961, introduced a guard-dog corps, reorganized its patrol system to increase its effectiveness, created additional police districts, built new stations in older districts, more than doubled its automotive equipment, established a community relations division, and put into operation a communication van, which acts as a field command post in times of emergency.

Police and crime

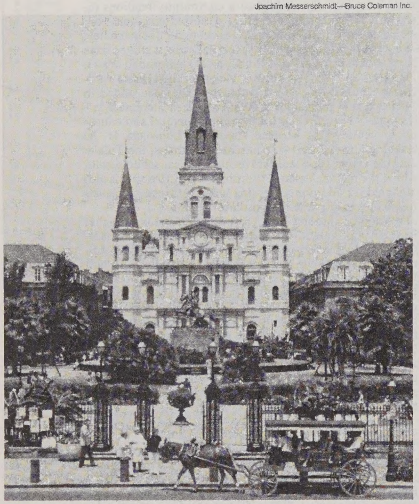
Police programs designed to mobilize citizen groups have been greatly increased to include the Neighborhood Watch Programs and the New Orleans Neighborhood Police Anti-Crime Council. A police psychologist has been added to the force, and the narcotics squad has been increased.

Health. New Orleans has become a medical and educational centre. The Medical Center of Louisiana is the teaching hospital for two adjacent institutions, the Tulane and the Louisiana State University medical schools, with which the nearby Veterans Administration Hospital is also affiliated. In addition to serving local residents, specialists frequently treat patients from Latin America.

Education. Among New Orleans' institutions of higher learning are Tulane University, Loyola University New Orleans, the University of New Orleans, Delgado Community College, Our Lady of Holy Cross College, Dillard University, Xavier University of Louisiana, and Southern University at New Orleans. The city has many private, parochial, and business schools. The public school system began in 1841 with 83 pupils and four teachers and now has some 1,000 times as many students and teachers. In 1960 a public school crisis, attracting international attention, developed when an attempt was made at the token integration of two white schools. Within 20 years the school system was overwhelmingly black, both students and teachers.

CULTURAL LIFE

The cultural life of New Orleans is a synthesis of contributions by both whites and blacks. The white American heritage is reflected in the business and commercial life of the city, while the immigrant heritage—Irish societies, German Oktoberfest, Italian St. Joseph's Day altars—adds ethnic colour to urban conformity. The black heritage is particularly rich. In antebellum days, free persons of colour were musicians, poets, journalists, business entrepreneurs, and landlords. Both black freemen and slaves were renowned for their craftsmanship in such trades as bricklaying, iron grillwork, and carpentry. The contribution of black musicians to the birth of jazz out of black blues and "field hollers" and white dance tunes and hymns is well known.



Facilities for recreation and relaxation in New Orleans are justly famous. New Orleans is often referred to as "the city that care forgot," and it has always been a town for those seeking a good time. Its residents love music, dancing, and a "Continental Sunday" spent in amusements. The three factors that have contributed to its popularity with tourists are the Old World charm of the Spanish–French architecture in its Vieux Carré (French: Old Square), the reckless abandon of its carnival and Mardi Gras, and its reputation as the birthplace, between the 1880s and World War I, of jazz.

The Vieux Carré, or French Quarter, is a sightseer's delight. Its Creole architecture, creating the atmosphere of a foreign city, combines native architectural ingenuity with adaptations of French colonial traditions of eastern Canada and West Indian Spanish colonial styles. Typical are one-story cottages opening directly on the sidewalks, with high-pitched roofs and windows reaching to the ground. Another style is the L-shaped two-story dwelling with a side entrance to an inner patio. Also built to the sidewalk, it has a roof that extends out over balconies on both the street and patio sides. Iron grillwork, designs for which were created locally and executed to a high perfection by slave craftsmen, decorates these balconies and also supports the roof. Such houses are built side by side with no openings between them, but the patios offer space for trees, flowers, and fountains and ensure privacy for the occupants.

The Vieux Carré: Creole architecture and ironwork

Central to the Vieux Carré is Jackson Square, facing the Cabildo and the Presbytère (former governmental centres, but now part of the Louisiana State Museum) and St. Louis Cathedral. All date from colonial times, but considerable stylistic changes have been made on these buildings since they were erected.

Joachim Messerschmidt—Bruce Coleman Inc.

St. Louis Cathedral in the Vieux Carré (French Quarter), in New Orleans.

On either side of this square are the Pontalba Buildings, apartments built in 1849–50, while nearby is the historic French Market. Curio and antique collectors throng the many shops on Royal Street. Side streets are lined with art galleries, perfume shops, sidewalk cafés, and tearooms. Bourbon Street is famous for its nightclubs, where a variety of music and risqué floor shows are a specialty. Devotees of jazz may visit Preservation Hall, where revivals of traditional styles may be heard. The New Orleans Jazz Club established a Jazz Museum and later donated the collection to the Louisiana State Museum system. The jazz collection is displayed in the Old U.S. Mint. Each spring the city puts on the New Orleans Jazz and Heritage Festival.

Every year during Spring Fiesta there are tours of private homes and patios in the Vieux Carré and also of the spacious Garden District uptown, the elite 19th-century neighbourhood. Boats tour the extensive harbour facilities and the magnificent scenery of nearby waterways. The observation point on the 31st floor of the World Trade Center at the foot of Canal Street offers a panoramic view of the river and city. The world-renowned Creole and spicy Cajun cuisine may be sampled in numerous restaurants, ranging from elegant dining rooms with French menus and waiters, to small cafés with checkered tablecloths, serving red beans and rice and crawfish, a local specialty.

The sporting life and the lively arts

Sports share an honoured position with jazz and carnival activities in New Orleans. The city is the home of the New Orleans Saints, a member of the National Football League, and the site of the Louisiana Superdome, one of the world's largest sports arenas. Horse racing is held at the local Fair Grounds Race Course. Boating and fishing are popular pastimes on the city's many waterways. The city's Southern Yacht Club, on Lake Pontchartrain, is the second oldest in the country. In addition to the lakefront, popular recreation areas include the city's two largest parks, City and Audubon, the latter of which has one of the nation's best zoos. The New Orleans Recreation Department operates more than 100 playgrounds and directs organized recreation activities for thousands of youngsters. In early January the Sugar Bowl football game between outstanding college teams is held at the Superdome; in conjunction with the game are competitions in other major sports.

Since World War II, New Orleans has become an art centre, with many artists and galleries offering original works to collectors. The New Orleans Museum of Art is a public museum displaying many treasures. Live theatre is represented by several community theatre groups. Musical events include operas staged annually by the New Orleans Opera Association, concerts given by the Louisiana Philharmonic Orchestra, performances by the New Orleans Ballet Association, and concerts presented by the New Orleans Jazz Club. Other attractions include the Aquarium of the Americas, one of the top aquariums in the country; the Historic Voodoo Museum; and the Contemporary Arts Center. Tours of the city's unique above-ground cemeteries are also popular.

Mardi Gras

The New Orleans carnival season begins January 6 and culminates in Mardi Gras, the "Fat Tuesday" before Ash Wednesday. The two weeks before Mardi Gras are filled with parades, both day and night, climaxing on Mardi Gras with the Rex parade. The first parading carnival group (called a "krewe") was the Mystick Krewe of Comus, which appeared in 1857, though celebrations by masked participants date back to the 1820s. The krewe of Rex came into existence in 1872. In 1992 the city council began requiring all krewes to be racially integrated; as a result, several krewes stopped parading and held only private balls. The Presbytère has an exhibit devoted to Mardi Gras.

In the latter half of the 19th century there were about a half-dozen leading newspapers, including one in French. Through a process of gradual consolidation, New Orleans now has only one major daily, the *Times-Picayune.* The city also has weekly newspapers, trade publications, college journals, and regional magazines of considerable circulation. Competitive journalism is kept alive among the city's television and radio stations.

History

FOUNDATION AND EARLY SETTLEMENT

The decision to found New Orleans, or Nouvelle-Orléans, was made in Paris in 1717 by John Law's Company of the West, which had taken control of Louisiana that year. The colony's new proprietors envisioned New Orleans (named for the French regent, the duc d'Orléans) as a "port of deposit," or transshipment centre, for future trade from upriver in the Mississippi Valley. Jean-Baptiste le Moyne, sieur de Bienville, the man who suggested the site, was entrusted with the actual foundation of the city. Clearing of underbrush for the new city probably began in March 1718. The engineers charged with this task met with problems arising from uncooperative convict labour, a shortage of supplies, two severe hurricanes (in 1721 and 1722), and the unpleasant physical conditions of mosquito-infested swamps as they set up the first crude dwellings covered with bark and reeds. An engineer, Adrien de Pauger, drafted the first plan for the town, encompassing what is now the Vieux Carré and consisting of 66 squares forming a parallelogram.

Hostility of the environment

The first residents were a colourful mixture of Canadian backwoodsmen, company craftsmen and troops, convicts, slaves, prostitutes, and indigents. In a census taken in November 1721, New Orleans had a population of 470 people: 277 whites and 172 black and 21 Indian slaves. In 1722 New Orleans was designated the capital of Louisiana, and in 1731 the city returned to the control of the French crown. More respectable colonists began to arrive, but growth continued to be precarious. The main economic staples grown in the vicinity of New Orleans were tobacco and indigo for export and rice and vegetables for local consumption. Naval stores were also exported. French ships, however, were reluctant to call at New Orleans to pick up such cargo because its value did not match its bulk.

In 1762 France, ready to part with its unprofitable port, secretly agreed to cede Louisiana to Spain, and by the Treaty of Paris (1763) Spain received New Orleans and the Louisiana Territory west of the Mississippi. After a brief rebellion—which was sternly suppressed—the inhabitants of New Orleans enjoyed peace and a growing prosperity under Spanish law, while trade arose with the British colonies in spite of Spanish restrictions. At the same time English-speaking colonists were moving west to settle along the tributaries of the Mississippi. In the decade of the American Revolution, these "Kaintucks," as they were called, began floating their cargoes downriver to New Orleans; several times Spanish officials suspended the right of deposit of American goods at New Orleans in response to the boisterous conduct of American frontiersmen along the city's upper levee.

In 1800 Louisiana was secretly returned to Napoleon's France, and by 1803 the French emperor had negotiated its sale to the United States. The ceremonies transferring Louisiana to France and later to the United States took place in New Orleans' Cabildo and main square, the Place d'Armes (now Jackson Square), in the winter of 1803.

The Louisiana Purchase

THE GROWTH OF THE CITY

The early 19th century. New Orleans' population in 1803 was approximately 8,000, consisting of 4,000 whites and 2,700 enslaved and about 1,300 free persons of colour. Its prosperity was reflected in its 1803 exports, which had a value approaching $2,000,000 and were bound mainly for American ports. In 1805, when it was incorporated as a municipality, New Orleans took on an identity separate from that of Louisiana's territorial government. As the city expanded out of its original limits, one of the first new tracts of land to be added was the Faubourg Ste. Marie, a suburb lying on the uptown side of the Vieux Carré and separated from it by a broad "commons" (now Canal Street, New Orleans' main street). It became the "American section" in the early 19th century and the hub of most business activities. Other *faubourgs* (outskirts, or suburbs) were laid out above and below the two nuclear settlements and across the river and were finally absorbed into the city by the 1870s.

During the War of 1812, New Orleans was threatened by a British invasion force, which approached the city from the Gulf of Mexico. Gen. Andrew Jackson, with an army of frontiersmen and local volunteers, won a smashing victory on January 8, 1815, saving the city, though, unknown to him, the war already had been concluded.

The era of cotton

The next 40 years constituted the golden age of New Orleans as a great cotton port. The first steamboat to reach the city, in 1812, was appropriately called the *New Orleans.* Mississippi River steamboats increased to 400 by 1840, and local commerce skyrocketed in value, reaching $54,000,000 by 1835. By 1840 the city was rated the fourth port in the world; after the 1840s canals and railroads diverted produce eastward to New York City.

German and Irish immigrants arrived in New Orleans in large numbers in the 1840s. By 1850 the city's total population had swelled to 116,375. New Orleans, however, had not learned to cope with the health hazards of its mushrooming growth: drinking water came from the river or cisterns; no sewerage system existed; drainage was deficient; and flooding was common after heavy rains. The results were sporadic outbreaks of cholera and yellow fever, the worst of which was the yellow fever epidemic of 1853, accounting for more than 8,000 deaths.

The Civil War and its aftermath. During the American Civil War, the strategic location of the city was inadequately appreciated by the Confederate military. The Union fleet of Adm. David Farragut was able to capture New Orleans in April 1862. The city was placed under the military command of Gen. Benjamin Butler, and city officials were removed from office. Although Butler was replaced as commander by Nathaniel Banks by the end of 1862, his brief régime became infamous in local history for his roughshod handling of the population.

During the period of Reconstruction, 1865–77, racial tensions ran high. "Scalawags" (white Southerners who cooperated with Republican forces) and "carpetbaggers" (Northerners accused of exploiting the situation for personal gain) cooperated to gain political control of the city and state, with the support of black voters. By 1872 amnesty had been granted to the ex-Confederates, and the municipal government returned to traditional white control, although the state government and the city police force remained under Radical Republican control until 1877.

In the 1880s the debt of $24,000,000, incurred under carpetbag regimes, increased steadily with each subsequent administration. This municipal debt had to be paid before the city could undertake any new bond issues for sorely needed municipal improvements. In the last 20 years of the 19th century, therefore, New Orleans made limited, though steady, progress. Between 1840 and 1900, it had dropped from third to 12th place in national rank, although its population had increased to 287,104.

Yellow fever was sharply curtailed after the Civil War and was finally eradicated by 1906. By the early 20th century the river steamboats, unable to compete with railroads, disappeared; the Port of New Orleans, attracting less railroad freight than Eastern ports, reached a low ebb shortly before World War I. With the development of towboats and barges large enough to hold almost an entire trainload of cargo, however, the port grew to be second in the nation after World War II. Substantial progress, at least in physical improvements, came to the city in the 1950s. During the administration of Mayor DeLesseps S. Morrison a vast railroad consolidation program was achieved, and a $15,000,000 railroad terminal constructed. Streets were widened, railroad ground crossings were spanned with overpasses, and a $20,000,000 civic centre, which includes the 11-story City Hall, was built.

20th-century growth

Also in the 1950s petrochemical industries began locating in New Orleans, followed by oil refineries in the 1970s. The 1984 Louisiana World Exposition revitalized the warehouse district but was a financial disaster. In the mid-1980s the local oil industry went bust, and the city's fortunes began to decline. Movement of middle-class citizens to the suburbs, which had begun in the '60s, continued in earnest. A high crime and murder rate and police corruption characterized the city into the mid-1990s; subsequently, however, the situation improved considerably, buoyed by a strong tourism-based economy.

CHRISTOVICH *et al.* (eds. and comps.), *New Orleans Architecture,* 5 vol. (1971–77), a scholarly study. Detailed period studies are JOHN G. CLARK, *New Orleans, 1718–1812: An Economic History* (1970); ROBERT C. REINDERS, *End of an Era: New Orleans, 1850–1860* (1964); GERALD M. CAPERS, *Occupied City: New Orleans Under the Federals, 1862–1865* (1965); and JOY J. JACKSON, *New Orleans in the Gilded Age: Politics and Urban Progress, 1880–1896* (1969). Port history and activity is discussed in ALEXANDER I. WARRINGTON, *Economic Geography of New Orleans and the Middle South* (1952); and LOUISIANA. BOARD OF COMMISSIONERS OF THE PORT OF NEW ORLEANS, *Report* (annual). For politics and government, see JOHN R. KEMP (ed.), *Martin Behrman of New Orleans: Memoirs of a City Boss* (1977); EDWARD F. HAAS, *DeLesseps S. Morrison and the Image of Reform* (1974); and L. VAUGHAN HOWARD and ROBERT S. FRIEDMAN, *Government in Metropolitan New Orleans* (1959). Sources on the history and culture of Mardi Gras include REID MITCHELL, *All on a Mardi Gras Day: Episodes in the History of New Orleans Carnival* (1995, reissued 1999); and JAMES GILL, *Lords of Misrule: Mardi Gras and the Politics of Race in New Orleans* (1997). Detailed descriptions of historic places include AL ROSE, *Storyville, New Orleans: Being an Authentic, Illustrated Account of the Notorious Red-Light District* (1974, reissued 1994). Detailed statistical information on New Orleans is found in the *Louisiana Almanac* (irregular); *Statistical Abstract of Louisiana* (triennial); and NEW ORLEANS POLICE DEPARTMENT, *Annual Report.*

(J.J.J.)

New York City

New York City is the largest, most influential, and most international metropolis in the United States. Located in southeastern New York state where the Hudson and East rivers empty into one of the world's premier harbours, New York City is both the gateway to North America and its preferred exit to the oceans of the globe. With an area of 309 square miles (800 square kilometres), it encompasses Manhattan and Staten islands, the western sections of Long Island, and a small portion of the New York state mainland to the north of Manhattan. New York City is in reality a collection of many neighbourhoods scattered among the city's five boroughs—Manhattan, Brooklyn, the Bronx, Queens, and Staten Island—each exhibiting its own lifestyle. Moving from one city neighbourhood to the next may be like passing from one country to another. The urban area extends into adjoining parts of New York, New Jersey, and Connecticut.

Physical and human geography

CHARACTER OF THE CITY

New York is the most ethnically diverse, religiously varied, commercially driven, famously congested, and, in the eyes of many, the most attractive urban centre in the country. No other city has contributed more images to the collective consciousness of Americans: Wall Street means finance, Broadway is synonymous with theatre, Fifth Avenue is automatically paired with shopping, Madison Avenue means the advertising industry, Greenwich Village connotes bohemian lifestyles, Seventh Avenue signifies fashion, Tammany Hall defines machine politics, and Harlem evokes images of the Jazz Age, African American aspirations, and slums. The word *tenement* brings to mind both the miseries of urban life and the upward mobility of striving immigrant masses. New York has more Jews than Tel Aviv, more Irish than Dublin, more Italians than Naples, and more Puerto Ricans than San Juan. Its symbol is the Statue of Liberty, but the metropolis is itself an icon, the arena in which Emma Lazarus's "tempest-tost" people of every nation are transformed into Americans—and if they remain in the city, they become New Yorkers.

Immigrant groups

For the past two centuries, New York has been the largest and wealthiest American city. More than half the people and goods that ever entered the United States came through its port, and that stream of commerce has made change a constant presence in city life. New York always meant possibility, for it was an urban centre on its way to something better, a metropolis too busy to be solicitous of those who stood in the way of progress. New York—while the most American of all the country's cities—thus also achieved a reputation as both foreign and fearsome, a place where turmoil, arrogance, incivility, and cruelty tested the stamina of everyone who entered it. The city was inhabited by strangers, but they were, as James Fenimore Cooper explained, "essentially national in interest, position, pursuits. No one thinks of the place as belonging to a particular state but to the United States." Once the capital of both its state and the country, New York surpassed such status to become a world city in both commerce and outlook. It also became a target for terrorism—most notably the destruction in 2001 of the World Trade Center, which for three decades had been the most prominent symbol of the city's global prowess. However, New York remains for its residents a conglomeration of local neighbourhoods which provide them with familiar cuisines, languages, and experiences.

THE LANDSCAPE

Geology

The city site. Sections of the granite bedrock of New York date to about 100 million years ago, but the topography of the present city is largely the product of the glacial recession that marked the end of the Wisconsin Glacial Stage about 10,000 years ago. Great erratic boulders in Manhattan's Central Park, deep kettle depressions in Brooklyn and Queens, and the glacial moraine that remains in parts of the metropolitan area provide silent testimony to the enormous power of the ice. Glacial retreat also carved out the waterways around the city. The Hudson and East rivers, Spuyten Duyvil Creek, and Arthur Kill are, in reality, estuaries of the Atlantic Ocean, and the Hudson is tidal as far north as Troy. The approximately 600 miles (1,000 kilometres) of New York shoreline are locked in constant combat with the ocean, as it erodes the land and adds new sediments elsewhere. Although the harbour is constantly dredged, ship channels are continually filled with river silt and are too shallow for more modern deep-sea vessels.

South of the rockbound terrain of Manhattan stretches a sheltered, deepwater anchorage offering easy access to the Atlantic Ocean. In 1524 the Italian navigator Giovanni da Verrazzano was the first European to enter the harbour, which he named Santa Margarita. Verrazzano's daring expedition was commemorated in 1964, when what was then the world's longest suspension bridge was dedicated to span the Narrows at the entrance to Upper New York Bay.

Only the third largest American port at the time of the U.S. War of Independence, New York gradually achieved trade domination and by the mid-1800s handled more than half of the country's oceangoing travelers and commercial trade. After 1900 New York was the world's busiest port, a distinction it held until the 1950s. Cargo containerization, the obsolescence of its waterfront piers, and soaring labour costs shifted business to the New Jersey side of the river after the 1960s, but at the end of the 20th century the Port Authority of New York and New Jersey still dominated the water trade of the northeastern United States.

Climate and plant and animal life. The average temperature in January is about 31° F (0° C) and in June about 72° F (22° C), but recorded temperature extremes range from −15° to 106° F (−26° to 41° C). Because of New York's moderate climate, the harbour rarely freezes. The annual precipitation is 44 inches (1,120 millimetres).

The city's flora and fauna are testimony to the rapid changes in the ecosystem imposed by urban settlement. In areas that once were hunting and fishing paradises for several bands of Native Americans, the most prevalent animals today are the cockroach and the Norway rat, both introduced to the city via trade with Europe. A wide variety of animal species are still found within the city, including 80 species of fish, scores of birds from the peregrine falcon to the pigeon, and such mammals as the raccoon and the occasional coyote. Wildlife refuges at Jamaica Bay and in Clove Lakes (Staten Island) and Alley Pond (Queens) parks provide sanctuaries for many species, allowing them to survive even within an unfavourable city environment. Vegetation has enough precipitation but has been reduced and destroyed with the advance of urban sprawl. The main characteristics of contemporary city plants are their ability to thrive despite acid rain and air that contains large components of ozone, vehicle emissions, and industrial by-products. However, the city's two botanical gardens, one in the Bronx and the other in Brooklyn, are highly regarded throughout the country, and zoos in every borough enchant visitors of all ages.

Skyscrapers

The city layout. The city's ancient bedrock provides the immovable foundation for hundreds of modern skyscrapers. New York has more of these awesome structures than any other world city. Architects may argue about the origin of the modern skyscraper, but most agree that Manhattan was where structures with steel skeletons were combined with the elevator to create a genre of buildings where great height could be reached practicably.

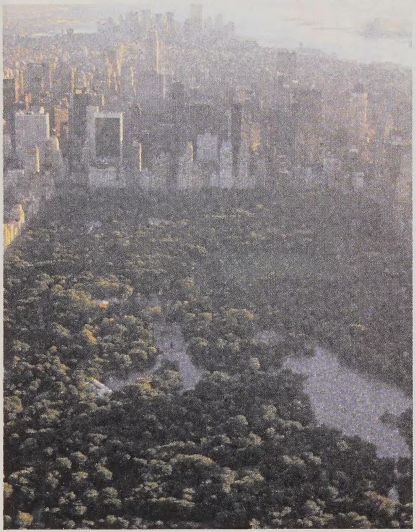
The earliest pathways for moving around Manhattan Island followed animal and Native American trails across difficult terrain; Broadway still follows one of these routes, which extended northward through the island. City planning was foreign to burghers in the 17th century, and roads were haphazardly authorized; only a few important ones to outlying agricultural communities were maintained, and it was not until 1798 that the city appointed a commissioner of streets. Colonial nonchalance is still visible in the meandering streets of Lower Manhattan. The optimistic spirit of the town is apparent in the street plan adopted in 1811, a grid of blocks, avenues, streets, and lots extending to the northern reaches of the island. City Hall, located now as then in Manhattan, was at that time so far removed from the centre of activity that its northern facade was left unfinished, since few could imagine it would ever be seen. Although often modified in specific cases, the rectilinear patterns imposed upon Manhattan in its infancy have determined its developmental patterns, and other boroughs adopted the system after the creation of Greater New York in 1898. The building of Central Park interrupted the grid, and road construction there pioneered concepts of limited-access and transverse-running roadways. In the 20th century, parkways were incorporated into the traffic patterns of all boroughs, as Eastern and Ocean parkways in Brooklyn, Riverside Drive (Manhattan), the Grand Concourse (the Bronx), and Queens Boulevard attest. Regardless of all its efforts, the modern city is infamous for the volume of traffic that clogs its well-laid-out street system.

The boroughs. The administrative structure of New York was shaped by the consolidation of the greater city in January 1898. Following the 19th-century pattern of urban imperialism, and spurred by the challenge that Chicago posed to its primacy, modern New York was formed when the independent city of Brooklyn, the portion of Westchester county called the Bronx, Staten Island, and large parts of Queens county were added to Manhattan following a referendum. Although the population of the city expanded from about 2 million to 3.4 million, much of the new territory was still rural, and only two-fifths of all roads in the expanded city were paved. The five boroughs, which were all soon designated counties of New York state, became the basic municipal administrative units. The office of borough president was created, its duties from 1901 to 1990 including service on the Board of Estimate, a central financial agency. Borough presidents now also serve as conduits of neighbourhood concern to the mayor, the city's chief administrator, and are responsible for appointing members of community boards, the City Planning Commission, and the Board of Education. These officials carry much of the burden in the continuous battle between strong mayors seeking central authority and local leaders aspiring to independent action.

New York City metropolitan area.

The subway system

In the early 20th century, when the population of Greater New York more than doubled, a major concern of city administrators was interlacing communication and transportation systems to create coherence within the metropolitan area. The first segment of the subway system opened in 1904, and soon all the boroughs were linked except Staten Island; the world's most extensive subway system soon became the best way to move about the metropolis. An ever-growing number of bridges, tunnels, and highways, designed to facilitate commerce, now take, along with the subways, hordes of commuters into Manhattan in the morning and return them home at night. Hundreds of thousands of "outer borough" residents and suburbanites work in and travel to Manhattan every day, in one of the great marvels of urban planning. Except for Staten Island, each of the boroughs considered independently would rank among the largest cities in the United States. Borough legislators constantly complain that their concerns are ignored, and many believe that local interests are usually sacrificed for the welfare of New York county (Manhattan). This perception led Staten Island to contemplate seceding from New York City and becoming an independent city in the 1990s.



Manhattan. More than 30 million tourists visit New York annually, but most of these rarely see much beyond the 22.6 square miles of Manhattan island, the smallest city borough. Divided by 12 north-south avenues and crossed by 220 east-west streets, Manhattan is the original New York, boasts the world's largest collection of skyscrapers, and is overloaded with cultural institutions and places of enduring interest. Even to residents of the other boroughs, Manhattan is "the city," the administrative, business, and financial centre of the metropolis and the basis of their renown. In no other part of New York are there such stark contrasts between rich and poor. The high-rise elegance of Park Avenue and the Upper East Side

Central New York City.

rapidly gives way to the teeming streets of Harlem to the north and to the crowded bohemian existence of the Lower East Side and Greenwich Village to the south. This cruel modern dichotomy echoes the 19th-century city, where industrial millionaires lived in luxury in Fifth Avenue mansions (now largely converted into cultural centres) far from the immigrant masses on the Lower East Side.

Neighbourhoods

Within this formidable historical imbalance, Manhattan is really composed of neighbourhoods that offer peaceful havens to contented residents. Many areas of the island are world famous, among them such ethnic enclaves as Chinatown, Yorkville, Little Italy, and Spanish and Black Harlem. In the streets snaking north from the ancient Dutch Battery, twisting lanes remind walkers that Manhattan was a trade centre before Boston, Philadelphia, or Williamsburg existed. Wall Street, the financial centre of the globe, was originally a Dutch fortification (1653) against feared British or Native American attacks that never came. The jumble of pre-Revolutionary streets continues up to Houston Street, where the grid pattern becomes dominant and continues up the island. Soho (short for "south of Houston") covers much of the old immigrant East Side and now has been matched by a Noho neighbourhood. To the west is Henry James's Washington Square and beyond that Greenwich Village, formerly a haven for artists but today home to the affluent and professional classes. Chelsea and Gramercy Park offer diverse attractions before one reaches Times Square, the "Crossroads of the World," recently transformed from a sleazy strip to a centre of tourism. At Columbus Circle visitors may enter Central Park, some 840 acres (340 hectares) of greenery created by Frederick Law Olmsted and Calvert Vaux in the mid-19th century. The Upper West Side is filled with brownstone blocks and high-rise apartments and is home ground to the liberal, Democratic Party politics long identified with the modern city. East Harlem is Hispanic, as is Washington Heights, but the two are separated by Black Harlem and the academic bastion of Columbia University on Morningside Heights. At the far north of the island—where Manhattan actually spills into the Bronx—Irish influence predominates. Only in the few blocks of Marble Hill is Manhattan part of the mainland.

No area of New York demonstrates change and dynamism as fully as Manhattan. Millions enter it daily to seek their fortunes, and millions more come to marvel at their efforts. It is Manhattan that they label a "great place, but I wouldn't want to live there." More than half of the buildings in the world with 50 or more floors are located there, but its storied past can be partly recaptured at the South Street Seaport, on the Staten Island Ferry, or in its distinctive neighbourhoods. Manhattan means Tammany Hall, the archetype of the political machine, as well as the reformers that overthrew the "Tiger." It is supremely cosmopolitan, boasting the world's best restaurants and a myriad of cultural institutions, yet folksy enough to have block parties. Manhattan's variety and pace make New York the number one tourist city in America.

The Bronx. The Bronx is the northernmost borough and (except for a tiny sliver of Manhattan) the only part of New York on the mainland. It was first settled by farmers and for centuries remained rural. It was the scene of much conflict during the American Revolution, but afterward it became the area where wealthy politicians and merchants established summer homes. In the late 19th century it was home to a racetrack where the Belmont Stakes were run until 1889. Railroads, bridges, and commerce gradually bound the Bronx to the lower city, and in 1874 the towns of Morrisania, West Farms, and Kingsbridge were annexed by Manhattan. Elevated rail lines soon arrived, and vast parks were authorized; the modern borough, 42 square miles in area, is still one-fourth parkland. When additional land from the Bronx was added to New York in the consolidation of 1898, the modern borough was created. Prior to 1910 subway lines snaked their way north to facilitate population growth in the former farmland. By the time Bronx county was established in 1914, it had large groups of Italians, Jews, Irish, and Armenians. Many found work on public works projects, such as those that built parks, the Bronx Zoo, the New York Botanical Garden, or the Jerome Park Reservoir. Others laboured on the uptown campus of New York University, which is home to the country's first Hall of Fame (for Great Americans), expanded the subway system, or constructed Yankee Stadium (1923). Fordham Road became a major shopping street, and the Grand Concourse won favour as one of the most prestigious addresses in the city.

Early history

Few areas of the country experienced such a precipitous drop from prosperity as did the Bronx. For a decade after the mid-1960s, the Bronx became the scene of classic urban decay caused by crime, drug dealers, renegade landlords, and the strain of accepting wave after wave of immigrants. Puerto Ricans won political power when they elected Herman Badillo as borough president; they later sent him to the U.S. Congress. However, the reputation of the borough came not from enlightened ethnic advance but from the fires that consumed its buildings and the drug and gang wars that destroyed its young people. Although fully linked to the metropolis by railroads and such bridges as the Triborough (1936), Whitestone (1939), and Throgs Neck (1961), the South Bronx became a place to leave as quickly as possible. Jewish residents fled the Grand Concourse to Co-op City, an enormous housing complex near Eastchester Bay. The spread of slum conditions northward from Mott Haven, Hunt's Point, and Morrisania threatened to turn the entire borough into a blighted area.

Rebirth of the borough

During the last quarter of the 20th century, the tide of decay reversed, and the Bronx rebounded in remarkable fashion. Vacant lands were filled with single-family and row housing, thousands of apartments were rehabilitated or restored with city funds, and hundreds more were saved by individuals who refused to give in to lawlessness. Tensions between competing populations—the borough is one-third African American, one-third Hispanic, and one-third Asian and white—have eased, and attendance at the universities in the borough has increased. The population has risen, and the upper-class enclaves of Riverdale and

City Island once again ranked as sought-after housing areas for the city elite.

Brooklyn. The most populous borough of New York, Brooklyn occupies 81 square miles to the east of Manhattan on the western fringe of Long Island. Sections of the area were first settled by the Dutch in the 1630s, and six largely agricultural towns—Brooklyn, Flatlands, Flatbush, New Utrecht, Bushwick, and Gravesend—soon thrived. Consolidated as Kings county in 1683, the region grew modestly as an appendage of Manhattan. During the U.S. War of Independence, Brooklyn was the scene of the Battle of Long Island (Aug. 27, 1776). After the British occupied New York, their notorious prison ships were anchored in Wallabout Bay; a memorial to the thousands who died stands in Fort Greene Park. Early in the 19th century, Brooklyn became the world's first modern commuter suburb, and Brooklyn Heights was transformed into a wealthy residential community. Modern-day entrepreneurs have restored ferry service across the East River, and the esplanade along the heights rewards visitors with an unrivaled view of Manhattan's shore and skyline.

To the chagrin of New York, Brooklyn became an independent city in 1834. By the 1880s it had about 20,000 industrial jobs and handled more waterborne tonnage than its rival. Brooklyn had its own Academy of Music (1859) and Historical Society (1863) and, in Prospect Park (1870s), an urban green space that represented a more mature version of Olmsted's vision across the river; it ranked among the largest cities in the country in the last four decades of the 19th century. However, the construction of John Roebling and Washington Roebling's Brooklyn Bridge to Manhattan (completed 1883) doomed its independence, as business interests craved closer ties to the metropolis. Overcoming the opposition of the local Democratic machine, Brooklyn accepted consolidation by a margin of only 277 votes and became a part of Greater New York in 1898.

Contemporary Brooklyn retains much of the independent character it displayed as an industrial city. It has its own shopping mecca (around Flatbush Avenue), a Civic Center, and even a Chinatown in Sunset Park. Additional access to Manhattan came with the construction of the Williamsburg (1903) and Manhattan (1909) bridges and later through Battery Tunnel (1950). In the 1920s full subway service was extended as far as Coney Island, and in 1931 the borough became home to New York's first airport, Floyd Bennett Field (now part of Gateway National Recreation Area). Brooklyn had something that Manhattan could never match, a beloved baseball team, the Dodgers, playing in a wonderfully intimate ball park, Ebbets Field; many hearts were broken when the team decamped to California in 1957, and the field was subsequently demolished. Brooklyn remains famous for its multiplicity of houses of worship serving neighbourhoods as varied as Brighton Beach and Bensonhurst, Bay Ridge and Ridgewood, and Canarsie and Cobble Hill. The majority of its people live in apartments, mammoth housing projects, or upgraded row housing. Bedford-Stuyvesant and Brownsville have some of the worst slums in New York, with blocks of burned-out and abandoned buildings. Tensions between African Americans and Hasidic Jews in the biracial area of Crown Heights led to a prolonged conflict in the 1990s, and their relationship has remained strained. On the other hand, careful use of landmark protection legislation has enabled several historic neighbourhoods to restore their viability. The originality of the borough is visible in the creation of new areas such as DUMBO (Down Under the Manhattan Bridge Overpass).

The Dodgers

Queens. Queens county would constitute a major American city were it not a part of New York. Its 120 square miles, more than one-third of the city, feature a primarily middle-class population owning private homes, although in such areas as Forest Hills apartments predominate. During colonial times a significant battle for religious freedom, the Flushing Remonstrance (1657), was fought in Queens; it was a first victory for the tolerance necessary in an urban centre. In the 19th century Queens had several racetracks and two shorelines that attracted the wealthy, and it served as the final resting place for deceased New Yorkers. Its Calvary Cemetery is still the largest in the nation, while 7,000 veterans of the American Civil War are buried in Cypress Hills on its border with Brooklyn. The Long Island Rail Road (1836), originally intended to shorten the trip from New York to the Boston ferry, traversed land that was largely agricultural. That situation changed after 1870 when what essentially were company towns were established by William Englehardt Steinway (pianos) and Conrad Poppenhusen (rubber); the later development of the Newtown Creek area brought heavy industry and drew many immigrant workers into the county.

In 1894 the communities of western Queens endorsed the creation of Greater New York, but parts of its eastern territory ultimately became Nassau county. The borough grew rapidly once the Queensboro Bridge opened (1909) and the Long Island Rail Road was connected to Manhattan's Pennsylvania Station (1910), and subway service was established soon thereafter. Queens was the centre of the silent-film industry until displaced by Hollywood in the late 1920s. The growing borough had more than a million people even before it was lashed to the Bronx by three bridges and to Manhattan by the Midtown Tunnel (1940). Pioneer aviator Glenn Curtiss's flight from Albany to New York City in 1910 issued in the age of domestic aviation, and the flat, open spaces of Queens became popular for airfields. It became an international arrival centre when La Guardia Airport opened in 1939 and Idlewild International Airport in 1948, the latter subsequently renamed for President John F. Kennedy in 1963. Access to transportation and a lower-density population made Flushing Meadows in Queens a natural site for the two world's fairs held in the city in 1939–40 and 1964–65. The borough also hosts the annual United States Open Tennis Championships.

Ethnic diversity

In a diverse and cosmopolitan city, Queens ranks as the most ethnically varied of all the boroughs. It is perhaps too simple to refer to Irish Woodside, Greek Astoria, Polish-Lithuanian Maspeth, or Italian Corona, but those groups do predominate. Vast numbers of Chinese, Koreans, and East Indians have transformed Flushing into the largest of New York's three Asian centres and revived a once anemic local economy. More than half of the city's Latin Americans live in Queens, and their restaurants and travel agencies dominate entire neighbourhoods. African Americans are more fully integrated in Queens than elsewhere in the metropolis, residing primarily in areas such as Hollis, Cambria Heights, St. Alban's, and Springfield Gardens.

Staten Island. Geographically isolated at the juncture of Upper and Lower New York Bays, Staten Island is 5 miles removed from Manhattan by ferry and a mile from Brooklyn across the Narrows. Its 60 square miles are still the least densely populated, most rural part of the city, even though it ranks as the fastest-growing county in the state. When the English conquered New York in 1664, they decided that Staten Island would remain part of that province despite its proximity to New Jersey. A century later, in 1776, British troops launched their conquest of the city from the island. After independence, Richmond borough (later Staten Island) held forts to protect access to New York, quarantine stations for sick immigrants, homes for aged seamen and orphans, and railroad terminals for Manhattan's freight. When its voters chose to become part of the greater city, its population was slightly more than 65,000.

After 1900 a civic centre and borough hall were constructed in St. George near the ferry ramps. Water-system real estate speculators attempted to start a boom when Richmond was connected to the city, but the prospect faded away once direct subway access failed to materialize. Until the 1930s the borough experienced slow industrial and population growth, and only after the Goethals (1928), Outerbridge Crossing (1928), and Bayonne (1931) bridges were built did stagnation cease. Construction of the Verrazano-Narrows Bridge (1964) finally opened the borough to rapid development and made it a functional part of city life. Truck farming has ended and factories have closed on the island, but borough residents have managed to retain the integrity of their nearly 3,000-acre park, the Greenbelt, the largest such amenity in the metropolis.

Staten Island is the most homogeneous borough in New York; it has the lowest proportion of ethnic minorities and is the youngest and most politically conservative. Its politicians call the borough underserviced, its residents feel under attack by environmental pollutants from New Jersey, and everyone resents being home to New York's largest garbage disposal site. A dumping area since 1948, the Fresh Kills site will ultimately reach an elevation of 500 feet (150 metres), the highest point on the East Coast.

Planning the modern metropolis. Early city leaders dealt with the needs of citizens less than systematically. Administrations in the 19th century created the street grid, regulated the port and immigration, provided water and sewers, authorized transportation lines, and built parks. No one pretended that Manhattan offered a picture of rational planning, but with a consolidated population of more than three million, a more orderly approach was necessary. Uncontrolled building and atrocious housing conditions were among the primary concerns of progressive thinkers, and their first achievement was a Tenement House Law (1901) that required the installation of fire escapes and toilets in existing "old law" structures. City officials became the overseers of "new law" construction—six-story buildings with dumbwaiters, cooking facilities, hot water, and no inside rooms without windows—and within 15 years an additional 200,000 apartments were built. Progressivism's greatest accomplishment was the city zoning ordinance of 1916, the first attempt by any city to control density, regulate land use, and guarantee light and air to the streets by reshaping structures. By that time, Manhattan was already famed for its skyscrapers, and their height had escalated from the 11 floors of the Tower Building (1889) to the 20 of the Flatiron (1902) and finally to the unprecedented 792-foot Woolworth Building (1913). The new zoning code mandated building setbacks to permit daylight to reach the streets and altered the shape of future construction. Under its restrictions the Chrysler (1930) and Empire State (1931) buildings were completed, still two of the most famous silhouettes on earth. After World War II, a corridor of buildings was constructed along Park Avenue that has been called the architectural heart of the 20th century. In 1961 the zoning code was altered to encourage developers to add public amenities to their building plans in return for variances. The revision was less than successful, and in 1990 the City Planning Commission established new building districts in an attempt to decrease the flood of new building in Manhattan.

Tenement House Law

In 1921 the Port of New York Authority (PA) was formed to deal with regional transportation issues, and it quickly initiated a series of massive construction projects that still serve the city. The PA added the George Washington Bridge (1931), Lincoln Tunnel (1937), bus and Port Authority Trans-Hudson terminals, satellite communication centres, and the World Trade Center. Officials from the PA deferred to the judgments of Robert Moses, the dominant city planner from 1934 until the 1960s, who provided the city with 13 major bridges, more than 400 miles of high-speed highways, and hundreds of parks and playgrounds. He also led city efforts at slum clearance, urban renewal, and public housing. More than any other single individual, Moses shaped the contemporary city.

But not even Moses could totally control the chaos of development characteristic of New York. In truth, aside from a few farmhouses, little remains from the colonial era, and the construction boom after 1945 consumed 19th-century structures at a rapid pace. As Walt Whitman described it, the city had the "pull down and build over again spirit," which became a New York tradition. However, in 1963, when Pennsylvania Station went under the wrecking ball, outrage led to the creation of the Landmarks Preservation Commission (1965), whose purview was soon extended to interiors and to scenic landmarks. The commission has established historic districts, designated more than 1,000 individual landmarks, and preserved a past that has become increasingly important to New Yorkers.

In 1969 city planners offered a massive regional plan for development, but it failed to win approval. Instead, successive amendments of the city charter in 1975 and 1989 have been used to broaden popular input into city projects. Borough presidents and local community boards have now become involved in the preparation of new initiatives. In a city as complex as New York, architectural change is constant, and the total transformation of the Times Square district illuminates the power of design to alter the city. In the 1990s it went from being the national symbol of urban decadence and seediness to a centre of corporate consumerism that now draws families of tourists to its attractions. Elsewhere in the city, such prominent real estate developers as Donald Trump have often won approval for vast projects, but planning officials and local communities have often blocked what they saw as unsuitable land use.

Renewal of Times Square

THE PEOPLE

Ethnic and religious diversity. In a city that embraces change as its primary tradition, the shifting population base of New York remains its most dramatic story. Representatives of some 200 national groups are counted among its people. While people of European ancestry still make up one-third of the population, Hispanics account for nearly one-third, and African Americans about one-fourth. The fastest-growing component of the population is Asian, soaring from a tiny proportion in 1970 to about one-tenth. Dominicans were the most numerous immigrants during the last decade of the 20th century, but they were closely followed by Russians and Chinese. The Statue of Liberty, more than a century after its dedication in the harbour (1886), continues to welcome newcomers into the city's "golden door."

People from each ethnic group have climbed the ladder of acculturation, achieved their goals to a greater or lesser extent, and then, in turn, found fault with the masses that followed them. As early as 1643, Father (later Saint) Isaac Jogues catalogued 18 languages that were being used on the streets of New Amsterdam, and that cosmopolitan atmosphere was retained when Dutch control ended and Britain assumed power. Jews, Roman Catholics, and numerous ethnic groups lived in Manhattan before 1700, but political control remained in the hands of the established merchant elite. When the U.S. War of Independence began, more prominent Dutch families—the Van Cortlandts, De Peysters, and Schuylers—supported the cause than did their English counterparts. One unanticipated result of the fighting was that many slaves, perhaps one-fifth of the city population in 1776, won freedom. One of the first "history" books of New York was a satiric look at the merchant elite and the city's Dutch past written in 1809 by Diedrich Knickerbocker (Washington Irving). Spoken Dutch was heard on city streets until the late 19th century, when such families as the Roosevelts and the Vanderbilts were important members of Manhattan's elite.

The dedication of the first St. Patrick's Cathedral in 1815 signaled the rising prominence of the Irish. By 1844, 15 parishes served more than 80,000 Irish Roman Catholics, and it was clear even before the Great Famine immigration of 1845–49 that New York was becoming predominantly Irish. More than 24,000 Germans also lived in Manhattan, a number that vastly increased following the failed revolutions of the 1840s. Irish workers had to contend with signs warning "No Irish need apply," and their poor circumstances soon created one of New York's most notorious slums, the Five Points District. Germans, who were largely Protestant or Jewish, were more middle-class and perhaps had a slightly easier acclimation; they created the Kleindeutschland ("Little Germany") neighbourhood east of the Bowery. So great was the pressure of immigration that Castle Garden, near the Battery, was converted into a reception centre, a role it fulfilled from 1855 to 1890. By the time of the American Civil War, Irish, Germans, and several other ethnic groups made the city's population more than half foreign-born.

The Irish and Germans

The arrival of "new" immigrants from eastern and southern Europe after 1880 again changed Manhattan. The Irish and Germans, who by then held a vast proportion of political and economic power, deeply resented the Italians, Greeks, Russians, Hungarians, and Poles crowding into their city. Ellis Island, a new immigrant reception station, was built in 1892 to deal with the unprecedented numbers of newcomers, and by 1900 the Lower East Side recorded

one of the greatest population densities in world history. Ellis Island processed about 12,000 people per day, and in 1907 some 1.2 million entered the United States through the port. The austere *New York Times* wrote that "cleanliness is an unknown quality to these people. They cannot be lifted to a higher plane because they do not want to be." Tuberculosis became the "Jewish" disease, and New York's police commissioner played the demagogue in 1909 when he asserted that half of all city crime was committed by Russian Jews. Nevertheless, Jews were to transform labour and education in the city, while Italians would become the largest ethnic group. Yet toleration of "the other" became a New York virtue.

Internal migration. An often ignored force of change in New York is the constant internal migration it attracts. Over the years a large proportion of America's brightest and most ambitious and driven individuals have been drawn to Manhattan. New York displaced Boston as the national cultural centre as early as the mid-19th century, as its newspapers, magazines, and artistic freedom lured the different-minded. By 1900 both Mark Twain and William Dean Howells had lived in New York, and Greenwich Village emerged as a haven for nonconformity before World War I. Modern sculpture, Beat poetry, and Abstract Expressionism are only three of the 20th-century artistic movements that trace their origins to the Village scene.

African Americans

After 1900 the largest group of internal refugees were African Americans fleeing the rural South. New York was one of their preferred destinations, and the growth of Harlem as the "black metropolis" was the unintended result. In the first decade of the 20th century, the Afro-American Realty Company began to rent homes to African Americans in what was then a predominantly Jewish neighbourhood, and the churches they attended downtown soon relocated to the north. Growing ethnic and economic hostility led to a white exodus, although East Harlem did remain largely Italian, and by 1930 more than 200,000 African Americans lived in Harlem. Their artistic talents led to the Harlem Renaissance, and their musicians were leaders of the Jazz Age, but the reality remained that the Harlem they dominated was becoming the largest slum in the city. The Great Depression destroyed economic opportunity; high rents forced the subdivision of apartments; and the well-known pathologies of tenement life devastated a poor community. Harlem endured a long decline from which it did not emerge until the 1990s.

White ethnics found no difficulty in deciding that African Americans were ignorant, lazy, and prone to engage in criminal activities. As the first large group entitled to the social reforms of the New Deal era, African Americans were accused of being parasitic users of the welfare system. Similar accusations were later directed at Puerto Ricans, long a presence in the city but whose numbers soared after World War II. However, within a generation, the influx of Dominicans, Cubans, Colombians, and most recently Mexicans altered the fabric of New York in an unexpected manner. In the 1990s the Hispanic population of the city grew by about 400,000, and bilingualism became a reality. Some 2.2 million New Yorkers of Hispanic origin now constitute the largest single group in the city, and it is estimated that one-fifth of the city speaks only Spanish at home. Relations between African Americans and Hispanics have deteriorated, as one wave of early immigrants tends to disdain those who come later.

THE ECONOMY

Early industries. The seal of the city of New York, adopted in 1686, includes the beaver and the flour barrel, images that document the first major phase of Manhattan's economic history. New Amsterdam was important to the Dutch because it offered access to the immensely valuable fur trade of a continent. One of the richest men in 19th-century New York was John Jacob Astor, whose fortune was based on fur before he became a real estate speculator. After the British conquest in 1664, the city won a monopoly to grind and pack grain and sent its flour to all world markets. Merchant incomes soared as commerce, both legitimate and via smuggling, became the lifeblood of New York. Any threat to city prosperity was harshly dealt with, and William Kidd's turn from privateering to piracy led him to the gallows (in London) in 1701.

Shipping and transportation. The shipping enterprise has always characterized New York. Its Dutch-English merchant class dominated the colonial assembly and after 1756 controlled the annual salary grant awarded to the royal governor. A group of 20 merchants organized the country's first chamber of commerce (1768) at a time when small manufacturing establishments—cloth, timber processing, ropes, and sails—were becoming more common. Rapidly overcoming years of British occupation during the American Revolution, the city filled Caribbean, European, and coastal ports with its vessels within a decade of independence. New Yorkers were the ones who sent the *Empress of China* on its historic first voyage to East Asia in 1784, and Manhattan was the national leader in both exports and imports by the late 1790s. When inventor Robert Fulton's steamboat, the *Clermont,* made its first trip to Albany in 32 hours in 1807, it revolutionized transportation. New York launched the first scheduled shipping to Europe, and its thriving boatyards constructed every type of vessel from harbour lighters to inland steamers to transatlantic passenger ships. The yacht *America* (1851), first winner of the race henceforth called America's Cup, was built there as were many of the fabled clipper ships. From 1830 until the 1950s New York ranked as the busiest port in the world.

Shipbuilding

Banking and finance. Commercial banking began in Manhattan in 1784 when the Bank of New York opened for business. It was soon joined by a branch of the First Bank of the United States (1792) and the Manhattan Company (1799), ancestor of what is now The Chase Manhattan Corporation. The origins of the New York Stock Exchange (NYSE) can be traced to the Buttonwood Agreement of 1792, although the Exchange Board itself was not

organized until 1817. After the Erie Canal opened in 1825, banking services became even more centred in the city, and when its merchants entered the cotton trade the commerce of the entire nation flowed into the port. Several financial panics in the 19th century could not prevent the city from dominating the national money markets. Investors and banks from the metropolis provided much of the capital that financed the industrialization of the United States. So great was the influence of New York that the country's largest firms found it expedient to locate their headquarters there even though—as with Carnegie Steel, American Tobacco, and Standard Oil—the focus of their manufacturing was elsewhere.

The development of industry and trade. Shipping and finance secured New York's international standing, but manufacturing provided jobs for its teeming population. A multitude of small businesses were centred in Manhattan by the 1850s, and the clothing, furniture, pianos, cigars,

and dozens of other products they created boosted city exports. By mid-century New York was the printing centre of the United States with more than 1,000 establishments; in the period 1865–85 the number of magazines published in the city quintupled to 3,300. The influx of skilled Jewish immigrants transformed an already dominant clothing industry into a gargantuan one, employing nearly half of all city workers by 1910. New York quickly developed advertising, insurance, and legal services to deal with the needs of its burgeoning manufacturing sector.

The centre of business. By the beginning of the 20th century, New York was the headquarters for more than two-thirds of the top 100 American corporations, and its 25,000 factories manufactured several hundred different industrial products. It led the nation in total factory workers, number of factories, capital valuation, and product value. New York held its leadership position for another three generations and provided nearly one million industrial jobs into the 1950s. In 1960–75 the city lost more than 600,000 of these jobs, as its old economy collapsed and an information age took shape. Banking and financial services became the new engine of development—abetted by the traditional print and advertising sectors of the economy—while white-collar workers with computer skills replaced most of the blue-collar labourers of the past. Although much has been made of the move of clothing production out of New York, it remains the city's leading industry, and sweatshop conditions reminiscent of the early 1900s still exist in small factories in the Bronx and Queens. The metropolitan area is still home to more than one-fifth of the Fortune 500 companies.

Economic collapse and recovery

The 1970s represented a low point for New York; its national reputation collapsed as the government experienced virtual bankruptcy. High rents, congestion, arson, and crime led to an exodus by businesses and the middle class even after the city began the rebuilding process. Industrial parks, where businesses were given cheaper rents, better utilities, and safety, were authorized in response to the crisis, and major tax incentives were granted to those corporations that remained in the city. The NYSE even threatened to leave, but in the late 1990s it agreed to remain in Manhattan and to construct a new facility. The port, where facilities were outmoded and corruption endemic, began to convert its docks for containerized shipping, to dredge deeper channels, and to plan a direct rail connection between Manhattan and Brooklyn.

By constantly enhancing its key economic advantages, New York has remained prosperous even as it underwent change, its strength lying in its diversity. The port, which lost some percentage of its shipping to other cities, is still the busiest port on the East Coast and generates billions of dollars of revenue, creates thousands of jobs, and is the focus of major plans for renewal and renovation. Manufacturing positions have declined, but smaller specialty producers of neckties, purses, and leather goods have joined the ready-made-clothing industry to maintain New York's dominance. A major portion of the country's software and computer-related industry has located itself in New York and built an urban "Silicon Alley" to mirror California's Silicon Valley. The city's continuing financial supremacy was apparent in the 1990s, a decade in which the Dow Jones average quadrupled. New York marketed its monetary expertise to the globe; its banks dealt with the Latin American debt crisis of the 1980s as well as the Asian financial meltdown of the late 1990s, and in the process the city became the "economic capital of the world." The vast numbers of bars, restaurants, hotels, health clubs, and theatres across New York are necessary to care for and feed the millions of visitors who come to the city annually.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. New York City is administered by a mayor who chooses department heads and criminal-court justices and prepares the annual budget. Mayors hold considerable power but are constantly involved in legislative battles with the 51 members of the City Council. Both mayor and council members serve a maximum of two four-year terms. In general, beginning with Fiorello La Guardia in the 1930s, the mayors usually have led their own parties and have been stronger than other party leaders.

Two themes are constant in the administrative history of New York: tension between the city leadership and the superior authority of the state in the struggle for home rule, and the municipality's desire to contain the decentralizing tendencies caused by its component elements. In the Dutch colonial period, the director general of New Netherland was a city resident who ruled both province and burgh, but after 1664 England's provincial governor named a mayor. In the 1680s Governor Thomas Dongan granted New York its first municipal charter and permitted the election of aldermen, but he retained the right to appoint the mayor, recorder, clerk, and sheriff. Effective control remained in the hands of the governors until it was wrested away by the city aristocracy after 1740.

Colonial administration

During the time of the American Revolution, New York suffered from a long British occupation and two fires that destroyed one-third of its buildings. Federalist Mayor James Duane, whose own home had been burned to the ground, supervised rebuilding efforts in the 1780s, and his successor Richard Varick completed the reconstruction of city and government. Their efforts, abetted by those of DeWitt Clinton after 1803, established the foundations for New York's national dominance. After 1800 New York was the nation's largest city, a commercial dynamo that worked efficiently even as the city became a great melting pot of different peoples. Yet New Yorkers still lacked the right to elect their own mayor; only in 1834 did Jacksonian Cornelius Lawrence initiate democratic control, which subsequently has been characteristic of the metropolis. One area in which voters of all classes agreed was the need to improve city services, and in April 1835 they approved the creation of a new water supply. New York's Croton Aqueduct opened in 1842, inaugurating a century of city efforts to tap regional water resources and provide citizens with some of the nation's best-quality drinking water; this better water was also vital in ending the epidemics that periodically struck the city. Manhattan's desire for home rule was often at odds with the plans of upstate legislators, and in 1857 Albany authorized the Metropolitan Police District to cover four urban counties. Involvement by the state created two competing police forces, and their subsequent battles were ended only by the intervention of the state militia. Not until 1870—after massive bribery by "Boss" William Magear Tweed—was local police power restored. Tweed's charter increased the authority of the office of mayor in governance matters and, after the "Tweed ring" was overthrown in 1871, a reform charter added power to the office of comptroller. The Board of Estimate and City Council also were established to direct city development.

New York in the 19th century, while primarily under the control of the Tammany Hall political machine, constructed Manhattan's basic water, sewer, fire, police, transportation, and park facilities. There was, naturally, some corruption and a great deal of what insiders like George Washington Plunkitt called "honest graft," but the experience gained in building Manhattan permitted the greater city to construct an infrastructure capable of serving a far denser population. In 1899 social reformer Jacob Riis described a metropolis "barely yet out of its knickerbockers" yet poised for greatness; Riis believed its enduring challenge would be to care for the poor. Novelist Theodore Dreiser agreed, for in New York the strong "are so very strong, and the weak so very, very, weak—and so very, very, many." The wealth generated by economic success in New York was never totally subservient to the demands of the affluent.

Compassion is hardly part of the city's cold image, but caring for its less fortunate citizens has been a major theme of its modern history. In this most capitalist of all American cities, a strong element of socialist ideology fostered the creation of the nation's largest municipal hospital and university systems, vast areas of public housing, and generous welfare benefits for the poor. City programs exist in uneasy proximity to a remarkable collection of the world's best private hospitals, some of its most expensive apartments, and dozens of private universities. Social initiatives first attempted in New York became precursors of New Deal programs in the 1930s, while the city's American Labor and

Social programs

Liberal parties constantly advanced an agenda of public responsibility. Although the Democratic Party organization served many constituencies, it held political power because it never forgot the poorest citizens, who also voted. The enormous wealth of the city funded a wide range of altruistic programs without major difficulty until the 1960s, when welfare rolls exceeded one million people and crime rates soared. The vast decline in manufacturing and the taxes it provided also undermined the city economy, and New York suddenly became a metropolis out of control. Mayor John Lindsay never mastered the crisis; he attempted to create "superagencies" to deal with human resources, the environment, health, housing, and parks even as the borough presidents and community groups demanded greater local control. Lindsay's long feud with the state government eventually led to loss of central control over the school system in 1969. By 1975 the city nearly fell into bankruptcy, its finances were administered from Albany, and its social compact appeared on the verge of anarchy.

In the last decades of the 20th century, New York's rebirth was spectacular. Mayor Edward I. Koch restored fiscal security to the city, and his administration began the slow task of restoring lost confidence. Commercial construction boomed, and multibillion-dollar refurbishing programs of subsidized housing and transportation systems were instigated. Not even the great stock disaster of October 19, 1987—when the Dow Jones average dropped by more than one-fifth—halted the turnabout. The 1990s were a decade of unprecedented wealth accumulation in the country's richest city, but poverty and homelessness endured as societal realities.

In 1989 the U.S. Supreme Court declared that New York's government system, which gave equal representation to populous Brooklyn and underdeveloped Staten Island, violated the "one man, one vote" mandate of the Constitution. The Board of Estimate was to be abolished, and a November referendum decided that the City Council would be expanded to 51 members in order to enhance the power of minorities. Council authority over the budget, land use, zoning, and franchises was increased, and a new planning commission was established. The renovated council remained under Democratic control but now had the potential to oppose mayoral initiatives; when voters elected Republican Rudolph Giuliani as mayor in 1993, the urban political scene became confrontational. Battles over educational leadership, city planning, and spending projections marked Giuliani's administration, even as it successfully reduced city crime in all categories and slashed welfare rolls. Aggressively preventive tactics pioneered in New York substantially reduced the national crime rate, while "quality of life" policing made citizens feel safe on the streets. Acting with national welfare reform, Giuliani's administration established the country's largest workfare program. In 2001, near the end of his administration, Giuliani reversed the earlier perception that he had turned his back on the city's tradition of compassion by leading the vast rescue and recovery effort at the site of the World Trade Center disaster.

Crime prevention

Education. *Primary and secondary systems.* Ever since the first school opened in New Amsterdam in the 1630s, New York has sought fine schools, but until after the American Revolution education was largely handled by tutors. Public funds for education became available after 1795, and in Manhattan a Free School Society was formed to disperse the state money. The growing numbers of New York Roman Catholics were distressed by what they interpreted to be Protestant indoctrination within the school system. In the 1840s Archbishop John Hughes was instrumental in establishing a Catholic parochial school system, which has continued to offer an alternative to public education. Neither system ever achieved universal attendance during the 19th century, however, for not until 1874 was a compulsory attendance law for the primary grades enacted; new immigration subsequently overloaded all city schools. After consolidation, Greater New York launched a massive public building program to provide schools where a half-million eligible students could be educated each year. Secondary education was not even offered to its children until the late 19th century, but by 1920 massive construction made primary education, along with both ordinary and specialized high schools, available for everyone. Several New York high schools—Stuyvesant, Bronx Science, Brooklyn Tech, and Performing Arts—have retained national reputations for excellence, and the school system has also provided evening classes in adult education and practical skills for the city's large immigrant population.

In the late 1990s New York administered the nation's largest public school system; more than one million students attend in excess of a thousand public schools. In the last decades of the 20th century, education became a sphere of unending controversy. The postwar white exodus to suburbia drained students from public schools and transformed them into minority-dominated institutions most of whose instructors were white and Jewish. During the 1960s a series of strikes and ugly racial confrontations caused disorder in the city, and in 1969 the state legislature divided the city into 32 districts. Henceforth primary education was to be controlled by elected governing boards so that educational goals could be established by local communities. Each board would select its superintendent, but resources would still be allocated by a chancellor of the entire school system, who was named by a mayor-dominated Board of Education.

The unwieldy system worked only sporadically, and by the 1990s its failures were apparent. Wage levels declined relative to those of suburban systems, racial segregation in schools caused by housing patterns and economic stratification increased, and many tenured teachers were accused of ignoring the special needs of minority students. Dropouts increased, performance levels fell precipitously, and violence in schools appeared endemic. Colleges and businesses alike complained bitterly that schools turn out "functional illiterates." In the last two decades of the 20th century, the system was led by a dozen chancellors, and the mayor's role in their selection became as highly politicized as district appointment of school principals. In 1996 the state legislature once again intervened, ending local authority to name principals and attempting to remove party and ethnic politics from the system. In 1999 principals agreed to surrender their tenure rights in return for larger wage increases. The long decline of a once-praised system has benefited parochial and private schools in New York, although the cost of a nonpublic education has escalated considerably.

Decline of the system

Higher education. The metropolitan area has more than 80 colleges, including such nationally famed institutions as Columbia (1754), New York (1831), Fordham (1841), and Rockefeller (1901) universities and Cooper Union (1859). Its vast municipal system, the City University of New York (CUNY), has more than 20 units and traces its origin to City College (1847). However, the introduction of open admissions in the 1970s brought the ills of the high schools into the college system. CUNY's strong academic tradition soon mutated into what became derisively known as "Remediation U," and from the late 1990s university trustees were engaged in an effort to strengthen the baccalaureate. Even the most selective colleges found it necessary to enhance basic student skills. Despite these difficulties, New York remains one of the nation's premier university towns and, from Ivy League to community college, its streets pulsate with student life.

CULTURAL LIFE

As real as the bedrock beneath Manhattan is the cultural attraction generated by New York. For more than a century, talented but unrecognized artists as well as ambitious wanna-bes from every part of the globe and nation have gravitated to a city they feel is their spiritual home. A steady stream of the cultural elite flows toward the metropolis and creates an electric atmosphere. In virtually every artistic field—theatre, music, dance, painting, literature, fashion, film, print, and sports—the city is the "place to go" to see if you can "make it." No environment offers a harsher test of one's abilities. Literary figures as diverse as Washington Irving, Herman Melville, Walt Whitman, O. Henry, the members of the Algonquin Round Table, Rex Stout, and Ed McBain (Evan Hunter) have all attempted to explain the allure and the dangers of the city;

Role as an artistic centre

all succeeded and failed, to some degree. In the 19th century Manhattan was home to the Hudson River school of artists, and the Tenth Street Studio in Greenwich Village and its surrounding area shaped the national imagination. Willa Cather, who grew up in Nebraska, came to write of the West on Bank Street in the Village, while Jackson Pollock came from the West to create Abstract Expressionism and help change the direction of modern art. But perhaps the greatest proof of New York's dynamic appeal are the millions of annual visitors who come to experience its vibes, variety, and vitality. Whether artist, visitor, or resident, all seem united in the belief that New York is, as writer Joan Didion described it, "an infinitely romantic nation, the mysterious mixture of all love, money and power, the shining and perishable dream."

Undoubtedly culture is big business in New York, and no city in the country has more institutions and people dedicated to serving its demands. The Metropolitan Museum of Art (1870) is probably the best known and most visited of the city museums, but the metropolis has scores of concert halls, schools of art, music and acting, restaurants, and galleries, as well as agents, promoters, and hucksters of every type. It is the city of promoter P.T. Barnum, philanthropist James ("Diamond Jim") Brady, and financier Malcolm Forbes. It can fulfill every desire, from photography to pornography to publicity. The Cloisters (1938), part of the Metropolitan Museum, specializes in medieval art, while the avant-garde sensibility is catered to at the Museum of Modern Art (MOMA; 1929) and at the Whitney (1930) and Guggenheim (1939) museums. Natural sciences and the shape of the skies can be studied at the American Museum of Natural History (1869), while those who seek the best pre-Columbian or Egyptian art should journey to the Brooklyn Museum of Art (1823). Those interested in Native Americans, the tenement house, dolls, or African art will find institutions specific to their needs. Great stone lions, dubbed "Patience" and "Fortitude" by Mayor La Guardia, guard the New York Public Library (1895), whose mammoth holdings include the Schomburg Center (African American history) and are exceeded in the nation only by the Library of Congress. Researchers are also drawn to the Morgan Library (notably for medieval and Renaissance Europe) and Ellis Island (immigration). Whether the crowds who come to New York expect Fun City, the Big Apple, or Gotham, the city can fulfill every expectation of an admiring public.

Richard Drew—AP/Wide World Photos

West 44th Street in Manhattan's Theater District, just west of Times Square in New York City.

The arts. Ever since the 1890s Broadway has reigned as the "Great White Way," the major theatrical centre of the country. New York produces, casts, and consumes the legitimate plays and musical extravaganzas that Americans desire as well as thousands of other shows that only true supporters come to see. Theatre is New York's "fabulous invalid," periodically near death and at other times revived, and *Variety* (1905) is the news magazine that informs the world of its health. The city's Off Broadway and Off-Off Broadway venues are where experimental theatre apprentices playwrights, actors, dancers, and directors. In the last decades of the 20th century, major new stages in Times Square, skyscrapers, and a suddenly chic 42nd Street drew new audiences, and the increased price of tickets showed wider interest. For bargain seekers, Manhattan also offers free Shakespeare in Central Park, while cut-rate tickets to current productions are always available. In every borough local groups offer more performances than anyone can attend.

Lincoln Center for the Performing Arts

Completed in the 1960s, the Lincoln Center for the Performing Arts is a mecca for the arts patron. It is home to the Metropolitan Opera Association; the New York Philharmonic performs in Avery Fisher Hall; and the New York State Theater offers a variety of attractions, including the New York City Ballet, which has the highest reputation of any troupe in the country. The finest concerts in a very musical city are heard in Carnegie Hall (1891); the two million dollars donated by Andrew Carnegie for its construction have perhaps given more pleasure per dollar than any other philanthropic endowment. Town Hall in Manhattan and the Brooklyn Academy of Music, the latter the oldest performing arts centre in the nation, offer viable alternatives. Performance art is always available and is enjoyed by the complete range of audiences.

No city is as recognizable to other Americans as is New York; its glittering nightlife and its gritty neighbourhoods are equally part of the national consciousness. Film directors love to use the city as their set, and city administrations have increasingly encouraged them. Until World War I, Queens was the centre of the early film industry, and afterward New York remained vital to documentary and independent film production. Astoria regained its position as a studio centre in the 1980s. It is also fitting that the city that transmitted the first television signals became the setting for many of the most successful shows. From *The Goldbergs* to *I Love Lucy* to *All in the Family* to *Seinfeld,* New York City became part of the American cultural experience. The Museum of Television and Radio (1975) allows anyone to recapture famous episodes from this somewhat fictionalized yet also very real New York.

Recreation. New York never ignores the needs of its ordinary people. Since the colonial period, parades and festivals have been part of city life and the Halloween and Thanksgiving Day parades of modern times illustrate the strength of the tradition; in the 19th century parades also provided occasions for Roman Catholic and Protestant Irish to battle in the streets. Yiddish theatre was born on the Lower East Side, while vaudeville and burlesque were invented to draw audiences to more earthy delights. After 1898 the greater city understood that it had obligations to create green space beyond the expanses of Central and Prospect parks, so gardens, along with zoos in every borough, were provided for residents. New York has hundreds of parks, but its myriad of other entertainment possibilities include a miniature reproduction of the metropolis constructed in the Queens Museum, a restored Staten Island village at Richmondtown, or the jewel-like Orchard Beach in the Bronx. No public beach is as famous as Coney Island, and thousands of bathers often crowd there close to the sea; the Cyclone Roller Coaster at its amusement park became a national landmark in 1988.

Many professional as well as recreational sports are pop-

Baseball

ular in the metropolis, but probably no sport is as closely identified with New York as baseball. In 1903 a professional baseball club, the Highlanders, moved from Baltimore to New York and was renamed the Yankees in 1913. The team has since played in every borough except Staten Island, won more than two dozen world championships, and become history's most dominant sports franchise. Manhattan also loved its Giants baseball team, before the club's departure for San Francisco in 1957; Brooklyn lived for "next year" with the Dodgers; and Queens (since 1962) has been home to the New York Mets. New York teams have won professional championships in football, basketball, hockey, and association football (soccer) as well. Madison Square Garden, now in its fourth incarnation, has been the site of many championship boxing matches, innumerable other sporting matches, musical events, and political conventions and may well be the most storied indoor arena in American history. Whether in watching sports, picnicking in the parks, visiting museums, attending the theatre, capitalizing on the city's rich array of eateries (from ethnic delis and sidewalk carts to five-star restaurants), or simply watching its street life, the quality of cultural activities available in New York is unsurpassed.

History

THE COLONIAL CITY

As every schoolchild knows, Europe's desire to open trade with the East inspired the explorations that discovered the New World. Giovanni da Verrazzano (1524) and Henry Hudson (1609) were part of that long effort, and they were among the first Europeans to visit and gaze at the vast expanse of New York harbour. The primary result of Hudson's voyage, and his report of a protected anchorage near good farmland, was the Dutch West India Company's decision to place a trading post on the southern shore of Manna-hata Island; by 1626 a settlement called New Amsterdam was established. It was not the first Dutch settlement in North America, but the advantages of its location made it immensely valuable. In May 1626 Peter Minuit arrived with orders to secure title to the land. He quickly negotiated the real estate deal of the millennium, purchasing the area from a band of Native Americans who probably did not own it for trade goods worth the equivalent of 60 guilders (converted to the legendary $24). Minuit and his successor governors knew that expanding Dutch access to furs and trade were their primary tasks, and commerce fueled city development. In 1638 a new governor reported that one-fourth of all buildings were "grog shops" devoted to sailor demands. Despite revelries and intermittent clashes with local Native American tribes, the settlement gradually moved northward, laid out farms, and expanded trade with New England and the world.

Peter Stuyvesant

The most famous governor of the Dutch period was Peter Stuyvesant, director general of New Netherland in 1647–64. Stuyvesant's military background enabled him to spruce up a disorderly town, and he soon granted it recognition as an independent city (1653). The religious orthodoxy he attempted to impose on his already multicultural domain, however, soon led him to clash with the Quaker population of Flushing (1657). Ultimately, Stuyvesant was ordered by his superiors to "shut his eyes" to dissenters so long as they did not disrupt society or trade. The governor found such official blindness difficult, and his imperious nature continued to alienate town burghers. When a British fleet sent by James, Duke of York (the future James II), appeared off Gravesend in August 1664, Stuyvesant discovered that no one would fight for his colony. "Old Peg Leg" was soon forced to surrender without even firing a shot. Interestingly, he chose to take an oath of allegiance to the English crown and lived out his life in the city. Despite a brief Dutch reoccupation in 1673–74, the destiny of the colony (which had been renamed in honour of James) had shifted to London. Within the conquered city, resident Dutch and incoming English merchants got along quite well, and representatives of both groups constituted a city elite into the 19th century.

A series of English governors ruled New York and hoped that its commerce would make them rich. New York held the flour-bolting monopoly for the area (1680), was declared the sole port of entry for the colony, and its active community of merchants carried on a world trade. Thomas Dongan, a Roman Catholic governor, granted a royal charter of incorporation to the city in 1686 and furthered religious toleration and representative government within the colony. Following the Glorious Revolution in England (1688–89), the brief tenure of Jacob Leisler marked a period of intolerance new to the city and left a heritage of class factionalism that endured for several decades after his execution for treason in 1691. By 1700 the city had nearly 5,000 residents and was connected to the mainland for the first time by the construction of the Kings Bridge to the Bronx.

Tensions between merchant aristocrats, who sought to avoid imperial trade regulations, and venal governors, who were willing to turn a blind eye if they were suitably rewarded, were abundant. Class and ethnic conflict was present, and in 1712 and 1741 public fear of African Americans led to repression and numerous executions. Indicative of a growing spirit of independence was the libel case of John Peter Zenger, a journalist whose weekly journal criticized the political machinations and cupidity of Governor William Cosby. In 1735 a jury of his peers found Zenger not guilty, determining that he had published the truth. The decision was a signal victory for freedom of the press and demonstrated growing civic disobedience within New York during pre-Revolutionary decades. By 1756 assembly leaders humbled royal governors by forcing them to accept annual salary appropriations. The city hosted the Stamp Act Congress (1765), and the Sons of Liberty used violence to prevent the use of excise-tax stamps. New York's merchant community led the nonimportation program that forced repeal of the measure in 1766, even as the assembly refused to deliver food and cider to British soldiers quartered in the city. Clashes between the Sons of Liberty and soldiers were unending, and the first "battle" of the American Revolution was fought on Golden Hill (south of present City Hall) in January 1770. New York's "tea party" took place in April 1774, months after Boston's famous depredations, but it was held in daylight and without any disguises. New York issued the proclamation calling for a Continental Congress, and its citizens forced the resident royal governor to take refuge on a ship in the harbour long before independence was declared.

Growth of civic disobedience

Almost one-third of all the battles in the Revolution occurred in New York state, but the city's role was less than heroic. George Washington recognized the "infinite importance" of strategic New York, but in battles between August and October 1776 he was unable to defend the city. For seven years the city was occupied, during which its population declined and two fires destroyed many of its structures. Washington eventually returned to New York after the British evacuation in 1783. Quickly rebuilt, the city served both as state capital (until 1797) and as capital of the Confederation (1785–90); it hosted the inauguration of Washington as president, in April 1789. As the first capital of the United States, New York entertained the first meeting of Congress and the first sessions of the Supreme Court. When the capital was moved to Philadelphia for political reasons, Abigail Adams left the city in despair, for her new home would "not be Broadway."

GROWTH OF THE METROPOLIS

Despite the loss of the national government, New York's population skyrocketed in 1781–1800, and it became America's largest city. Once again trade grew rapidly, and not even the War of 1812 hindered development; an auction system for surplus British merchandise dumped in New York solidified the city's economic position after 1816. Even before the opening of the Erie Canal in 1825, New York enjoyed commercial primacy, but as trade from the interior continent flowed onto its piers the city also attained legal, insurance, and manufacturing primacy. Steamships, cheap transportation by rail and canal, abundant labour, and professional expertise made New York increasingly dominant. By the mid-1800s it handled more goods and people than all the other American ports combined. So secure was its position that in 1861 Mayor Fer-

nando Wood suggested it become a "free city" rather than fight against the South. New York instead provided more soldiers to the Union than any other city and survived the turbulent, violent Draft Riot of 1863. Despite the financial panics between 1837 and 1893, the city remained an economic juggernaut, and by 1900 it was the busiest port and one of the wealthiest cities in the world.

Prosperity in Manhattan was not shared by everyone. Two centuries of domination by the merchant elite ended in the city as the Democratic Party gradually assumed control of political power. Tammany Hall, a fraternal organization that formed in 1789, had been transformed into a party vehicle by Aaron Burr before the early 19th century; the group supported such popular reforms as universal male suffrage, the end of imprisonment for indebtedness, and lien laws. Most important, Tammany opposed the anti-Catholic attitudes of the elite and ministered to the needs of impoverished immigrants entering the city. By the 1850s it was able to count on their votes, and the resulting power base lasted for more than a century.

Draft riots of 1863

During the American Civil War, the city was shaken by its worst riots. For four days in July 1863 many thousands of rioters, mostly impoverished Irish immigrants who were infuriated by the new draft law that permitted a draftee to buy his way out of service, swept the city, looting, burning, and killing. African Americans were hanged from the streetlights and trees. Warships trained guns on the city, as rioters clashed repeatedly with the police, national guardsmen, and the army. At least 2,000 people were killed and thousands more wounded, and all business halted in the face of the armed conflict.

After the war there was a steady clamour in the city for a merger with Brooklyn, Queens, the Bronx, and Staten Island. The strongest resistance came from Brooklyn, a city in its own right; with good reason it feared that the corruption so evident in Tammany Hall under the first recognized political "boss," William Magear Tweed—who never rose higher in the city hierarchy than supervisor but who controlled mayors, governors, and legislatures—and later Richard Croker, would be extended to Brooklyn through any consolidation. "Tweed ring" corruption siphoned tens, perhaps hundreds, of millions of dollars into private hands until, in 1871, a coalition of reformers overthrew the boss. Tweed's successor as county leader, John Kelly, was a more astute politician who transformed the undisciplined hordes of Tammany into an army. Regimentation down to the block level replaced greed as a ruling party principle, although the organization always remained a source of food, legal help, and jobs for its faithful supporters.

GREATER NEW YORK

The Democratic machine reigned, its excesses became apparent, reformers arose and were temporarily triumphant, and then voters restored a chastened Tammany to power. A generation after Tweed fell, the Croker regime was successfully challenged by reformers who elected Mayor William Strong. Once consolidation won voter support, the addition of nearly 1.5 million people to the city and the opportunity to expand Tammany's patronage base lured Croker back to Manhattan. After January 1, 1898, the machine ruled Greater New York, its power constantly enhanced by new waves of arriving immigrants. As always, the machine added to urban infrastructure: the subways with their fixed five-cent fare, new bridges, and an expanded park system brought the boroughs together and added to its authority. The booming garment industry, ceaseless construction, and extensive manufacturing provided jobs for the strong, while an excellent educational system trained millions for the white-collar and civil-service jobs that would become increasingly preponderant after the mid-20th century. In the "good years" before World War I and in the "Roaring Twenties" that followed the war, Tammany, under the leadership of Charles Murphy, generally held sway.

Scandals and reforms

In the mid-1920s and early 1930s a series of municipal scandals, which led to another wave of reform, were perhaps the result of Mayor James Walker. A playboy addicted to the wonders of city nightlife, Walker left the mechanics of governing to Tammany. Despite the ravages of the Great Depression and the hardships of World War II, Fiorello La Guardia's administration represented a high point in the city's history. Enormous amounts of New Deal funding enabled the city to complete vast construction and other projects; the Tammany Tiger was caged, the government was centralized and modernized, and the subway system was completed and unified. La Guardia dominated the news, cracked down on crime, and even read comic strips to children during a newspaper strike. Only when he chose to retire did Tammany regain control.

Postwar New York experienced an era in which alarming structural problems in urban society became ever more apparent. New York port lost its dominance, manufacturing began its long decline, massive city debt made it increasingly difficult to fund expensive services, and levels of municipal bureaucracy proliferated. In the 1950s Robert Wagner initiated major housing programs and granted collective bargaining rights to city unions but was often accused of ignoring long-term problems. Ultimately, he found it expedient to publicly break with a Tammany Hall that had twice gotten him elected. Wagner destroyed the power of the machine and its last boss, Carmine DeSapio. He was able to install his own Manhattan county leader and undermine Tammany's influence in the outer boroughs, but he did little to deal with the looming problems. Wagner prepared the electorate for another reform administration, as Republican-Liberal candidate John Lindsay unexpectedly won election in 1965.

During Lindsay's two terms, New York's downward spiral accelerated as he attempted to impose administrative order. A massive transit strike coincided with his inauguration and was settled only with the first of several generous union contracts. Lindsay's attempt to further undermine the power of the machine by merging departments and creating "superagencies" only added new levels of bureaucratic structure. His efforts to decentralize the school system and broaden minority participation in government led to greater ethnic animosity. Above all, he failed to gain control of a soaring municipal budget, even though he increased taxes. Denied renomination in 1969 by outraged Republicans, Lindsay won reelection as a Liberal-Independent candidate, because the old Democratic machine had been gutted. His subsequent feud with a Republican governor led him to become a Democrat. During his last years in office, the metropolis continued to deteriorate financially.

Beame's administration

The election of Abraham Beame in 1973 was the last gasp of old-style politics in New York. Beame was a product of the organization, and as the first Jewish mayor he represented the ethnic succession to power that Irish and Italians had previously achieved. Conditions had changed, and Beame's term was dominated by fiscal disaster. In every way but formally the city went bankrupt, and in 1975 budgetary control was assumed by state agencies. The federal Securities and Exchange Commission later condemned Beame's fiscal policies. Much of the country, always suspicious of New York's foreignness and arrogance, cheered as the Big Apple was shown to be full of worms. Many believed it would be years before it could recover from the debacle.

In the late 1970s Edward Koch restored fiscal health to the city in a single term. By working closely with state officials, rigorously controlling expenditures, and instituting a modern accounting system, Koch once again marketed city notes. His extraordinary feat won him nomination by both major parties in 1981, a unique accomplishment but also clear proof that politics in the metropolis had changed. Democratic nominations were soon negotiated by five relatively equal borough organizations that had to be media-friendly. The Republicans were so powerless that they amassed fewer votes than the Liberal Party in the election of 1985. Koch was outspoken, intolerant of opposition, frequently capricious, and prone to see himself as above politics. Fittingly, his third term became a public relations nightmare when some of his important appointees and elected Democrats were involved in municipal scandals. His attempt to become the first four-term mayor ended when he lost the Democratic primary to David Dinkins, the borough president of Manhattan. Some saw Dinkins, an African American, as fulfilling the theme of ethnic succession, but he proved to be a poor administrator and was

so dependent on African American votes that he alienated other parts of the coalition that elected him. Both ethnic tensions and crime statistics increased during his term, and he became the first black mayor of a major U.S. city to be denied reelection.

Race and competence, not party affiliation, were the major factors that led to the election of Republican Rudolph Giuliani in 1993. A successful career prosecutor, he pledged to reduce taxes, improve or privatize city services, and regain control of the streets from criminals. His great successes in reducing crime won him national fame. Giuliani nurtured his reputation as an angry man indifferent to criticism. Although New York reduced its welfare caseload and instituted a vast workfare alternative, the mayor was unable to eliminate other parts of the social "safety net." Courts consistently limited his initiatives in cases involving free speech, land use, and the rights of the homeless, and many observers held him responsible for instances in which the city's police department used excessive force in its war on crime. His elections may perhaps be best interpreted not as Republican triumphs but as mandates for a stern teacher empowered to deal with a disorderly classroom.

In the 1990s New York experienced sustained growth in both population and financial stability. Hundreds of thousands of immigrants were added to its population, while a sustained boom on Wall Street invigorated the economy of every borough. In addition, major renovations of its infrastructure were completed, such as the restoration of Grand Central Station.

Because of its prominence and its central role in world commerce, however, the city remained vulnerable to acts of terrorism, most notably two attacks on the World Trade Center complex. In 1993 a bomb in one of the complex's twin towers killed several people and injured some 1,000. The attacks of September 11, 2001, were far more devastating: Islāmic militants flew hijacked commercial airliners into the towers, leading to their collapse. The attacks on the towers killed some 2,800 people and badly shook the residents of both the city and the country. The aftermath of the attacks, near the end of Giuliani's term in office, was seen even by the mayor's detractors as his finest hour, when he stalwartly led the city through perhaps its greatest crisis. He was succeeded by fellow Republican Michael R. Bloomberg.

September 11 attacks

In spite of the attacks New York's importance did not wane. The host city of the United Nations, it continued to be the country's most international city and one of the world's foremost tourist destinations. New York, at the outset of the 21st century, remained the preeminent American city.

BIBLIOGRAPHY. A good first approach to the city's history is KENNETH T. JACKSON (ed.), *The Encyclopedia of New York City* (1995), a magnificent compilation by hundreds of scholars. In addition, volumes such as ERIC HOMBERGER, *The Historical Atlas of New York City,* 2nd ed. (1996, reissued 1998); ELLIOT WILLENSKY and NORVAL WHITE (eds.), *AIA Guide to New York City,* 3rd ed. (1988); and FEDERAL WRITERS' PROJECT, *New York City Guide,* rev. ed. (1939, reprinted as *The WPA Guide to New York City,* 1982), are excellent histories of the city.

Accounts of the 19th-century city include ALLAN NEVINS (ed.), *The Diary of Philip Hone, 1828–1851,* 2 vol. (1927, reprinted 2 vol. in 1, 1969), and *The Diary of George Templeton Strong,* 4 vol. (1952, reprinted 1974), also available in an abridged one-volume version with the same title (1988); JAMES D. MCCABE, JR., *Lights and Shadows of New York Life* (1872, reissued 1970); WILLIAM L. RIORDAN, *Plunkitt of Tammany Hall* (1905, available in many later printings); and JACOB A. RIIS, *How the Other Half Lives* (1890, reprinted 1972). Insights into the 20th century are found in EDWARD J. FLYNN, *You're the Boss* (1947, reprinted 1983); MEYER BERGER, *Meyer Berger's New York* (1960); JOSEPH MITCHELL, *The Bottom of the Harbor* (1959, reissued 1994); and EDWARD I. KOCH and WILLIAM RAUCH, *Mayor* (1984), and *Politics* (1985).

Discussions of political life include ALFRED CONNABLE and EDWARD SILBERFARB, *Tigers of Tammany: Nine Men Who Ran New York* (1967); and EDWARD N. COSTIKYAN, *Behind Closed Doors: Politics in the Public Interest* (1966). The changing face of the people is documented in SEAN WILENTZ, *Chants Democratic: New York City & the Rise of the American Working Class, 1788–1850* (1984, reissued 1986); and EDWARD K. SPANN, *The New Metropolis: New York City, 1849–1857* (1981). Immigrant life is covered by IRVING HOWE and KENNETH LIBO, *World of Our Fathers* (1976, reissued 1994; also published as *The Immigrant Jews of New York, 1881 to the Present,* 1976); NATHAN GLAZER and DANIEL PATRICK MOYNIHAN, *Beyond the Melting Pot: The Negroes, Puerto Ricans, Jews, Italians, and Irish of New York City,* 2nd ed. (1970, reprinted 1995); and FREDERICK M. BINDER and DAVID M. REIMERS, *All the Nations Under Heaven: An Ethnic and Racial History of New York City* (1995). Publications for the centennial of Greater New York include EDWIN G. BURROWS and MIKE WALLACE, *Gotham: A History of New York City to 1898* (1999); and GEORGE J. LANKEVICH, *American Metropolis: A History of New York City* (1998).

The contemporary city is covered in ROBERT A. CARO, *The Power Broker: Robert Moses and the Fall of New York* (1974); and THOMAS KESSNER, *Fiorello H. La Guardia and the Making of Modern New York* (1989; reissued 1991). The financial collapse of New York is treated in KEN AULETTA, *The Streets Were Paved with Gold* (1979); and CHARLES R. MORRIS, *The Cost of Good Intentions: New York City and the Liberal Experiment, 1960–1975* (1980); while the relationship of the city to its natural surroundings is covered by ANN L. BUTTENWIESER, *Manhattan, Water-Bound,* 2nd ed. (1999).

Surveys of the city's culture are THOMAS BENDER, *New York Intellect* (1987), tracing intellectual history since 1750; LEWIS A. FRENBERG, *Steppin' Out: New York Nightlife and the Transformation of American Culture, 1890–1930* (1981, reissued 1984); and DAVID W. DUNLAP, *On Broadway: A Journey Uptown Over Time* (1990). Monographs on various facets of city life include GEORGE CHAUNCEY, *Gay New York* (1994); VIRGIL W. PETERSON, *The Mob: 200 Years of Organized Crime in New York* (1983); CLIFTON HOOD, *722 Miles: The Building of the Subways and How They Transformed New York* (1993, reissued 1995); and NATHAN SILVER, *Lost New York* (1967, reissued 1993). New Zealand

New Zealand is an independent member of the Commonwealth. It is remote from other lands, being situated in the South Pacific more than 1,000 miles (1,600 kilometres) southeast of Australia, its nearest neighbour. The country comprises two main islands—the North and South islands—and a number of small islands, some of them hundreds of miles from the main group. New Zealand is about 1,000 miles long (north-south) and about 280 miles across at its widest point. The land area is approximately 100,000 square miles (268,000 square kilometres)—slightly smaller than the state of Colorado and a little larger than the United Kingdom. About two-thirds of the land is economically useful, the remainder being mountainous. Because of its numerous harbours and fjords, the country has an extremely long coastline relative to its area. The capital city is Wellington, and the largest urban area is Auckland, both located on the North Island. New Zealand administers the South Pacific island group of Tokelau and claims a section of the Antarctic continent. Niue and the Cook Islands are self-governing states in free association with New Zealand.

New Zealand was the largest country in Polynesia before it was annexed by the British in 1840. Thereafter it was, successively, a crown colony, a self-governing colony (1856), and a dominion (1907). By the 1920s it controlled almost all of its internal and external policies, although it did not become fully independent until 1947, when it adopted the Statute of Westminster.

The country's isolation has played an important part in its development. Nevertheless, New Zealand has been fully engaged in international affairs, being an active member of both the League of Nations and the United Nations. It has also participated in several wars, including World Wars I and II. Economically, the country was dependent on the export of agricultural products, especially to Great Britain, for much of the 20th century. The entry of Britain into the European Community in the early 1970s, however, forced New Zealand to expand its trade relations with other countries. It also has begun to develop a much more extensive and varied industrial sector. (J.W.R./M.A.Ro./Ke.S.)

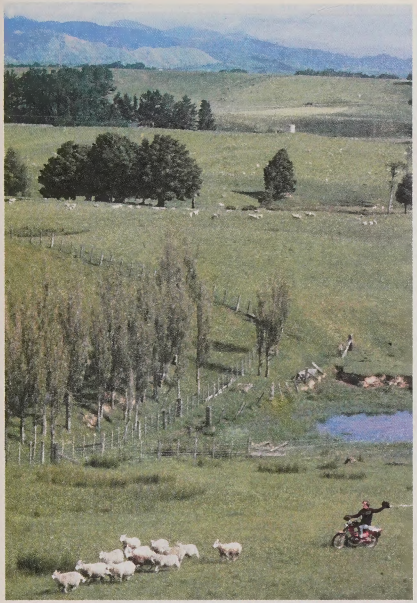
Physical and human geography



THE LAND

Relief. Although New Zealand is small, its geological history is as complex as that of a continent. Land has existed in the vicinity of New Zealand for most of the last 500,000,000 years. The earliest known rocks originated as sedimentary deposits of Late Precambrian (older than 570,000,000 years) or Early Cambrian age; their source area was probably the continental forelands of Australia and Antarctica, then part of a nearby single supercontinent. Continental drift (the movement of large plates of the Earth's crust) created a distinct island arc and oceanic trench structure by Carboniferous time (315,000,000 to 280,000,000 years ago), when deposition began in the synclines (trenches) of the sedimentary rocks that today make up some three-fourths of New Zealand. This environment lasted about 250,000,000 years and is typified by both synclinal oceanic sedimentary rocks and by terrestrial volcanic rocks. This period was terminated in the west at the beginning of the Cretaceous (about 135,000,000 years ago) by the Rangitata Orogeny (mountain-building episode), although synclinal deposition continued in the east. These mountains were slowly worn down by erosion, and the sea transgressed, eventually covering almost all of the land. At the end of Oligocene time (about 26,000,000 years ago) the Kaikoura Orogeny began, raising land above the sea again, including the Southern Alps of the South Island. Many of the great earth movements associated with this final orogeny took place (and take place today) along faults, which divide the landscape into great blocks, chief of which is the Alpine Fault of the South Island. The erosion and continued movement of these faulted blocks, together with the continuing volcanism of the North Island, define to a large extent the landscape of the country.

The role of continental drift

Both the North and South islands are roughly bisected, by mountains in the South and by ranges of hills in the North. Swift, snow-fed rivers drain from the hills, although only in the east of the South Island have extensive alluvial plains been built up. The alluvial Canterbury Plains contrast sharply with the precipitous slopes and narrow coastal strip of the Westland region on the west coast of the South Island. The Southern Alps are a 300-mile-long chain of fold mountains containing New Zealand's highest mountain—Mt. Cook (in Maori, Aorangi) at 12,316 feet (3,754 metres)—and some 20 other peaks that rise above 10,000 feet, as well as an extensive glacier system with associated lakes.

There are more than 360 glaciers in the Southern Alps. The Tasman Glacier, the largest in New Zealand, with a length of 18 miles and a width of more than one-half mile, flows down the eastern slopes of Mt. Cook. Other important glaciers on the eastern slopes of the Southern Alps are the Murchison, Mueller, and Godley; Fox and Franz Josef are the largest on the western slopes. The North Island has seven small glaciers on the slopes of Mt. Ruapehu.

In the north of the South Island, the Alps break up into steep upswelling ridges. On their western face there are mineral deposits, and to the east they continue into two parallel ranges, terminating in a series of sounds. To the south, the Alps break up into rugged, dissected country of difficult access and magnificent scenery, particularly toward the western tip of the island (called Fiordland). On its eastern boundary this wilderness borders a high central plateau called Central Otago, which has an almost continental climate.

The North Island is much less precipitous than the South and has a more benign climate and greater economic potential. In the centre of the island the Volcanic Plateau rises abruptly from the southern shores of New Zealand's largest natural lake, Taupo, itself an ancient volcanic crater. To the east ranges form a backdrop to rolling country in which pockets of great fertility are associated with the river systems. To the south more ranges run to the sea. On the western and eastern slopes of these ranges the land is generally poor, although the western downland region is fertile until it fades into a coastal plain dominated by sand dunes. To the west of the Volcanic Plateau fairly mountainous country merges into the undulating farmlands of the Taranaki region, where the mild climate favours dairy farming even on the slopes of Mt. Egmont, an isolated, extinct volcano.

The northern shores of Lake Taupo bound a large area of high economic activity, including forestry. Even further north there are river terraces sufficiently fertile for widespread dairy and mixed farming. The hub of this area is Auckland, which is situated astride an isthmus with a deep harbour on the east and a shallow harbour to the west. The region north of Auckland, called Northland, becomes gradually subtropical in character, marked generally by numerous deep-encroaching inlets of the sea bordered by mangrove swamps.

Hydrography

Drainage. The mountainous country of both islands is cut by many rivers, which are swift, dangerous, and a barrier to communication. The longest is the Waikato, in the North Island, and the swiftest, the Clutha, in the South. Many of the rivers arise from or drain into one or other of the numerous lakes associated with the mountain chains. A number of these lakes have been used as reservoirs for hydroelectric schemes, and artificial lakes, including Lake Benmore, New Zealand's largest, have been created for hydroelectric purposes.

Soils. New Zealand's soils are often deeply weathered, lacking in many nutrients, and, most of all, highly variable over short distances. Soils based on sedimentary rock formations are mostly clays and are found over about three-fourths of the country. Pockets of fertile alluvial soil in river basins or along river terraces form the orchard and market-gardening regions of the country.

In the South Island, variations in mean annual rainfall have had an important effect. The brown-gray soils of Central Otago are thin and coarse-textured and have subsoil accumulations of lime, whereas the yellow-gray earths of much of the Canterbury Plains, as well as areas of lower rainfall in the North Island, are partially podzolized (layered) with a gray upper horizon. The yellow-brown soils that characterize much of the North Island are often podzolized from acid leaching in humid forest environments. Their fertility varies with the species composition of their vegetation. Forests of false beech (*Nothofagus*), as well as of tawa and taraire, indicate soils of reasonably high fertility, while forests of kauri pine and rimu indicate podzolized soils.

Climate. New Zealand's climate is determined by its latitude, its isolation, and its physical characteristics. Across such vast oceans as surround it, weather from elsewhere has little influence. There are no extremes of temperature.

A procession of high-pressure systems (anticyclones) separated by middle-latitude cyclones and fronts cross New Zealand from west to east. Characteristic is the sequence of a few days of fine weather and clear skies separated by days with unsettled weather and often heavy rain. In summer subtropical highs are dominant, bringing protracted spells of fine weather and intense sunshine. In winter middle-latitude lows and active fronts increase the blustery wet conditions, although short spells of clear skies also occur. Because of the high mountain chains that lie across the path of the prevailing winds, the contrast in climate from west to east is sharper than that from north to south. Mountain ranges are also responsible for the semicontinental climate of Central Otago.

Changes in altitude make for an intricate pattern of temperature variations, especially on South Island, but some generalizations for conditions at sea level can be made. The average seasonal and diurnal temperature range is about 18° F (10° C). Variation in mean monthly temperature from north to south is about 10° F (6° C). In most parts of the country daytime highs in summer are above 70° F (21° C), occasionally exceeding 81° F (27° C) in the north, while in winter daytime highs throughout the country are rarely below 50° F (10° C).

Rainfall is highest in areas dominated by mountains exposed to the prevailing westerly and northwesterly winds. Although mean annual rainfall ranges from an arid 12 inches (300 millimetres) in Central Otago to as much as 315 inches in the Southern Alps, for the whole country it is typical of temperate zone countries (25–60 inches), usually spread reliably throughout the year. Snow is common only in mountainous regions, but frost is frequent in inland valleys in winter. Humidity ranges from 70 to 80 percent on the coast, generally being 10 percent lower inland. In the lee of the Southern Alps, where the effect of the foehn (a warm, dry wind of leeward mountain slopes) is marked, humidity can become very low.

Plant and animal life. The indigenous vegetation of New Zealand consisted of mixed evergreen forest covering perhaps two-thirds of the total land area. The islands' prolonged isolation has encouraged the development of species unknown to the rest of the world; almost 90 per-

cent of the indigenous plants are peculiar to the country. Today, dense "bush" survives only in areas unsuitable for settlement and in parks and reserves. On the west coast of the South Island this mixed forest still yields most of the native timber used by industry. Along the mountain chain running the length of the country, the false beech is the predominant forest tree.

European settlement made such inroads on the natural forest that erosion in high-country areas became a serious problem. The State Forest Service was established to repair the damage by forest-management techniques and reafforestation with exotic trees. Experimental areas on the Volcanic Plateau were planted with radiata pine, an introduction from California. This conifer has adapted to New Zealand conditions so well that it is now the staple plantation tree, growing to maturity in 25 years and having a high rate of natural regeneration. Large areas of the Volcanic Plateau, together with other marginal or subagricultural land north of Auckland and near Nelson, are now planted with this species.

European broadleafs are widely used ornamentally, and willows and poplars are frequently planted to help prevent erosion on hillsides. Gorse has acclimatized so readily that it has now become a menace, spreading over good and bad land alike, its only virtue being as a nursery for regenerating bush.

Because of New Zealand's isolation there was no higher animal life in the country when the Maori arrived (some 1,000 or more years ago). There were two species of lizard: the gecko, which is born directly instead of being hatched from an egg, and the tuatara, a "beak-headed" reptile extinct elsewhere for 100,000,000 years. There were also a few primitive species of frog and two species of bat. These are all extant, although confined to outlying islands and isolated parts of the country.

In addition to their domestic animals, Europeans also brought other species with them. The red deer, introduced for sport, and the Australian opossum (for skins) have multiplied beyond imagination and do untold damage when browsing in the high-country bush. The control of

Snowcapped Mitre Peak, reflected in the waters of Milford Sound, Fiordland National Park, South Island.
© Delias and John Heaton—CUCK/Chicago

goats, deer, opossums, and rabbits—even in the national parks—is a continuing problem.

Flightless birds

In the absence of predatory animals, New Zealand was a paradise for birds, the most interesting of which are flightless. The moa was a very large bird, easily exterminated by the Maori. The kiwi, another flightless species, is extant, though only in secluded bush areas. The weka and the notornis, or takahe (barely rescued from extinction), probably became flightless after arrival. The pukeko, a swamphen relative of the weka, is even now in the process of losing the use of its wings. Some birds, such as the saddleback and the native thrush (thought to be extinct), are peculiar to New Zealand, but many others, such as the tui, the fantail, and the bellbird, are closely related to Australian birds. Birds that breed in or near New Zealand include the Australian (Australasian) gannet, the skua, the penguin, the shag, and the royal albatross.

Because New Zealand is the meeting place of warm and cool currents, a great variety of fish is found in its waters. Tropical species such as tuna, marlin, and some big-game sharks are attracted by the warm currents, which are locally populated by snapper, trevally, and kahawai. The Antarctic cold currents, on the other hand, bring the blue and red cod and the hake, while some fish, tolerant to a considerable range of water temperature, are found off the entire coastline—tarakihi, grouper, and bass. Flounder and sole abound on tidal mudflats, and crayfish are prolific in rocky areas off the coastline.

(J.W.R./M.A.Ro./W.Mo.)

THE PEOPLE

Ethnic structure. New Zealand was one of the last sizable land areas suitable for habitation to be populated by human beings. It was first settled by Polynesians who came from somewhere in eastern Polynesia, possibly from what is now French Polynesia. They remained isolated in New Zealand until the arrival of European explorers, the first of whom was the Dutchman Abel Janszoon Tasman (1642). During that time they grew in numbers to between 100,000 and 200,000, living almost exclusively on North Island. They had no name for themselves but eventually adopted the name Maori (meaning "normal") to distinguish themselves from the Europeans, who, after the voyages of the Englishman Capt. James Cook (1769–77), began to come with greater frequency.

Threats to the Maori population

The Europeans brought with them an array of diseases to which the Maori had no resistance, and this precipitated a rapid decline in the Maori population. Their reduction in numbers was exacerbated by widespread intertribal warfare (once the Maori had acquired firearms) and by warfare with Europeans. By 1896 there were only about 42,000 Maori left. Early in the 20th century, however, their numbers began to increase as they acquired resistance to such diseases as measles and influenza and as their birth rate subsequently recovered.

Europeans had begun to settle in New Zealand in the 1820s; they arrived in increasing numbers after the country was annexed by Great Britain in 1840. By the late 1850s settlers outnumbered Maori, and in 1900 there were some 772,000 Europeans, most of whom by then were New Zealand-born. Although the overwhelming majority of immigrants were of British extraction, other Europeans came as well, notably from Scandinavia, Germany, Greece, Italy, and the Balkans. Groups of central Europeans came between World Wars I and II, and a large body of Dutch immigrants arrived after World War II. Asians coming to New Zealand have included Chinese and Indians and more recently a growing community of Pacific Islanders from Western Samoa, the Cook Islands, Niue, and Tokelau.

Contemporary New Zealand thus has a great majority of people of European origin, a significant minority of Maori, and smaller numbers of Pacific Islanders, Chinese, and Indians. This diverse society has produced some racial tensions, but they have been small compared with those found in other parts of the world. Although the Maori have legal equality with those of European descent (called *pakeha* by the Maori), many feel unable to take their full place in a European-type society without compromising their traditional values.

Language and religion. New Zealand is predominantly an English-speaking country. Virtually all Maori speak English, and about one-third of them also speak Maori. The Maori language is taught at a number of schools. The

only other non-English language spoken by any significant number of people is Samoan.

New Zealand is nominally Christian, some three-fifths of the population adhering to the Anglican, Presbyterian, Roman Catholic, and Methodist denominations. Minor Protestant sects, the Eastern Orthodox churches, Jewish congregations, and Maori adaptations of Christianity (the Ratana and Ringatu churches) account for nearly all of the rest, although a significant proportion of the population does not claim any religious affiliation. There is no established (official) religion, but Anglican cathedrals are generally used for state occasions.

Regional population. Because New Zealand is small and the population is relatively homogeneous, there are no sharply differentiated social or political regions. The North, however, is popularly regarded as being more enterprising, while the South is traditionally regarded as being conservative. While the west coast is romantically nostalgic for its rollicking gold-rush days, the east coast conjures up the picture of sheep barons on their extensive stations.

The New Zealand countryside is thinly populated, but there are many small towns and a number of provincial cities. Very small towns or villages are becoming more deserted as people drift to the bigger towns and cities.

The main urban areas are Auckland, the centre of the North and the main industrial complex; Hamilton, in the middle of the North Island; Wellington, centrally located at the southern tip of North Island and the political and commercial capital; Christchurch, in the middle of the South Island and the second largest industrial area; and finally, still farther south, Dunedin. Although New Zealand is notable for the strength of its rural sector, the great majority of people live in cities, and urban concentration is proceeding apace. There is also a marked difference in the degree of population growth of the two main islands—the North having about three-fourths of the total population, in sharp contrast to the earlier years of systematic settlement. As in the past, the great majority of Maori live on the North Island; since World War II, however, most Maori have become urban dwellers, as have the Pacific Islanders.

Demographic trends. The natural rate of increase has been highest for the Pacific Islanders and for the Maori, both having a more youthful population. Since World War II New Zealand has generally had an annual excess of arrivals over departures, a major contributor to overall population growth causing frequent debates over limiting immigration. Although in the past most immigrants came from Great Britain and The Netherlands, they have been surpassed by Pacific Islanders and Asians. Australia is the preferred destination of emigrants.

(J.W.R./M.A.Ro./Ke.S.)

THE ECONOMY

New Zealand has a small, developing economy with a relatively low standard of living compared with those of countries with similar economies, such as Australia and Canada. In the late 19th and early 20th centuries New Zealand's standard of living was one of the highest in the world, but since World War II the rate of growth has been one of the slowest among the developed countries. The main causes of this retardation have been the slow growth of the economy of the United Kingdom (which formerly was the main destination of New Zealand's exports) and the high tariffs imposed by the major industrial nations against the country's agricultural products (*e.g.*, butter and meat). Agricultural exports increased, however, after more liberalized international trade agreements took effect in the mid-1990s. Also, New Zealand attempted to evade these protectionist constraints by diversifying its farm economy and by expanding its manufacturing base. This has been achieved partly by large-scale government intervention.

Resources. Most minerals, metallic and nonmetallic, occur in New Zealand, but few are found in sufficient quantities for commercial exploitation. The exceptions are gold, which in the early years of organized settlement was a major export; coal, which is still mined to a considerable extent; iron sands, which are exploited both for export and for domestic use; and, most recently, natural gas. In addition to mining, construction materials, with which the country is well endowed, are quarried.

Apart from gold's brief heyday, biological resources have always been more significant than minerals. Domestic animals introduced from Europe have thrived in New Zealand. Forestry has always been important, but the emphasis has swung from felling the original forest for timber to afforestation with pine trees for both timber and pulp.

Use of hydroelectric power

The country has exploited its great hydroelectric potential to such an extent that hydroelectricity supplies a major percentage of the country's power. A notable feature of the New Zealand electricity grid is the direct-current cable linking the two main islands, enabling the South's surplus hydroelectric power to be used by the North's concentration of industry and people. Since the early 1970s geothermal and coal- and gas-fired stations have also been constructed. In addition, partnerships between government and private interests have undertaken the development of natural-gas reserves and the construction of the world's first plant producing gasoline from natural gas.

Agriculture, industry, and trade. New Zealand's farming base required a relatively complex economy. Highly productive pastoral farming, embracing extensive sheep grazing and large-scale milk production, was made possible by a temperate climate, heavy investment in land improvement (including the introduction of European grasses and regular application of imported fertilizers), and highly skilled farm management by owner-occupiers, who used one of the highest ratios of capital to labour in farming anywhere in the world. The farms supported and required many specialized services: finance, trade, transport, building and construction, and especially the processing of butter, cheese, and frozen lamb carcasses and their by-products. This economy could be described as an offshore European farm, which exported wool and processed dairy products and imported a variety of finished manufactured consumer and capital goods, raw materials, and petroleum.

Industry

Even in the 19th century New Zealand's relative geographic isolation made necessary a proportionately large industrial labour force engaged in the manufacture and repair of agricultural machinery and in shipbuilding, brewing, and timber processing. After the 1880s the factory processing of farm products swelled these numbers, while the temporary isolation of World Wars I and II stimulated the production of a wide range of manufactured goods that previously had been imported. Protectionist policies first espoused, although weakly, by governments in the late 19th century were strengthened after World War I. From the end of World War II until the early 1970s manufacturing industries were protected by import licensing fees in order to maintain full employment. Thus, there developed some labour-intensive, heavily protected, and uneconomic activities—such as automobile and consumer-electronics assembly—that have not been able to remain competitive (see below *Administration of the economy*).

Trade

Since the 1960s there has been a proportionate decline in pastoral farming in relation to growth in forestry (and the production of paper and other wood products), horticulture, fishing, and deer farming, as well as manufacturing. Tourism has also become an important component of the economy. There has been a related change in the composition of exports, although wool, meat, and dairy products have continued to predominate. Since the importance of trade with Great Britain has been reduced, that with Japan, the United States, and East Asian countries has grown. Trade with Australia has always been significant. A succession of trade agreements (1933, 1965, 1977) provided the basis of the Australia and New Zealand Closer Economic Relations Trade Agreement (CER), signed in 1983. This agreement eventually eliminated duties and commodity quotas between the two countries and was seen by some as the first step toward integrating their economies. In 1995 CER joined with the Association of Southeast Asian Nations Free Trade Area to promote trade and investment between the two regions.

Finance. Banking was established early in New Zealand. By the early 1970s an oligopolistic structure had emerged, consisting of several large trading banks (the largest being state-owned and the others foreign-owned), presided over

by a central bank—the Reserve Bank of New Zealand—and supplemented by other types of specialty institutions. Since the early 1980s the financial sector has been transformed by the trading banks' loss of their privileged position and by the removal of government controls over financial institutions. The capital market has become highly competitive, with new, often foreign-owned specialty institutions emerging. In addition, in the mid-1980s transactions in foreign exchange were freed, and for the first time the exchange rate was floated in a competitive market.

Transportation. In spite of the rugged nature of the country, most of the inhabited areas of New Zealand are readily accessible; the road system is good even in rural districts, and modern freeways have been built around the main cities. The private automobile has long been the most important mode of transportation. In addition, bus services link most centres. The difficult country makes for slow journeys, although the distances involved are seldom great.

The railway network, owned and operated by the Tranz Rail Limited is independent of direct government control. It comprises a main trunk line spanning both islands via roll-on ferries and branch lines linking most towns. Narrow tunnels limit the gauge of line, which until the late 20th century precluded the introduction of fast express trains. Rail travel is notoriously slow, discouraging passenger travel, but service is efficient for large-scale movement of goods over considerable distances. Long-standing regulations protecting the railways against competition by road carriers were abolished in the early 1980s, and as a consequence long-distance road cartage has increased.

The difficult terrain has greatly encouraged air travel in New Zealand; most provincial towns have airports, and all major centres are linked by air service. The main internal airline, Air New Zealand, was privatized in the late 1980s; it, along with several foreign airlines, handles the country's international service, with the main international air terminals at Auckland, Christchurch, and Wellington.

Administration of the economy. New Zealand has had a long history of government intervention in the economy, ranging from state institutions competing in banking and insurance to an extensive social security system. Until the early 1980s most administrations strengthened and supported this paternalism or state socialism, but since then government policy has generally shifted away from intervention, although no move has been made to dismantle the basic elements of social security. Some of the subsidies and tax incentives to agricultural and manufacturing exporters have been abolished, and such government enterprises as the Post Office have become more commercially oriented and depend less on government subsidies. In addition, the government has attempted to resolve the difficult issue of restrictive practices in the labour market, such as restrictions on the entry into some occupations.

The labour force has long been organized into strong trade unions. Like Australia, New Zealand evolved a system of compulsory arbitration in which the government played a major role. Beginning in the late 1960s, however, government policy generally alternated between periods of government-imposed freezes in wages and prices and periods of officially tolerated bargaining between unions and employers, although the strong link between the labour markets of New Zealand and Australia was a major constraint on the establishment of a set policy. However, compulsory union membership was ended in 1991, after which the number of union members fell dramatically.

Taxation

Taxation in New Zealand in relation to national income is not particularly high in comparison to other developed countries. Direct taxation (taxation of personal income) has traditionally been the primary tax. In the mid-1980s a value-added tax was introduced on goods and services.

(J.W.R./M.A.Ro./C.A.Bl./Ed.)

ADMINISTRATION AND SOCIAL CONDITIONS

Government. *Constitutional practice.* New Zealand has a parliamentary form of government. Legislative power is vested in the single-chamber House of Representatives (Parliament), the members of which are elected for three-year terms. There are two dominant parties, National and Labour; the party that commands a majority in the House forms the government. The leader of the governing party becomes the prime minister, who forms a cabinet. The cabinet is the central organ of executive power. Most legislation is introduced by the government; Parliament must then pass it by a majority vote before it can become law. The cabinet, however, has extensive regulatory powers that are subject to only limited parliamentary review. Because cabinet ministers sit in the House and because of invariably strong party discipline, legislative and executive authority are effectively fused.

The British monarch is the formal head of state and is represented technically by a governor-general appointed by the monarch (upon the recommendation of the New Zealand government) to a five-year term. The governor-general has only limited authority but does have some residual powers to protect the constitution and to act in a situation of constitutional crisis (*e.g.*, the governor-general can dissolve Parliament under certain circumstances).

The structure of the New Zealand government is relatively simple, but the country's constitutional provisions are more complex. Like that of Great Britain, New Zealand's constitution is a mixture of statute and convention. Where the two clash, convention has tended to prevail. The Constitution Act of 1986 simplified this by consolidating and augmenting constitutional legislation dating from 1852.

Electoral system. There is universal suffrage for those 18 years of age and older. In 1993 the electorate voted to replace the country's plurality system with the mixed-member proportional system, which gave each voter two votes, one for an individual candidate and one for a party. The new system also enlarged the Parliament to 120 seats, with 67 representatives elected (including 6 reserved for Maoris) from multi-member constituencies and 53 through party lists.

The two-party system

While the new system gave a boost to smaller parties, National and Labour remain New Zealand's two major parties. The National Party's base of support is in rural and affluent urban districts and among those involved in business and management. The Labour Party draws support from trade unions and urban blue-collar workers. Over time, however, both parties have broadened their electoral bases. Labour has gained the support of some areas of the business sector and has succeeded in attracting more professionals, while the National Party has had some success among higher paid workers in key small-town and provincial districts. Increasingly, ideological differentiation between the two parties has become complex, and intraparty differences in such areas as economic policy have often been greater than they have been between parties.

Bureaucratic organization. The business of government is carried out by some three dozen government departments of varying size and importance. Most departments correspond to a ministerial portfolio, department heads being responsible to their respective ministers for administration of their departments. Recruiting and promoting civil servants is under the control of the State Services Commission, which is independent of partisan politics. Heads of departments and their officials do not change with a change of government, thus ensuring a continuity of administration.

As a check upon possible administrative injustices, the office of parliamentary commissioner for investigations (ombudsman) was established in 1962; the scope of the office's jurisdiction was enlarged in 1968 and again in 1975. In addition, the Official Information Act of 1982 permits public access, with specific exceptions, to government documents.

There are also a certain number of non-civil service appointees within the government. These fill positions in government corporations—commercial ventures, such as the Broadcasting Corporation of New Zealand and the Bank of New Zealand, in which the government is the sole or major stockholder—and in a host of bodies with administrative or advisory functions. Political affiliations, as well as expertise and experience, often figure in appointment decisions for these institutions.

Local government. Local government, the power of which is limited to all but peculiarly local matters, is di-

rectly empowered by parliamentary statute. Local authorities are thus relatively autonomous, although they do depend upon the central government for financial assistance. The definition of their function and powers is constantly being revised to meet changing conditions.

Local bodies perform general-purpose duties such as those of counties, boroughs, cities, and town districts or else consist of ad hoc authorities with specialized functions such as harbour and electric-power boards. Every local authority activity is controlled by an elected council or board of local members, whose work is largely honorary. The platform for election is sometimes based on party affiliation, although this does not noticeably affect the working of the councils or boards.

Justice. New Zealand derives from the common law of Britain certain statutes passed before 1947 by the British Parliament. New Zealand law usually follows the precedents of English law. Nevertheless, the New Zealand courts have taken a more independent stance and have begun to play a more significant constitutional and political role with respect to public and administrative law. In addition, some members of the legal community have challenged the traditional doctrine that future Parliaments are not bound by laws passed by the Parliament, contending that certain common-law rights might override the will of Parliament.

The law is administered by the Ministry of Justice through its courts. The apex of New Zealand's judicial system is the Court of Appeal, which hears civil and criminal appeals from the High Court and District Courts. The British Privy Council is the final court of appeal for New Zealand. Law enforcement is the responsibility of the New Zealand Police, a cabinet-level department largely independent (with respect to law enforcement) of executive authority. (J.W.R./M.A.Ro./J.Vo./Ed.)

Education. Education in New Zealand is free and secular. It is compulsory between the ages of six and 16. In practice almost all children enter primary school at age five, while many of them have already begun their education in preschools, all of which are subsidized by the state. Education is administered by the Department of Education. Elected education boards control all of the primary and secondary state schools. There are also more than 100 private primary and secondary schools, most of them Roman Catholic or run by other religious groups. They also receive state subsidies and must meet certain standards of teaching and accommodation. State primary schools are coeducational, but there are still many single-sex secondary schools.

Technical institutes, community colleges, and teachers' colleges form the basis of higher education. There are also several universities and an agricultural college. Entry to the universities requires a modest educational achievement, which is often waived for people 21 years of age or older.

Since the early years of the colony, a great emphasis has been placed on education, and virtually the entire population is literate. There is a correspondence school that caters to children living in remote places, and various continuing education and adult education centres provide opportunities for lifelong education.

Social security

Welfare. New Zealand has one of the oldest social security systems in the world. Noncontributory old-age pensions paid for from government revenues were introduced in 1898. Pensions for widows and miners followed soon after, and child allowances were introduced in the 1920s. In 1938 the New Zealand government introduced the most extensive system of pensions and welfare in the world, which included free hospital treatment, free pharmaceutical service, and heavily subsidized treatment by medical practitioners.

Since then the system has been eroded in some respects but greatly extended in others. Doctors' fees, though still subsidized by the state, have become relatively high. Many people invest in private medical insurance and seek treatment in private hospitals. There is still a universal system called New Zealand superannuation, in which all citizens over the age of 65 are granted an income up to 65 percent of the average after-tax wage. However, this system was being phased out and was to be replaced by the retirement savings scheme in 2003; the transition to the new plan was expected to take more than 40 years.

There are numerous other pensions and welfare payments. These include an allowance for each child up to the age of 16 and additional "family care" payments for low-income families, as well as benefits for single parents, invalids, and the sick. Under the Accident Compensation Act of 1972, all persons suffering personal injury from any sort of accident, whether at work or not, can receive compensation for disability and loss of earnings, and they are covered by insurance for any medical or other treatment; in addition they waive the right to sue for damages. The act led to the establishment of the government-run Accident Compensation Corporation, to which all New Zealanders must pay premiums and which handles claims.

Nearly three-fourths of New Zealand's housing stock is owner-occupied. State agencies provide limited financial assistance toward home purchases and renovation work, as well as subsidized rental accommodations for those on low incomes. The state also subsidizes pensioner accommodations through local authorities.

CULTURAL LIFE

The cultural milieu in New Zealand is complex: it is predominantly European but also contains elements from many other peoples, particularly the Maori. Immigrant groups have generally tended to assimilate into the European life-style, although traditional customs are still followed by many Tongans, Samoans, and other Pacific Islanders. The Maori, however, have found themselves torn between the pressure to assimilate and the desire to preserve their own culture. The loss of much of their land in the 19th century undermined their political structures, and large-scale conversion to Christianity caused them to abandon traditional religious observances; but there has been a determined effort—especially since the mid-20th century—to preserve and revive artistic and social traditions. A renaissance has occurred in Maori wood carving and weaving and in the construction of carved and decorated meeting houses (*whare whakairo*). Maori songs and dances have become increasingly popular, especially among the young. Maori meetings—whether *hui* (assemblies) or *tangi* (funeral gatherings)—are conducted in traditional fashion, and ancient greeting ceremonies are strictly observed. The general public has become familiar with Maori art, which is displayed in numerous galleries and museums in New Zealand as well as worldwide.

Revival of Maori traditions

European cultural life has progressed rapidly since the early 20th century. Numerous writers were active in the late 19th century, the most successful of whom were historians, such as William Pember Reeves, and ethnologists, including S. Percy Smith and Elsdon Best. The work of the first genuinely original writers of fiction, the short-story writer Katherine Mansfield and the poet R.A.K. Mason, did not appear until the 1920s. During the difficult years of the Great Depression of the 1930s a group of poets appeared and established a national tradition of writing. Although influenced by contemporary English literature—T.S. Eliot and W.H. Auden were greatly respected—they wrote about their New Zealand experience. The most notable member of this group was Allen Curnow. A.R.D. Fairburn, Denis Glover, and Charles Brasch were other major poets. At the same time Frank Sargeson began writing the superb stories in New Zealand vernacular for which he became well known internationally.

Since World War II the work of these pioneering writers has been followed by that of such widely published and acclaimed poets as James K. Baxter and Kendrick Smithyman. Other notable poets include Ian Wedde and Elizabeth Smither. A number of novelists have also earned international reputations, notably Janet Frame, Keri Hulme, and Sylvia Ashton-Warner. These and other New Zealand writers have been greatly aided by the growth of the publishing industry in New Zealand during this time.

In the second half of the 20th century, painters began to rival writers in artistic accomplishment. The first to achieve international recognition, Frances Hodgkins, spent most of her life abroad. Since the 1960s, however, an unprecedented "art scene" has emerged, created initially by a

group of artists, including Colin McCahon and Don Binney, who were helped by the rise of private galleries in most large towns and cities. While often New Zealand in subject, the paintings from this group indicate how aware the painters were of international influences. This group paved the way for what has become a small legion of acclaimed artists.

Since the 1970s successful professional theatre companies have been established in the cities—including the Downstage in Wellington and the Mercury Theatre in Auckland—in contrast to the early companies that folded for want of sufficient audiences. Several symphony orchestras also have had growing support. New Zealand has produced some world-renowned singers, including Dame Kiri Te Kanawa, Inia Te Wiata, and Donald McIntyre. Some of the country's popular musical groups have also achieved international success.

Support of the arts

The state has moved progressively to assist and encourage the arts. The Queen Elizabeth II Arts Council through Creative New Zealand, its funding arm, gives annual grants in support of literature, theatre, music, modern dance and ballet, and opera, including for the preservation of Maori culture. In addition, New Zealand was one of the first countries to establish a fund to compensate writers for the loss of royalties on books borrowed from libraries rather than purchased. The national orchestra and a weekly cultural publication, the *New Zealand Listener,* are supported by the government through the Broadcasting Corporation of New Zealand, which controls Radio New Zealand and both channels of Television New Zealand. A Maori-language radio station began operations in 1996. The government also subsidizes a motion-picture industry that has received growing international recognition. The films by New Zealand directors Jane Campion and Peter Jackson have garnered particular notice.

Newspapers

Newspapers provide a high standard of reporting, with substantial coverage of world news provided largely by foreign agencies. No daily paper has a national circulation, but some from the large cities are distributed widely over their respective islands. Numerous local and regional dailies are also published.

Sports are the main leisure-time activity of most of the population in New Zealand. Participation in most major sports, particularly rugby football, is widespread. The inaugural World Cup of rugby, which New Zealand cohosted in 1987, was won by the country's national team, the All Blacks. Sailing is much enjoyed, particularly around Auckland, and New Zealand won the America's Cup yachting race in 1995 and again in 2000. Hiking and mountain climbing are popular outdoor activities; New Zealander Sir Edmund Hillary, who, with the Sherpa Tenzing Norgay, was the first to climb Mount Everest, became a national figure. The country has extensive ski slopes, especially on the South Island. Adventure sports have long been common on the islands, and in the late 20th century New Zealand helped popularize bungee jumping.

(J.W.R./M.A.Ro./Ke.S./Ed.)

For statistical data on the land and people of New Zealand, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR.

History

DISCOVERY

The Maori

No precise archaeological records exist of when and from where the first human inhabitants of New Zealand came; but it is generally agreed that Polynesians from eastern Polynesia in the central Pacific reached New Zealand more than 1,000 years ago, possibly by AD 800 or even earlier. There has been much speculation on how these people made the long ocean voyage. Polynesians are known to have sometimes set sail in search of new lands, their canoes well-provisioned with food and plants for cultivation, and it is likely that the discoverers of New Zealand were on such a voyage. Few canoes probably made the dangerous journey, but the people from even one of these large, double-hulled craft could have produced the Maori population that the Europeans encountered in New Zealand in the 17th and 18th centuries. With them they brought the dog and the rat and several plants, including the kumara (a variety of sweet potato), taro, and yam.

The Polynesian period has been divided roughly into an early "Archaic" and a later "Classic Maori" phase. The transition between these two phases is uncertain, but it is thought to be linked to improvements in the raising and storage in a cooler climate of what had been tropical vegetables. In the South Island, if not elsewhere, the first Polynesians found moas (flightless birds) in immense numbers on tussock grasslands, and these became their major food supply. The agriculturalist Classic Maori encountered later by Europeans had only faint memories of the moa. The 18th-century Maori population was densest in the warmer northern parts of the country, where the Maori variant of Polynesian culture had reached its high point, particularly in the arts of war, canoe construction, building, weaving, and agriculture.

The first European to arrive in New Zealand was a Dutch sailor, Abel Janszoon Tasman, who sighted the coast of Westland in December 1642. His sole attempt to land brought only a clash with a South Island tribe in which several of his men were killed. After his voyage the western coast of New Zealand became a line upon European charts and was thought of as the possible western edge of a great southern continent.

In 1769–70 the British naval officer and explorer James Cook completed Tasman's work by circumnavigating the two major islands and charting them with a remarkable degree of accuracy. His initial contact with the Maori was violent, but harmonious relations were established later. On this and on subsequent voyages Cook, with the explorer and naturalist Joseph Banks, made the first systematic observations of Maori life and culture. Cook's journal, published as *A Voyage Towards the South Pole and Round the World* (1777), brought the knowledge of a new land to Europeans. He stressed the intelligence of the natives and the suitability of the country for colonization, and soon colonists as well as other discoverers followed Cook to the country he had made known.

EARLY EUROPEAN SETTLEMENT

European colonies

Apart from convicts escaping from Australia and shipwrecked or deserting sailors seeking asylum with Maori tribes, the first European New Zealanders sought profits—from sealskins, timber, New Zealand flax, and whale oil. Early New Zealand was an offshoot of Australian enterprise in whaling and other activities; Sydney, founded as a convict settlement in 1788, became a base for whaling in the South Pacific; and Kororareka (now called Russell), in the far north of New Zealand, became a stopping place for American, British, and French deep-sea whalers. Around both islands Australian firms set up tiny settlements of land-based bay whalers. Traders supplying whalers drew Maori into their economic activity, buying provisions and supplying trade goods, implements, muskets, and rum. Initially the Maori welcomed the newcomers; while the tribes were secure, the European was a useful dependent.

Maori went overseas, some as far as England. A northern chief, Hongi Hika, amassed presents in England, which he exchanged in Australia for muskets; back in New Zealand he waged devastating war on hereditary enemies. The use of firearms spread southward; a series of tribal wars, spreading from north to south, displaced populations and disturbed landholdings, especially in the Waikato, Taranaki, and Cook Strait areas. Europeans were soon to found colonies in these unsettled regions. Missionaries quickly followed the traders. Between 1814 and 1838 Anglicans, Wesleyan Methodists, and Roman Catholics set up stations. Conversion was initially slow, but by the mid-19th century most Maori adhered, for varying reasons, to some form of Christianity.

All of these newcomers had a profound effect upon Maori life. Warfare and disease reduced numbers, while new values, pursuits, and beliefs modified tribal structure. Christianity cut across the sanctions and prohibitions that had supplied Maori social cohesion. A capitalist economy, to which Maori were introduced both by traders offering new inducements (for instance, the brief demand for flax) and by missionaries bringing new agricultural techniques,

affected the whole material basis of life. At first in the north and later over the whole country a process of adjustment began, which has continued to the present day. By the late 1830s, chiefly through the Australian link, New Zealand had been joined to Europe. Settlers numbered at least some hundreds, and there were certain to be more. Colonization schemes were afoot in Great Britain, and Australian graziers were buying land from the Maori. These circumstances determined British policy.

ANNEXATION AND FURTHER SETTLEMENT

In 1838 the British government decided upon at least partial annexation. In 1839 it commissioned William Hobson, a naval officer, as lieutenant governor and consul to the Maori chiefs, and he, in the event, annexed the whole country, the North Island by the right of cession from the Maori chiefs and the South Island by the right of discovery. At first New Zealand was legally part of New South Wales; but in 1841 it became a separate crown colony, and Hobson was named governor. Before declaring the annexation of New Zealand, Hobson went through a process of discussion with the northern chiefs from which emerged the Treaty of Waitangi (February 1840). Under this instrument the Maori ceded sovereignty to the crown in return for protection and guaranteed possession of their lands; they also agreed to sell land only to the crown. Hobson promised an investigation into past "sales" of land to private individuals to ensure fair dealing. This treaty imposed a strong moral obligation upon the British government to act as guardian to the Maori.

The Treaty of Waitangi

Even before annexation had been proclaimed, the first organized planting of an English colony was under way. The New Zealand Association, founded in 1837 to colonize on the principles laid down by Edward Gibbon Wakefield, sent a survey ship, the *Tory*, in 1839. The agents on board were to buy land in both islands around Cook Strait. The company moved hastily because its founders were aware that British annexation was likely and would entail a crown monopoly of land sales and a consequent increase in price. "Purchases" were effected in great haste before Hobson could bring to an end such private transactions. Little effort was made to seek out the true Maori owners; this would have been difficult anyway, as Maori ownership was communal and titles had been disturbed by the warfare of the preceding quarter century. The company, combining skillful propaganda with outright trickery and brutality, enforced its claim to the land upon which New Plymouth, Wanganui, and Wellington in the North Island and Nelson in the South Island were founded in the 1840s. Later, through the crown, it secured other areas in the South Island where Otago (1848) and Canterbury (1850) were planted by separate associations. Meanwhile, Hobson moved the seat of government south from the Bay of Islands, bringing Auckland into existence (1840).

In the early 1840s settlement and government began to alarm the Maori. In the Cook Strait area a formidable chief, Te Rauparaha, obstructed settlement. Near the Bay of Islands there was open warfare, and Kororareka was repeatedly raided. Neither Hobson (died 1842) nor his successor, Robert FitzRoy, was able to overcome the Maori. George (afterward Sir George) Grey, who became governor in 1845, had money and troops and the will to use them. His victories brought a peace that lasted from 1847 until 1860. Hone Heke, the principal leader in the north, was thoroughly defeated (1846), and in the south a likely uprising was prevented. Racial strife had been accompanied by economic distress. In the mid-1840s the nascent economy was depressed until the Australian gold rushes of the 1850s offered a market for foodstuffs to the New Zealand farmer, settler and Maori alike.

War with the Maori

By the end of the 1840s racial and economic trouble gave way to political agitation. The leading settlements, apart from Auckland, began to campaign for representative government in place of Grey's personal rule. He, while refusing to give way, helped to draft the New Zealand Constitution Act of 1852, which was designed to meet all demands of the settlers. Grey sought not to prevent the introduction of self-government but to delay it until he had determined both native and land policy. He wished to begin the rapid assimilation of the Maori (with whom his relations were excellent) to the British pattern. He also wished to bring in a land policy that would safeguard the small farmer against the great owner. He believed he had secured these goals by the time of his departure at the end of 1853.

Responsible government. After the Constitution Act came into operation, New Zealand was divided into six provinces—Auckland, New Plymouth (Taranaki), Wellington, Nelson, Canterbury, and Otago—each with a superintendent and a provincial council. The central government consisted of a governor and a two-chamber legislature (General Assembly): a Legislative Council nominated by the crown, and a House of Representatives elected upon a low property franchise for a five-year term. This General Assembly did not meet until 1854; it then embarked upon a quarrel with the acting governor, Col. Robert Henry Wynyard, that was not ended until the achievement of full responsible government—*i.e.,* a system under which the governor could act in domestic matters only upon the advice of ministers enjoying the confidence of the elected chamber. Henry Sewell and James FitzGerald, of Canterbury, led the representatives in this struggle, against the opposition of Edward Gibbon Wakefield, who, having first moved the resolution for responsible government, then secretly opposed it while serving as extra-official adviser to the acting governor. The Colonial Office conceded responsible government in 1856. The next governor, Thomas (later Sir Thomas) Gore Browne, reserved Maori affairs to the competence of the governor alone.

For most purposes, during the 1850s New Zealand was administered not by central but by provincial institutions. These authorities (10 in number by the time of their abolition in 1876) directly affected the settler through their administration of land and control of immigration and public works. The native department, directly under the governor, bought land from the Maori; the provincial governments settled it, regulated immigration, and built roads and bridges. Until the wars of the 1860s the central legislature was less important, though its ultimate authority remained.

Provincial institutions

Each province disposed of a revenue arising from land sales, and upon this revenue depended its strength. Canterbury and Otago, with hardly any Maori, grew wealthy spending their money upon communications, immigration, and education. Other provinces were either less fortunate or less wise and enjoyed smaller success. In the North Island numerous and anxious Maori held onto desirable land. Here most of the land available for settlement had been taken up by the end of the 1850s, a good deal of it by speculators, and some of it was given away to attract immigrants. The island remained largely without roads until the 1870s, so impecunious were its governments. But by that time the major obstacle to settlement had been removed—the continuing power of the tribes. This was the result of a decade of war.

Racial conflict. In the 1850s race relations deteriorated. The settler population and the demand for land, especially pastoral land, increased. Many Maori, fearing for their future, became reluctant to sell more land. In the Taranaki Province, where the land shortage was acute, both settlers and those Maori willing to sell were opposed by Wiremu Kingi (Te Rangitake), chief of Te Atiawa. In the Waikato, where good land was coveted by settlers and speculators, an elderly chief, Te Wherowhero, became "king" in 1858, largely through the support of the Waikato and Maniopoto tribes, and reigned as King Potatau I. The Maori King Movement and also the unrest in the Taranaki headed by Wiremu Kingi (the two movements remained distinct though related) were opposed to further land sales.

Land sales

The likelihood of conflict was not reduced by any particular wisdom in government policy. Gore Browne was guided in native policy by the head of the Native Land Purchase Department, Donald (later Sir Donald) McLean, who, responsive to settler demands, increased pressure upon potential sellers. Grey's caution and his recognition that a chief could veto sales proposed by any section of his tribe were forgotten. McLean sowed a rich harvest of distrust. Christopher Richmond, the member of the Cabinet

in charge of native affairs, was also a Taranaki representative, fully responsive to the needs of his settler neighbours. The central ministry, theoretically unconcerned with native policy, could not, despite the promise of protection made to the Maori in the Treaty of Waitangi, neglect a matter so vital to the colony's future. In 1859 the representative of the crown unwittingly supplied the occasion for the outbreak of civil strife.

Gore Browne accepted an offer to sell from a Taranaki subchief, Te Teira, and ignored the veto imposed by the paramount chief, Wiremu Kingi. Early in 1860 troops were used to dislodge Kingi from the land in question, the Waitara block. A decade of fighting began. In 1861 Grey was sent back for a second term as governor in the hope that he would again prove to be a peacemaker. In fact he accelerated the extension of conflict. Fearing that Auckland was menaced by the followers of the Maori king, he took defensive measures that could easily be interpreted as acts of aggression, and the fighting subsequently spread from Taranaki to the Waikato. Imperial troops, colonial militia, and Maori allies (for not all the tribes supported the Maori nationalist movement) had no easy task, but their victory could not be postponed for long. By the mid-1860s Maori resistance in the Taranaki and Waikato was ended. But the "king" tribes were by no means crushed, and the fear that they would embark upon war again haunted the colony for many years.

In the later 1860s the fighting was of a different character, in which religion acted as a last, desperate stiffener of Maori resistance. Pai Marire (Hauhauism), an amalgam of Jewish, Christian, and native beliefs, was the first of many cults in which the Maori, rejecting the religion of settler and missionary, put their own imprint upon Christianity. Toward the end of the decade Te Kooti Rikirangi organized resistance on the east coast of North Island. He was the founder of another religious cult as well as a guerrilla of some note; his adaptation of Christianity, Ringatu, still has thousands of followers. Te Kooti was never finally defeated, but by the early 1870s he was forced to retreat into the "King Country" (the centre of the island), where he devoted the rest of his life to religious leadership.

An uneasy peace settled upon the colony in 1870. Casualties had not been high, but the loss of life was serious for the tribes concerned. Especially in those areas in which the Maori king retained some authority, defeat led to a period of withdrawal from settler society. Resentment was deepened by a punitive policy of land confiscation adopted by the victors, a policy improper in its nature and made worse in some places by undiscriminating application to "guilty" and "innocent" tribes alike. The Maori future looked black. By the Native Land Act of 1862, private land transactions between settler and Maori had been legalized, and during the next 40 years the Maori lost most of their best land. Many years were to elapse before Maori numbers, morale, and confidence could revive over the whole country.

Native Land Act

DEVELOPMENT OF THE COLONY

Fluctuation of the economy. Economic growth in the North Island had been considerably retarded by the wars. Meanwhile, the South Island, especially Canterbury and Otago, had grown increasingly prosperous. Pastoral farming expanded steadily, and the discovery of gold, first in Otago and then on the west coast, led to a sudden boom in production and trade. Population rose as diggers poured in; economic life quickened as gold brought prosperity, less to the digger than to bankers, merchants, land sellers, and farmers supplying provisions. The South Island share of the European population jumped from about 40 percent to 60 percent during the 1860s. The North Island did not recover its previous lead until the 20th century.

Discovery of gold

Attempts by other provinces to emulate the development of Canterbury and Otago normally ended in embarrassment (in one case in bankruptcy) as money was recklessly borrowed and spent. To preserve the colony's reputation, the central government in 1867 banned further provincial overseas borrowing. About this time depression struck the greater part of the country, especially the South Island, where the first alluvial gold had by then been worked out. The South Island was thus looking for a stimulus, while the ending of the wars now made further development possible in the North Island. It was widely agreed that only the central government could adequately revitalize the economy.

In 1870 a development policy was provided by Julius (later Sir Julius) Vogel, who at the time was colonial treasurer and who later served two terms (1873–75; 1876) as prime minister. He was convinced (not altogether accurately) that New Zealand was bursting with potential resources needing no more than the stimulus of capital and labour for their exploitation. He borrowed overseas capital for public works on an unprecedented scale and swelled the labour force with assisted immigrants.

Julius Vogel's development policy

Not all of Vogel's schemes were wisely conceived; the prosperity of the mid-1870s was more an investment boom than a solid growth of productivity. But the colony ended the decade with a doubled population (about 500,000) and the beginnings of efficient internal and external communications. Roads, bridges, railways, and telegraph systems had been built, and overseas shipping services improved. Private lending agencies contributed to the boom, and in a heady atmosphere land values and interest rates climbed alarmingly. The public debt greatly increased, and many of the men who had acquired land were in desperate financial straits. Falling overseas prices for farm products (chiefly wool and wheat), a declining gold output, a cautious note in government finance, and widespread unemployment marked the 1880s. Emigrant ships discharged their passengers at ports where unemployment was already rife. There had been growth in the 1870s, but it was succeeded by a depression that lasted until 1895.

Vogel abolished the provincial governments in 1876. They had earned his enmity by refusing to allow their lands to be used as security for public works and by blocking a forest conservation scheme. Essentially, they became outmoded when in the early 1870s the initiative in development passed to the central government. Provincial governments had been set up to colonize their districts; when the centre assumed this function they lost their raison d'être. Abolition came fairly painlessly; it was an affront more to local pride than to local prosperity. Only in Otago was there a strong attempt to resist change. Thereafter, provincial interests were long pursued by the respective delegates in the General Assembly, whose achievements were in no way diminished by the lack of particularist (provincial) institutions.

Economic depression

The governments of the 1880s, though led by men of some ability and imagination, such as Sir Robert Stout and Sir Harry Atkinson, did not deal effectively with the depression. The time-honoured remedy, spending loan money on development, was not fully given up until 1887. The basic problem was to find productive work for the country's labour force; closer land settlement was the remedy suggested in the 1880s and applied in the 1890s. Great areas, especially in the South Island, had fallen to large owners; these "monopolists" were attacked by the radicals, though probably the pastoral industry could not have been established under any other system. William Rolleston, minister of lands in the early 1880s, first proposed that the state should help men to become small farmers as state tenants; John (later Sir John) McKenzie and the Liberal government applied this remedy with vigour in the 1890s. But closer settlement and intensive farming did not of themselves create economic benefits, which in fact could not accrue until small farmers had a product to export and gained a good price for that product. Refrigeration and rising world prices provided the answer. It became possible in the 1880s to send to Great Britain refrigerated cargoes of butter, cheese, and meat; this encouraged the spread of small-scale intensive farming.

The Liberal era (1891–1912). The energetic Liberal government led by John Ballance, which took office in 1891, accelerated the process of change. It opened more land (much of it bought from the Maori), established farmers on perpetual state leaseholds, provided credit for land purchase and improvements, and built roads. So came into existence great dairying and meat producing areas, especially in the North Island. Dairy, meat, and also

wool prices rose in about 1895 and stayed generally high until about 1920.

This economic stimulus was not limited to farmers. Urban distress had been serious in the 1880s, for many recent immigrants had been townsmen who had stayed in New Zealand towns on arrival. The ultimate cure for their distress was for the towns to share in the farmers' high prices. Urban New Zealand depended upon the prosperity of the country. But other remedies were considered, and some of them were applied. In the 1880s there was serious discussion of insurance against sickness, poverty, and old age; the Old Age Pensions Act of 1898 was the first measure of social security. Tariff protection to foster industrial employment was halfheartedly applied in the late 1880s. Revelations of oppression in industry led in the 1890s to a labour code to protect workers.

But the chief Liberal industrial policy, formulated by William Pember Reeves, minister of labour from 1892 to 1896, was to encourage trade unions and to introduce, in the Industrial Conciliation and Arbitration Act of 1894, a conciliation and compulsory arbitration system intended to end industrial unrest and give the unions the means of protecting their members. The growth of unions was stimulated by the fact that only through them could the workers use the system. Reeves's act, amended and occasionally suspended but still essentially his own handiwork, remained in effect until the late 1960s. It enabled the worker in good times to resist wage cuts and to press for increases; but it did not manage to prevent cuts and unemployment when falling overseas prices brought depression to New Zealand. It was not strikingly radical in effect; employers and governments used it to break strikes, such as that of miners at Waihi in 1912. It built up the power of those majority elements in the unions that preferred coming to terms with capitalism to any effort to destroy it. Some occupations, such as transport, cargo handling, meat processing, and mining, fostered unions keen to relinquish arbitration for direct action, but they were in a minority and seldom, in the long run, successful. Farmers and governments have usually acted with severity in disputes affecting the movement of exports.

The growth of trade unions

The Liberal era, from 1891 to 1912, transformed political life. Previously politics had not been marked by neat party divisions. Local advantage had determined political behaviour in the development period during and after the 1870s; men had argued over the scope and details of policies and had advanced the claims of locality and province for a proper share of largess. Acute depression ended development and with it the politics of local advantage. In 1890 the Liberals began to act as a more or less unified party. Their 20 years in office, the success of their land and labour policies, and the formidable qualities of leadership discovered in Richard John Seddon, premier from 1893 to his death in 1906, welded the Liberals into a fairly coherent parliamentary and popular party.

R.J. Seddon as premier

Seddon was a portent of a new age. In 1893 this energetic goldfields trader-turned-politician provided a sharp contrast to the gentlemanly premiers who had preceded him. But his crudeness assisted rather than hindered the attainment of popularity none of them had known. He was devoted to political success and skilled in the manipulation of the means of success—parliamentary procedure, patronage, and party organization. By the time of his death he had established a kind of elective despotism over the country.

THE 20TH CENTURY

Seddon's successors, in his own and in other parties, were of the same stamp—men of the people devoted to a political career. Politics ceased to be a duty of the well-to-do amateur. The Liberal government, under Sir Joseph Ward, survived Seddon by six years. In 1912 it fell before a new party, Reform, led by a dairy farmer, William Ferguson Massey, prime minister until 1925. Based on prospering farmers and townsmen, especially of the North Island, and closely connected with their professional organizations, it was more narrowly sectional than the Liberals had been. Except for views borrowed from the Liberals, it had little positive policy. Reform made much of a promise to enable the state leaseholder to buy the freehold of his farm at original valuation; this promise was an emotional rallying cry for conservatives fearing land nationalization and complete socialism. Only a small minority of farmers were state tenants, and not all bought the freehold when the Reform government gave them the chance.

While the Liberals lost support in rural areas, they were further weakened by urban left-wing defections, which eventually led to a separate Labour Party. The initiative, on the right and on the left, was passing to other parties, and the Liberals were gradually eclipsed. The period before World War I was one of discontent and anxiety. Prosperity, though still considerable, had somewhat declined. The farmers were disturbed by what they took to be the threat of socialism, detected in the radicalism of a Liberal minority but chiefly in the rebirth of direct action in some trade unions. This change in temper arose from labour dissatisfaction with wage levels achieved under arbitration and from the growth of syndicalist and socialist ideas. After 1906 the Arbitration Court refused to grant further increases of real wages. Discontent flared up in the strikes of 1912–13, the biggest occurring on the waterfront when the farmers' government, headed by Massey, repressed a movement that had overtones of revolution.

Nationalism and war. By the late 19th century many New Zealanders were coming to regard themselves as a new nation. Most of them had been born in New Zealand and had no memories of or nostalgia for Britain, often called "home." In the 1890s New Zealand Natives Associations were established by native-born European New Zealanders. Their success in sports, especially rugby football, spurred national pride. An even greater influence was war. New Zealanders served on the British side during the South African War (1899–1902), during which time they earned a reputation as being superior to the British at fighting a guerrilla war. World War I greatly stimulated national sentiment. During the warfare at Gallipoli and later in France New Zealanders proved themselves to be excellent soldiers. But while the war boosted nationalist sentiment among both troops and civilians, the price was terrible: nearly one of every three men between the ages of 20 and 40 was killed or wounded. The loss in leadership in the following years was considerable.

At home the war brought prosperity, as export markets were assured and prices good. Domestic unity was hardly shaken by the antiwar feeling of a handful of left-wingers. Massey remained prime minister, but in the wartime coalition government (1915–19) Ward and the Liberals carried great weight. Reform stayed in office until 1928, led after Massey's death in 1925 by Joseph Gordon Coates. The party survived the first postwar depression but not that of the mid-1920s. Led by Ward, the Liberals, under the new name of United Party, were victorious in 1928; they thus had to face the deepening depression of 1929–30. After Ward's death (1930) and at the height of the depression, Reform and United formed a new coalition (1931) under the premiership of George Forbes, which lasted until the election of 1935 brought in a Labour government.

Some postwar developments were of great importance. In external affairs, Massey led a delegation to the peace conference, signed the Treaty of Versailles, and so committed New Zealand to membership in the League of Nations. New Zealand thus began to acquire the status of a sovereign state, though Massey denied this consequence. The Liberals, especially Seddon, had already taken steps toward autonomy within the empire. At the series of colonial and imperial conferences from 1887 onward, New Zealand had followed Canada and Australia in asserting its right to a voice in certain foreign policy issues. Seddon argued vehemently against British reluctance to acquire more Pacific islands while permitting German influence to grow in Samoa.

Sovereign status

New Zealand legislation to restrict Asian immigration was sharply and obstinately at variance with British policy. Western Samoa, which New Zealand had captured from the Germans in 1914 and over which it was granted a mandate in 1920, also provided occasions for British and New Zealand differences.

Reform leaders professed little love for the principle of

Commonwealth autonomy. New Zealand took a passive part in the conferences leading to the Statute of Westminster in 1931 and did not adopt it until 1947. But the substance of autonomy had been enjoyed before.

The major domestic achievement of the Reform administration was a system of export marketing agencies in which authority was shared by producer and state. These laid the foundations of a collectivist marketing structure. J.G. Coates was the most energetic minister in Forbes' coalition government. His attempts to counter depression concentrated upon the farmer in order to revive the country. To increase export receipts, he devalued the New Zealand pound; he protected the farmer against foreclosure and set up a credit agency.

When overseas prices began to recover in 1934, the country was financially strong, but little had been done for the unemployed. Conditions in towns and relief camps led to rioting, violence, and widespread discontent, all of which were favourable to the Labour Party. The Labour Party had been formed by socialist and radical groups in 1916. During the 1920s it was predominant only in working-class electorates. In its quest for votes, however, Labour increasingly abandoned its socialist theories and adopted welfare and credit-reform proposals, which had wider appeal. In the election of 1935 Labour won a considerable victory; successful in the towns, the party also won in many rural areas. Prices for dairy exports were slowest to recover, and many dairy farmers were drawn by Labour promises of a guaranteed price. The victory was particularly notable in terms of seats, for a right-wing third party (the Democrat Party) split the conservative vote to Labour's advantage. The National Party, successor to the coalition, was rendered temporarily ineffective.

Labour in power

The new ministers, among whom the most notable were Peter Fraser and Walter Nash, showed great energy; led by Michael Joseph Savage, they had the good fortune to govern a country to which prosperity was returning. The farmer enjoyed increased earnings; the worker, increased wages and shorter hours. Jobs were multiplied by a public works and housing program. The education system was revitalized. In 1938 the Social Security Act provided a state medical service, extended the pension system, and increased benefits. The expansion of secondary industry was accelerated after the outbreak of World War II in 1939.

World War II and after. The alacrity with which New Zealand went to war in 1939 showed that dominion autonomy had not weakened the country's ties with Great Britain. At first the war resembled that of 1914; troops were sent to Egypt to train for the European conflict. There they were directly involved by the enemy advance and saw action in Greece, Crete, North Africa, and Italy. After 1941 New Zealand was directly threatened by Japan, and New Zealand forces were also engaged in the Pacific. Well before the end of the war, the strain upon the country's manpower, together with the demands of home production, forced a reduction of commitments in the Pacific.

The Pacific theatre was dominated by the United States, the forces of which provided New Zealand's sole defense. The fact that disaster was averted by American and not by British forces required a change in New Zealand's attitudes; security was conferred by a foreign, though friendly, power. External relations in the postwar period reflected this new situation, chiefly through the ANZUS pact (1951), a defensive alliance between Australia, New Zealand, and the United States.

War economy

At home the total economy was mobilized in the war effort. Controls were extended over the whole economy. Conscription and direction (directed allocation of the labour force to strategic industries) sent manpower into the military forces and essential occupations; heavy taxation, war loans, bulk purchase, and controlled marketing kept the economy in a firm grip. They also kept inflation in check; with price control and wage restraint, they amounted to a complete policy of economic stabilization, applied by a Labour government that remained in power until 1949. Savage died early in the war. Fraser, his successor, and Nash were chiefly responsible for the tasks of administration during the war and of reconstruction after peace returned.

Sidney Holland led the revival of the National Party, which culminated in victory in 1949. Discontent with controls and with the rising cost of living helped to swing support away from Labour. The National government benefited from its vigorous handling of a serious waterfront dispute in 1951, but in later elections its majority narrowed until Labour returned in 1957. In 1960 the National Party, led by Keith Holyoake, was returned to power, which it retained until 1972. In that year Labour won a huge victory under Norman Kirk; his death in office in 1974 was the prelude to as great a National victory in 1975, under a new leader, Robert Muldoon.

After World War II New Zealand began to play a relatively independent role in world affairs. This development, in fact, began before the war, when the Labour government's attitude to the League of Nations was coloured by an idealism that clashed with British policy. During the war Fraser had insisted upon an independent voice in the councils of the Allied Powers. At the formation of the United Nations in 1945 he became a notable spokesman for the small powers and made a large impression upon the Trusteeship Council. None of these developments weakened New Zealand's close affinity with Great Britain, its loyalty to the Commonwealth, or its dependence upon the United States.

Postwar foreign policy

Geography and insecurity shaped postwar foreign policy. With Australia, New Zealand claimed a voice in settlement in the South Pacific Commission and in the transfer of authority in Western Samoa, successfully completed in 1962. New Zealand became deeply involved in Southeast Asia. From 1951 it provided assistance through the Colombo Plan. New Zealanders fought in Malaya, Korea, and Vietnam; further, New Zealand became a member of the Southeast Asia Treaty Organization (SEATO) in 1954 and supported the United States by sending troops to Vietnam. This reflected fear at the growth of Communist power in Asia. The independent spirit of the postwar years was modified to a greater dependence on Western powers during the 1950s and '60s. In the later 1960s involvement in the Vietnam War led to a vigorous and continuing public debate on foreign affairs. After Vietnam, debate turned largely on the problem of South African apartheid, especially in the contexts of sports relations with South Africa and with African countries at Commonwealth and Olympic games.

The 1970s and '80s were difficult economically for New Zealand. The combination in the early 1970s of high energy prices and Great Britain's entry into the EEC brought about a severe economic recession. Inflation skyrocketed, unemployment soared, and thousands emigrated to Australia. The response of Muldoon's National government was interventionism on an unparalleled scale: the government borrowed funds from overseas and ran up huge budgetary deficits, in part to finance large industrial developments; in the early 1980s it placed a freeze on wages and prices; and it attempted to regulate interest rates. Dissatisfaction with this program led in 1984 to the election of a Labour government, headed by David Lange.

(W.H.O./Ke.S.)

The Labour government initiated one of the most sweeping policy reversals in the country's history as, one after another, restrictions on free enterprise that had been imposed progressively over some 50 years were lifted. Among the reforms were the elimination of agricultural subsidies, the reduction of income tax rates, and the lifting of controls on wages, prices, interest rates, and foreign exchange. The government also took a strong stand against the proliferation of nuclear weapons in the region, and its decision to ban nuclear-powered and nuclear-armed vessels from New Zealand's ports strained relations with the United States. Popular support for the Labour program was reflected by the party's 1987 general election victory.

In the late 1980s, inflation had finally been brought under control, but unemployment continued to rise. Prime Minister Lange began to face substantial opposition within his own party, especially as a result of the privatization of state-owned enterprises, which was initiated in 1987, and over his conflict with finance minister Roger Douglas. Douglas was pushing for economic measures, such as a

flat-scale tax system and the deregulation of the labour unions, that the prime minister considered extreme. Lange dismissed Douglas in December 1988, but in August 1989, with the aim of shoring up Labour's poor standing in the polls, Labour MPs voted to return Douglas to the Cabinet. Lange resigned a few days later and was replaced by Geoffrey Palmer. In just 13 months, however, Palmer was himself replaced by Mike Moore, a former minister of foreign affairs, who held on to the position of prime minister for only eight weeks before the National Party's landslide victory in the October 1990 general election. Jim Bolger, the National Party leader, became prime minister. The National Party had campaigned for reduced government spending on social programs and the elimination of such labour practices as compulsory unionism but pledged to maintain New Zealand's antinuclear stand.

The National Party won a narrow victory over Labour in 1993. Bolger saw his popularity rise with strong economic growth and his condemnation in 1995 of France's nuclear testing in the South Pacific. In 1996 the country held its first elections under the mixed-member proportional system, which voters had approved by referendum three years earlier. Although no single party managed a majority, the National Party was able to form a coalition government with the New Zealand First Party. The new administration, however, was plagued by inexperience and factionalism. In addition, the government's inability to allay concerns over social welfare issues, particularly the country's superannuation (retirement savings) program, caused unrest.

In November 1997 Bolger resigned, and the National Party appointed Jennifer Shipley as the country's first female prime minister. However, the new government also struggled. After Shipley dismissed New Zealand First's Winston Peters as deputy prime minister and treasurer in 1998, the coalition dissolved, and Shipley oversaw a minority government. In 1999 the National Party was ousted by a coalition between Labour and the Alliance (a breakaway group of smaller parties), and Labour leader Helen Clark became prime minister. The government focused on labour relations, taxation, and the superannuation scheme. Clark was reelected as prime minister in 2002.

Ethnic relations emerged as a major issue in the late 20th century. The Maori sought the return of and compensation for natural resources under the terms of the Treaty of Waitangi of 1840. The validity of that treaty was in question, however, owing both to the circumstances of its signing (the chiefs who did sign had only a loose translation of the document in their language) and to the fact that the treaty had never been formally written into New Zealand's constitution. In 1975 the Treaty of Waitangi Act was passed, establishing a tribunal to examine and make recommendations on Maori claims. In the late 1980s, Maori activism intensified; demands included using the Maori language in education, broadcasting, and official settings and preserving Maori arts and culture. Maori land claims in the early 1990s involved a large proportion of New Zealand's territory, but the government faced pressure to turn land and water resources, in particular fisheries, over to profitable private enterprise. Beginning in 1993, however, the government began approving money, and later land, awards to the Maori, culminating in the 1997 settlement of the largest and oldest land claim in the country's history. The government also apologized for injustices inflicted on the Maori. Such acts were seen as positive steps toward reconciliation. (Ed.)

BIBLIOGRAPHY

Physical and human geography. *General:* Basic descriptive information is available in A.H. MCLINTOCK (ed.), *An Encyclopaedia of New Zealand,* 3 vol. (1966); and GORDON MCLAUCHLAN (ed.), *The Illustrated Encyclopedia of New Zealand,* updated ed. (1989). The *New Zealand Official Yearbook* (annual) contains descriptive text and statistics on all aspects of New Zealand life; each chapter also has an extended bibliography.

The land: New Zealand's physiographic features are discussed in D.W. MCKENZIE (ed.), *Heinemann New Zealand Atlas* (1987); A. GRANT ANDERSON (ed.), *New Zealand in Maps* (1977); and IAN WARDS (ed.), *New Zealand Atlas* (1976). Works discussing geology and climate include MAXWELL GAGE, *Legends in the Rocks: An Outline of New Zealand Geology* (1980); JACOBUS T. KINGMA, *The Geological Structure of New Zealand* (1974); J.M. SOONS and M.J. SELBY, *Landforms of New Zealand* (1982); and H.S. GIBBS, *New Zealand Soils* (1980). CONON FRASER, *Beyond the Roaring Forties* (1986), describes the geology, ecology, and natural history of New Zealand's subantarctic islands. Information on animal and plant forms in New Zealand can be found in HARRIET FLEET, *The Concise Natural History of New Zealand* (1986); GORDON R. WILLIAMS (ed.), *The Natural History of New Zealand: An Ecological Survey* (1973); R.A. FALLA, R.B. GIBSON, and E.G. TURBOTT, *The New Guide to the Birds of New Zealand and Outlying Islands,* rev. ed. (1979); RUSSELL JACKSON, *Wildlife New Zealand* (1982); A.L. POOLE (comp.), *Wild Animals in New Zealand,* 2nd ed. (1973); H.H. ALLAN, *Flora of New Zealand,* vol. 1, *Indigenous Tracheophyta* (1961, reprinted 1982); and J.T. SALMON, *The Native Trees of New Zealand* (1980). JOHN PASCOE (ed.), *National Parks of New Zealand,* 3rd ed. (1974); and NOEL W. CUSA and RONALD M. LOCKLEY, *New Zealand Endangered Species* (1980), are also useful.

The people: Overviews are provided in R.J. WARWICK NEVILLE and C. JAMES O'NEILL (eds.), *The Population of New Zealand: Interdisciplinary Studies* (1979); and PAUL SPOONLEY, DAVID PEARSON, and IAN SHIRLEY (eds.), *New Zealand: Sociological Perspectives* (1982). Histories of the Maori people before and after the arrival of Europeans and discussions of modern interaction may be found in TE RANGI HIROA (PETER BUCK), *The Coming of the Maori,* 2nd ed. (1950, reissued 1966); MICHAEL KING (ed.), *Te Ao Hurihuri: The World Moves On: Aspects of Maoritangi* (1975), essays by Maori authors; JOAN METGE, *The Maoris of New Zealand,* rev. ed. (1976); DAVID LEWIS, *The Maori: Heirs of Tane* (1982); and MICHAEL KING, *Maori: A Photographic and Social History* (1983). I.H. KAWHARU (ed.), *Waitangi: Maori and Pakeha Perspectives of the Treaty of Waitangi* (1989); and ANDREW SHARP, *Justice and the Maori: Maori Claims in New Zealand Political Argument in the 1980s* (1990), discuss the recent history of ethnic relations. Regional and demographic trends are discussed in BRIAN COLLESS and PETER DONOVAN (eds.), *Religion in New Zealand Society* (1980); and R.J. JOHNSTON (ed.), *Urbanisation in New Zealand: Geographical Essays* (1973), and *Society and Environment in New Zealand* (1974). Two works from the NEW ZEALAND PLANNING COUNCIL, POPULATION MONITORING GROUP, *The New Zealand Population: Contemporary Trends and Issues* (1985), and *The New Zealand Population: Patterns of Change* (1984), are also useful.

The economy: Economic history and contemporary conditions are documented by G.R. HAWKE, *The Making of New Zealand: An Economic History* (1985); JOHN GOULD, *The Rake's Progress? The New Zealand Economy Since 1945* (1982); BRIAN EASTON and NORMAN THOMSON, *An Introduction to the New Zealand Economy* (1982); PETER LANE, *Economy in the Balance: An Introduction to the New Zealand Economy* (1976); RESERVE BANK OF NEW ZEALAND, *Financial Policy Reform* (1986); and FRANK HOLMES (ed.), *Economic Adjustment: Policies and Problems* (1987), a collection of seminar papers.

Administration and social conditions: New Zealand's government is discussed in GRAHAM W.A. BUSH, *Local Government and Politics in New Zealand* (1980); and HYAM GOLD (ed.), *New Zealand Politics in Perspective* (1985), and *New Directions in New Zealand Foreign Policy* (1985). Public administration and social policy are examined by R.C. MASCARENHAS (ed.), *Public and Private Enterprise in New Zealand* (1984); R.C. MASCARENHAS, *Public Enterprise in New Zealand* (1982); BRIAN EASTON, *Social Policy and the Welfare State in New Zealand* (1980); and MARGARET CLARK (ed.), *The Politics of Education in New Zealand* (1981).

Cultural life: Information on art in New Zealand is available in TERENCE BARROW, *Maori Art of New Zealand* (1978); GORDON H. BROWN and HAMISH KEITH, *An Introduction to New Zealand Painting: 1839–1980,* rev. and enlarged ed. (1982); and SIDNEY MOKO MEAD (ed.), *Te Maori: Maori Art from New Zealand Collections* (1984). See also relevant sections in BRIAN BRAKE, JAMES M. MCNEISH, and DAVID SIMMONS, *Art of the Pacific* (1979). Introductory works on New Zealand literature include WYSTAN CURNOW (comp.), *Essays on New Zealand Literature* (1973); and C.K. STEAD, *In the Glass Case: Essays on New Zealand Literature* (1981). Further information on New Zealand art and literature can be found in the bibliographies of the *Macropædia* articles OCEANIC ARTS and AUSTRALIA AND NEW ZEALAND, LITERATURES OF.

History. *General:* Overviews are provided by KEITH SINCLAIR, *A History of New Zealand,* rev. and enlarged ed. (1980), and *A Destiny Apart: New Zealand's Search for National Iden-*

tity (1986); W.H. OLIVER and B.R. WILLIAMS (eds.), *The Oxford History of New Zealand* (1981); and KEITH SINCLAIR and WENDY HARREX, *Looking Back: A Photographic History of New Zealand* (1978).

Early history: Works on various aspects include, on the pre-European Maori, JOHN WILSON (ed.), *From the Beginning: The Archaeology of the Maori* (1987); RAYMOND FIRTH, *Economics of the New Zealand Maori* (1959, reprinted 1973); D.R. SIMMONS, *The Great New Zealand Myth: A Study of the Discovery and Origin Traditions of the Maori* (1976); and GEORGE GREY, *Polynesian Mythology and Ancient Traditional History of the New Zealand Race, as Furnished by Their Priests and Chiefs* (1885, reissued 1970 as *Polynesian Mythology and Ancient Traditional History of the Maori as Told by Their Priests and Chiefs*); and, on early European contact, JOHN CAWTE BEAGLEHOLE, *The Discovery of New Zealand*, 2nd ed. (1961); and HARRISON M. WRIGHT, *New Zealand, 1769–1840: Early Years of Western Contact* (1959, reprinted 1967). Annexation and early government are treated by IAN M. WARDS, *The Shadow of the Land: A Study of British Policy and Racial Conflict in New Zealand 1832–1852* (1968); and PETER ADAMS, *Fatal Necessity: British Intervention in New Zealand, 1830–1847* (1977). Early settlement is covered by JOHN OWEN MILLER, *Early Victorian New Zealand: A Study of Racial Tension and Social Attitudes, 1839–1852* (1958); and STEVAN ELDRED-GRIGG, *A Southern Gentry: New Zealanders Who Inherited the Earth* (1980).

Later 19th century: The period to about 1870 is covered by KEITH SINCLAIR, *The Origins of the Maori Wars*, 2nd ed. (1961, reprinted 1976); JAMES BELICH, *The New Zealand Wars and the Victorian Interpretation of Racial Conflict* (1986), a reinterpretation; ALAN WARD, *A Show of Justice: Racial "Amalgamation" in Nineteenth Century New Zealand* (1974); and W.P. MORRELL, *The Provincial System in New Zealand, 1852–76*, 2nd rev. ed. (1964). Subsequent development, especially in politics and economics, see R.M. DALZIEL, *The Origins of New Zealand Diplomacy: The Agent-General in London, 1870–1905* (1975); ANGUS ROSS, *New Zealand Aspirations in the Pacific in the Nineteenth Century* (1964); PATRICIA GRIMSHAW, *Women's Suffrage in New Zealand* (1972); and C.G.F. SIMKIN, *The Instability of a Dependent Economy: Economic Fluctuations in New Zealand, 1840–1914* (1951).

The 20th century: Modern developments are broadly presented in ROBERT CHAPMAN and KEITH SINCLAIR (eds.), *Studies of a Small Democracy* (1963, reissued 1965); and J.B. CONDLIFFE, *New Zealand in the Making: A Study of Economic and Social Development*, 2nd rev. ed. (1959, reprinted 1963), and *The Welfare State in New Zealand* (1959, reprinted 1975). Specific themes are discussed in H. ROTH, *Trade Unions in New Zealand Past and Present* (1973); F.L.W. WOOD, *New Zealand in the World* (1940), and *The New Zealand People at War: Political and External Affairs* (1958, reprinted 1971); BRUCE M. BROWN, *The Rise of New Zealand Labour: A History of the New Zealand Labour Party from 1916 to 1940* (1962); BARRY GUSTAFSON, *Labour's Path to Political Independence: The Origins and Establishment of the New Zealand Labour Party, 1900–19* (1980); RICHARD KENNAWAY, *New Zealand Foreign Policy, 1951–1971* (1972); COLIN JAMES, *The Quiet Revolution: Turbulence and Transition in Contemporary New Zealand* (1986); and ALAN BURNETT, *The A-NZ-US Triangle* (1988).

Newton

Isaac Newton, English physicist and mathematician, was the culminating figure of the scientific revolution of the 17th century. In optics, his discovery of the composition of white light integrated the phenomena of colours into the science of light and laid the foundation for modern physical optics. In mechanics, his three laws of motion, the basic principles of modern physics, resulted in the formulation of the law of universal gravitation. In mathematics, he was the original discoverer of the infinitesimal calculus. Newton's *Philosophiae Naturalis Principia Mathematica* (*Mathematical Principles of Natural Philosophy*), 1687, was one of the most important single works in the history of modern science.

Newton, oil painting by Sir Godfrey Kneller, 1702. In the National Portrait Gallery, London.

Formative influences. Born on December 25, 1642 (January 4, 1643, new style), in the hamlet of Woolsthorpe, Lincolnshire, Newton was the only son of a local yeoman, also Isaac Newton, who had died three months before, and of Hannah Ayscough. That same year, at Arcetri near Florence, Galileo Galilei had died; Newton would eventually pick up his idea of a mathematical science of motion and bring his work to full fruition. A tiny and weak baby, Newton was not expected to survive his first day of life, much less 84 years. Deprived of a father before birth, he soon lost his mother as well, for within two years she married a second time; her husband, the well-to-do minister Barnabas Smith, left young Isaac with his grandmother and moved to a neighbouring village to raise a son and two daughters. For nine years, until the death of Barnabas Smith in 1653, Isaac was effectively separated from his mother, and his pronounced psychotic tendencies have been ascribed to this traumatic event. That he hated his stepfather we may be sure. When he examined the state of his soul in 1662 and compiled a catalog of sins in shorthand, he remembered "Threatning my father and mother Smith to burne them and the house over them." The acute sense of insecurity that rendered him obsessively anxious when his work was published and irrationally violent when he defended it accompanied Newton throughout his life and can plausibly be traced to his early years.

After his mother was widowed a second time, she determined that her first-born son should manage her now considerable property. It quickly became apparent, however, that this would be a disaster, both for the estate and for Newton. He could not bring himself to concentrate on rural affairs—set to watch the cattle, he would curl up under a tree with a book. Fortunately, the mistake was recognized, and Newton was sent back to the grammar school in Grantham, where he had already studied, to prepare for the university. As with many of the leading scientists of the age, he left behind in Grantham anecdotes about his mechanical ability and his skill in building models of machines, such as clocks and windmills. At the school he apparently gained a firm command of Latin but probably received no more than a smattering of arithmetic. By June 1661, he was ready to matriculate at Trinity College, Cambridge, somewhat older than the other undergraduates because of his interrupted education.

Influence of the scientific revolution. When Newton arrived in Cambridge in 1661, the movement now known as the scientific revolution was well advanced, and many of the works basic to modern science had appeared. Astronomers from Copernicus to Kepler had elaborated the heliocentric system of the universe. Galileo had proposed the foundations of a new mechanics built on the principle of inertia. Led by Descartes, philosophers had begun to formulate a new conception of nature as an intricate, impersonal, and inert machine. Yet as far as the universities of Europe, including Cambridge, were concerned, all this might well have never happened. They continued to be the strongholds of outmoded Aristotelianism, which rested on a geocentric view of the universe and dealt with nature in qualitative rather than quantitative terms.

Like thousands of other undergraduates, Newton began his higher education by immersing himself in Aristotle's work. Even though the new philosophy was not in the curriculum, it was in the air. Some time during his undergraduate career, Newton discovered the works of the French natural philosopher René Descartes and the other mechanical philosophers, who, in contrast to Aristotle, viewed physical reality as composed entirely of particles of matter in motion and who held that all the phenomena of nature result from their mechanical interaction. A new set of notes, which he entitled "Quaestiones Quaedam Philosophicae" ("Certain Philosophical Questions"), begun sometime in 1664, usurped the unused pages of a notebook intended for traditional scholastic exercises; under the title he entered the slogan "Amicus Plato amicus Aristoteles magis amica veritas" ("Plato is my friend, Aristotle is my friend, but my best friend is truth"). Newton's scientific career had begun.

Importance of the "Quaestiones"

The "Quaestiones" reveal that Newton had discovered the new conception of nature that provided the framework of the scientific revolution. He had thoroughly mastered the works of Descartes and had also discovered that the French philosopher Pierre Gassendi had revived atomism, an alternative mechanical system to explain nature. The "Quaestiones" also reveal that Newton already was inclined to find the latter a more attractive philosophy than Cartesian natural philosophy, which rejected the existence of ultimate indivisible particles. The works of the 17th-century chemist Robert Boyle provided the foundation for Newton's considerable work in chemistry. Significantly, he had read Henry More, the Cambridge Platonist, and was thereby introduced to another intellectual world, the magical Hermetic tradition, which sought to explain natural phenomena in terms of alchemical and magical concepts. The two traditions of natural philosophy, the mechanical and the Hermetic, antithetical though they appear, continued to influence his thought and in their tension supplied the fundamental theme of his scientific career.

Although he did not record it in the "Quaestiones," Newton had also begun his mathematical studies. He again started with Descartes, from whose *La Géometrie* he branched out into the other literature of modern analysis

with its application of algebraic techniques to problems of geometry. He then reached back for the support of classical geometry. Within little more than a year, he had mastered the literature; and, pursuing his own line of analysis, he began to move into new territory. He discovered the binomial theorem, and he developed the calculus, a more powerful form of analysis that employs infinitesimal considerations in finding the slopes of curves and areas under curves.

Development of the calculus

By 1669 Newton was ready to write a tract summarizing his progress, *De Analysi per Aequationes Numeri Terminorum Infinitas* ("On Analysis by Infinite Series"), which circulated in manuscript through a limited circle and made his name known. During the next two years he revised it as *De methodis serierum et fluxionum* ("On the Methods of Series and Fluxions"). The word fluxions, Newton's private rubric, indicates that the calculus had been born. Despite the fact that only a handful of savants were even aware of Newton's existence, he had arrived at the point where he had become the leading mathematician in Europe.

Work during the plague years. When Newton received the bachelor's degree in April 1665, the most remarkable undergraduate career in the history of university education had passed unrecognized. On his own, without formal guidance, he had sought out the new philosophy and the new mathematics and made them his own, but he had confined the progress of his studies to his notebooks. Then, in 1665, the plague closed the university, and for most of the following two years he was forced to stay at his home, contemplating at leisure what he had learned. During the plague years Newton laid the foundations of the calculus and extended an earlier insight into an essay, "Of Colours," which contains most of the ideas elaborated in his *Opticks.* It was during this time that he examined the elements of circular motion and, applying his analysis to the Moon and the planets, derived the inverse square relation that the radially directed force acting on a planet decreases with the square of its distance from the Sun—which was later crucial to the law of universal gravitation. The world heard nothing of these discoveries.

CAREER

The optics. *Inaugural lectures at Trinity.* Newton was elected to a fellowship in Trinity College in 1667, after the university reopened. Two years later, Isaac Barrow, Lucasian professor of mathematics, who had transmitted Newton's *De Analysi* to John Collins in London, resigned the chair to devote himself to divinity and recommended Newton to succeed him. The professorship exempted Newton from the necessity of tutoring but imposed the duty of delivering an annual course of lectures. He chose the work he had done in optics as the initial topic; during the following three years (1670–72), his lectures developed the essay "Of Colours" into a form which was later revised to become Book One of his *Opticks.*

Beginning with Kepler's *Paralipomena* in 1604, the study of optics had been a central activity of the scientific revolution. Descartes's statement of the sine law of refraction, relating the angles of incidence and emergence at interfaces of the media through which light passes, had added a new mathematical regularity to the science of light, supporting the conviction that the universe is constructed according to mathematical regularities. Descartes had also made light central to the mechanical philosophy of nature; the reality of light, he argued, consists of motion transmitted through a material medium. Newton fully accepted the mechanical nature of light, although he chose the atomistic alternative and held that light consists of material corpuscles in motion. The corpuscular conception of light was always a speculative theory on the periphery of his optics, however. The core of Newton's contribution had to do with colours. An ancient theory extending back at least to Aristotle held that a certain class of colour phenomena, such as the rainbow, arises from the modification of light, which appears white in its pristine form. Descartes had generalized this theory for all colours and translated it into mechanical imagery. Through a series of experiments performed in 1665 and 1666, in which the spectrum of a narrow beam was projected onto the wall of a darkened chamber, Newton denied the concept of modification and replaced it with that of analysis. Basically, he denied that light is simple and homogeneous—stating instead that it is complex and heterogeneous and that the phenomena of colours arise from the analysis of the heterogeneous mixture into its simple components. The ultimate source of Newton's conviction that light is corpuscular was his recognition that individual rays of light have immutable properties; in his view, such properties imply immutable particles of matter. He held that individual rays (that is, particles of given size) excite sensations of individual colours when they strike the retina of the eye. He also concluded that rays refract at distinct angles—hence, the prismatic spectrum, a beam of heterogeneous rays, *i.e.,* alike incident on one face of a prism, separated or analyzed by the refraction into its component parts—and that phenomena such as the rainbow are produced by refractive analysis. Because he believed that chromatic aberration could never be eliminated from lenses, Newton turned to reflecting telescopes; he constructed the first ever built. The heterogeneity of light has been the foundation of physical optics since his time.

Analysis of colour

There is no evidence that the theory of colours, fully described by Newton in his inaugural lectures at Cambridge, made any impression, just as there is no evidence that aspects of his mathematics and the content of the *Principia,* also pronounced from the podium, made any impression. Rather, the theory of colours, like his later work, was transmitted to the world through the Royal Society of London, which had been organized in 1660. When Newton was appointed Lucasian professor, his name was probably unknown in the Royal Society; in 1671, however, they heard of his reflecting telescope and asked to see it. Pleased by their enthusiastic reception of the telescope and by his election to the society, Newton volunteered a paper on light and colours early in 1672. On the whole, the paper was also well received, although a few questions and some dissent were heard.

Controversy. Among the most important dissenters to Newton's paper was Robert Hooke, one of the leaders of the Royal Society who considered himself the master in optics and hence he wrote a condescending critique of the unknown parvenu. One can understand how the critique would have annoyed a normal man. The flaming rage it provoked, with the desire publicly to humiliate Hooke, however, bespoke the abnormal. Newton was unable rationally to confront criticism. Less than a year after submitting the paper, he was so unsettled by the give and take of honest discussion that he began to cut his ties, and he withdrew into virtual isolation.

Colours in thin films

In 1675, during a visit to London, Newton thought he heard Hooke accept his theory of colours. He was emboldened to bring forth a second paper, an examination of the colour phenomena in thin films, which was identical to most of Book Two as it later appeared in the *Opticks.* The purpose of the paper was to explain the colours of solid bodies by showing how light can be analyzed into its components by reflection as well as refraction. His explanation of the colours of bodies has not survived, but the paper was significant in demonstrating for the first time the existence of periodic optical phenomena. He discovered the concentric coloured rings in the thin film of air between a lens and a flat sheet of glass; the distance between these concentric rings (Newton's rings) depends on the increasing thickness of the film of air. In 1704 Newton combined a revision of his optical lectures with the paper of 1675 and a small amount of additional material in his *Opticks.*

A second piece which Newton had sent with the paper of 1675 provoked new controversy. Entitled "An Hypothesis Explaining the Properties of Light," it was in fact a general system of nature. Hooke apparently claimed that Newton had stolen its content from him, and Newton boiled over again. The issue was quickly controlled, however, by an exchange of formal, excessively polite letters that fail to conceal the complete lack of warmth between the men.

Newton was also engaged in another exchange on his theory of colours with a circle of English Jesuits in Liège,

perhaps the most revealing exchange of all. Although their objections were shallow, their contention that his experiments were mistaken lashed him into a fury. The correspondence dragged on until 1678, when a final shriek of rage from Newton, apparently accompanied by a complete nervous breakdown, was followed by silence. The death of his mother the following year completed his isolation. For six years he withdrew from intellectual commerce except when others initiated a correspondence, which he always broke off as quickly as possible.

Influence of the Hermetic tradition. During his time of isolation, Newton was greatly influenced by the Hermetic tradition with which he had been familiar since his undergraduate days. Newton, always somewhat interested in alchemy, now immersed himself in it, copying by hand treatise after treatise and collating them to interpret their arcane imagery. Under the influence of the Hermetic tradition, his conception of nature underwent a decisive change. Until that time, Newton had been a mechanical philosopher in the standard 17th-century style, explaining natural phenomena by the motions of particles of matter. Thus, he held that the physical reality of light is a stream of tiny corpuscles diverted from its course by the presence of denser or rarer media. He felt that the apparent attraction of tiny bits of paper to a piece of glass that has been rubbed with cloth results from an ethereal effluvium that streams out of the glass and carries the bits of paper back with it. This mechanical philosophy denied the possibility of action at a distance; as with static electricity, it explained apparent attractions away by means of invisible ethereal mechanisms. Newton's "Hypothesis of Light" of 1675, with its universal ether, was a standard mechanical system of nature. Some phenomena, such as the capacity of chemicals to react only with certain others, puzzled him, however, and he spoke of a "secret principle" by which substances are "sociable" or "unsociable" with others. About 1679, Newton abandoned the ether and its invisible mechanisms and began to ascribe the puzzling phenomena—chemical affinities, the generation of heat in chemical reactions, surface tension in fluids, capillary action, the cohesion of bodies, and the like—to attractions and repulsions between particles of matter. More than 35 years later, in the second English edition of the *Opticks,* Newton accepted an ether again, although it was an ether that embodied the concept of action at a distance by positing a repulsion between its particles. The attractions and repulsions of Newton's speculations were direct transpositions of the occult sympathies and antipathies of Hermetic philosophy—as mechanical philosophers never ceased to protest. Newton, however, regarded them as a modification of the mechanical philosophy that rendered it subject to exact mathematical treatment. As he conceived of them, attractions were quantitatively defined, and they offered a bridge to unite the two basic themes of 17th-century science—the mechanical tradition, which had dealt primarily with verbal mechanical imagery, and the Pythagorean tradition, which insisted on the mathematical nature of reality. Newton's reconciliation through the concept of force was his ultimate contribution to science.

The Principia. *Planetary motion.* Newton originally applied the idea of attractions and repulsions solely to the range of terrestrial phenomena mentioned in the preceding paragraph. But late in 1679, not long after he had embraced the concept, another application was suggested in a letter from Hooke, who was seeking to renew correspondence. Hooke mentioned his analysis of planetary motion—in effect, the continuous diversion of a rectilinear motion by a central attraction. Newton bluntly refused to correspond but, nevertheless, went on to mention an experiment to demonstrate the rotation of the Earth: let a body be dropped from a tower; because the tangential velocity at the top of the tower is greater than that at the foot, the body should fall slightly to the east. He sketched the path of fall as part of a spiral ending at the centre of the Earth. This was a mistake, as Hooke pointed out; according to Hooke's theory of planetary motion, the path should be elliptical, so that if the Earth were split and separated to allow the body to fall, it would rise again to its original location. Newton did not like being corrected, least of all by Hooke, but he had to accept the basic point; he corrected Hooke's figure, however, using the assumption that gravity is constant. Hooke then countered by replying that, although Newton's figure was correct for constant gravity, his own assumption was that gravity decreases as the square of the distance. Several years later, this letter became the basis for Hooke's charge of plagiarism. He was mistaken in the charge. His knowledge of the inverse square relation rested only on intuitive grounds; he did not derive it properly from the quantitative statement of centripetal force and Kepler's third law, which relates the periods of planets to the radii of their orbits. Moreover, unknown to him, Newton had so derived the relation more than ten years earlier. Nevertheless, Newton later confessed that the correspondence with Hooke led him to demonstrate that an elliptical orbit entails an inverse square attraction to one focus—one of the two crucial propositions on which the law of universal gravitation would ultimately rest. What is more, Hooke's definition of orbital motion—in which the constant action of an attracting body continuously pulls a planet away from its inertial path—suggested a cosmic application for Newton's concept of force and an explanation of planetary paths employing it. In 1679 and 1680, Newton dealt only with orbital dynamics; he had not yet arrived at the concept of universal gravitation.

Correspondence with Hooke

Universal gravitation. Nearly five years later, in August 1684, Newton was visited by the British astronomer Edmond Halley, who was also troubled by the problem of orbital dynamics. Upon learning that Newton had solved the problem, he extracted Newton's promise to send the demonstration. Three months later he received a short tract entitled *De Motu* ("On Motion"). Already Newton was at work improving and expanding it. In two and a half years, the tract *De Motu* grew into *Philosophiae Naturalis Principia Mathematica,* which is not only Newton's masterpiece but also the fundamental work for the whole of modern science.

Significantly, *De Motu* did not state the law of universal gravitation. For that matter, even though it was a treatise on planetary dynamics, it did not contain any of the three Newtonian laws of motion. Only when revising *De Motu* did Newton embrace the principle of inertia (the first law) and arrive at the second law of motion. The second law, the force law, proved to be a precise quantitative statement of the action of the forces between bodies that had become the central members of his system of nature. By quantifying the concept of force, the second law completed the exact quantitative mechanics that has been the paradigm of natural science ever since.

The quantitative mechanics of the *Principia* is not to be confused with the mechanical philosophy. The latter was a philosophy of nature that attempted to explain natural phenomena by means of imagined mechanisms among invisible particles of matter. The mechanics of the *Principia* was an exact quantitative description of the motions of visible bodies. It rested on Newton's three laws of motion: (1) that a body remains in its state of rest unless it is compelled to change that state by a force impressed on it; (2) that the change of motion (the change of velocity times the mass of the body) is proportional to the force impressed; (3) that to every action there is an equal and opposite reaction. The analysis of circular motion in terms of these laws yielded a formula of the quantitative measure, in terms of a body's velocity and mass, of the centripetal force necessary to divert a body from its rectilinear path into a given circle. When Newton substituted this formula into Kepler's third law, he found that the centripetal force holding the planets in their given orbits about the Sun must decrease with the square of the planets' distances from the Sun. Because the satellites of Jupiter also obey Kepler's third law, an inverse square centripetal force must also attract them to the centre of their orbits. Newton was able to show that a similar relation holds between the Earth and its Moon. The distance of the Moon is approximately 60 times the radius of the Earth. Newton compared the distance by which the Moon, in its orbit of known size, is diverted from a tangential path in one second with the distance that a body at the surface of

the Earth falls from rest in one second. When the latter distance proved to be 3,600 (60 × 60) times as great as the former, he concluded that one and the same force, governed by a single quantitative law, is operative in all three cases, and from the correlation of the Moon's orbit with the measured acceleration of gravity on the surface of the Earth, he applied the ancient Latin word *gravitas* (literally, "heaviness" or "weight") to it. The law of universal gravitation, which he also confirmed from such further phenomena as the tides and the orbits of comets, states that every particle of matter in the universe attracts every other particle with a force that is proportional to the product of their masses and inversely proportional to the square of the distance between their centres.

Charge of plagiarism

When the Royal Society received the completed manuscript of Book I in 1686, Hooke raised the cry of plagiarism, a charge that cannot be sustained in any meaningful sense. On the other hand, Newton's response to it reveals much about him. Hooke would have been satisfied with a generous acknowledgment; it would have been a graceful gesture to a sick man already well into his decline, and it would have cost Newton nothing. Newton, instead, went through his manuscript and eliminated nearly every reference to Hooke. Such was his fury that he refused either to publish his *Opticks* or to accept the presidency of the Royal Society until Hooke was dead.

International prominence. The *Principia* immediately raised Newton to international prominence. In their continuing loyalty to the mechanical ideal, Continental scientists rejected the idea of action at a distance for a generation, but even in their rejection they could not withhold their admiration for the technical expertise revealed by the work. Young British scientists spontaneously recognized him as their model. Within a generation the limited number of salaried positions for scientists in England, such as the chairs at Oxford, Cambridge, and Gresham College, were monopolized by the young Newtonians of the next generation. Newton, whose only close contacts with women were his unfulfilled relationship with his mother, who had seemed to abandon him, and his later guardianship of a niece, found satisfaction in the role of patron to the circle of young scientists. His friendship with Fatio de Duillier, a Swiss-born mathematician resident in London who shared Newton's interests, was the most profound experience of his adult life.

Warden of the mint. Almost immediately following the *Principia*'s publication, Newton, a fervent if unorthodox Protestant, helped to lead the resistance of Cambridge to James II's attempt to Catholicize it. As a consequence, he was elected to represent the university in the convention that arranged the revolutionary settlement. In this capacity, he made the acquaintance of a broader group, including the philosopher John Locke. Newton tasted the excitement of London life in the aftermath of the *Principia.* The great bulk of his creative work had been completed. He was never again satisfied with the academic cloister, and his desire to change was whetted by Fatio's suggestion that he find a position in London. Seek a place he did, especially through the agency of his friend, the rising politician Charles Montague, later Lord Halifax. Finally, in 1696, he was appointed warden of the mint. Although he did not resign his Cambridge appointments until 1701, he moved to London and henceforth centred his life there.

In the meantime, Newton's relations with Fatio had undergone a crisis. Fatio was taken seriously ill; then family and financial problems threatened to call him home to Switzerland. Newton's distress knew no limits. In 1693 he suggested that Fatio move to Cambridge, where Newton would support him, but nothing came of the proposal. Through early 1693 the intensity of Newton's letters built almost palpably, and then, without surviving explanation, both the close relationship and the correspondence broke off. Four months later, without prior notice, Samuel Pepys and John Locke, both personal friends of Newton, received wild, accusatory letters. Pepys was informed that Newton would see him no more; Locke was charged with trying to entangle him with women. Both men were alarmed for Newton's sanity; and, in fact, Newton had suffered at least his second nervous breakdown. The crisis passed, and Newton recovered his stability. Only briefly did he ever return to sustained scientific work, however, and the move to London was the effective conclusion of his creative activity.

Nervous breakdown

As warden and then master of the mint, Newton drew a large income, as much as £2,000 per annum. Added to his personal estate, the income left him a rich man at his death. The position, regarded as a sinecure, was treated otherwise by Newton. During the great recoinage, there was need for him to be actively in command; even afterward, however, he chose to exercise himself in the office. Above all, he was interested in counterfeiting. He became the terror of London counterfeiters, sending a goodly number to the gallows and finding in them a socially acceptable target on which to vent the rage that continued to well up within him.

Interest in religion and theology. Newton found time now to explore other interests, such as religion and theology. In the early 1690s he had sent Locke a copy of a manuscript attempting to prove that Trinitarian passages in the Bible were latter-day corruptions of the original text. When Locke made moves to publish it, Newton withdrew in fear that his anti-Trinitarian views would become known. In his later years, he devoted much time to the interpretation of the prophecies of Daniel and St. John, and to a closely related study of ancient chronology. Both works were published after his death.

Leader of English science. In London, Newton assumed the role of patriarch of English science. In 1703 he was elected President of the Royal Society. Four years earlier, the French Académie des Sciences (Academy of Sciences) had named him one of eight foreign associates. In 1705 Queen Anne knighted him, the first occasion on which a scientist was so honoured. Newton ruled the Royal Society magisterially. John Flamsteed, the Astronomer Royal, had occasion to feel that he ruled it tyrannically. In his years at the Royal Observatory at Greenwich, Flamsteed, who was a difficult man in his own right, had collected an unrivalled body of data. Newton had received needed information from him for the *Principia,* and in the 1690s, as he worked on the lunar theory, he again required Flamsteed's data. Annoyed when he could not get all the information he wanted as quickly as he wanted it, Newton assumed a domineering and condescending attitude toward Flamsteed. As president of the Royal Society, he used his influence with the government to be named as chairman of a body of "visitors" responsible for the Royal Observatory; then he tried to force the immediate publication of Flamsteed's catalog of stars. The disgraceful episode continued for nearly 10 years. Newton would brook no objections. He broke agreements that he had made with Flamsteed. Flamsteed's observations, the fruit of a lifetime of work, were, in effect, seized despite his protests and prepared for the press by his mortal enemy, Edmond Halley. Flamsteed finally won his point and by court order had the printed catalog returned to him before it was generally distributed. He burned the printed sheets, and his assistants brought out an authorized version after his death. In this respect, and at considerable cost to himself, Flamsteed was one of the few men to best Newton. Newton sought his revenge by systematically eliminating references to Flamsteed's help in later editions of the *Principia.*

Difficulties with Flamsteed

In Gottfried Wilhelm Leibniz, the German philosopher and mathematician, Newton met a contestant more of his own calibre. It is now well established that Newton developed the calculus before Leibniz seriously pursued mathematics. It is almost universally agreed that Leibniz later arrived at the calculus independently. There has never been any question that Newton did not publish his method of fluxions; thus, it was Leibniz's paper in 1684 that first made the calculus a matter of public knowledge. In the *Principia* Newton hinted at his method, but he did not really publish it until he appended two papers to the *Opticks* in 1704. By then the priority controversy was already smouldering. If, indeed, it mattered, it would be impossible finally to assess responsibility for the ensuing fracas. What began as mild innuendoes rapidly escalated into blunt charges of plagiarism on both sides. Egged on by followers anxious to win a reputation under his auspices,

Priority dispute with Leibniz

Newton allowed himself to be drawn into the centre of the fray; and, once his temper was aroused by accusations of dishonesty, his anger was beyond constraint. Leibniz's conduct of the controversy was not pleasant, and yet it paled beside that of Newton. Although he never appeared in public, Newton wrote most of the pieces that appeared in his defense, publishing them under the names of his young men, who never demurred. As president of the Royal Society, he appointed an "impartial" committee to investigate the issue, secretly wrote the report officially published by the society, and reviewed it anonymously in the *Philosophical Transactions*. Even Leibniz's death could not allay Newton's wrath, and he continued to pursue the enemy beyond the grave. The battle with Leibniz, the irrepressible need to efface the charge of dishonesty, dominated the final 25 years of Newton's life. It obtruded itself continually upon his consciousness. Almost any paper on any subject from those years is apt to be interrupted by a furious paragraph against the German philosopher, as he honed the instruments of his fury ever more keenly. In the end, only Newton's death ended his wrath.

Final years. During his final years Newton brought out further editions of his central works. After the first edition of the *Opticks* in 1704, which merely published work done 30 years before, he published a Latin edition in 1706 and a second English edition in 1717–18. In both, the central text was scarcely touched, but he did expand the "Queries" at the end into the final statement of his speculations on the nature of the universe. The second edition of the *Principia*, edited by Roger Cotes in 1713, introduced extensive alterations. A third edition, edited by Henry Pemberton in 1726, added little more. Until nearly the end, Newton presided at the Royal Society (frequently dozing through the meetings) and supervised the mint. During his last years, his niece, Catherine Barton Conduitt, and her husband lived with him. He died on March 20 (March 31, N.S.), 1727, in London.

MAJOR WORKS

Philosophiae Naturalis Principia Mathematica (1687; *Mathematical Principles of Natural Philosophy*, 1729); *Opticks* (1704); *Arithmetica Universalis* (1707; *Universal Arithmetick*, 1720); *The Chronology of Ancient Kingdoms Amended* (1728); *Observations Upon the Prophecies of Daniel and the Apocalypse of St. John* (1733).

BIBLIOGRAPHY. I. BERNARD COHEN, *Introduction to Newton's "Principia"* (1971), a history of the development and modification of Newton's major work, is the first volume of Cohen's edition of the *Principia* and includes variant readings. Additional collections of Newtonian materials, all with valuable introductory essays, include D.T. WHITESIDE (ed.), *The Mathematical Papers of Isaac Newton*, 8 vol. (1967–81); A. RUPERT HALL and MARIE BOAS HALL (eds. and trans.), *Unpublished Scientific Papers of Isaac Newton* (1962, reissued 1978); I. BERNARD COHEN and ROBERT E. SCHOFIELD (eds.), *Isaac Newton's Papers & Letters on Natural Philosophy and Related Documents*, 2nd ed. (1978); and H.W. TURNBULL *et al.* (eds.), *Correspondence*, 7 vol. (1959–77), a collection of Newton's letters, 1661–1727. PETER WALLIS and RUTH WALLIS, *Newton and Newtoniana, 1672–1975* (1977), is a bibliography.

A standard biography of Newton is DAVID BREWSTER, *Memoirs of the Life, Writings, and Discoveries of Sir Isaac Newton*, 2 vol. (1855, reprinted 1965). A more modern work by RICHARD S. WESTFALL, *Never at Rest: A Biography of Isaac Newton* (1980, reissued 1990), also available in a shorter version, *The Life of Isaac Newton* (1993), is a comprehensive study of Newton in light of new scholarship. GALE E. CHRISTIANSON, *In the Presence of the Creator: Isaac Newton and His Times* (1984), includes much contextual information. FRANK E. MANUEL, *A Portrait of Isaac Newton* (1968, reprinted 1990), offers a fascinating Freudian analysis, and his *The Religion of Isaac Newton* (1974) is a thorough discussion of his religious thought. DEREK GJERTSEN, *The Newton Handbook* (1986), comprises hundreds of brief entries on topics related to Newton and his era.

General treatments of the major problems in Newtonian science are found in Cohen's *Franklin and Newton* (1956, reissued 1966); JOHN FAUVEL (ed.), *Let Newton Be!* (1988), a collection of essays on Newton and his work, with illustrations; and A. RUPERT HALL, *Isaac Newton, Adventurer in Thought* (1992), a summary of recent research. JOHN HERIVEL, *The Background to Newton's Principia: A Study of Newton's Dynamical Researches in the Years 1664–84* (1965); and RICHARD S. WESTFALL, *Force in Newton's Physics* (1971), explore the development of Newton's mechanics. Newton's *Optiks* is treated in Hall's *All Was Light* (1993). BETTY JO TEETER DOBBS, *The Foundations of Newton's Alchemy* (1975, reissued 1983), and *The Janus Faces of Genius* (1991), examine Newton's alchemical studies. Cohen's *The Newtonian Revolution* (1980), evaluates the historical importance of Newton's style of scientific thought. ALEXANDRE KOYRÉ, *Newtonian Studies* (1965), contains a collection of essays by one of the master historians of science. PHILLIP BRICKER and R.I.G. HUGHES (eds.), *Philosophical Perspectives on Newtonian Science* (1990), is an advanced treatment, requiring familiarity with Newton's texts. (R.S.W./Ed.)

Nietzsche

Friedrich Nietzsche, a 19th-century German philosopher and writer, was one of the most influential modern thinkers. His attempts to unmask the root motives that underlie traditional Western religion, morality, and philosophy deeply affected generations of theologians, philosophers, psychologists, poets, novelists, and playwrights. He thought through the consequences of the triumph of the Enlightenment's secularism, expressed in his observation that "God is dead," in a way that determined the agenda for many of Europe's most celebrated intellectuals after his death in 1900. Although he was an ardent foe of nationalism, anti-Semitism, and power politics, his name was later invoked by Fascists to advance the very things he loathed.

Louis Held—Deutsche Fotothek, Dresden

Nietzsche, 1888.

The early years. Nietzsche was born on Oct. 15, 1844, in Röcken, a village in Prussian Saxony. His home was a stronghold of Lutheran piety. His paternal grandfather had published books defending Protestantism and had achieved the ecclesiastical position of superintendent; his maternal grandfather was a country parson; his father, Carl Ludwig Nietzsche, was appointed pastor at Röcken by order of King Friedrich Wilhelm IV of Prussia, after whom Friedrich Nietzsche was named. His father died in 1849, before Nietzsche's fifth birthday, and he spent most of his early life in a household consisting of five women: his mother Franziska, his younger sister Elisabeth, his maternal grandmother, and two maiden aunts.

In 1850 the family moved to Naumburg on the Saale River, where Nietzsche attended a private preparatory school, the Domgymnasium. In 1858 he earned a scholarship to Schulpforta, Germany's leading Protestant boarding school. He excelled academically at Pforta, received an outstanding classical education there, and, having graduated in 1864, went to the University of Bonn to study theology and classical philology. Despite efforts to take part in the university's social life, the two semesters at Bonn were a failure, owing chiefly to acrimonious quarrels between his two leading classics professors, Otto Jahn and Friedrich Wilhelm Ritschl. Nietzsche sought refuge in music, writing a number of compositions strongly influenced by Robert Schumann, the German Romantic composer. In 1865 he transferred to the University of Leipzig, joining Ritschl, who had accepted an appointment there.

University years

Nietzsche prospered under Ritschl's tutelage in Leipzig. He became the only student ever to publish in Ritschl's journal, *Rheinisches Museum* ("Rhenish Museum"). He began military service in October 1867 in the cavalry company of an artillery regiment, sustained a serious chest injury while mounting a horse in March 1868, and resumed his studies in Leipzig in October 1868 while on extended sick leave from the military. During the years in Leipzig, Nietzsche discovered Arthur Schopenhauer's philosophy, met the great operatic composer Richard Wagner, and began his lifelong friendship with fellow classicist Erwin Rohde (author of *Psyche*).

The Basel years (1869–79). When a professorship in classical philology fell vacant in 1869 in Basel, Switz., Ritschl recommended Nietzsche with unparalleled praise. He had completed neither his doctoral thesis nor the additional dissertation required for a German degree; yet Ritschl assured the University of Basel that he had never seen anyone like Nietzsche in 40 years of teaching and that his talents were limitless. In 1869 the University of Leipzig conferred the doctorate without examination or dissertation on the strength of his published writings, and the University of Basel appointed him extraordinary professor of classical philology. The following year Nietzsche became a Swiss citizen and was promoted to ordinary professor.

Nietzsche obtained a leave to serve as a volunteer medical orderly in August 1870, after the outbreak of the Franco-Prussian War. Within a month, while accompanying a transport of wounded, he contracted dysentery and diphtheria, which ruined his health permanently. He returned to Basel in October to resume a heavy teaching load, but as early as 1871 ill health prompted him to seek relief from the stultifying chores of a professor of classical philology; he applied for the vacant chair of philosophy and proposed Rohde as his successor, all to no avail.

During these early Basel years Nietzsche's ambivalent friendship with Wagner ripened, and he seized every opportunity to visit Richard and his wife, Cosima. Wagner appreciated Nietzsche as a brilliant professorial apostle, but Wagner's increasing exploitation of Christian motifs, as in *Parsifal,* coupled with his chauvinism and anti-Semitism proved to be more than Nietzsche could bear. By 1878 the breach between the two men had become final.

Nietzsche's break with Wagner

Nietzsche's first book, *Die Geburt der Tragödie aus dem Geiste der Musik* (1872; *The Birth of Tragedy from the Spirit of Music*), marked his emancipation from the trappings of classical scholarship. A speculative rather than exegetical work, it argued that Greek tragedy arose out of the fusion of what he termed Apollonian and Dionysian elements—the former representing measure, restraint, harmony, and the latter representing unbridled passion—and that Socratic rationalism and optimism spelled the death of Greek tragedy. The final 10 sections of the book are a rhapsody about the rebirth of tragedy from the spirit of Wagner's music. Greeted by stony silence at first, it became the object of heated controversy on the part of those who mistook it for a conventional work of classical scholarship. It was undoubtedly "a work of profound imaginative insight, which left the scholarship of a generation toiling in the rear," as the British classicist F.M. Cornford wrote in 1912. It remains a classic in the history of aesthetics to this day.

By October 1876 Nietzsche requested and received a year's sick leave. In 1877 he set up house with his sister and Peter Gast, and in 1878 his aphoristic *Menschliches, Allzumenschliches* (*Human, All-Too-Human*) appeared. Because his health deteriorated steadily he resigned his professorial chair on June 14, 1879, and was granted a pension of 3,000 Swiss francs per year for six years.

Decade of isolation and creativity (1879–89). Apart from the books Nietzsche wrote between 1879 and 1889,

it is doubtful that his life held any intrinsic interest. Seriously ill, half-blind, in virtually unrelenting pain, he lived in boarding houses in Switzerland, the French Riviera, and Italy, with only limited human contact. His friendship with Paul Rée was undermined by 1882 by their mutual if unacknowledged affection for Lou Salomé (author, later the wife of the Orientalist F.C. Andreas, mistress of the poet Rainer Maria Rilke, and confidant of Sigmund Freud) as well as by Elisabeth Nietzsche's jealous meddling.

Nietzsche's acknowledged literary and philosophical masterpiece in biblical narrative form, *Also sprach Zarathustra* (*Thus Spoke Zarathustra*), was published between 1883 and 1885 in four parts, the last part a private printing at his own expense. As with most of his works it received little attention. His attempts to set forth his philosophy in more direct prose, in the publications in 1886 of *Jenseits von Gut und Böse* (*Beyond Good and Evil*) and in 1887 of *Zur Genealogie der Moral* (*On the Genealogy of Morals*), also failed to win a proper audience.

Nietzsche's final lucid year, 1888, was a period of supreme productivity. He wrote and published *Der Fall Wagner* (*The Case of Wagner*) and wrote a synopsis of his philosophy, *Die Götzen-Dämmerung* (*Twilight of the Idols*), *Der Antichrist* (*The Antichrist*), *Nietzsche contra Wagner* (Eng. trans., *Nietzsche contra Wagner*), and *Ecce Homo* (Eng. trans., *Ecce Homo*), a reflection on his own works and significance. *Twilight of the Idols* appeared in 1889, *Der Antichrist* and *Nietzsche contra Wagner* were not published until 1895, the former mistakenly as book one of *The Will to Power,* and *Ecce Homo* was withheld from publication until 1908, 20 years after its composition.

Collapse and misuse. Nietzsche collapsed in the streets of Turin, Italy, in January 1889, having lost control of his mental faculties completely. Bizarre but meaningful notes he sent immediately after his collapse brought Franz Overbeck to Italy to return Nietzsche to Basel. Nietzsche spent the last 11 years of his life in total mental darkness, first in a Basel asylum, then in Naumburg under his mother's care and, after her death in 1897, in Weimar in his sister's care. He died on Aug. 25, 1900. Informed opinion favours a diagnosis of atypical general paralysis caused by dormant tertiary syphilis.

Nietzsche's sister's misuse of his literary estate

The association of Nietzsche's name with Adolf Hitler and Fascism owes much to the use made of his works by his sister Elisabeth. She had married a leading chauvinist and anti-Semite, Bernhard Förster, and after his suicide in 1889 she worked diligently to refashion Nietzsche in Förster's image. Elisabeth maintained ruthless control over Nietzsche's literary estate and, dominated by greed, produced collections of his "works" consisting of discarded notes, such as *Der Wille zur Macht* (1901; *The Will to Power*). She also committed petty forgeries. Generations of commentators were misled. Equally important, her enthusiasm for Hitler linked Nietzsche's name with that of the dictator in the public mind.

Nietzsche's mature philosophy. Nietzsche's writings fall into three well-defined periods. The early works, *The Birth of Tragedy* and the four *Unzeitgemässe Betrachtungen* (1873; *Untimely Meditations*), are dominated by a Romantic perspective influenced by Schopenhauer and Wagner. The middle period, from *Human, All-Too-Human* up to *The Gay Science,* reflects the tradition of French aphorists. It extols reason and science, experiments with literary genres, and expresses Nietzsche's emancipation from his earlier Romanticism and from Schopenhauer and Wagner. Nietzsche's mature philosophy emerged after *The Gay Science.*

In his mature writings Nietzsche was preoccupied by the origin and function of values in human life. If, as he believed, life neither possesses nor lacks intrinsic value and yet is always being evaluated, then such evaluations can usefully be read as symptoms of the condition of the evaluator. He was especially interested, therefore, in a probing analysis and evaluation of the fundamental cultural values of Western philosophy, religion, and morality, which he characterized as expressions of the ascetic ideal.

The ascetic ideal is born when suffering becomes endowed with ultimate significance. According to Nietzsche the Judeo-Christian tradition, for example, made suffering tolerable by interpreting it as God's intention and as an occasion for atonement. Christianity, accordingly, owed its triumph to the flattering doctrine of personal immortality, that is, to the conceit that each individual's life and death have cosmic significance. Similarly, traditional philosophy expressed the ascetic ideal when it privileged soul over body, mind over senses, duty over desire, reality over appearance, the timeless over the temporal. While Christianity promised salvation for the sinner who repents, philosophy held out hope for salvation, albeit secular, for its sages. Common to traditional religion and philosophy was the unstated but powerful motivating assumption that existence requires explanation, justification, or expiation. Both denigrated experience in favour of some other, "true" world. Both may be read as symptoms of a declining life, or life in distress.

Nietzsche's etymological approach to the interpretation of morality

Nietzsche's critique of traditional morality centred on the typology of "master" and "slave" morality. By examining the etymology of the German words *gut* ("good"), *schlecht* ("bad"), and *böse* ("evil"), Nietzsche maintained that the distinction between good and bad was originally descriptive, that is, a nonmoral reference to those who were privileged, the masters, as opposed to those who were base, the slaves. The good/evil contrast arose when slaves avenged themselves by converting attributes of mastery into vices. If the favoured, the "good," were powerful, it was said that the meek would inherit the earth. Pride became sin. Charity, humility, and obedience replaced competition, pride, and autonomy. Crucial to the triumph of slave morality was its claim to being the only true morality. This insistence on absoluteness is as essential to philosophical as to religious ethics. Although Nietzsche gave a historical genealogy of master and slave morality, he maintained that it was an ahistorical typology of traits present in everyone.

God is dead

"Nihilism" was the term Nietzsche used to describe the devaluation of the highest values posited by the ascetic ideal. He thought of the age in which he lived as one of passive nihilism, that is, as an age that was not yet aware that religious and philosophical absolutes had dissolved in the emergence of 19th-century Positivism. With the collapse of metaphysical and theological foundations and sanctions for traditional morality only a pervasive sense of purposelessness and meaninglessness would remain. And the triumph of meaninglessness is the triumph of nihilism: "God is dead." Nietzsche thought, however, that most men could not accept the eclipse of the ascetic ideal and the intrinsic meaninglessness of existence but would seek supplanting absolutes to invest life with meaning. He thought the emerging nationalism of his day represented one such ominous surrogate god, in which the nation-state would be invested with transcendent value and purpose. And just as absoluteness of doctrine had found expression in philosophy and religion, absoluteness would become attached to the nation-state with missionary fervour. The slaughter of rivals and the conquest of the earth would proceed under banners of universal brotherhood, democracy, and socialism. Nietzsche's prescience here was particularly poignant, and the use later made of him especially repellent. For example, two books were standard issue for the rucksacks of German soldiers during World War I, *Thus Spoke Zarathustra* and *The Gospel According to St. John.* It is difficult to say which author was more compromised by this gesture.

Nietzsche often thought of his writings as struggles with nihilism, and apart from his critiques of religion, philosophy, and morality he developed original theses that have commanded attention, especially perspectivism, will to power, eternal recurrence, and the superman.

Perspectivism is a concept which holds that knowledge is always perspectival, that there are no immaculate perceptions, and that knowledge from no point of view is as incoherent a notion as seeing from no particular vantage point. Perspectivism also denies the possibility of an all-inclusive perspective, which could contain all others and, hence, make reality available as it is in itself. The concept of such an all-inclusive perspective is as incoherent as the concept of seeing an object from every possible vantage point simultaneously.

Critical responses to Nietzsche's concept of perspectivism

Nietzsche's perspectivism has sometimes been mistakenly identified with relativism and skepticism. Nonetheless, it raises the question of how one is to understand Nietzsche's own theses, for example, that the dominant values of the common heritage have been underwritten by an ascetic ideal. Is this thesis true absolutely or only from a certain perspective? It may also be asked whether perspectivism can be asserted consistently without self-contradiction, since perspectivism must presumably be true in an absolute, that is a nonperspectival sense. Concerns such as these have generated much fruitful Nietzsche commentary as well as useful work in the theory of knowledge.

Nietzsche often identified life itself with "will to power," that is, with an instinct for growth and durability. This concept provides yet another way of interpreting the ascetic ideal, since it is Nietzsche's contention "that all the supreme values of mankind *lack* this will—that values which are symptomatic of decline, *nihilistic* values, are lording it under the holiest names." Thus, traditional philosophy, religion, and morality have been so many masks a deficient will to power wears. The sustaining values of Western civilization have been sublimated products of decadence in that the ascetic ideal endorses existence as pain and suffering. Some commentators have attempted to extend Nietzsche's concept of the will to power from human life to the organic and inorganic realms, ascribing a metaphysics of will to power to him. Such interpretations, however, cannot be sustained by reference to his published works.

The doctrine of eternal recurrence, the basic conception of *Thus Spoke Zarathustra,* asks the question "How well disposed would a person have to become to himself and to life to crave nothing more fervently than the infinite repetition, without alteration, of each and every moment?" Presumably most men would, or should, find such a thought shattering because they should always find it possible to prefer the eternal repetition of their lives in an edited version rather than to crave nothing more fervently than the eternal recurrence of each of its horrors. The person who could accept recurrence without self-deception or evasion would be a superhuman being (*Übermensch*), a superman whose distance from the ordinary man is greater than the distance between man and ape, Nietzsche says. Commentators still disagree whether there are specific character traits that define the person who embraces eternal recurrence.

Nietzsche's influence. Nietzsche once wrote that some men are born posthumously, and this is certainly true in his case. The history of 20th-century philosophy, theology, and psychology are unintelligible without him. The German philosophers Max Scheler, Karl Jaspers, and Martin Heidegger laboured in his debt, for example, as did the French philosophers Albert Camus, Jacques Derrida, and Michel Foucault. Existentialism and deconstructionism, a movement in philosophy and literary criticism, owe much to him. The theologians Paul Tillich and Lev Shestov acknowledged their debt as did the "God is dead" theologian Thomas J.J. Altizer; Martin Buber, Judaism's greatest 20th-century thinker, counted Nietzsche among the three most important influences in his life and translated the first part of *Zarathustra* into Polish. The psychologists Alfred Adler and Carl Jung were deeply influenced, as was Sigmund Freud, who said of Nietzsche that he had a more penetrating understanding of himself than any man who ever lived or was ever likely to live. Novelists like Thomas Mann, Hermann Hesse, André Malraux, André Gide, and John Gardner were inspired by him and wrote about him, as did the poets and playwrights George Bernard Shaw, Rainer Maria Rilke, Stefan George, and William Butler Yeats, among others. Nietzsche is certainly one of the most influential philosophers who ever lived; and this is due not only to his originality but also to the fact that he was the German language's most brilliant prose writer.

MAJOR WORKS

Definitive editions of Nietzsche's collected works have been edited by Giorgio Colli and Mazzino Montinari, *Werke: Kritische Gesamtausgabe* (1967–), projected for 30 vol., of which 21 had been published by 1984, and *Sämtliche Werke: Kritische Studienausgabe,* 15 vol. (1980). These strictly chronological editions render all earlier collections obsolete. All books authorized for publication by Nietzsche exist in English translations, the most reliable of which are by Walter Kaufmann. The original works in the following list have been translated and edited by Walter Kaufmann unless noted otherwise: *Die Geburt der Tragödie* (1872; *The Birth of Tragedy*); *Unzeitgemässe Betrachtungen,* 4 vol. (1873–76; *Untimely Meditations,* trans. by R.J. Hollingdale); *Menschliches, Allzumenschliches* (1878; *Human, All-Too-Human,* trans. by Marion Faber and Stephen Lehmann); *Morgenröte* (1881; *Daybreak,* trans. by R.J. Hollingdale); *Die fröhliche Wissenschaft* (1882), new ed. augmented by book 5 and *Lieder des Prinzen Vogelfrei* (1887; *The Gay Science*); *Also sprach Zarathustra,* parts 1–3 (1883–84) and part 4 (1885; *Thus Spoke Zarathustra*); *Jenseits von Gut und Böse* (1886; *Beyond Good and Evil*); *Zur Genealogie der Moral* (1887; *On the Genealogy of Morals*); *Der Fall Wagner* (1888; *The Case of Wagner*); *Götzen-Dämmerung* (1889; *Twilight of the Idols*); *Der Antichrist* (1895; *The Antichrist*); *Nietzsche contra Wagner* (1895); *Ecce Homo* (1908). A selection from Nietzsche's notes never intended for publication appeared as *Der Wille zur Macht* (1901; *The Will to Power,* trans. by Walter Kaufmann and R.J. Hollingdale). An important translation and selection of Nietzsche's early unpublished writings is *Philosophy and Truth* (1979), ed. and trans. by Daniel Breazeale. The fundamental chronological edition of Nietzsche's letters by Giorgio Colli and Mazzino Montinari, *Briefwechsel: Kritische Gesamtausgabe* (1975–), is planned for 20 vol., of which 17 had appeared by 1984, containing the correspondence of 1850–89. A fine selection in English is *Selected Letters of Friedrich Nietzsche* (1969), ed. and trans. by Christopher Middleton.

BIBLIOGRAPHY. The *International Nietzsche Bibliography,* ed. by HERBERT W. REICHERT and KARL SCHLECHTA, rev. and expanded ed. (1968), lists more than 4,500 studies in 27 languages. Especially noteworthy English-language studies are WALTER KAUFMANN, *Nietzsche: Philosopher, Psychologist, Antichrist,* 4th ed. (1974), a work that exposed many myths about Nietzsche; R.J. HOLLINGDALE, *Nietzsche: The Man and His Philosophy* (1965), an intellectual biography; and ARTHUR C. DANTO, *Nietzsche as Philosopher* (1965, reissued 1980), a treatment through the eyes of Analytic philosophy. See also RONALD HAYMAN, *Nietzsche: A Critical Life* (1980), an excellent biography for the general reader; BERND MAGNUS, *Nietzsche's Existential Imperative* (1978), a comprehensive discussion of eternal recurrence; RICHARD SCHACHT, *Nietzsche* (1983), a comprehensive interpretation that makes extensive use of *The Will to Power;* and ALEXANDER NEHAMAS, *Nietzsche: Life as Literature* (1985), a treatment of Nietzsche's philosophy on the analogy of the interpretation of a literary text. (Be.M.)

North Africa

The geographic entity North Africa has no single accepted definition. It has been regarded by some as stretching from the Atlantic shores of Morocco in the west to the Suez Canal and the Red Sea in the east, though this is more commonly referred to as northern Africa. Others limit the designation to the countries of Morocco, Algeria, and Tunisia, a region known by the French during colonial times as Afrique du Nord. The more commonly accepted definition, and the one used here, includes the three above-mentioned countries, as well as Libya, but excludes Egypt. The regions encompassed by both the second and third definitions, however, have also been called Northwest Africa.

Seen from across the Mediterranean Sea in Europe, from which it is separated by only 8 miles (13 kilometres) at the Strait of Gibraltar and 85 miles at the Strait of Sicily, North Africa has often been called the Barbary States, or simply Barbary, after the name of the indigenous Berbers, who are now outnumbered by Arabs and Arabized Berbers. Frequently, the countries of Morocco, Algeria, and Tunisia have also been known as the Atlas Lands, after the long mountain ranges that dominate their northern landscapes, although all three countries, especially Algeria, incorporate sizable sections of the Sahara desert. Farther east in Libya, only the northwestern and northeastern parts of the country, known as Tripolitania and Cyrenaica respectively, are outside of the desert.

Seen through Arab eyes from the east, North Africa is known as the Maghrib (the West), an extensive area that is frequently further differentiated into the Maghrib al-Adna (the Near West), comprising Libya and Tunisia; the Maghrib al-Ausat (the Middle West), including Algeria; and the Maghrib al-Aqṣā (the Far West), comprising Morocco and sometimes Western Sahara and Mauritania. The Atlas Lands are often graphically called Djezirah (Jazīrat) al-Maghrib (the Western Isle), signifying their isolated position above the empty Sahara and the Mediterranean Sea.

North Africa as defined here stretches from longitudes 13° W to 25° E and from latitudes 19° N to nearly 38° N. Covering more than 1,830,000 square miles (4,750,000 square kilometres), it is about half the size of the United States or China, but well over four-fifths of the area is desert.

The result of unusual evolution, peculiar geographic circumstances, and isolation, North Africa is, in fact, neither wholly African nor European nor Middle Eastern, but it has its own distinctive identity and internal diversity. Its transitional position—between the Mediterranean and the Sahara, between Europe and Africa, and between West and East—gives rise to much of its distinctiveness.

Geologically, the Atlas Mountains constitute part of the Tertiary fold mountains (*i.e.*, those that formed about 66.4 to 1.6 million years ago) that characterize so much of southern Europe, whereas most of the Sahara is underlain by Precambrian crystalline rock (dating from 3.96 billion to 570 million years ago) or horizontally bedded limestone characteristic of the vast plateau surfaces of Africa. Climatically, the Maghrib is greatly affected by Mediterranean conditions in winter and by Saharan conditions in summer. The resulting north-south climatic and vegetational gradient, from Mediterranean to steppe to desert, is well marked and is generally associated with a decline in agricultural activity and population density.

Culturally, North Africa is the only part of Africa to have been continuously in contact with Europe over millennia, culminating during classical times with the imprint of Greece and Rome and during the 19th and 20th centuries with the colonial impact of France, Italy, and Spain, of which only the Spanish enclaves of Ceuta and Melilla remain. Its relative isolation from sub-Saharan Africa was breached only by hazardous trans-Saharan caravan trade. Bringing slaves as well as goods into the region, trans-Saharan trade also led to black admixtures with the prevailing white populations of North Africa. Cultural influences from the Middle East were much more profound, bringing Arabization of the language, the development of cities, and the near religious uniformity of the region in Islām. Yet, its high degree of cultural uniformity, particularly in contrast to black Africa, has not been enough to bring about political unity—a luxury North Africa has never known. Now, separated by political boundaries—many of which, largely delineated by Turks and Europeans, follow geometric lines across the deserts—the four main states have developed distinctive political identities and economies.

Ecological contrasts between the Mediterranean, steppe, and desert zones have led to traditional contrasts between sedentary cultivation in the north and various types of seminomadic and nomadic pastoralism in the steppes and deserts. Regional contrasts were intensified during colonial rule, whose impact was greatest in the Mediterranean zone, with the growth of export agriculture, mining, and city-ports. This situation has been reinforced by the exploitation and export of oil from Libya and Algeria from the 1950s on. Today, large cities are heightening the urban-rural contrast and are increasingly polarizing the region's population distribution. The principal cities are Casablanca (in Morocco), Algiers (in Algeria), Tunis (in Tunisia), and Tripoli (in Libya).

THE REGION

Physical and human geography

THE LAND

Relief, drainage, and soils. *Relief and drainage.* The relief of North Africa falls into two broad categories: the Atlas Lands and the Sahara. The Atlas Mountains, a group of related ranges stretching some 1,200 miles (2,000 kilometres) in length from southwestern Morocco to northeastern Tunisia, are the result of complex mountain-building processes that occurred during the Tertiary Period. Limestone and sandstone deposited upon an older surface of Hercynian age (roughly 374 to 286 million years old) were pressured upward and folded and faulted by northward movements of the African Plate, in the process incorporating blocks of older rocks that resisted the pressures and that today form intervening plateaus between the ranges. Evidence of persistent structural instability in the ranges is seen in the periodic occurrence of earthquakes, such as the one that devastated Agadir, Mor., in 1960.

Atlas Mountains

The Atlas system runs from southwest to northeast roughly adjacent and parallel to the Mediterranean coastline, one of the reasons why there are so few natural harbours along the coast (Bizerte in northern Tunisia being a notable exception). In the far northwest along the northern coast of Morocco, the Rif Mountains stretch in an arc from Tangier to the Moulouya basin, whose river flows irregularly into the Mediterranean. To the south of the Rif Mountains lies the plain of the Sebou River, which brings water down from the highly dissected Middle Atlas range, a source of water also for the tilted Moroccan Plateau to the west as well as for the Moulouya River. The Middle Atlas stretches southwest to the High Atlas, both ranges together creating a formidable barrier around Atlantic Morocco. The High Atlas are the highest and most spectacular mountains in North Africa, with many snow-capped peaks south of Marrakech exceeding 12,800 feet (3,900 metres) and culminating in Mount Toubkal at 13,665 feet (4,165 metres). Some 500 miles long, they dominate south-central Morocco, their well-watered northern slopes contrasting sharply with their arid southern ones. To the southwest the triangular plain of the Wadi Sous is a synclinal depression separating the High Atlas from the parallel-trending Anti-Atlas range, an uplifted edge of the Saharan shield.

Eastward in Algeria and Tunisia the Atlas system is not as lofty, and the ranges gradually converge. In the north lie the coastal Tell Atlas mountains, sometimes known as the Maritime Atlas, which comprise younger limestones and sandstones in a varied assemblage of massifs, hills, valleys, and plains. East of Algiers the Tell Atlas culminate in the heavily dissected Great Kabylie (Kabylia) Massif, a centre of Berber culture. In Tunisia, the coastal Kroumirie and Mogod mountains are known as the Northern Tell.

The High Plateau

South of the Tell Atlas lies the monotonous High Plateau of Algeria, which stretches some 500 miles from the Moulouya valley in the west to the Aurès Mountains in the east. Lying between 2,500 and 3,300 feet in elevation and being higher in the west than in the east, the High Plateau has a surface comprising a series of closed basins of interior drainage that are occupied by numerous salt flats known as chotts (*shaṭṭ*); hence the fact that the region is often called the Plateau of the Chotts.

Bordering the High Plateau to the south is a series of low mountains—the Ksour, Amour, and Oulad Naïl—collectively termed the Saharan Atlas. Heavily eroded and largely buried in their own debris, the Saharan Atlas mountains are more impressive from the south than from the north. They gradually die out in the east where they merge with the High Plateau to form a natural routeway between the desert south and cultivated north.

Farther east are the weathered ridges of the Aurès Mountains, which extend northeast toward the High Tell Mountains of Tunisia, a series of ridges, domes, and basins often referred to as the Tunisian Dorsale, or backbone of that country. Between the High Tell and the Northern Tell lies the fertile Majardah valley, since ancient times a rich agricultural area, much altered now by irrigation developments. South of the High Tell lie the High and Low Steppes of Tunisia, extensive plains broken in places by a few ridges representing the last remnants of the Atlas ranges. South of the Low Steppes is the Shaṭṭ al-Jarīd, a dry salt lake that effectively defines the edge of the desert.

In Libya, only the northwestern and northeastern corners of the country (known as Tripolitania and Cyrenaica, respectively), separated by the southward projection of the Gulf of Sidra, lie outside of the Sahara. The Al-Jifārah (Gefara) Plain, running along the Mediterranean coast of Tripolitania, is an eastward extension of the Tunisian plain south of Qābis (Gabès) and is backed by the Nafūsah Plateau, a crescentic limestone escarpment that rises to more than 2,600 feet in elevation and, as in the mountains of Tunisia, is remarkable for the profusion of fortified granaries, or *ksour*s, it contains. The Mediterranean coast of northeastern Libya is dominated by the limestone Akhḍar (El-Achdar) Mountains, which stretch some 20 miles inland and are deeply dissected by narrow gorges.

Saharan landforms

To the south lie the vast expanses of the Sahara. Underlain by crystalline rocks of the African Shield, the Sahara is essentially a vast platform that was folded and denuded to a peneplain and afterward covered by younger deposits, especially limestone of Cretaceous age (144 to 66.4 million years old), which now forms prominent escarpments and whose basins are associated with accumulations of petroleum.

The great aridity of the desert means that watercourses are rare and their flow irregular. Termed wadis or oueds, meaning ephemeral streams, they often have dimensions reflecting earlier, more pluvial phases of climate. The longest wadi is the Saoura, which runs nearly 600 miles south from the High Atlas to the Saharan interior, where it eventually dies out. Wadis also radiate from the rugged volcanic peaks of the Ahaggar Mountains in southern Algeria, which rise to 9,573 feet (2,918 metres) at Tahat Peak.

The vast sand seas, known as ergs, which are characteristic of the Sahara, result from the prolonged weathering and erosion of deposits of Tertiary and Quaternary age (at least 1.6 million years old) that make up much of the surface. The Great Western and Great Eastern ergs of Algeria are the most impressive, though expanses of sand almost as huge occur in the Libyan desert. Two prominent erosional desert landforms found extensively in the Sahara are the hammada, a bare plateau covered with boulders and exposed bedrock, and the reg, a gravel- and pebble-strewn plain. Both are products of the desert's unusually strong and nearly continual wind erosion.

Soils. Soil development is extremely limited in the arid landscapes of the Sahara. Low organic matter content and lack of biological activity in the desert's unstable windblown deposits impedes soil development processes. In semiarid areas thin, light-coloured soils with limited humus occur. Soil development is also minimal in the higher altitudes of the Atlas Mountains, where weathered material is thin and easily eroded downslope. It is only in the more stable moister areas, such as on terraced slopes and in valley bottoms, that soil depth and humus

The barren landscape of the Ahaggar Mountains, in the Sahara, southern Algeria.

accumulation are appreciable. There brown and reddish brown soils occur together with rendzinas and terra rossas in the numerous areas with a limestone substrate.

Climate. Climate exerts a major influence on the ecology and all aspects of life in North Africa. Ranging as it does from the temperate shores of the Mediterranean and Atlantic to the snowcapped peaks of the High Atlas to the heart of the Sahara, North Africa is a region of climatic extremes. The region is particularly affected by the seasonal movement of the Azores high-pressure cell, which in summer merges with the Iberian high and bars cyclones from entering the Mediterranean, while in winter it moves south over North Africa, permitting their entry. Consequently, in summer Saharan climatic conditions prevail over the whole of North Africa, complete with frequent incursions of the desert's hot desiccating winds.

Local winds

Variously known as the sirocco in Algeria, the *chehili* in Tunisia, and the *chergui* in Libya, these winds are accompanied by marked rises in morbidity and mortality. In contrast, winter brings the northern parts moister and cooler Mediterranean climatic conditions, which gradually fade south toward the interior.

North Africa is therefore largely transitional between a Mediterranean climate in the north and a desert climate in the south with an intervening steppe, or semiarid, zone. The line dividing the Mediterranean and steppe climates is usually taken to be the 16-inch rainfall isohyet, broadly corresponding to the limit of wheat and barley cultivation without irrigation, and that between steppe and desert the 4-inch isohyet, but naturally these limits are only approximate.

Generally, however, average rainfall diminishes toward the interior while rainfall variability, evaporation, and temperature range all increase, though the simple alignment of climatic zones from Mediterranean in the north to steppe farther south and then desert is complicated by the arrangement of coasts and relief. In the far west, for example, much of Morocco coastward of the mountains benefits from the ameliorating effects of Atlantic maritime conditions, which lower annual temperatures and increase orographic, or relief, rainfall. To a lesser extent, eastern Tunisia, notably the As-Saḥil coast, is also favoured by maritime effects, but farther east the southward projection of the Gulf of Sidra brings the Libyan desert virtually to the shores of the Mediterranean Sea.

The Mediterranean climatic zone, characterized by mild moist winters and hot dry summers, includes the northern part of Morocco as far south as the northern and western slopes of the Middle and High Atlas, all of the Mediterranean coast east to Tunisia, the Tell Atlas, northern Tripolitania, and the Akhḍar Mountains of Cyrenaica. The variety of relief within this area means, however, that maritime, semicontinental, and mountain subtypes occur in places. Many mountain locations receive more than 32 inches of rainfall, with higher elevations receiving twice that amount. Most precipitation falls during the three winter months, and autumn rains generally exceed spring rains, but variations in this pattern occur frequently over space and time.

Steppe climate

The steppe climatic zone, lying between the 16-inch and the 4-inch rainfall isohyets, covers about two-thirds of the Atlas Lands, in particular the Moroccan Plateau, the plains of eastern Morocco that lie in the rain shadow of the Middle Atlas, the High Plateau and Saharan Atlas of Algeria, the steppes and Al-Jifārah Plain of Tunisia and Libya, and the rain-shadowed southern slopes of the Akhḍar Mountains in northeastern Libya. Summer drought in the steppe zone normally lasts from five to six months, but in bad years it may last much longer. Only where the steppes reach the coast is humidity higher and dewfall appreciable. Rainfall reliability generally diminishes southward, and rainfall is often more torrential when it occurs, causing flash floods that sometimes devastate huge areas.

The climate of the Sahara is examined separately in AFRICA. Suffice it to say that there is an increase in climatic extremes of aridity, rainfall unreliability, and high temperature toward the interior of the Sahara.

Plant life. The vegetational patterns of North Africa are greatly influenced by climate, relief, and soils. The Mediterranean climatic zone has vegetation typical of the western Mediterranean floristic region, with adaptations to summer drought and with most growth occurring in spring and autumn. Forests are sparse and are dominated by xerophilous oaks and conifers. In the wetter areas on siliceous rocks, especially in the Rif and Tell Atlas mountains, cork oaks and holm oaks occur, but they give way in drier areas and on limestone to Aleppo pines, Barbary cedars, and junipers. Cedar and juniper forests also are found at higher altitudes in Morocco—in the Rif and the Middle and High Atlas mountains. Deforestation has been extensive, variously caused by the spread of cultivation, especially in Roman and colonial times, and by the depredations of livestock and the collection of firewood for charcoal. As a result, bushes and shrubs are more common than woodland. Maquis thickets of laurel, thyme, myrtle, lentisc, arbutus, broom, and rosemary exhibiting characteristic xerophytic features, such as spiny and waxy leaves and thorns, abound. Sometimes, especially on thin, rocky soils, the shrub vegetation degenerates into a poor variety mixed with heath, known as garigue, in which gorse and lavender provide colour and aroma.

Deforestation

The steppes have much poorer vegetation. Trees give way to shrubs, except along wadis where jujube trees and dwarf palms are found, especially in Morocco and west-

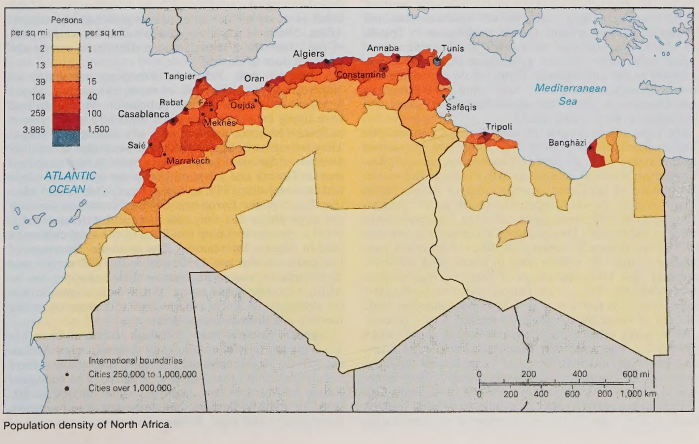
ern Algeria. Dwarf palms are a source of local fibre, but farther east the wild olive, Atlantic turpentine, and Barbary almond are more prominent. Degradation of steppe vegetation leads to a secondary growth of thorn shrub dominated by ziziphus lotus, a hardy bush whose fruits provide succour in times of drought and famine. Farther south alfa grass is widespread on the sandy drier areas of the steppes, and esparto grass, common on the High Steppes of Tunisia and Algeria, has long been exported for paper production. On more fertile loams and clays, artemisia and dwarf sage are common, while Barbary figs appear on the better soils along the wadis. On saline soils near the salt flats, saltbush is commonly found.

The vegetation of the desert is generally sparse, with scat-

tered concentrations of grasses, shrubs, and trees in the highlands, in oases, and along wadis. Various halophytes (salt-tolerant plants) occupy the chott depressions, while some drought- and heat-tolerant grasses and shrubs are found on the arid plains and plateaus (see AFRICA: *Sahara*).

Animal life. North Africa forms part of the Palaearctic zoogeographic region. Its fauna is similar to that of the Middle East, though its birdlife is more like that of the southern Mediterranean. Species are far less numerous and diverse than in the Ethiopian and Madagascan zoogeographic regions that lie in sub-Saharan Africa. Rupestrian art (*i.e.,* inscribed on rock) bears witness to greater diversity during past pluvial climatic phases, but climate alone is not to blame for the region's faunal degradation; many wild animals have disappeared or become extremely rare through widespread killing by humans over the centuries, some quite recently: elephants, bears, lions, leopards, hyenas, ostriches, and cheetahs to name but a few. The wild boar, Barbary red deer, jackal, lynx, and Barbary sheep, or aoudad, are still found in forested mountain areas, however, and gazelles and oryx still inhabit the desert. Reptiles and insects are also fewer than in other parts of Africa, though locust swarms occasionally do tremendous damage to vegetation. In recent years greater efforts have been made to control and conserve the region's wildlife.

Settlement patterns. North Africa's close juxtaposition of Mediterranean, steppe, and desert climates has had a profound influence on the region's patterns of population distribution and settlement. So also have the varied traditions, histories, and priorities of the peoples who have dominated parts of the region, which, over the centuries, have included Berbers, Greeks, Phoenicians, Romans, Arabs, Turks, French, Spanish, and Italians. They have come as conquerors, colonists, pillagers, tax-collectors, rulers, pirates, missionaries, and proselytizers. Viewing the local peoples and landscapes from different origins and perspectives, they utilized them in different ways and left different imprints upon the landscapes and settlements, especially in the more accessible lowlands. Thus, whereas the Romans and, much later, the French established vast rectilinear olive plantations in eastern Tunisia, pastoral nomadism was prevalent during the intervening centuries. The mountains, on the other hand, have acted more as refuges for traditional modes of life, particularly that of the Berbers.



"Tell" and "sahara"

The Mediterranean coastal zone has always been the preferred environment for settlement. Known to North Africans as "the tell," it is the area where harvests are more regular, where pastures are rarely completely scorched, and where olives, figs, and almonds grow without irrigation. Inevitably its more favoured lands attracted sedentary cultivators, villagers and town-dwellers, and a much greater concentration of population than either the steppe or the Sahara. Indeed, for Algerians at least, all that was not tell was "sahara," the area where harvests are very unreliable, where cultivation depends on irrigation, and where pastoral nomadism has prevailed in the past. This duality between tell and sahara can be overstressed, as it undoubtedly oversimplifies the situation, but it does help to facilitate a broad understanding of the social, economic, and political past, for North Africa has long been a region of contact between the desert and the sown, between nomadic and sedentary societies.

Rural settlements. In rural landscapes the types and patterns of settlement reflect, to a large extent, the different agrarian systems, the availability of water, the traditions of the people, and the needs for defense. These influences have varied over space and time, especially as the domain of nomadism and the levels of security have changed. Sedentary cultivators in the Mediterranean zone, in oases, and in areas like the As-Sāḥil coast of Tunisia have traditionally lived in villages rather than in dispersed settlements, although in the Kabylie region of Algeria small hamlets are common. European colonization in the 19th and 20th centuries introduced dispersed farm settlements, often of a characteristically similar style. They contrast markedly today with the more picturesque traditional villages, which are usually made up of flat-roofed, windowless, earthen or stone houses set around a mosque and often a bathhouse. Frequently arranged like terraces on hillslopes, the villages overlook their cultivated areas below. For defensive purposes they sometimes have been situated on hilltops, despite the difficulties of water supply. In moister areas ridge and red tiled roofs occur, as in the Rif.

Along the Saharan fringe, by contrast, houses are often built of vaulted rooms (*ghorfas*), which are characteristically grouped into large fortified granaries known as *ksours* in southern Tunisia and as *agadirs* in southern Morocco. For centuries these structures provided defensive strongholds and food reserves, but many in the mountains have been deserted, sometimes for sites on the plains. Cave dwellings are also common along the Saharan fringe, as in the Ksour Mountains of southern Tunisia and the Nafūsah Plateau of northwestern Libya, where they are carved out of soft limestone.

More commonly in the semiarid areas the tent has been the main dwelling of nomadic peoples. Formerly arranged

Population density of North Africa.

Nomad dwellings

in groups, or douars, tent settlements have become less agglomerated as security has increased. Not all nomads live in tents, however. Many occupy temporary shelters, known often as *gourbis*, which are made of local materials such as straw, diss grass, brushwood, palm trunks, stones, and earth. In Morocco bottle-shaped straw huts (*nouallas*) reflect West African influences. Sedentarization of nomads has meant that many now have fixed abodes for at least part of the year.

Many villages have weekly markets, or souks (suqs), which are widespread throughout North Africa, and in arid areas they are often located in open sites to serve the nomadic peoples. Souks in a particular area are organized on different days of the week, so that traders move cyclically from one to another.

Urban settlement. Town life has ancient traditions in North Africa. Many town sites date back nearly 2,500 years, and the remains of Phoenician, Greek, and Roman cities abound, as at Cyrene, Leptis Magna, Sabratha, Carthage, Thysdrus, and Thugga. The creation of Arab cities in medieval times, however, has had the greatest impact on the region, for most of the sites form the bases of the urban pattern today. The Arab medinas (native quarters) of cities like Tripoli, Tunis, Al-Qayrawān (Kairouan), Tlemcen, Fès, Meknès, and Marrakech became the main centres of North African urban life. Surrounded by walls and dominated by a fort, or casbah, as the centre of government and by the minaret of the great mosque, the medinas were very compact. Along some of the winding narrow streets were souks, or bazaars, in which each trade—reflecting an elaborate hierarchy—focused its activity on a particular street, the more noble trades being located near the great mosque and the noisier and smellier ones occupying positions toward the gates. Peoples of different origins lived in identifiable quarters, but with the expansion of the cities new quarters emerged around the gates. Today these old medinas pose considerable problems for urban planners, as they are virtually impregnable to modern traffic.

European colonial activities resulted in rapid expansion of many urban areas. With four-fifths of the Europeans living in towns and with the colonial export economies growing rapidly, port cities such as Casablanca, Oran, Algiers, Annaba (Bône), Tunis, Şafāqis (Sfax), Tripoli, and Banghāzī all developed into major metropolitan centres. Towns in the interior grew less rapidly except where they became important administrative and service centres, as at Marrakech, Fès, Meknès, and Constantine. In the main cities Europeans created their own quarters. In Algiers this led to the destruction of much of the city's old medina; in Tunisian and Libyan cities the new quarters were built alongside, or even around, the old medinas, as in Tripoli; in Morocco a policy of twin cities, the European town being built some distance away from the medina, was adopted at Fès and Meknès. Plans for similar twin cities, however, were submerged by early rapid growth in cities like Casablanca, where the layout became confused and shantytowns proliferated quickly.

The rapid urban growth initiated during European rule has persisted to the present day, stimulated by various factors such as war, drought, independence, the oil industry, industrialization, and the growth of the service sector. With some of the fastest-growing cities in Africa, North Africa is now the most urbanized region on the African continent. In 1960, immediately after the independence of three of the region's four countries and shortly before that of Algeria, its largest country, less than a third of the population of about 28 million lived in towns. By 1990 about one-half of a total population of some 64 million were town dwellers. The urban growth rate was particularly high in oil-rich Libya at 5 to 10 percent annually, while in each of the other countries it averaged 3 to 4 percent.

As in many other parts of the developing world, urban growth has been especially localized in the major cities, and by 1990 North Africa could boast several "millionaire" cities: Casablanca with nearly three million inhabitants, Algiers with almost two million, and Tunis and Tripoli with a million each. This rapid growth has resulted from a high natural rate of increase of the population as well as from strong rural-urban migration, which has, since independence, focused almost exclusively upon the major cities, all of which are their countries' capitals and also their main industrial centres. Heavy centralization of activities upon such principal cities poses special problems of unemployment and housing, both of which have been easier to ameliorate in oil-rich and underpopulated Libya than in the other three overpopulated countries of the Maghrib.

THE PEOPLE

Ethnic composition. North Africa is vastly more uniform ethnically than anywhere in Africa south of the Sahara. It is principally inhabited by Arabs and Berbers, who are scarcely distinguishable physically. The Berbers are the indigenous people, but their origin is obscure. An ancient people speaking an Afro-Asiatic language, they were in North Africa when the Phoenicians came as traders. Their name, however, derives from the Latin Barbari, which meant all people foreign to the Romans. Of the numerous peoples with whom they came into contact, they were most affected by the Arabs, who invaded between the 7th and 11th centuries. From them they eventually accepted Islām and many other aspects of Arab culture. Calling themselves Imazighen, or free men, Berbers comprised both nomadic and settled tribes that congregated periodically, especially in mountain refuge areas. A rural society with elaborate forms of social stratification, Berber groups have been mainly concerned with preserving their local autonomy rather than with establishing a national political identity. Open to Arab invasions from the east, Libya and Tunisia now contain only small pockets of Berbers and Arabized Berbers in hilly areas; in Algeria Berbers are more common, as in the Aurès Mountains and Kabylie region. They are most numerous, however, in the mountainous areas of Morocco; among them the Shluh (Chleuh) tribe are well-known traders. In the Sahara the most famous of all Berbers are the wide-ranging, nomadic Tuareg. The Berbers are a minority people overall, greatly outnumbered by the Arabs; nonetheless, they have left a strong and pervasive influence on the culture of North Africa.

Indigenous Berbers

The Arabs came initially as invaders and later as pastoralists, bringing with them Islām, Islāmic civilization, the Arabic language, and new customs. Gradually they assimilated more and more Berbers into their culture, as their nomadic members spread the Arabic language and Arab culture and as their cities acted as centres of Islāmic religion and civilization. Because Arabs are so widely dispersed throughout northern Africa, including parts of the Sahel zone, as well as along the coastal zone of eastern Africa, North Africa is considered to be the western end of the Arab world, though also a distinctive part at the southern door of Europe.

During the early 1950s the European population of North Africa reached a peak of nearly two million, about 9 percent of the region's total population. More than half were living in Algeria, though a third of a million were in French Morocco and a quarter of a million in Tunisia. They were mostly French, but there were also substantial numbers of Spaniards, especially in Spanish Morocco; Italians in Tunisia and Libya, although the Italians in Libya had declined after 1939; as well as many Greeks and Maltese. Most of the Europeans lived in towns, particularly the large cities, but they also occupied extensive cultivated areas—as much as two-fifths of the total cultivated land in Algeria, for example. The dramatic departures of Europeans in the late 1950s and early '60s meant that decolonization was more massive than anywhere else in Africa. One significant aspect of this mass migration was the departure of half a million Jews to Europe or to the recently established state of Israel.

Departure of Europeans

Linguistic composition. Although North Africa has much greater linguistic uniformity than any other African region—the Arabic language prevailing throughout—there is more variability than might be expected. The colloquial Arabic of Morocco, for example, would not be understood in the Middle East, and there are sharp contrasts between city and rural dialects. Moreover, the Arabic of

newspapers differs considerably from classical Arabic, the language of the Qur'ān (Koran). Efforts have been made in Libya to promote Arabic against the persistent penetration of English, but in Morocco, Algeria, and Tunisia a distinctive Arab-French culture has evolved that has been sustained by scholarship and by the continuous back-and-forth flow of migrant workers to France. The Berber language is spoken by less than a fifth of the population, and it is not generally written, except by the Tuareg.

Religions. With the departure of Europeans and Jews during decolonization, North Africa became almost uniformly Muslim, in its Sunnite form. It constitutes the western extremity of the Muslim world, which stretches across Africa and Asia to Indonesia. As with any of the major historical religions, Islām's influence has been pervasive, extending into all aspects of life: demographic characteristics, through its exaltation of marriage and the family and its impact upon the role of women in society; commerce, through its condemnation of moneylending; urban life, through the construction of mosques and the cloistering of women; land tenure, through the provision of a juridical framework; and community service, through the importance it places on the pious foundation, or *habous,* for carrying out local religious and charitable tasks.

Pervasive influence of Islām

Two particular features of Islām in North Africa have in the past had an important pacifying influence on the tribes: first, the growth of religious brotherhoods to which most men of religion were affiliated; and second, maraboutism, or the cult of saints and holy men, whose piety, asceticism, and teachings carried out in local *zāwiyahs* (religious lodges) attracted emulation and whose many shrines dot the landscape.

Demographic trends. North Africa has had a rapidly growing population throughout the latter half of the 20th century. Its rapid growth has been caused largely by sharp declines in mortality, along with much more modest declines in fertility, resulting in annual rates of natural increase well above average for the developing world. Death rates in all four countries in the region have dropped to very low levels, owing to better medical facilities, improved sanitation, better nutrition, and higher standards of living. Its death rates, in fact, are lower than in many more developed countries because of the relatively youthful age structures of the populations—generally about 40 percent of the population in each country is under 15 years of age—a factor contributing also to the region's high fertility. There is still much progress to be made in reducing infant mortality rates, however, which remain a high 40 to 80 deaths per 1,000 live births. Life expectancy has risen steadily in the region since the 1950s to between 64 and 69 years, being lowest in Morocco and highest in Tunisia.

Birth rates in North African countries have fallen more than in most countries in the more traditional Middle East. Tunisian women bear about four children each, while Moroccan women have four to five, and Algerian and Libyan women five or more. Several factors account for these differences. There has been a considerable increase in the use of contraception in Tunisia and to a lesser extent in Morocco, the former being a pioneer Muslim country in family planning and in raising the status of women. Divorce reform, later age of marriage, increased educational opportunities for women, and the entrance of women into the labour force have all been promoted in Tunisian society. These changes have come more slowly in Morocco, Algeria, and Libya, but a demographic transition throughout the region has been initiated.

A demographic transition in progress

Oil-rich Libya's long-term labour shortage has understandably influenced its attitudes toward fertility, as it relies upon hundreds of thousands of migrant workers from other North African countries, the Middle East, and other parts of the world. In contrast, Morocco, Algeria, and Tunisia have long been sources of migration, as hundreds of thousands of their workers have gone abroad, especially to the cities of France, but now also to Italy, Spain, and elsewhere in search of employment.

THE ECONOMY

Overview. The economy of North Africa has changed qualitatively between each of its three main historical phases: precolonial, colonial, and postcolonial. The precolonial period was marked by the prevalence of a largely subsistence agriculture dominated by pastoral nomadism on the steppes and sedentary cultivation in the mountains and more favoured Mediterranean zone. Pastoralists migrated northward and to better pastures in higher country in the summer, often participating in the harvests of cereals and tree crops, especially olives. Economic well-being was heavily dependent on the vicissitudes of climate, and urban life was restricted to a few important cities where handicrafts were the main industries. Transport was greatly influenced by the ubiquity of nomadism, and thus pack animals, able to go almost anywhere, prevailed over wheeled vehicles, which were rare.

The colonial phase saw the steady growth of public and private colonization superimposed on the traditional economy. The more favoured agricultural areas were especially affected, and the development of modern, commercialized colonial agriculture geared to the growth of cash crops for export—especially wheat, barley, wine, citrus fruits, olive oil, dates, and early vegetables—proceeded on a large scale. The impact of colonialism was particularly great in Algeria and Libya, which were administered as parts of France and Italy respectively, and was somewhat less in the two French protectorates of Tunisia and Morocco. Generally, pastoralism was pushed south and experienced little modernization. At the same time, mineral resources were exploited, mainly phosphates and iron ore, though in the final years of French rule in Algeria the export of petroleum began. Industrialization evolved only gradually, being impeded by limited investment, lack of coal resources, and little potential for hydroelectric power. Industries were concentrated in the larger, rapidly growing cities, which were connected by a sound, modern transport network of railways, roads, and, later, airways. Such a network facilitated control over the countries and enhanced the evolution of a matured colonial economy involving the export of mostly raw materials and the import of manufactured goods.

The impact of colonialism

During the relatively brief postcolonial period there has inevitably been persistence of some aspects of both the previous periods, but there have been important transformations as well. Because of the massive exploitation of oil that has gone on in Libya, its economic situation has been transformed the most. Algeria and to a lesser extent Tunisia have also benefited greatly from oil extraction. The per capita gross national product (GNP) of the region's countries during the 1980s reflects this situation: Libya sustained the highest figure in all Africa and Algeria the third highest (though only half that of Libya), while Tunisia and Morocco—both of which also ranked high among African countries—had significantly lower figures. Despite the growth of oil exports, all four countries have tried to reduce their dependence on the export of raw materials, often by processing them prior to export to give them added value.

All faced shortages of skilled labour for industrialization and initially had to rely upon foreign expertise, especially Libya, which also suffered, unlike the other countries, from a shortage of unskilled and semiskilled labour, making it dependent on a large foreign labour force like the other oil-rich countries of the Middle East. Despite much progress in industrialization in the postcolonial period, including heavy industries, industrialization by itself has not proved to be the answer to all North Africa's economic problems; it has, moreover, accelerated the process of urbanization by attracting labour from the countryside.

Skilled labour shortages

The redistribution of colonial lands in rural North Africa in the 1950s and '60s and the collectivist solution to agricultural development in Algeria also did not solve the related problems of trying to increase agricultural production and reduce its annual fluctuations. All the countries faced severe difficulties in supplying sufficient food to their rapidly growing populations. The considerable expansion of tourism in Morocco and Tunisia transformed parts of their coastal zones and provided some promise for development, but the long-term benefits of tourism have been questioned, especially as it is vulnerable to changes in the international economic and political climate.

The four countries have all adopted very different economic policies. Algeria's initial stance as a centrally planned economy has been relaxed to permit some development of the private sector. Under Colonel Muammar al-Qaddafi, Libya has been economically radical and individualistic. Tunisia abandoned its early socialist experiment in agricultural collectivization and, with increasing privatization, has become economically liberal, while Morocco under monarchic rule has retained conservative economic policies. All four countries, however, have been unable to avoid the influence of external forces on their economies, in particular the fluctuations in the economies of the European Community (EC), which have affected trade, investment, tourism, and the movements of migrant workers. Such fluctuations have not been offset by intraregional trade or cooperation, which has been limited despite various agreements.

Morocco, Algeria, and Tunisia all faced severe debt in the late 20th century owing to extravagant developments in the early decades of independence and to heavy borrowing. Morocco was forced to reschedule its debts under International Monetary Fund–Paris Club arrangements, a fate that would have befallen Algeria and Tunisia had they not introduced reforms to reduce budget deficits.

Resources. Although Africa is rich in numerous mineral resources, North Africa's mineral wealth is limited primarily to its petroleum and natural gas reserves. The Libyan and Algerian deserts have about 2 percent and 1 percent respectively of the proven world reserves of petroleum, and Algeria about 3 percent of the reserves of natural gas. In contrast, North Africa's other energy resources are minor. Coal deposits are small and remotely located, mainly in eastern Morocco, and hydroelectric power potential is limited—except in Morocco—largely by the aridity of the region.

Petroleum and natural gas reserves

The two other major mineral resources of North Africa are phosphates, found especially in Morocco and Tunisia, and iron ore, found in Algeria, Tunisia, and Libya. Many other minerals have been mined in smaller quantities when world prices have been favourable, including lead, zinc, manganese, cobalt, antimony, copper, and molybdenum. In addition, the region's abundant limestone deposits are used for cement production in all countries.

Agriculture, forestry, and fishing. North Africa's agricultural and timber resources are limited by its dry climate, and its agricultural products are those typical of the Mediterranean, steppe, and desert regions: wheat, barley, olives, grapes, citrus fruits, early vegetables, dates, sheep, and goats. It is not a region noted for its timber resources, though cork is an unusual product.

Agriculture employs between 20 and 25 percent of the working population in Algeria and Tunisia, less in Libya, but about 40 percent in less urbanized Morocco. Since independence, agricultural production has failed to keep pace with population growth and has remained susceptible to large annual fluctuations. All four countries have only small areas of prime arable land and no large reserves suitable for expansion. Cropland occupies about one-third of Tunisia and one-fifth of Morocco, the two countries where agriculture contributes most to the gross domestic product (GDP), but less than one-thirtieth of Algeria and one-sixtieth of Libya. Countries that were formerly important food exporters saw a marked decline in export production in the 1970s, with severe social consequences. Not only were these countries compelled to increase food production rapidly for their growing populations, but they also had to import more food because of changed consumption patterns resulting from rising standards of living. Some export crops, moreover, like wine grapes, citrus fruits, tobacco, and cotton, have suffered from strong international competition, though others, like sugar beets in Morocco, have expanded.

Decline in nomadism

Desertification in the drier areas has contributed to a decline in nomadism and to the settlement of nomads. Both trends have also been intensified by the growth of the oil and gas industries in Libya and Algeria and by the extension of arable farming into marginal lands. Livestock farming, however, especially of sheep and goats, still plays an important role in the region's economy.

The bulk of North Africa's forestry production is for local firewood, charcoal, and industrial timber, but cork is produced for export from the large areas of cork oak (*Quercus suber*) trees that grow near the Mediterranean, especially in the west.

As a region, North Africa is not a major contributor to the continent's fish catch, accounting for less than one-tenth of the total take, but Morocco, with its cool, plankton-rich Atlantic waters and access to the Mediterranean, is the largest fish producer in the Arab world. Pilchards, sardines, bream, hake, sea bass, anchovies, and mullet are the principal species landed, with the unusual addition of sponges in Tunisian waters. Although comprising only a small part of the total economy, fish processing and canning occurs in many North African ports. The introduction of exclusive economic zones beyond territorial waters beginning in the 1970s has led to disputes over fishing rights between Morocco and Spain and between Tunisia and Italy.

Industry. North Africa's industries are largely related to the mining and processing of its energy and mineral resources. Following discoveries of oil in the desert in the 1950s and '60s, Libya and Algeria both became major petroleum producers. Although Tunisia is only a minor producer, oil is prominent in its economy as well, being its chief export. Libya is particularly reliant upon its petroleum production, which accounts for a high percentage of its GDP. To capitalize on their petroleum resources, Algeria and Libya have both developed major oil-refining and petrochemical industries. Most production goes to Europe and the United States.

Natural gas was an underutilized resource until it was exported in liquefied form to European and American markets. Since the late 1980s significant expansion of Algeria's gas exports has occurred with the completion of a gas pipeline linking Algeria with Sicily via Tunisia and the Mediterranean. Algeria is now one of the world's largest producers of natural gas, with about 2 percent of the total world production. Natural gas is also produced in Libya, though on a much smaller scale. The only other important mineral production is of phosphate rock in Morocco and Tunisia. Both countries have large ancillary superphosphate industries. Iron ore production from eastern Algeria is also significant and no doubt has stimulated the huge investments in that country's iron and steel industry.

Most electricity is generated in thermal installations, but hydroelectric power production accounts for a small share of the electricity generated. In Morocco, the country most dependent on hydropower, it accounts for more than one-tenth of the electricity produced and constitutes more than a quarter of net installed electricity-generating capacity. In 1990 a valuable electricity interchange link was established between Morocco, Algeria, and Tunisia. Rural electrification has made much progress in the final decades of the 20th century, though nearly all electricity generated is still transmitted to the cities.

Industrial diversification

All the countries of North Africa have tried to increase and diversify their industries, equating industrialization with modernization. Morocco and Tunisia, less endowed with oil and gas, have been forced to more diversification than either Libya or Algeria. Inevitably industrial development has not met with quick success, as EC and other major markets have not been easy to penetrate. Agriculture-related and food industries still produce a considerable proportion of all industrial output, but there have been important developments in metallurgy, automobile assembly, radio and television, pharmaceutical products, and textiles and clothing.

Tunisia and Morocco both attract millions of European tourists annually to their beaches and historic cities, and tourism has become an important industry in both countries, especially in terms of employment. For political and social reasons Algeria and Libya have not developed their tourist industries to the same extent.

Trade. Minerals and mineral products are the region's main exports, notably petroleum and petroleum products (Libya, Algeria, Tunisia), natural gas (Algeria, Libya), phosphates and superphosphates (Morocco, Tunisia), and iron and steel (Algeria). Agricultural products such as

wheat, olives, olive oil, citrus fruits, and dates, once mainstays of the export economy, have been surpassed by manufactured products, which now contribute substantially to the exports of Morocco and Tunisia. Imports include food, industrial supplies and machinery, consumer goods, and transport equipment.

Algeria and Libya generally export far more than they import, but both Morocco and Tunisia suffer from chronic trade imbalances. Foreign trade is dominated by the former colonial powers, France and Italy, with Spain, Germany, the United States, and Belgium as other important trading partners.

Transportation. Because of the extensive rail network built by the French during the colonial period, Morocco, Algeria, and Tunisia have emphasized railways in their transportation infrastructures. The modern network includes new electrified lines, such as those between Casablanca and Rabat, and light rapid-transit systems in major cities like Algiers and Tunis. Road building has been given less emphasis in these three countries than in Libya, where the old Italian railways failed to survive and where a major road-building program has been implemented. Consequently, Libya has almost as many vehicles as the much more populous countries of Algeria and Morocco.

Major ports

The major port cities of Casablanca, Oran, Algiers, Tunis, and Tripoli handle most of the region's general traffic, while the smaller ports of Marsā al-Burayqah, Ra's al-Unūf, Skikda, and Arzew are sites of the main oil terminals. Other smaller ports handle mineral products or are important for fishing (*e.g.,* Safi, Larache, Ṣafāqis). International airways have become particularly important to Morocco and Tunisia because of their considerable tourist traffic, and each country has a number of international airports. However, the larger countries of Algeria and Libya have a bigger network of domestic airports to handle their internal communications. (J.I.C.)

History

ANCIENT NORTH AFRICA

Geography and prehistory. North Africa as here used means the area of present-day Morocco, Algeria, Tunisia, and Libya. In ancient times the Greeks used the word Libya, derived from the name of a tribe on the Gulf of Sidra, to describe the land north of the Sahara, the territory whose native peoples were subjects of Carthage, and also as a name for the whole continent. The Romans applied the name Africa (of Phoenician origin) to their first province in the northern part of Tunisia, as well as to the whole area north of the Sahara and also to the entire continent. The Arabic term Jazirat al-Maghrib, meaning island of the west, applied first of all to land west of Egypt but more particularly to present-day Tunisia, Algeria, and Morocco. French scholars regularly use Maghrib in this sense, and it is so used here. The Arabs used the word Barbar (Berber), perhaps derived from the Latin *barbari,* to describe the non-Latin-speaking peoples of the Maghrib at the time of the Arab conquest, and it has been used in modern times to describe the non-Arabic-speaking population (French *Berbères*). A frequent usage refers to the non-Phoenician and non-Roman inhabitants of classical times, and their language, as Berber. It should be stressed, however, that the theory of a continuity of language between ancient inhabitants and the modern Berbers has not been proved; consequently, the word Libyan is used here to describe these people in ancient times.

Ancient Libya

The description of the area as an island refers to its isolation, bounded as it is by the sea to the north and west and by the Sahara to the south and east. Since antiquity, the desert has been the dominant factor in the North African environment, though it has not always been as dry as it is today. At various times during the past million years there have been periods of abundant rainfall, the last occurring about the 6th millennium BC at the beginning of the Neolithic Period (see below). A major trade route connecting the Mediterranean with the African world existed along the Ahaggar-Tibesti ridge in the central Sahara, and it is probable that communications existed across the western Sahara also. Nevertheless, the Sahara always constituted a formidable barrier to the movement of technology and peoples. In ancient historical times much of North Africa was evergreen forest or scrub, and the fauna included animals such as the elephant, zebra, and ostrich.

The mountains were of the utmost importance in the historical development of the area. They run generally from east to west, parallel to the coast, with their highest elevations in the Atlas Mountains. They are not continuous but constitute separate blocks, especially in the coastal areas. Although it was in the mountains that the rainfall was highest, the forest there was intractable, and early settlements tended to choose the plains and valleys between or south of the mountains. The Mediterranean coast, for much of its length, is extremely inhospitable, offering few natural harbours and still fewer natural lines of communication into the interior. Even the major rivers, such as the Majardah (Medjerda) and Chelif, are unnavigable. Only in northeastern Tunisia is the coastline more favourable, and the main movement of culture and conquest has naturally been from there westward.

The coastal strip in the area of Tripoli (Ṭarābulus) in western Libya is an extension of Tunisia's coastal plain. To the east, some 800 miles of the Surt Desert separates it from Cyrenaica (Barqah) at the eastern end of modern Libya, which thus has had a very different history from the Maghrib. Settlement there was effectively confined to the Akhḍar Mountains and did not extend more than about 70 miles south of the coast. Cyrenaica's contact with Egypt was limited by an intervening 600 miles of semidesert.

The Maghrib provides the paradox of being an area in which various cultures have imposed some measure of uniformity, while political unity has been rare; for this, geography is largely responsible. The area of settlement is of vast length but little breadth and has no natural centre from which political uniformity could be imposed; its natural communications have never been easy, and the mountain blocks have been large enough to maintain populations to a greater or lesser degree independent of and hostile to those that controlled the plains.

Earliest inhabitants

Although there is uncertainty about some factors, Aïn el-Hanech (in Algeria) is the site of one of the earliest traces of hominid occupation in the Maghrib. Somewhat later but better attested are sites at Ternifine (near Tighennif, Alg.) and at Sidī ʿAbd ar-Raḥmān, Mor. The former produced hand axes associated with the hominid *Homo erectus,* a more primitive being than the Neanderthaloids of the same period. Sidī ʿAbd ar-Raḥmān produced evidence of the same hominid, with a date of at least 200,000 BC.

Succeeding these early hand-ax remains are the Levalloisian and Mousterian industries similar to those of the Levant. It is claimed that nowhere did the Middle Paleolithic evolution of flake-tool techniques reach a higher state of development than in North Africa. Its high point in variety, specialization, and standard of workmanship is named Aterian, after the type site of Bīʾr al-ʿAtīr in Tunisia; assemblages of this material occur all over the Maghrib and the Sahara. Radiocarbon testing from Morocco indicates a date for early Aterian material of about 30,000 BC. Its diffusion over the region appears to have taken place during one of the periods of desiccation, and the carriers of the tradition were clearly adept desert hunters. The few associated human remains are Neanderthaloid, with substantial differences between those found in the west and those in Cyrenaica. In the latter area, a date of about 43,000 BC for the Levalloisian and Mousterian industries has been obtained (at Haua Fteah). The tools and a fragmentary human fossil of Neanderthaloid type are almost identical to those of Palestine.

The earliest blade industries of the Maghrib, associated as in Europe with the final supersession of Neanderthaloids by *Homo sapiens,* are named Ibero-Maurusian, or Oranian (type site, La Mouilla, near Oran in western Algeria), an industry of obscure origin, which seems to have spread along all the coastal areas of the Maghrib and Cyrenaica between about 15,000 and 10,000 BC. Following the Ibero-Maurusian was the Capsian, the origin of which is also obscure. Its most characteristic sites are in the area of the great salt lakes of southern Tunisia, the type site being al-Maqtaʿ (el-Mekta), near Qafṣah (Capsa, or Gafsa). The cli-

mate during both Ibero-Maurusian and Capsian appears to have been relatively dry and the fauna one of open country, ideal for hunting. Between about 9,000 and 5,000 BC, upper Capsian spread northward to influence the Ibero-Maurusian and also eastward to the Gulf of Sidra. Since there is much evidence that the Neolithic culture of the Maghrib was not introduced by invasion but through the acceptance of new ideas and technologies by the Capsian peoples, it is probable that they were the ancestors of the Libyans known in historic times.

Neolithic culture

The spread of early Neolithic culture in Libya and the Maghrib occurred during the 6th and 5th millennia BC and is characterized by the domestication of animals and the shift from hunting and gathering to self-supporting food production (often still including hunting). The pastoral economy, with cattle the chief animal, remained dominant in North Africa until the classical period. Although the new type of economy may have originated in Egypt or the Sudan, the character of the flint-working tradition of the Maghribian Neolithic argues in favour of the survival of much of the earlier culture, which has been called Neolithic-of-Capsian tradition. Accordingly, the technology of the transition, if not of independent local origin, is best explained by the gradual diffusion of new techniques rather than by the immigration of new peoples.

The Neolithic-of-Capsian tradition in the Maghrib persisted at least into the 1st millennium BC with relatively little change and development; there was no great flourishing of late Neolithic culture and little that can be described as a Bronze Age. North Africa was wholly lacking in metallic ores other than iron, hence most tools and weapons continued to be made of stone until the introduction of ironworking techniques.

Prehistoric rock carvings have been found in the southern foothills of the Atlas south of Oran and in the Ahaggar and Tibesti ranges. While some are relatively recent, the great majority appear to be of the Neolithic-of-Capsian tradition. Some show animals now locally or even totally extinct, such as the giant buffalo, elephant, rhinoceros, and hippopotamus, in areas now covered by desert. While Egyptian-like patterns may be discerned, the character of the rock art is so different from that of Egypt that it can hardly be said to derive from it. On the other hand, it is very much later than the rock paintings of Paleolithic times in southwestern Europe, and an independent development is probable. The art is primarily that of a culture that remained largely, though not exclusively, dependent on hunting and that survived on the Saharan fringes until historical times.

Prehistoric fauna

There are many thousands of large, stone-built surface tombs in North Africa that appear to have no connection with earlier megalithic structures found in northern Europe, and it is unlikely that any of them is earlier than the 1st millennium BC. Large structures in Algeria such as the tumulus at Mzora (177 feet [54 metres] in diameter) and the mausoleum known as the Medracen (131 feet in diameter) are probably of the 4th and 3rd centuries BC and show Phoenician influence, though there is much that appears to be purely Libyan.

The Carthaginian period. *The Phoenician settlements.* North Africa (with the exception of Cyrenaica) entered the mainstream of Mediterranean history with the arrival in the 1st millennium BC of Phoenician traders, mainly from Tyre and Sidon in modern Lebanon. The Phoenicians were not looking for land to settle but for anchorages and staging points on the trade route from Phoenicia to Spain, a source of silver and tin. Points on an alternative route by way of Sicily, Sardinia, and the Balearic Islands also were occupied. The Phoenicians lacked the manpower and the need to found large colonies as the Greeks did, and few of their settlements grew to any size. The sites chosen were generally offshore islands or easily defensible promontories with sheltered beaches on which ships could be drawn up. Carthage (from the Phoenician Kart-Hadasht, New City), destined to be the largest Phoenician colony and in the end an imperial power, conformed to the pattern.

Tradition dated the foundation of Gades (modern Cádiz; the earliest known Phoenician trading post in Spain) to 1110 BC, Utica (Utique) to 1101 BC, and Carthage to 814 BC. The dates appear legendary, and no Phoenician object earlier than the 8th century BC has yet been found in the west. At Carthage some Greek objects have been found, datable to about 750 or slightly later, which comes within two generations of the traditional date. Little can be learned from the romantic legends about the arrival of the Phoenicians at Carthage transmitted by Greco-Roman sources. Though individual voyages doubtless took place earlier, the establishment of permanent posts is unlikely to have taken place before 800 BC, antedating the parallel movement of Greeks to Sicily and southern Italy.

Material evidence of Phoenician occupation in the 8th century BC comes from Utica, and of the 7th or 6th century BC from Hadrumetum (Sūsah, Sousse), Tipasa (east of Cherchell), Siga (Rachgoun), Lixus, and Mogador (Essaouira), the last being the most distant Phoenician settlement so far known. Finds of similar age have been made at Motya (Mozia) in Sicily, Nora (Nurri), Sulcis, and Tharros (San Giovanni di Sinis) in Sardinia, and Cádiz and Almuñécar in Spain. Unlike the Greek settlements, however, those of the Phoenicians long remained politically dependent on their homeland, and only a few were situated where the hinterland had the potential for development. The emergence of Carthage as an independent power, leading to the creation of an empire based on the secure possession of the North African coast, resulted less from the weakening of Tyre, the chief city of Phoenicia, by the Babylonians than from growing pressure from the Greeks in the western Mediterranean; in 580 BC some Greek cities in Sicily attempted to drive the Phoenicians from Motya and Panormus (Palermo) in the west of the island. The Carthaginians feared that if the Greeks won the whole of Sicily they would move on to Sardinia and beyond, isolating the Phoenicians in North Africa. The successful defense of Sicily was followed by attempts to strengthen limited footholds in Sardinia; a fortress at Monte Sirai is the oldest Phoenician military building in the west. The threat from the Greeks receded when Carthage, in alliance with Etruscan cities, checked the Phocaeans off Corsica in about 540 BC and succeeded in excluding the Greeks from contact with southern Spain.

Relations with the Greeks

Carthaginian supremacy. By the 5th century BC, active military participation by Tyre in the west had doubtlessly ceased; from the latter half of the 6th century Tyre was under Persian rule. Carthage thus became the leader of the western Phoenicians and in the 5th century formed an empire of its own, centred on North Africa, which included existing Phoenician settlements, new ones founded by Carthage itself, and a large part of modern Tunisia. Nothing is known of resistance from the indigenous North African population, but it was probably limited owing to the scattered nature of local societies and the lack of state formation. The actual stages of the growth of Carthaginian power are not known, but the process was largely completed by the beginning of the 4th century. The whole of the Cap Bon (Jazirat Sharik) peninsula was occupied early, ensuring Carthage a fertile and secure hinterland. Subsequently, its control extended southwestward as far as a line running roughly from al-Kāf to the coast at Thaenae (now the ruins of Thīnah, or Tina). Penetration occurred south of this line later, Theveste (Tbessa, Tébessa) being occupied in the 3rd century BC. In the Cap Bon peninsula, where the Carthaginians developed a prosperous agriculture, the native population may have been enslaved, while elsewhere they were obliged to pay tribute and furnish troops.

Carthage maintained an iron grip on the entire coast, from the Gulf of Sidra to the Atlantic coast of Morocco, establishing many new settlements to protect its monopoly of trade. These were mostly small places, probably of only a few hundred inhabitants. The Greeks called them emporia, markets where native tribes brought articles to trade, which could also serve as anchorages and watering places. Permanent settlements in modern Libya were few and dated after the attempt of Dorieus to plant a Greek colony there. Though in time fishing and agriculture played a part in their wealth, Leptis Magna with its neighbours Sabratha and Oea (Tripoli) became rich through trans-Saharan trade; Leptis Magna was the terminus of the

Carthaginian settlements

shortest route across the Sahara linking the Mediterranean with the Niger. A Carthaginian named Mago is said to have crossed the desert several times, but doubtless much of the trade (in precious stones and other exotics) came through intermediate tribes. Other stations on the Gulf of Gabes included Zouchis, known for its salted fish and purple dye, Gigthis (Bū Ghirārah), and Tacape (Qābis, Gabès). North of Thaenae was Acholla, traditionally an offshoot of the Phoenician settlement on Malta, Thapsus (Rass Dimas), Leptis Minor, and Hadrumetum, the largest city on the east coast of Tunisia. From Neapolis (Nābul, Nabeul), a road ran direct to Carthage across the base of the Cap Bon peninsula.

West of Carthage there have been changes in the course of the Majardah (Bagradas) River; as a result, Utica, a port in Carthaginian and Roman times, is now some seven miles from the sea. Utica was second only to Carthage in importance among the Phoenician settlements and always maintained at least a nominal independence. Beyond Cape Farina (Ra's Sidi 'Alī al-Makkī) as far as the Strait of Gibraltar, the coast offered a number of anchorages, but few of the stations reached anything like the prosperity of those on the Gulf of Gabes and the east coast of Tunisia. One of the more important was Hippo Diarrhytus (Bizerte, Banzart), whose natural advantages as a port were utilized at an early date; another Hippo, later called Hippo Regius (Bône, modern Annaba), was also probably of Carthaginian origin. Along the same stretch of coast were Rusicade (Philippeville, Skikda) and Collo (Chullu). Still farther west, a number of place-names known from the Roman period betray an earlier Phoenician interest through the incorporation of a Phoenician element, *rus*, meaning "cape"; *e.g.*, Rusuccuru (Dellys) and Rusguniae (Matifou). Tingis (Tingi, Tangier) was already settled in the 5th century BC.

Trade. Ancient sources agree that Carthage had become perhaps the richest city in the world through its trade, yet very few traces of its wealth have been discovered by archaeologists. This is because most of it was in perishables—textiles, unworked metal, foodstuffs, and slaves; its trade in manufactured goods was only a part of the whole. There can be no doubt that the most profitable trade was that inherited from the Phoenicians in the western Mediterranean, in which tin, silver, gold, and iron were obtained in exchange for manufactures and consumer goods of small value. Carthage ruthlessly maintained its monopoly of this trade from the late 6th to the end of the 3rd century BC by sinking intruders and exacting recognition of its position from other states. Its wealth is attested by the vast mercenary armies it was able to maintain with a mintage of gold coins in the 4th century far in excess of that known for other advanced states.

Voyages of exploration

It was apparently in connection with this trade that during the 5th century there occurred two voyages of exploration and trade, evidently of particular importance since reports of them were known to later generations of Greeks and Romans. One was along the Atlantic coast of Morocco, the other northward along the Atlantic coast of Spain. They were led by Hanno and Himilco, respectively, both members of a leading family in Carthage. Hanno's voyage is generally associated with an account in Herodotus, writing about 430 BC, of Carthaginian trade on the Atlantic coast of Morocco. Herodotus describes a system of dumb barter with the coastal peoples, by which the Carthaginians exchanged manufactured goods for gold. It is not known where the exchanges took place; the Río de Oro is a possibility, and it is probable that Hanno's expedition went beyond Cape Verde. Nevertheless, the "gold route" did not survive the fall of Carthage and was not exploited by the Romans. This has led some scholars to argue that the Carthaginians' interest in the Atlantic coast of Morocco was stimulated by the more prosaic attraction of the abundant fish.

Himilco's voyage also was known to the Greeks and Romans. He sailed north along the Atlantic coast of Spain, Portugal, and France and reached the territory of the Oestrymnides, a tribe living in Brittany. The purpose of this voyage was apparently to consolidate control of the trade in tin along the Atlantic coast of Europe. It followed the route used by the Tartessians, a people of southern Spain, in the area where Cádiz had been founded, who knew of Ireland and Britain. This trade was no doubt the latest phase of contact between the various areas of the Atlantic seaboard that went back to late Neolithic times. There is no evidence that Himilco reached Britain, nor indeed has any Phoenician object ever been found on the island, but probably Cornish tin was obtained through the tribes of Brittany. Tin was also obtained from northwestern Spain. It is notable that, at Cádiz, the Carthaginian tombs found at intervals there over the past century have produced nothing earlier than the 5th century, which would indicate that it was not until that date that Cádiz became a large and permanent base for the exploitation of trading opportunities in the west.

Trading contacts with the Greek world had been substantial from the earliest period of Phoenician colonization, in spite of the intermittent wars with the Greeks of Sicily. Pottery from Corinth, Athens, Ionia, Rhodes, and other Greek centres has been found at Carthage, Utica, and many other sites, as well as imports from Phoenicia itself and from Egypt. It is known that Selinus, a Greek city in Sicily, grew wealthy from trade with Carthage, probably in foodstuffs, before Carthage enlarged its Sicilian territory. During the 5th century there appears to have been a decline in imports from the Greek world. One factor that may have inhibited trade was the lack of a Carthaginian coinage before the early 4th century, though most important Greek states had had their own coinages for at least a century before that. Carthaginian merchants, however, did not cease to frequent Greek ports, and a number of them were established at Syracuse in 398. From that date, economic contacts with advanced states seem to have revived, especially after the conquests of Alexander the Great in the eastern Mediterranean created a new market for the cheap Carthaginian manufactured goods. The Carthaginian merchant became a familiar figure in such economic centres of the Greek world as Athens and Delos, so much so that there were Greek comedies in which the central figure was the Carthaginian trader.

Revival of economic contacts

Wars outside Africa. Except in politically backward or thinly populated areas Carthage's foreign policy was nonexpansive. One major departure from this policy was a disaster: in 480 Carthage intervened in intercity struggles among the Greeks of Sicily and suffered a heavy defeat at Himera. After a long period of peace, it went in 410 to the help of Segesta, an ally in Sicily, and turned the war into one of revenge for the earlier defeat. After initial successes, including the destruction of Himera, a treaty confirmed Carthage's control of the west of the island. During the 4th century most of the region's wars were caused by the attempts of various rulers of Syracuse to drive the Carthaginians out of Sicily; three of these (398–392, 382–375, and 368) were with Dionysius the Elder of Syracuse. Most of the time the eastern limit of Carthaginian power in the island was recognized as the Halycus (Platani) River. The only occasion in which Carthage suffered directly (since its armies were largely mercenary) was in 310, when the ruler of Syracuse, Agathocles, under heavy pressure in Sicily, launched a daring invasion of Africa, the first experienced by Carthage. Over a period of three years he caused great devastation in Carthaginian territory in eastern Tunisia but in the end was defeated.

Treatment of subject peoples. Carthage was accused by its enemies in antiquity of oppressing and exacting excessive tribute from its subjects. There were, however, different categories of subject community, the most favoured being the original Phoenician settlements and the colonies of Carthage itself. There is little evidence of opposition among them to Carthaginian control. Similar institutions and laws may be attributed to a common cultural background rather than to an attempt to impose uniformity. Carthage exacted dues on imports and exports and levied troops and probably sailors. Carthaginian subjects of various nationalities in Sicily also received favourable treatment, at least in economic matters. Relatively free trade was allowed until the end of the 5th century, and a number of cities had their own coinage. In the 4th century, some Sicilian Greek states became subject to

Carthage, paying a tribute amounting apparently to one-tenth of their produce. It was the Libyans of the interior who suffered most, though few were reduced to slavery. During the First Punic War, Libyans are said to have had to pay one-half of their crops as tribute, and it is supposed that the normal exaction was a quarter, a burdensome imposition. They also were required to provide troops, and from the early 4th century they formed the largest single element in the Carthaginian army; it is unlikely that they received pay except in booty before the Punic Wars. The Carthaginians are said to have "admired not those governors who treated their subjects with moderation but those who exacted the greatest amount of supplies and treated the inhabitants most ruthlessly." This hostile judgment (by the Greek historian Polybius) was made in connection with the Libyans and a destructive revolt—one of a number known—that followed the first Punic War. In this revolt (241–237 BC), mercenaries, unpaid after the Carthaginian defeat in the First Punic War, revolted and for a while controlled much of Carthage's North African territory. It was fought with great atrocities on both sides, and the Libyans were among the most fervent of the rebels. They even issued coins on which the name Libyan appears (in Greek), which probably indicates a growing ethnic consciousness. Notwithstanding this relationship, Carthaginian civilization had profound effects on the material culture of the Libyans (see below).

Political and military institutions. Hereditary kingship prevailed in Phoenicia down to Hellenistic times, and Greek and Roman sources refer to kingship at Carthage. It appears to have been not hereditary but elective, though in practice one family, the Magonid, dominated in the 6th century. The power of the kingship was diminished during the 5th century, a development that has its parallels in the political evolution of Greek city-states and of Rome. Roman sources directly transcribe only one Carthaginian political term—*sufet*, etymologically the same as the Hebrew *shofet*, generally translated "judge" in the Old Testament but implying much more than merely judicial functions. At some stage, probably in the 4th century, the *sufets* became the political leaders of Carthage and other western Phoenician settlements. Two *sufets* were elected annually by the citizen body, but all were from the wealthy classes. Real power rested with an oligarchy of the wealthiest citizens, who were life members of a council of state and decided all important matters unless there was serious disagreement with the *sufets*. A panel of judges chosen from among its members had obscure but formidable powers of control over all organs of government.

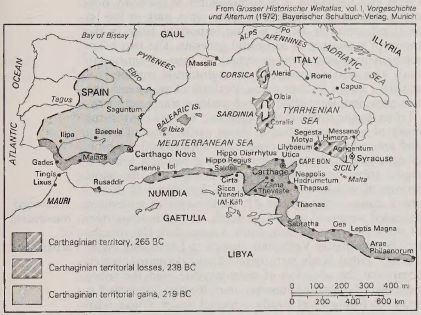
Carthaginian magistrates

During the 6th and 5th centuries, most military commands were held by kings, but later the generalship was apparently dissociated from civil office. Even in the time of the kings, military authority appears to have been conferred upon the kings only for specific campaigns or in emergencies. The generals are said to have been regarded as potential overthrowers of the legal government, but in fact there is no record of any army commander's having attempted a coup d'état.

Up to the 6th century, the armies of Carthage were apparently citizen levies similar to those of all city-states of the early classical period. But Carthage was too small to provide for the defense of widely scattered settlements, and it turned increasingly to mercenaries, officered by Carthaginians, with citizen contingents appearing only occasionally. Libyans were considered particularly suitable for light infantry, the inhabitants of the later Numidia and Mauretania for light cavalry; Iberians and Celtiberians from Spain were used in both capacities. In the 4th century the Carthaginians also hired Gauls, Campanians, and even Greeks. The disadvantages of mercenary armies were more than outweighed by the fact that Carthage could never have stood the losses incurred in a whole series of wars in Sicily and elsewhere. Very little is known about the manning of the Carthaginian fleet; technically, it was not overwhelmingly superior to those of the Greeks, but it was larger and had the benefit of experienced sailors from Carthage's maritime settlements.

The city. The Romans completely destroyed Carthage in 146 BC and a century later built a new city on the site, so that little is known of the physical appearance of the Phoenician city. The ancient artificial harbour—the Cothon—is represented today by two lagoons north of the bay of al-Karm (el-Kram). In the 3rd century BC it had two parts, the outer rectangular part being for merchant shipping, the interior, circular division being reserved for warships; sheds and quays were available for 220 warships. The harbour's small size probably means that it was used chiefly in winter when navigation almost ceased. The city walls were of great strength and 22 miles (35 kilometres) in length; the most vulnerable section, across the isthmus, was more than 40 feet high and 30 feet thick. The citadel on the hill called Byrsa was also fortified. Between Byrsa and the port was the heart of the city: its marketplace, council house, and temples. In appearance it may have been not dissimilar to towns in the eastern Mediterranean or Persian Gulf before the impact of modern civilization, with narrow winding streets and houses up to six stories high. The exterior walls were blank except for a solitary street door, but they enclosed courtyards. A figure of 700,000 for the city population is given by the geographer Strabo, but this probably included the population of the Cap Bon peninsula. A more reasonable figure could be about 400,000, including slaves, a size similar to that of Athens.

Physical appearance of Carthage



Religion and culture. The Carthaginians were notorious in antiquity for the intensity of their religious beliefs, which they retained to the end of their independence and which in turn influenced the religion of the Libyans. The chief deity was Baal Hammon, the community's divine lord and protector, who was identified by the Greeks with Cronus and by the Romans with Saturn. During the 5th century a goddess named Tanit came to be widely worshiped and represented in art. It is possible that her name is Libyan and that her popularity was connected with the acquisition of land in the interior, as she is associated with symbols of fertility. These two overshadow other deities such as Melqart, principal deity of Tyre, identified with Heracles, and Eshmoun, identified with Asclepius. Human sacrifice was the element in Carthaginian religion most criticized; it persisted in Africa much longer than in Phoenicia, probably into the 3rd century. The child victims were sacrificed to Baal (not to Moloch, an interpretation based on a misunderstanding of the texts) and the burned bones buried in urns under stone markers, or stelae. At Carthage thousands of such urns have been found in the "Sanctuary of Tanit," and similar burials have been discovered at Hadrumetum, Cirta, Motya, Calaris, Nora, and Sulcis. (For illustration, see MIDDLE EASTERN RELIGIONS, ANCIENT: *Religious practices and institutions.*) Carthaginian religion appears to have taught the weakness of human beings in the face of the overwhelming and capricious power of the gods. The great majority of Carthaginian personal names, unlike those of Greece and Rome, were of religious significance—*e.g.*, Hannibal, "Favoured by Baal," or Hamilcar, "Favoured by Melqart."

In comparison with the extent of its power and influence, the artistic and intellectual achievements of Carthage were small. What limited remains of buildings survive—mostly in North Africa and Sardinia—are utilitarian and uninspired. In the minor arts—pottery, jewelry, metalwork, objects in terra-cotta, and the thousands of carvings on stelae—a similar lack of inspiration may be felt. The influence of Phoenician, Egyptian, and Greek artistic traditions can be observed, but they failed to stimulate as they did, for example, in Etruria. There is no evidence that Greek philosophy and literature made much impact, though certainly many Carthaginians in the city's later history knew Greek and there were libraries in the city. One written work is known, a treatise on agriculture by a certain Mago, but this may have been based on Hellenistic models. On the whole, the Carthaginians adhered to traditional modes of thought, which no doubt gave them a sense of solidarity amid more numerous and hostile peoples. Their fanatical patriotism enabled them to offer a more prolonged resistance to Rome than any other power. Their influence on North African history was, in the first place, to bring it into the mainstream of the advancing civilization of the Mediterranean world; more particularly, it introduced

Carthaginian artistic and intellectual achievements

into North Africa advanced techniques leading to agricultural progress, which implied in turn a change by many Libyans from a seminomadic to a stable way of life, and the possibilities of urbanization, which were fully realized in the Roman period.

Carthage and Rome. In the 3rd and 2nd centuries BC, Carthage was weakened and finally destroyed by Rome in the three Punic Wars. Treaties between Carthage and Rome had been made in 508, 348, and 279, and for a long period the two powers had no conflicting interests. But by the 3rd century Rome dominated all southern Italy and thus approached the Carthaginian sphere in Sicily. In 264 Rome accepted the submission of Messana (Messina), though this state had previously had a Carthaginian garrison, partly because of exaggerated fears of a possible Carthaginian threat to Italy and partly because of hopes of gain in Sicily. For Carthage, a Roman foothold in Sicily would upset the traditional balance of power on the island. The ensuing First Punic War, which lasted until 241, was very costly in human life, with losses of tens of thousands being recorded in some naval engagements. Contrary to expectation, the Carthaginian fleet was worsted on several occasions by the newly built Roman; on land the Romans failed to drive the Carthaginians out of Sicily, and a Roman invasion of Tunisia ended in catastrophe. Carthage made peace after a final naval defeat off the Aegates (Egadi) Islands, surrendering its hold on Sicily. Sardinia and Corsica fell to Rome in 238.

Carthaginian Empire.

In response to the defeat, Carthage, under the leadership of Hamilcar Barca and his successors (usually described as the Barcid family), set about establishing a new empire in Spain. The object appears to have been to exploit the mineral wealth directly rather than through intermediaries and to mobilize the manpower of much of Spain into an army that could match that of Rome. Hamilcar and his son-in-law Hasdrubal built up an army of more than 50,000 Spanish infantry and occupied half of the Iberian Peninsula. Finally, in 219, Hannibal, Hamilcar's son, ignored Roman threats designed to prevent the consolidation or extension of the new empire. His invasion of Italy and the crushing defeats he inflicted on the Romans at Lake Trasimene (217) and Cannae (216) were the gravest danger Rome had ever faced. The majority of Rome's allies and subjects in Italy remained loyal, however, and Hannibal found increasing difficulty in getting supplies and reinforcements. After clearing Spain of the Carthaginians (209–206), Scipio Africanus landed near Utica in 204 with a Roman army. In 203 Hannibal was recalled from Italy; but he was defeated by Scipio at the Battle of Zama (in the vicinity of present-day Sāqiyat Sīdī Yūsuf, in Tunisia) in 202. Carthage made peace soon afterward, surrendering its fleet, its overseas possessions, and some of its African territory. During the next 50 years it retained some measure of prosperity, although frequently under pressure from the Numidians under King Masinissa. From 155 irrational fears of a Carthaginian revival were stimulated at Rome by Cato the Elder, and in 149, on flimsy pretexts, the Carthaginians were forced to choose between evacuating their city and settling inland or a doomed resistance. They chose the latter, and, after a three-year siege, the city was destroyed and its site ceremonially cursed by the younger Scipio.

New empire in Spain

Destruction of Carthage

The Greeks in Cyrenaica. The natural contacts of Cyrenaica were northward with Crete and the Aegean world. In the late 12th century BC Mycenaean Greek Sea Peoples landing in Cyrenaica armed the Libyans and with them attempted an unsuccessful invasion of Egypt. Cyrenaica's coast was visited by Cretan fishermen in the 7th century, and the Greeks became aware that it was the only area in North Africa still available for colonization. A severe overpopulation on the small Cyclades island of Thera (Thíra Santorini) led to the foundation of Cyrene (*c.* 630) on a site within easy reach of the sea, well watered, and in the fertile foothills of the Akhḍar Mountains. The founder's name was, or was changed to, Battus, a Libyan word meaning king. For some time friendly relations existed with the local peoples, and there was more intermarriage with non-Greek women than was usual in Greek colonies. Later, when more colonists were attracted by Cyrene's increasing prosperity, hostilities occurred in which the settlers were successful. Cyrene also repulsed an invasion by the Egyptians (570) but in 525 submitted to Persia. Meanwhile, Cyrene had established other Greek cities in the area—Barce (al-Marj), Taucheira (Tūkrah), and Euhesperides (Banghāzī), all of which were independent of their founding city. During the 6th century, Cyrene rivaled the majority of other Greek cities in its wealth, manifested in part by substantial temple building. Prosperity was based on grain, fruit, horses, and, above all, an apparently extinct species of the medicinal plant *Silphium.*

Constitutional changes in Cyrene

The dynasty of Battus ended about 440 BC with the establishment of a democratic constitution like that of Athens, and the general prosperity of Cyrenaica continued through the 4th century in spite of some political troubles. Cyrenaica submitted to Alexander the Great in the late 4th century and subsequently became subject to the Ptolemies of Egypt. The cities, nevertheless, enjoyed a good deal of freedom in running their own affairs. The constitution of Cyrene was elaborated as a fairly liberal oligarchy, with a citizen body of 10,000 and two councils. During the 3rd century a federal constitution for all the Cyrenaican cities was introduced. Apollonia, the port of Cyrene, became a city in its own right; Euhesperides was refounded as Berenice, and a new city, Ptolemais (Ṭulmaythah), was founded, while Barce declined; the term Pentapolis came to be used of the five cities Apollonia, Cyrene, Ptolemais, Taucheira, and Berenice. In 96 BC Ptolemy Apion bequeathed Cyrenaica to Rome, which annexed the royal estates but left the cities free. Disorders led Rome to create a regular province out of Cyrenaica in 74 BC, to which Crete was added seven years later. After Mark Antony temporarily granted the province to his daughter Cleopatra Selene, Augustus reestablished it, together with Crete, as a senatorial province.

The rise and decline of native kingdoms. Between the destruction of Carthage and the establishment of effective Roman control over the Maghrib there was a period that saw a brief flourishing of native kingdoms. Amid the shifting tribal nomenclature used in the sources of various periods, two main groups of relatively sedentary tribes may be distinguished: the Mauri, living between the Atlantic and the Moulouya or perhaps the Chelif rivers, who gave their name to Mauretania; and the Numidae, after whom Numidia was named, in the area to the west of that formerly controlled by Carthage. A third group, the Gaetuli, was a largely nomadic people of the desert and its fringe. The various tribes first emerge into history in the late 3rd century BC, after a period of social evolution resulting from contact with Carthaginian civilization. This is difficult to trace, as Carthaginian products were scarce in the interior of the Maghrib before the 2nd century BC, but the large tumuli at Mzora, Sīdī Sulaymān, Souk el-Gour, and the Medracen, apparently royal tombs of the 4th and 3rd centuries BC, testify to a developing economy

and society. No doubt service in the Carthaginian mercenary armies was a major stimulus to change.

King Masinissa of Numidia

This was most noticeable in Numidia and reached a high point under Masinissa. The son of a chief of the Massyli, a tribe dominating the area between Carthaginian territory and the Ampsaga River (Wadi al-Kabir), he had been brought up at Carthage and was 20 years old at the outbreak of the Second Punic War. At first his tribe was at variance with Carthage, but in 213 BC it became reconciled when its powerful western neighbours, the Masaesyli, under Syphax, deserted Carthage. From 213 to 207 BC Masinissa commanded Numidian cavalry in Spain for the Carthaginians against Rome. On Rome's victory at Ilipa in 206, he returned to Africa where Syphax, now reconciled with Carthage, had occupied some of his tribal territory, including Cirta (Constantine), and his own claims to succession to the chieftainship were disputed. When the Romans landed in Africa in 204, Masinissa rendered them invaluable assistance. Recognized by the Romans as king, he annexed the eastern part of Syphax' kingdom and reigned with success until 148 BC. The Greek geographer Strabo said that he "turned the nomads into a nation of farmers." This is exaggerated, since cereal culture had long been established in parts of Numidia, yet there is no doubt that the area of grain production was much enlarged. This was achieved by deliberate encouragement of Carthaginian civilization. Along with new techniques, Carthaginian language, religion, and art penetrated rapidly inland, and Masinissa's capital, Cirta, took on the aspects of a Carthaginian city; incipient urbanization of a number of Libyan villages is also possible. Masinissa issued copper, bronze, and lead coinage for local use, as did some of the Carthaginian coastal towns under his rule.

On Masinissa's death in 148, his kingdom was divided among his three sons, possibly on the insistence of the Romans, who did not, however, prevent its reunification under Micipsa (148–118 BC). The progress begun under Masinissa continued as refugees from the destruction of Carthage fled to Numidia. Meanwhile, the Romans had formed a province of the area of Tunisia northeast of a line from Thabraca to Thaenae but showed little interest in exploiting its wealth. The attempt by the Roman reformer Gaius Gracchus in 122 BC to found a colony on the site of Carthage failed, though individual colonists who had taken up allotments remained. When Micipsa died, another division of Numidia among three rulers took place, in which Jugurtha (118–105 BC) emerged supreme. He might have been recognized by Rome, but he provoked war when he killed some Italian merchants who were helping a rival to defend Cirta. After some successes due to the incompetence of Roman generals, Jugurtha was surrendered by Bocchus I, king of Mauretania. The kingdom was again reconstituted under other descendants of Masinissa. The boundaries of the Roman province were slightly enlarged in the area of the upper Majardah valley, where veterans of the army of Gaius Marius received lands. During the next 50 years there was further immigration by individual Roman settlers and merchants but no deliberate state action. The last relatively formidable king of Numidia was Juba I (*c.* 60–46 BC), who supported the Pompeian side in the Roman civil war between Pompey and Julius Caesar.

Formation of Africa Nova

The kingdom fell in 46 BC at the Battle of Thapsus. A new province, Africa Nova, was formed from the most developed part of the old Numidian kingdom east of the Ampsaga; it was subsequently (before 27 BC) amalgamated with the original province of Africa by the emperor Augustus. In 33 BC Bocchus II of Mauretania died, bequeathing his kingdom to Rome, but Augustus was unwilling to accept responsibility for so large and relatively backward an area. In 25 BC he installed Juba II, son of Juba I, as king; he ruled until his death about AD 24. He was married to Cleopatra Selene, daughter of Mark Antony and Cleopatra, and under them Iol, renamed Caesarea (Cherchell), and also Volubilis, near Fez (Fès), a secondary capital of the rulers of Mauretania, became centres of late Hellenistic culture. Juba himself was a prolific writer in Greek on a number of subjects, including history and geography. His son Ptolemy succeeded as king but was executed for unknown reasons by the Roman emperor Caligula in AD 40. A brief revolt followed but was easily suppressed, and the kingdom was divided into two provinces, Mauretania Caesariensis, with its capital at Caesarea, and Mauretania Tingitana, with its capital at Tingis (Tangier).

Roman North Africa. *Administration and defense.* For more than a century from its acquisition in 146 BC, the small Roman province of Africa (roughly corresponding to modern Tunisia) was governed from Utica by a minor Roman official, but changes were made by the emperor Augustus, reflecting the growing importance of the area. The governor was thenceforward a proconsul residing at Carthage, after its refounding by Augustus as a Roman Carthage, after its refounding by Augustus as a Roman colony, and responsible for the whole territory from the Ampsaga in the west to the border of Cyrenaica. The proconsul also commanded the army of Africa and was one of the very few provincial governors in command of an army and yet formally responsible to the Senate rather than to the emperor. This anomaly was removed in AD 39 when Gaius entrusted the army to a *legatus Augusti* of praetorian rank. Although the province was not formally divided until 196, the army commander was de facto in charge of the area later known as the province of Numidia and also of the military area in southern Tunisia and along the Libyan Desert. The proconsulship was normally held for only one year; like the proconsulship of Asia, it was reserved for former consuls and ranked high in the administrative hierarchy. In the 1st century it was held by several men who subsequently became emperor—*e.g.*, Galba and Vespasian. The commanders of the army normally held the post for two or three years, and, in the 1st and 2nd centuries AD, it was an important stage in the career of a number of successful generals. The two Mauretanian provinces were governed by men of equestrian rank who also commanded the substantial numbers of auxiliary troops in their areas. In times of emergency the two provinces were often united under a single authority.

Tribes on the fringe of the desert and beyond constituted more of a nuisance than a threat as the area of urban and semiurban settlement gradually approached the limit of cultivable land. A number of minor conflicts with nomadic tribes are recorded in the 1st century, the most serious of which was the revolt of Tacfarinas in southern Tunisia, suppressed in 23. As the area of settlement extended westward as well as south, so the headquarters of the legion moved also: from Ammaedara (Haydarah) to Theveste under Vespasian, thence to Lambaesis under Trajan. Tribal lands were reduced and delimited, which compelled the adoption of sedentary life, and the tribes were placed under the supervision of Roman "prefects." A southern frontier was finally achieved under Trajan with the encirclement of the Aurès and Nemencha mountains and the creation of a line of forts from Vescera (Biskra) to Ad Majores (Besseriani). The mountains were penetrated during the next generation but were never developed or Romanized. During the 2nd century, stretches of continuous wall and ditch—the *fossatum Africae*—in some areas provided further control over movement and also marked the division between the settled and nomadic ways of life. To the southwest of the Aurès a fortified zone completed the frontier defensive system, or limes, which extended for a while as far as Castellum Dimmidi (Messad), the most southerly fort in Roman Algeria yet identified. South of Leptis Magna (Labdah) in Libya, forts on the trans-Saharan route ultimately reached as far as Cydamus (Ghadāmis).

Westward movement of settlement

In the Mauretanias the problem was more difficult, because of the rugged nature of the country and the distances involved. The encirclement of mountainous areas, a policy followed in the Aurès, was again pursued in the Kabylie ranges and the Ouarsenis. The area round Sitifis (Sétif) was successfully settled and developed in the 2nd century, but farther west the impact of Rome was for long limited to coastal towns and the main military roads. The most important of these roads ran from Zarai (Zraïa) to Auzia (Aumale) and then to the valley of the Chelif. Subsequently, the frontier ran south of the Ouarsenis as far as Pomaria (Tlemcen). West of this area, it is doubtful whether a permanent road connected the two Mauretanias, sea communication being the rule. In Tingitana,

Roman control extended as far as a line roughly from Meknès to Rabat, including Volubilis. Evidence attests to periodic discussions between Roman governors and local chieftains outside Roman control, confirming peaceful relations. However, the tribes of the Rif Mountains must have lived in virtual independence, and they were probably responsible for a number of wars recorded in Mauretania under Domitian, Trajan, Antonius Pius (which lasted six years), and others in the 3rd century. They did little or no damage to the urbanized areas and never necessitated a permanent increase in the African garrison. The defense of the North African provinces was far less a problem than that of those on the northern periphery of the empire. For Numidia and the military district in the south of Tunisia and Libya, about 13,000 men sufficed; the Mauretanias had auxiliary units only, totaling some 15,000. This may be contrasted with the position in Britain, where three legions and auxiliaries were required. From the middle of the 2nd century AD, the African garrison was largely recruited locally.

The growth of urban life. The most notable feature of the Roman period in North Africa was the development in Tunisia, northern Algeria, and some parts of Morocco of a flourishing urban civilization. This was due to control of nomadic and pastoral movements, which opened large areas of thinly settled but potentially rich land to consistent exploitation. In addition, there was the incipient urbanization of some parts owing to the Carthaginians and the ambitions of Libyan rulers such as Masinissa and, last, the settlement in Africa of Italian immigrants, who, though relatively few in comparison with the population as a whole, provided the impetus to expansion. Julius Caesar settled many veterans in colonies, mostly coastal towns, and, equally important, established a military adventurer named Publius Sittius along with many Italians at Cirta, beginning the Romanization of Numidia. Caesar planned to refound Carthage, and this was effected by Augustus. The number of his original settlers was 3,000, but the colony grew remarkably quickly because of its favourable geographic position in relation to contact with Rome and Italy. A number of other colonies were founded in the interior of Tunisia and at widely separated places on the Mauretanian coasts. There was also immigration from Italy by private individuals at this time. Colonial foundations of veterans in Mauretania occurred under Claudius (*e.g.*, Tingis, Caesarea, Tipasa). Cuicul (Jamīlah) and Sitifis were founded by Nerva, and Thamugadi and a number of places nearby, in the area north of the Aurès, by Trajan. The army was a potent vehicle in the spread of Roman civilization and played a major part in the urbanization of the frontier regions. On limited evidence, a total of some 80,000 immigrants from Rome and Italy into the Maghrib in this period has been suggested.

Italian settlers

Though at first inferior to the Roman towns, native communities enjoyed the local autonomy that was the hallmark of Roman administration. Between 400 and 500 such communities were recognized, the majority of them villages or small tribal factions. Many, however, advanced in wealth and standing to rival the Roman colonies, acquiring the grant of Roman citizenship, which put the seal of imperial approval on the prosperity, stability, and cultural evolution of developing communities. Naturally, the earliest to show signs of increasing prosperity were the surviving Carthaginian settlements on the coast and places—particularly in the Majardah valley—where the Libyan population had been much influenced by Carthaginian culture and which now also had Italian immigrants. Leptis Magna and Hadrumetum received Roman citizenship and the status of a colony from Trajan, and Thubursicu Numidarum (Khemissa) and Calama (Guelma) probably the rank of municipality. But it was under Hadrian, the first emperor to visit Africa, that the flood tide of such grants occurred; Utica, Bulla Regia (Hammam Derradji), Lares (Lorbeus), Thaenae, and Zama achieved colonial rank, and the process continued throughout the 2nd century. Finally, Septimius Severus, who originated from a rich family of Leptis Magna, and of largely mixed descent, became emperor in AD 193 and showed a great deal of favour to his native land.

In the Maghrib, Roman rule was not superimposed upon established civic aristocracies, as in the Hellenized provinces of Asia Minor, nor upon strongly based tribal aristocracies, as in Celtic Gaul. Roman administration and the development of urban society in general depended, apart from immigrants, on the local leadership of small clan and tribal units and on the activity of individuals. In the 1st century AD there were a few very large estates owned by absentee Roman senators, most of which were subsequently absorbed into the extensive imperial estate in Africa. The later pattern was of landowning on a more moderate—though still substantial—scale by residents, both immigrant and indigenous. Many landowners made their homes in the towns and formed a local municipal leadership. Small independent landowners also existed, but the great majority of the inhabitants were tenant farmers (coloni). A significant portion of these farmers worked on a sharecropping basis and with labour obligations to their landlords. The number of slave workers was probably smaller than in Italy.

Growth of new social elite

Many of the wealthier Africans entered the imperial administration. The first African consul held office in the reign of Vespasian; at the beginning of the 3rd century, men of African origin held one-sixth of all the posts in the equestrian grade of the administration and also constituted the largest group of provincials in the Senate. It is uncertain what proportion were of native Libyan or mixed origin, but in the 2nd century they were certainly the majority.

During the 2nd and early 3rd centuries the wealthy classes in the towns expended vast sums on their communities in gifts of public buildings such as theatres, baths, and temples, as well as statues, public feasts, and distributions of money. This was a general phenomenon throughout the Roman Empire, as members of local elites competed for fame and prestige among their fellow citizens, but it is particularly well attested in Africa.

Economy. The density of the towns in no way implies the predominance of trade or industry; all but a few were residences of both landowners and peasants, and their prosperity depended on agriculture. By the 1st century AD African exports of grain provided two-thirds of the needs of the city of Rome. Some of this, for distribution by the emperors to the urban proletariat, came from the imperial estates and from taxes, but much went on to the open market. An estimate of annual grain production in Roman Africa has been made of more than a million tons, of which 25 percent was exported. Areas of grain production were the Cape Bon peninsula, the Miliana and Majardah valleys, and tracts of relatively level land north of a line from Sitifis to Madauros (M'Daourouch). Cereal crops were the most important in these areas, but fruit, figs, grapes, and beans also were produced.

The production of olive oil became almost as important as cereals by the 2nd century AD, particularly in southern Tunisia and along the northern slopes of the Aurès and Bou Taleb mountains. By the 4th century Africa exported oil to all parts of the empire. Successful cultivation of olives demanded careful management of available water, and the archaeological evidence indicates that much attention was paid to irrigation in the Roman period.

Livestock was an important part of the economy of Roman Africa, though direct evidence is slight. African horses were used in racing and no doubt also in the Roman cavalry. Cattle, sheep, pigs, goats, and mules were also raised. Africa was the major source of the wild animals for shows in Rome and other major cities of the empire, in particular panthers, lions, elephants, and monkeys. Fishing, which had been developed along the coast as far as the Atlantic in the Carthaginian period, continued to flourish. Timber, from the forests along part of the north coast, and marble, the most important North African source being Simitthu (Shimṭū), were also exported.

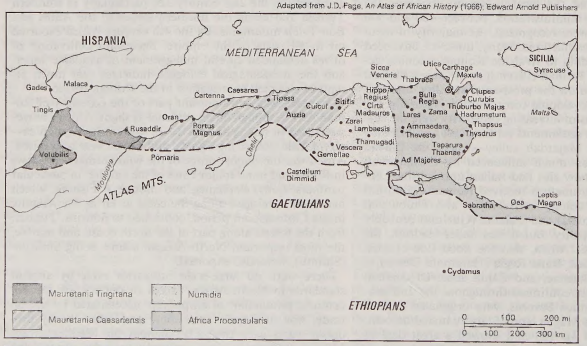
There were no large-scale industries even by ancient standards in North Africa, except in pottery. By the 4th century, production of amphorae, necessitated by the oil trade, was substantial, and these and other locally produced wares were traded throughout the Mediterranean. Mosaic pavements were extremely popular among the

wealthy throughout North Africa, and well over 2,000 have been discovered, with enormous variations in quality. The majority were made by local craftsmen, though some of the designs originated elsewhere. It is also clear that the building trades were major consumers of both skilled and unskilled labour.

Population increases

Prosperity undoubtedly led to a rise in the population of the Maghrib in the first two centuries AD; in the absence of reliable statistics, population estimates have varied between 4,000,000 and 8,000,000 (the latter being also the population about the beginning of the 20th century). The most recent study proposed about 6,500,000, of whom about 2,500,000 were in present Tunisia. Some 40 percent of the latter (perhaps more) lived in the towns. Of these, Carthage was in a class of its own, reaching at least 250,000. The next largest was Leptis Magna (80,000), followed by Hadrumetum, Thysdrus (el-Djem), Hippo Regius, and Cirta, with between 20,000 and 30,000 each. Many towns in close proximity to each other, especially in the Majardah valley, averaged between 5,000 and 10,000.

The road system in Roman Africa was the most complete of any western province; a total of some 12,500 miles has been supposed. In origin most roads were military but were open to commerce, and a number of minor roads linking towns off the main routes were built by the local communities. The main arteries were Carthage to Theveste; Carthage to Cirta through Sicca Veneria; Theveste to Tacapae through Capsa; Theveste to Lambaesis; Cirta to Sitifis; Cirta to Rusicade; and Cirta to Hippo Regius. Carthage handled by far the greatest volume of overseas official traffic and trade, being the natural port for the wealthiest area of North Africa. Nevertheless, most of the ports originally founded by Phoenicians and Carthaginians expanded during the Roman period; in view of the high costs of land transport, it was natural that agricultural products would go to the nearest port for shipment.



Later Roman Empire. The whole Roman Empire underwent a military and political crisis between the death of Severus Alexander (235) and the accession of Diocletian (284), resulting from serious attacks from outside on the empire's northern and eastern frontiers and from a series of coups d'état and civil wars. Africa suffered less than most parts of the empire, though there was an unsuccessful revolt by landowners in AD 238 against the fiscal policies of the emperor Maximinus Thrax, which ended in widespread pillage. There were tribal revolts in the Mauretanian mountains in 253–254, 260, and 288, and the situation finally brought a visit from the emperor Maximian in 297–298. The revolts had little effect on the urbanized areas, but the towns were injured by economic difficulties and inflation, and building activity almost ceased. There was a return of confidence under Diocletian (284–305), Constantine (312–337), and later emperors. Administrative changes introduced at this time included the division of the province of Africa into three separate provinces: Tripolitania (capital Leptis Magna), covering the western part of Libya; Byzacena, covering southern Tunisia and governed from Hadrumetum; and the northern part of Tunisia, which retained the name Africa. In addition, the eastern part of Mauretania Caesariensis became a separate province (capital Sitifis). In the far west, the Romans gave up much of Mauretania Tingitana, including the important town of Volubilis, apparently because of pressure from the tribe of the Baquates. In the general reorganization of the Roman army by Diocletian and Constantine, the field army (*comitatenses*) in Africa, numbering on paper some 21,000 men, was put under a new commander, the *comes Africae,* independent of the provincial governors. Only the governors of Tripolitania and of Mauretania Caesariensis also had troops at their disposal, but these were second-line soldiers, or *limitanei.* The whole frontier region along the desert and mountain fringes was divided into sectors and garrisoned by *limitanei.* The latter were locally recruited and closely identified with the farming population of their areas. The Tripolitanian Plateau, which was increasingly exposed to attacks by the nomadic Austuriani, is notable for having a large number of fortified farms.

Reforms under Diocletian

Africa, like the rest of the empire, experienced the economic difficulties and governmental pressures that were a feature of the later Roman Empire. The power of the landowners increased at the expense of their tenants and of smaller farmers, both of whom the imperial government sought to bind to the soil in a state of quasi-serfdom. In the cities, the tasks of local government that had earlier been eagerly undertaken by the wealthy became burdensome, and again the imperial government sought to make them compulsory and hereditary, while the councillors themselves sought by any means to enter the imperial administration or professions that provided immunity. The process is well attested in Africa. Nevertheless, the view that the 4th century saw a general decline in urban life throughout the empire must be modified, especially in the case of Africa, where the cities and towns withstood the pressures better than elsewhere and where some towns, Timgad for example, seem to have increased in population. Timgad's growth was doubtlessly due to its relative immunity from damage in civil and external wars and to a solid base of agricultural prosperity.

Christianity and the Donatist controversy. Christianity grew much more rapidly in Africa than in any other western province. It was firmly established in Carthage and other Tunisian towns by the 3rd century and had produced its own local martyrs and an outstanding apologist in Tertullian (*c.* 160–240). During the next 50 years there was a remarkable expansion; more than 80 bishops attended a council at Carthage in 256, some from the distant frontier regions of Numidia. Cyprian, bishop of Carthage from 248 until his martyrdom in 258, was another figure

Roman Africa in the 3rd century AD.

whose writing, like that of Tertullian, was of lasting influence on Latin Christianity. During the next half-century it spread extensively in Numidia (at least 70 bishops known in 312). The reasons for its exceptionally rapid growth are disputed. In northern Tunisia, urban communities provided a similar social and economic environment to that in which Christianity had first spread in Anatolia and Syria, and much the same can be said about smaller communities in which early Christianity can be identified. It has been held that the intermingling of religious currents of Libyan, Carthaginian, and Roman origin tended toward monotheism, but even if this were true, which is debatable, pagan monotheism was not a necessary stage toward the adoption of Christianity for more than a few. It does, however, appear that African Christianity always included a vigorous and fanatical element that must have had its effect in spreading the new religion, even though there is little evidence of positive missionary efforts.

Christians were still a minority at the end of the 3rd century in all levels of society, but they were in a good position to benefit from Constantine's adoption of the religion and his grants of various privileges to the clergy.

Beginning of schism

At this time (AD 313), a division occurred among the African Christians that lasted more than a century. Some Numidian bishops objected to the choice of Caecilian as the new bishop of Carthage, alleging that his ordination had been performed by a bishop who had weakened during Diocletian's persecution of the church and hence was invalid. They consecrated a rival bishop, and, when he died, another named Donatus, who gave his name to the ensuing schism. The churches in numerous communities, especially in Numidia, followed Donatus from the start and claimed that they alone constituted the true church of the martyrs, who were objects of particularly enthusiastic veneration among African Christians. Among Christians outside Africa, however, Caecilian was universally recognized as bishop of Carthage, and the emperor Constantine, when appealed to by the Donatists, followed the decisions of non-African church councils, recognizing Caecilian and his followers as the true church and hence as recipients of imperial favour. Confiscation of Donatist churches led to some deaths, the victims being honoured as martyrs, but in 321 Constantine rejected further pressure and the Donatists continued to increase rapidly in numbers. For the rest of the century they probably made up half of the Christians in North Africa. They were strongest in Numidia and Mauretania Sitifensis, and the antischismatics in the proconsular province; the position in the Mauretanias was more even, but Christianity did not spread rapidly there until the 5th century. In 347 the emperor Constans exiled a number of Donatist bishops and took repressive measures against the *circumcelliones,* seasonal farm workers who were particularly enthusiastic Donatists. But in 362 Julian the Apostate allowed the return of the exiles, who were welcomed with enthusiasm, and the movement proved as strong as ever. Some Donatists appear to have been associated with the revolt of a Mauretanian chieftain, Firmus, and in 377 the first of a series of general laws proscribing Donatism was issued. Nevertheless, these laws were enforced only sporadically, partly because provincial governors and many local magistrates were still pagan and, at a time of growing weakness in the imperial government, were inclined to ignore instructions they found unwelcome. Donatism was further supported by Gildo, brother of Firmus and *comes Africae* 387–397. Then Augustine of Hippo Regius applied his enormous powers of leadership and persuasion in stimulating resolute action, evolving at the same time a theory of the right of orthodox Christian rulers to use force against schismatics and heretics. In 411 an imperial commission summoned a conference at Carthage to establish religious unity; the Donatists had to obey, though the decision against them was a foregone conclusion. The laws that followed their condemnation were more generally enforced and, though there was some resistance, broke the schism as a powerful movement; some communities still existed in the 6th century, however.

Much controversy surrounds the interpretation of the significance of Donatism; an important view considers it in some sense a national or social movement. It is said to have been particularly associated with the rural population of less Romanized areas and with the poorer classes in the towns, whereas orthodox Christianity was the religion of the Romanized upper classes. The identification of the imperial government with these Christians would have intensified the strength of the movement, and the *circumcelliones'* violence, moreover, could be considered a form of incipient peasant revolt. Thus the movement is claimed as analogous to Monophysitism in Egypt and Syria, which produced a vernacular literature and a passive rejection of Greco-Roman culture. The hostility of the Donatists to the existing society was typified by Donatus' remark: "What has the emperor to do with the church?" Against this view it may be said that Donatism in the un-Romanized tribal areas was certainly weak, and the relationship of the sect with Firmus and Gildo was of little importance. In Numidia it was at least as strong in the towns as in the rural areas, and in any case the distinction between the two can be exaggerated. The entire controversy was conducted in Latin, and no vernacular literature was produced; in fact, until the time of Augustine, most of the educated class, of the same social background as Augustine himself and fully imbued with Roman tradition, were Donatists if they were not pagan. It was the reluctance of the landowners to have their peasants disturbed, and the negligence of many provincial governors (both attacked by Augustine), that long protected the Donatists. Lastly, in spite of the remark attributed to Donatus, there is no evidence that the movement attacked the imperial system as a whole, as opposed to individual emperors and officials, and it made full use of its many opportunities to defend itself at law both against the other Christians and against divisions in its own ranks.

Donatism as a national movement

Nevertheless, although it is difficult to sustain the view that Donatism, especially in Numidia, represented in some way a resurgence of local pre-Roman culture, or the speculative, though intriguing, notion that something similar led to the emergence of heretical movements of Islām in the same areas, Donatism certainly appealed to deep-seated traditions of African Christianity. Its fanatical devotion to the memory of martyrs, its doctrinal conservatism and total refusal to compromise on its claim to be the true church while its opponents were contaminated by the stain of weakness in the persecutions, were fully in line with the heroic days of Tertullian and Cyprian.

Extent of Romanization. The question whether Roman civilization in the Maghrib was a superficial phenomenon affecting only a small minority of the population who were economically successful, or whether it had profound effects on a majority, is similarly disputed. A priori the former view may be supported by the fact that, whereas Gaul and Spain emerged from the Dark Ages with a language and religion derived from their Roman past, in the Maghrib both disappeared, arguably because they were superficial. It is not disputed that in the mountainous areas, such as the Aurès, Kabylie, and Atlas, native Libyan language and culture continued little affected by Roman civilization, though the majority appear to have been Christian by the 7th century; nor that Libyan and Carthaginian traditions survived in other areas and affected the modes of acceptance of Roman civilization. As regards language, the late form of Phoenician known as Neo-Punic was still spoken fairly widely in the 4th century—for example, in the hills near Hippo Regius. Inscriptions in the language and script occurred often at the beginning of the Roman period but are very rare after the end of the 1st century AD. An exception may be in Tripolitania, where a form of Neo-Punic was inscribed in Latin script perhaps as late as the 4th century. There was also a Libyan script known solely from funerary stelae and akin to the script of the present Tuareg; it was known in some sense over much of the Maghrib but may not have been used later than the 3rd century. On the other hand, there is no evidence that these languages were ever literary languages, and the inscriptions are negligible in number compared with those in Latin. It may also be observed that the areas in which Libyan inscriptions occur do not correspond with the later areas of Berber dialects. The Latin language unquestion-

Use of Latin language

ably became general through the whole Maghrib, though to a limited extent in the mountains; it is impossible to define any precise social level at which it was unknown. There is a good deal to be said for the view that Christianity, whether Orthodox or Donatist, furthered the use of Latin among elements which up to that time had perhaps still not used it.

The Vandal conquest. The effect of the Donatist controversy on the economy and administration of the African provinces cannot be measured but was certainly profound. At the very moment of the effective victory of the African church, the rest of the Roman Empire was crumbling to ruin. In 406 the Rhine was crossed by Vandals, Alani, Suebi, and others who overran most of Gaul and Spain within the next few years. In 408 Alaric and the Visigoths invaded Italy and in 410 sacked Rome. Although the empire in the west survived for some time longer, the emperors were increasingly at the mercy of their barbarian generals. Meanwhile, large tracts of imperial territory were lost by the settlement of the invading tribes. Africa escaped for a while, though only death prevented Alaric from leading the Goths across the Mediterranean. The retention of Africa became ever more vital to the survival of what was left of imperial authority. In this situation the *comites Africae* were increasingly tempted to intrigue for their own advantage. One of them, Bonifacius, is said to have invited the Vandals, who at the time were occupying Andalusia, to his aid, but it is more likely that the Vandals were attracted to Africa by its wealth and needed no such formal excuse. Led by their king Gaiseric, the whole people, 80,000 in all, crossed into Africa in 429 and in the next year advanced with little opposition to Hippo Regius, which they took after a siege during which St. Augustine died. After defeating the imperial forces near Calama, they overran most of the country, though not all of the fortified cities. An agreement made in 435 allotted Numidia and Mauretania Sitifensis to the Vandals, but in 439 Gaiseric took and pillaged Carthage and the rest of the province of Africa. A further treaty with the imperial government (442) established the Vandals in Africa Proconsularis, Byzacena, Tripolitania, and Numidia as far west as Cirta.

Vandal impact on the economy

Although the Vandals were probably no more deliberately destructive than other German invaders (the notion of "vandalism" stems from the 18th century), their establishment had very adverse effects. The imperial authorities had to reduce the taxes of Mauretania by seven-eighths as a result of their devastation. Over much of northern Tunisia, landowners were expelled and the properties handed over to Vandals. Although the agricultural system remained based on the peasants, the expulsions had a serious effect on the towns with which the landowners had been connected. The Vandals, like other invading tribes except the Franks, were divided from their subjects by their Arian heresy. Although their persecution of Latin Christians was exaggerated by the latter, Vandal kings certainly exercised more pressure than others. This was no doubt in response to the vigour of African Christianity, which kept the loyalty even of those who had little to lose by the substitution of a Vandal for a Roman landlord.

Gaiseric was perhaps the most perceptive barbarian king of the 5th century in realizing the total weakness of the empire. He rejected the policy of formal alliance with it and from 455 used his large merchant fleet to dominate the western Mediterranean. Rome was sacked, the Balearics, Corsica, Sardinia, and part of Sicily were occupied, and the coasts of Dalmatia and Greece were plundered. Although there was no general cessation of trade, this activity accelerated the breakup of the economic unity of the western Mediterranean, already threatened by the creation of the other barbarian kingdoms. Gaiseric's successors were less formidable: Huneric (477–484) launched a general persecution on the Latin church, apparently from genuine religious fanaticism rather than for political reasons, but his successor adopted a milder policy. Under Thrasamund (496–523) there is evidence that many Vandals adopted Roman culture, but the tribe retained its identity until the Byzantine reconquest.

A significant development of the Vandal period was the emergence of independent kingdoms in the mountainous and desert areas, largely of Libyan character. They appeared first in the Mauretanias, where the Roman frontier, already drawn back under Diocletian, receded further under the Vandal kings. By the end of Vandal rule, independent kingdoms existed in the region of Altava (Lamoricière), in the Ouarsenis, and in the Hodna. After 480, towns to the north of the Aurès, such as Thamugadi, Bagai, and Theveste, were sacked by the inhabitants of another kingdom in the Aurès. All the names of the known chieftains are Libyan in character, though the survival of Romanized elements within some of the kingdoms is attested by the fact that epitaphs in Latin continued, by the use of Roman names, and even by the employment of a dating system based on the founding date of the Roman province of Mauretania. Finally, as a harbinger of a serious threat to settled life, whether Roman or Libyan, tribes that had retained a nomadic life on the borders of Cyrenaica and Tripolitania and caused much damage in the 4th century began to push westward and were already a serious threat to the southern parts of Byzacena by the end of Vandal rule.

The Byzantine period. North Africa held an important place in the emperor Justinian's scheme for reuniting the Roman Empire and destroying the Germanic kingdoms. His invasion was undertaken against the advice of his experts (an earlier attempt in 468 had failed disastrously), but his general Belisarius succeeded, though partly through the incompetence of the Vandals. He landed in 533 with only 16,000 men, and within a year the Vandal kingdom was destroyed. A new administrative structure was introduced, headed by a praetorian prefect with six subordinate governors for civil matters and a master of soldiers with four subordinate generals. It required some 12 years, however, to pacify Africa, owing partly to the resistance of the tribes in Mauretania to the reestablishment of an ordered government and partly to lack of support to the army in men and money, leading to frequent mutinies. A remarkable program of fortifications, many of which survive, was rapidly built under Belisarius' successor Solomon. Some were garrison forts in the frontier region, which again seems to have run, at least for a while, south of the Aurès, and then northward from Tubunae to Saldae. But many surviving towns in the interior were also equipped with substantial walls—*e.g.,* Thugga and Vaga (Bājah, Béja). After the death of Justinian (565) there were further difficulties with the Mauretanian tribes (the Mauri), but the most serious damage was done by the nomadic Louata from the Libyan Desert, who on several occasions penetrated far into Tunisia.

Administrative reorganization

Africa shows a number of examples of the massive help given by Justinian in the building, and particularly the decoration, of churches, and in the reestablishment of Christian orthodoxy, though this inevitably brought the persecution of surviving Donatists. Seriously weakened though it had been under the Vandals, some traces of the vigour of the African church remained when it led the opposition of the Western churches to the theological policies of emperors at Constantinople—*e.g.,* those of Justinian himself and also of Heraclius and Constans II immediately before the Arab invasions.

Little is known of the Byzantine period in the Maghrib after the death of Justinian. The power of the military element in the provinces grew, and between 585 and 591 a new official, the exarch, was introduced whose powers were almost viceregal. Economic conditions declined because of the increasing insecurity and also the notorious corruption and extortion of the administration, though whether this was worse in Africa than in other parts of the Byzantine Empire it is impossible to say. It is certain that the population of the towns was only a small proportion of what it had been in the 4th century. The court of Constantinople tended to neglect Africa because of the more immediate dangers on the eastern and Balkan frontiers. Only once in its latest phase was it the scene of an important historical event; in 610 Heraclius, son of the African exarch at the time, sailed from Carthage to Greece in a revolt against the unpopular emperor Phocas and succeeded him the same year. That Africa was still of some impor-

tance to the empire was shown in 619; the Persians had overrun much of the east including Egypt, and only Africa appeared able to provide money and recruits. Heraclius even thought of leaving Constantinople for Carthage but was prevented by popular feeling in the capital.

In view of the lack of evidence for the Byzantine period, and the still greater obscurity surrounding the period of Arab raids and final conquest (643–698) and its immediate aftermath, conclusions on the state of the Maghrib at the end of Byzantine rule are speculative. Much of it was in the hands of tribal groups, among which the level of Roman culture was in many cases no doubt negligible. Even before the Arab attacks began, the picture seems to be one of a continual ebb of Latin civilization and the Latin language from all of the Maghrib except along the coastal fringes of Tunisia, and the development and expansion of larger tribal groupings, some, though not all, of which were Christian. Also, the Byzantine administration was, in a sense, foreign to the Latin population. The military forces sent from Constantinople to stem the invasion were ultimately inadequate, though Arab conquest of the region could not be secure until the capture and destruction of Carthage and the interdiction of reinforcements by sea. The most determined resistance to the Arabs came from nomadic Libyan tribes living in the area around the Aurès Mountains. Destruction in the settled areas in the earlier attacks, which were little more than large-scale raiding expeditions, was certainly immense. It has been held that town life and even an ordered agricultural system almost disappeared at this time, though some scholars believe that a modicum of these survived until the invasions of larger nomadic groups, in particular the Banū Hilāl, in the 11th century. Latin was still in use for Christian epitaphs at en-Ngila in Tripolitania and even at Al-Qayrawān (Kairouan) in the 10th and 11th centuries. However, throughout the Maghrib the conversion to Islām of various population groups rapidly led to the Arabization of most of the region in language and culture, though the modalities of these profound changes remain obscure.

Maghrib on the eve of Arab conquest

The Arab conquest has its part in the widely discussed theory of Henri Pirenne that the essential break between the ancient and medieval European worlds came with the destruction of the unity of the Mediterranean not by the Germanic but by the Arab invasions. The history of the Maghrib is an important element in this debate, for there one can see the complete replacement of a centuries-old political, social, religious, and cultural system by another within a short span of time.

Roman Cyrenaica. Much of the Roman period in Cyrenaica was peaceful. Some Roman immigrants resided there at an early date, and some of the Greeks received Roman citizenship. A famous inscription of 4 BC contains a number of edicts of the emperor Augustus regulating with great fairness the relationship between Roman and non-Roman. The character of its civilization, however, remained entirely Greek. Jews formed a considerable minority group in the province and had their own organizations at Berenice and Cyrene. They took no part in the great revolt of Judaea in AD 66 but in 115 began a formidable rebellion in Cyrene that spread to Egypt. No reason for it is known. It caused great destruction and loss of life, and Hadrian took special measures to reconstruct Cyrene and also sent out some colonists. Peaceful conditions returned, but in 268–269 the Marmaridae, inhabiting the coast between Cyrenaica and Egypt, caused trouble. In the reorganization of the empire by Diocletian, Cyrenaica was separated from Crete and divided into two provinces, Libya Superior, or Pentapolis (capital Ptolemais), and Libya Inferior, or Sicca (capital Paraetonium, Marsā Maṭrūḥ). A regular force was stationed there for the first time under a *dux Libyarum*. At the end of the 4th century, the Austuriani, a nomad tribe that had earlier raided Tripolitania, caused much damage, and Cyrenaica began to suffer from the general decline of security throughout the empire, in this case from desert nomads. A notable phenomenon of the 5th and 6th centuries, as in Tripolitania, is the number of fortified farms, most frequent in the Akhḍar Mountains and south of Boreum (Bū Quraydah) and also apparently in the region of Banghāzī.

Christianity no doubt spread to Cyrenaica from Egypt. In the 3rd century the bishop of Ptolemais was metropolitan, but by the 4th century the powerful bishops of Alexandria consecrated the local bishops. The best known Cyrenaican is Synesius, a citizen of Cyrene of philosophic tastes who was made bishop of Ptolemais in 410 partly because of his ability to obtain help for his province from the imperial authorities. Under Justinian a number of defensive works were constructed as elsewhere in Africa—*e.g.*, Taucheira, Berenice, Antipyrgos (Tobruk), and Boreum. Recent excavations of a series of churches in the province also reveal the expenditure he devoted to their beautification, in what was a province of minor importance. On the eve of the Arab conquest (AD 643) the general condition of Cyrenaica would appear to have been on a par with most of the other eastern provinces of the empire. (B.H.W.)

FROM THE ISLĀMIC CONQUEST TO 1830

After completing the conquest of Egypt in 642 the Arabs started to raid the territory to its west inhabited by the Berbers, which they called Bilad al-Maghrib ("Lands of Sunset"), or simply the Maghrib. In 705 this region became a province of the Muslim empire then ruled from Damascus by the Umayyad caliphs (661–750). The Arab Muslim conquerors left a much more durable impact on the culture of the Maghrib than did the region's conquerors before and after them. By the 11th century the Berbers had become Islāmized and in part also Arabized. Indigenous Christian communities ceased to exist in the region, which before the Arab conquest had constituted an important part of the Christian world. The Islāmization of the Berbers was a consequence of the Arab conquest, although they were neither forcibly converted to Islām nor systematically missionized by their conquerors. Largely because its teachings became an ideology through which the Berbers justified both their rebellion against the caliphs and their support of rulers who rejected caliphal authority, Islām gained wide appeal and spread rapidly among these fiercely independent peoples.

Islāmization of the Berbers

Arab raids to the west of Egypt concentrated at first on the area of Cyrenaica in present-day Libya. Tunisia was raided several times after 647, but no attempt was made to establish Arab rule there before 670. Conflicts among the Muslim leaders, especially after the assassination of the third caliph 'Uthmān in 656, hindered Muslim territorial expansion. Only after the Umayyads had consolidated their authority as a caliphal dynasty in the 660s and had come to view the conquest of the Maghrib in the context of their confrontation with the Byzantine Empire was the systematic conquest of the Maghrib undertaken. 'Uqbah ibn Nāfi' (Sidi Okba) commanded the Arab army that occupied Tunisia in 670. Before his recall in 674 'Uqbah founded the town of Al-Qayrawān (Kairouan), which became the first centre of Arab administration in the Maghrib.

When the conquest of the Maghrib west of Tunisia was initated by 'Uqbah's successor, Abū al-Muhājir Dīnār al-Anṣārī, the Arabs had to fight semisettled Berber communities that had developed some tradition of centralized political authority. In the course of his campaign, Abū al-Muhājir Dīnār prevailed upon the Berber "king" Kusaylah to become Muslim. From his base in Tlemcen, Kusaylah dominated a confederation of the Awrāba tribes living between the western Aurès Mountains and the area of present-day Fès. Since Kusaylah's profession of Islām implied his recognition of caliphal authority, it served as a basis for coexistence between him and the Arabs. However, when 'Uqbah was reinstated as commander of the Arab army in the Maghrib in 681, he insisted on imposing direct Arab rule over the whole region. In 682 he led his troops across Algeria and northern Morocco, reaching the Atlantic Ocean and penetrating south to the areas of Sūs (Sous) and Drâa in southern Morocco. On his way back to Al-Qayrawān, 'Uqbah was attacked near Biskra in present-day Algeria on orders from Kusaylah by Berbers supported by Byzantine contingents. Through his death in this battle and his extended campaign, 'Uqbah became the legendary hero of the Muslim conquest of the Maghrib.

By the 680s the Arabs had gone too far in the conquest

of the Maghrib to be willing to accept defeat at the hands of a Berber leader, albeit one professing Islām. Two large armies had to be sent from Egypt, however, before organized Berber resistance could be suppressed. The first, commanded by Zuhayr ibn Qays al-Balawī, reoccupied Al-Qayrawān, then pursued Kusaylah westward to Mams, where he was defeated and killed. The dates of these operations are uncertain, but they must have occurred before 688 when Zuhayr ibn Qays himself was killed in an attack on Byzantine positions in Cyrenaica. The second Arab army, commanded by Ḥassān ibn an-Nu'mān, was dispatched from Egypt in 693. It faced stiff resistance in the eastern Aurès Mountains from the Jawāra Berbers, who were commanded by a woman whom the Arabs referred to as Kāhinah (al-Kāhina; "the Priestess"). After Kāhinah was defeated in 698, Ibn an-Nu'mān occupied Carthage, the centre of Byzantine administration in Tunisia, and began the construction of the town of Tunis nearby. These successes and Arab naval supremacy in the Mediterranean forced the Byzantines to evacuate their remaining positions on the Maghribī coast. Consequently, under Ibn an-Nu'mān's successor, Mūsā ibn Nuṣayr, the Maghrib was made into a province of the Umayyad Caliphate in 705 known as the *wilāyah* of Ifrīqīyah, thus separating it from the *wilāyah* of Egypt, to which it had been administratively attached until that time.

Khārijī Berber resistance to Arab rule. Political life of the Maghrib in the 8th century was dominated by the contradiction in the position of the Arab rulers who, while posing as the champions of a religion recognizing the equality of all believers, emphasized their ethnic distinctiveness and exercised authority without much regard for Islāmic religious norms. This contradiction surfaced in their relations with the Berbers after the latter became Muslim in large numbers, especially through serving in the Arab army, which is known to have included Berber contingents when it was commanded by Ḥassān ibn an-Nu'mān and his successor Mūsā ibn Nuṣayr. Many Berber warriors participated in the conquest of Spain in 711. Though professing Islām, they were treated as mawālī (clients) of the Arab tribes and consequently had a status inferior to, and received less pay than, the Arab warriors. Furthermore, the Arab ruling class alone reaped the fruits of conquest, as was clearly the case in Spain. The grievances of the warriors highlighted the resentment of Berbers in general, caused by such practices as the levying of human tribute on the Berber tribes, through which the Arab ruling class was provided with slaves, especially female slaves. 'Umar II (717–720) was the only Umayyad caliph who is known to have condemned the levying of human tribute and ordered its discontinuation. He also sent 10 *tābi'un* (disciples of the Prophet Muḥammad's companions) to teach Islām to the Berbers. The enlightened policy of this pious caliph did not survive his short reign, however. Rather it contributed toward confirming the conviction of Muslims in the Maghrib that Islām could not be equated with Umayyad caliphal rule.

Berber grievances against Arab rule

The Muslim Khārijī sect exploited this revolutionary potential in their struggle against Umayyad rule. Khārijī doctrine apparently appealed to the Berbers because it rejected the Arab monopoly on political leadership of the Muslim community, stressed piety and learning as the main qualifications of the head of the community, and sanctioned rebellion against the head when he acted unjustly. In 740 a major Berber rebellion broke out against Arab rule in the region of Tangier. Its first leader was a Berber called Maysara who had come to Al-Qayrawān under the influence of the Ṣufrites (Ṣufriyah), the extremist branch of the Khārijī sect. The Berber rebels achieved an astounding military success against the Arab army. By 742 they had taken control of the whole of Algeria and were threatening Al-Qayrawān. In the meantime, the Ibāḍites (Ibāḍīyah), who constituted the moderate branch of the Khārijī sect, had taken control of Tripolitania by converting the Berber tribes living there, especially the Hawwāra and Nafusa, to their doctrine. Ibāḍite domination in Tripolitania resulted from the activities of *dā'is* sent there from the main centre of the group in Iraq after the Khārijī rebellion there had been suppressed by the Umayyad army in 697.

Political and religious fragmentation

Umayyad caliphal rule in the Maghrib came to an end in 747 when the Fihrids, the descendants of 'Uqbah ibn Nāfi', taking advantage of the preoccupation of the Umayyads with the 'Abbāsid rebellion that led to their downfall, seized power in Ifrīqīyah. The Fihrid dynasty controlled all Tunisia except for the south, which was dominated at the time by the Warfajūma Berber tribe associated with the Ṣufrite Khārijī. Fihrid rule came to an end in 756 when the Warfajūma conquered the north and captured Al-Qayrawān. Immediately thereafter, however, the Ibāḍites in Tripolitania proclaimed one of their religious leaders as imam (the Khārijī equivalent to the Sunnite caliph) and in 758 conquered Tunisia from the Ṣufrites. An Ibāḍite state comprising Tunisia and Tripolitania thus came into being, which lasted until the 'Abbāsids, having consolidated their authority as caliphs in the Middle East, sent an army to the region in 761 to restore caliphal rule in the Maghrib.

The 'Abbāsids could impose their authority only on Tunisia, eastern Algeria, and Tripolitania. Their governors of the reconstituted *wilāyah* of Ifrīqīyah were hampered in the exercise of their authority by their dependence on an army that was recruited predominantly from among the unruly Arabs of the province. A mutiny of the Arab troops against the 'Abbāsid governor in 800 led to the transformation of Ifrīqīyah into an Arab kingdom ruled by the Aghlabid dynasty in the name of the 'Abbāsid caliphs. The founder of the dynasty, Ibrāhīm I ibn al-Aghlab, commanded until then the Arab army in eastern Algeria. After using his troops to restore order in Tunisia, he established himself as ruler of the province. The acquiescence of the caliph, Hārūn ar-Rashīd, to Ibn al-Aghlab's usurpation of authority was linked to the latter's continued recognition of 'Abbāsid suzerainty and payment of tributes to Baghdad.

The Maghrib under Muslim dynasties, 8th–11th centuries. Through their rebellion against caliphal rule in the name of Islām, the Berbers forged religious bonds with other Muslim opponents of the caliphs, and Islāmic political concepts and religious norms gained favour in Berber society. Their rebellion also led to the replacement of rule by the caliphs with four separate Muslim states ruled by dynasties that either nominally recognized caliphal authority, as was the case with the Aghlabids, or totally rejected it, as was the case with the three other states. Only the smallest and most politically insignificant state, the principality of the Banū Midrār in Sijilmāssah (southern Morocco), was ruled by a Berber dynasty. The four states were dependent for their survival on the balance of political forces within the region itself.

Opposition to rule by the caliphs

The Rustamid state of Tāhart. The 'Abbāsid conquest of Ifrīqīyah in 761, which led to the collapse of the Ibāḍite state in Tunisia and Tripolitania, resulted in the migration of important Ibāḍite tribes from Tripolitania and southern Tunisia to western Algeria. There they were led in attacks on 'Abbāsid positions by 'Abd ar-Rahmān ibn Rustam, an Ibāḍite of Persian origin, born and brought up in Tunisia. Ibn Rustam had acquired prominence among the Ibāḍites as governor of Tunisia between 758 and 761. In 776 or 777 he was proclaimed imam by the Ibāḍite tribes of Algeria, and immediately afterward he started construction of his own capital, Tāhart, in the area where the most important Ibāḍite tribes of Algeria were settled. Until the 760s the Berber tribes affiliated with the Ṣufrite branch of Khārijism were the major forces of opposition to caliphal rule in Algeria. After the foundation of the Rustamid state, these tribes became subordinate allies of the Ibāḍites.

The imamate of Tāhart was inherited within the family of 'Abd ar-Rahmān ibn Rustam. This breach of Khārijī doctrine led to a split within the Ibāḍite leadership, which, however, had little effect on the position of the Rustamid imams as leaders of Berber opposition to 'Abbāsid authority. The tribes that recognized the religio-political leadership of and paid tribute to the imams of Tāhart lived in western Algeria, southern Tunisia, and Tripolitania. The imams maintained contacts with them by encouraging visits of their chiefs to Tāhart and by sending emissaries that toured their areas. With the Nafusa of Tripolitania, who had been associated with the Ibāḍite movement in

the Maghrib since the beginning of the 8th century, the Rustamid imams maintained especially close contacts and entrusted important state offices to them. Tāhart became prosperous and developed a cosmopolitan character both by serving as a meeting place for numerous trade caravans connecting the various parts of the Maghrib and by playing an important role itself in Maghribi and trans-Saharan trade. The Rustamids' readiness to live in peace with their neighbours, including the Aghlabids, caused discontent among the Ibāḍite tribes of Tripolitania and southern Tunisia but enabled the Rustamids to retain power until Tāhart was conquered by the Fāṭimids in 909.

The Banū Midrār of Sijilmāssah. As a result of migration after the 740s of Miknāsah Berbers, a group affiliated with the Ṣufrites, from northern Morocco to the oasis of Tafilalt in the south, the principality of the Banū Midrār came into existence. The principality was named after Abū al-Qāsim ibn Wāsūl, nicknamed Midrār, the Miknāsah chief who in 757 founded tha town of Sijilmāssah. Tafilalt had played a role in trans-Saharan trade before the influx and settlement of the Miknāsah. After the establishment of Sijilmāssah, however, it became the foremost centre of trans-Saharan trade in the western Maghrib. At the zenith of its power during the reign of Yasa' ibn Midrār (790–823), the principality controlled the entire region of Drāa in southern Morocco. Nevertheless, the state remained primarily a trading principality, playing almost no role in the political life of the rest of the Maghrib until it too was conquered by the Fāṭimids in 909.

The Idrisids of Fez. The Idrīsid state of Fez (modern Fès) had its origins in the desire of Isḥāq ibn 'Abd al-Ḥamīd, chief of the powerful tribal confederation of the Awrāba, to consolidate his authority in northern Morocco by giving his rule an Islāmic religious character. For that purpose he invited Idrīs ibn 'Abd Allāh, a sharīf (descendant of the Prophet Muḥammad) then living in Tangier, to settle at his seat of government in Walīla (Oulili). Idrīs moved to Walīla in 788 and was recognized imam Idrīs I of the Awrāba the following year, but he was assassinated by agents of the 'Abbāsids in 791. His son, born a few months later and also called Idrīs, was proclaimed imam of the Awrāba in 803, when he was still a young boy. Idrīs II founded the state called, after himself, Idrīsid, with the help of Arab refugees coming from both Spain and Aghlabid territory. By moving the seat of his authority in 809 to Fez, the capital city he had started to build a year earlier, he made clear he was establishing a state that was distinct from the Awrāba confederation. The arrival of more Arabs from Spain and Aghlabid territory in the following two decades gave the Idrisid state a distinctly Arab character.

Although Idrīs I had Shī'ite sympathies, the state founded by his son was in matters of religious doctrine Sunnite. Its rulers, however, identified themselves with Berber rejection of caliphal rule and stressed their own descent from the Prophet as a means of legitimizing their authority. During Idrīs II's reign (809–828) the state included the greater part of present-day Morocco. From the 860s, however, the authority of the Idrisids started to decline, and the tribes of northern Morocco that had previously followed them allied themselves with the Umayyad rulers of Spain. Nevertheless, they continued to rule in Fez until they were deposed by the Fāṭimids in 921. Under the Idrisids, Islāmic urban culture began to make its appearance in Morocco. The foremost urban centre was Fez, which continued to exercise a dominant influence on the religious and cultural as well as the political life of Morocco until the imposition of the French protectorate in 1912.

The Aghlabids. After their usurpation of power in 800, the Aghlabids adapted their government to the requirements of political survival in a land still dominated by an Arab class of large landowners, who also provided the government its regular troops. The urban, ethnically mixed communities resented the domination of the state by the old Arab families and the heavy taxes that they and the peasant communities had to pay. Emphasizing Islāmic religious norms was the means by which these groups articulated their grievances against the state and the Arab ruling class. By the beginning of the 9th century such grievances could be expressed formally when two of the four Sunnite schools of Islāmic religious law, the Hanafite (Hanafīyah) and the Malikite (Mālikiyah), had become established in the Maghrib. The Hanafite school developed in Iraq; as it was recognized by the 'Abbāsid caliphs, it also was adopted by the Aghlabids. Most of the religious scholars in Tunisia, however, adhered to the simpler and stricter teachings of the Malikite school. By teaching the religious law and adominishing the rulers to adhere to its provisions in the administration of justice and in such matters as taxation and the prohibition of alcohol, Malikite scholars have emerged since the 820s as defenders of the rights of the common people against the state.

Schools of Islāmic religious law

Political life in the Aghlabid state reflected the rulers' constant fear of rebellion by their Arab troops and preoccupation with the need to allay the grievances of the religious scholars. They tried to placate the Malikite scholars by appointing many of them to the office of qadi ("judge") and by instituting a program of sacred building construction. The Grand Mosque of Tunis, the Zaytūnah, among others, was built in the Aghlabid period. In order to reduce the threat of Arab troop rebellions, the Aghlabids channeled their energies into conquering Sicily. Initiated in 827, the conquest of Sicily was given a religious character by entrusting the command of the army to the qadi Asad ibn al-Furāt.

The Fāṭimids and Zirids. The grievances that the inhabitants of Ifrīqīyah harboured against Aghlabid rule were transformed into a revolutionary movement by the Ismā'īlites (Ismā'īlīyah), the extremist branch of the Shī'ite sect. From the middle of the 9th century Ismā'īlite leadership, operating from Salamyah in northern Syria, sent out *dā'is* to organize opposition to the 'Abbāsid caliphs. One of these, Ḥusayn ibn Zakariyyā', better known as Abū 'Abd Allāh ash-Shī'ī, operated among the Kutāma of the Little Kabylie region in eastern Algeria from 901. The sedentary Kutāma were pious and unsophisticated Muslim Berbers living in small village communities. Aghlabid rule in the region was represented by fortified garrison posts manned by Arab troops, by whom the Kutāma were constantly harassed. Through patient preaching, Abū 'Abd Allāh molded the Kutāma into a highly motivated and disciplined militant movement. After defeating the Arab troops in the Little Kabylie, he conquered the rest of the Aghlabid territory in Algeria between 904 and 907 and then conquered Tunisia itself. Raqqādah, the fortified residence of the Aghlabids near Al-Qayrawān, was conquered in March 909. The head of the Ismā'īlites in Salamyah, 'Ubayd Allāh Sa'id, made his entry into Raqqādah in January 910.

The state that 'Ubayd Allāh then founded was intended to be completely Shī'ite in character. He styled himself as the imam who, according to Shī'ite doctrine, was the only legitimate head of the Muslim community and the final authority on religious law. The state he founded, known as Fāṭimid (*Ad-Dawla al-Fāṭimiyya*) after the Prophet Muḥammad's daughter Fāṭimah, was viewed as a stepping-stone to the overthrow of the 'Abbāsids. Nevertheless, 'Ubayd Allāh was intent on consolidating Shī'ite rule first in the Maghrib itself. He built a fortified capital, Al-Mahdīyah, on the Tunisian coast and initiated the conquest of the western Maghrib in 917. The Fāṭimids soon brought Idrisid rule in Fez to an end, but after 40 years of campaigning in western Algeria and Morocco they were unable to impose their authority on the powerful Berber tribes living there. The Umayyads of Spain, moreover, occupied the enclaves of Melilla and Sabtah (Ceuta) on the northern coast of Morocco in 927 and 931, respectively, and from there organized tribal resistance to the Fāṭimids. In eastern Algeria, however, the Fāṭimids were loyally supported by Zīrī ibn Manād, chief of the Takalata branch of the Ṣanhājah Confederation, to which the Kutāma Berbers belonged. The parts of the Maghrib that the Fāṭimids controlled therefore consisted only of the former province of Ifrīqīyah, ruled before them by the Aghlabids.

In Ifrīqīyah itself the Arab aristocratic families, previously affiliated with the Hanafite school of law, converted in their entirety to Shī'ism and, consequently, preserved under Fāṭimid rule some of their former privileges. The

Malikite scholars, however, opposed the Fāṭimids, who, accordingly, resorted to repression and had several of them tortured. Differences in ritual and religious law, and the exorbitant system of taxation made necessary by the large army that the Fāṭimids had to maintain, were the main causes of Malikite opposition. Out of desperation, the Malikite leaders of Al-Qayrawān in 944 even supported the rebellion of one of their Khārijī rivals, Abū Yazīd, against the Fāṭimids.

Direct Fāṭimid rule in the Maghrib effectively came to an end in 973, when the Fāṭimid imam, Al-Muʿizz, whose armies had conquered Egypt four years earlier, took up residence in Cairo. As his viceroy in the Maghrib, Al-Muʿizz appointed the Berber chief Buluggin, son of the Fāṭimids' chief ally in Algeria, Zīrī ibn Manād. In the 70 years during which the Zīrids (Banū Zīrī) ruled Ifrīqīyah in the name of the Fāṭimids, they fell progressively under the influence of the Arab Islāmic culture of the region. In this period the Malikite school of Islāmic law reasserted itself in Ifrīqīyah and produced one of its most prominent scholars, Ibn Abī Zayd al-Qayrawānī (d. 996), whose *Risalah* is one of the most widely used and commented on expositions of Malikite law. Malikite riots broke out between October 1016 and March 1017, which led to the killing of a large number of Shīʿites—estimated at some 20,000—and the looting of their property. These developments resulted in the renunciation of Fāṭimid authority by the Zīrids in 1044.

Invasion of Arab tribes

The Fāṭimids reacted to this by unleashing two large nomadic Arab tribes on the Maghrib, the Banū Hilāl and the Banū Sulaym (Sulaim), both of which had until then lived in Upper Egypt. The Zīrids were overwhelmed by the sheer number of the invaders, who are said to have included 50,000 warriors when they crossed into Cyrenaica in 1050. After suffering defeat at their hands in 1052 in southern Tunisia, the Zīrids vacated Al-Qayrawān and retreated to the well-fortified former Fāṭimid capital of Al-Mahdīyyah on the coast. The Banū Hilāl ravaged the Tunisian countryside and then infiltrated into eastern Algeria. Here, they brought to an end the rule of the Banū Hammād, a dynasty related to the Zīrids that had made itself independent of them in 1015. The Arab invasion introduced into the eastern Maghrib unruly tribal groups, who remained a source of political instability in the region until well into the 15th century.

The Maghrib under the Almoravids and the Almohads. The fragmentation of political life in the Maghrib, following both the Arab invasion and a general decline in the authority of the Fāṭimids, was arrested by the Almoravids. These were the founders of the first of two empires that unified the Maghrib under Berber Islāmic rule.

The Almoravid empire came into being through the success of a militant Islāmic movement that was initiated among the Ṣanhājah Confederation of tribes in Mauretania by one of its chiefs in about 1035. Religious reform was a means of cementing the unity of the Ṣanhājah tribes at a time when the control that they previously had on trans-Saharan trade had become threatened, from the south by the Soninke state of Ghana and from the north by the infiltration of Zanātah Berbers into southern Morocco. The movement's leader, ʿAbd Allāh ibn Yāsīn, was a Ṣanhājah religious scholar from southern Morocco. Before joining the Ṣanhājah tribes, Ibn Yāsīn was attached to a centre of religious learning, Dār al-Murābiṭīn, in Sūs (southern Morocco), then headed by a scholar who had studied previously in Al-Qayrawān. Two theories have been proposed to explain the name "Al-Murābiṭūn (Almoravids)," meaning inmates of a ribat (fortified monastery), a term by which Ibn Yāsīn's followers were known. The first is that he founded a ribat somewhere in Mauretania to train his followers. The other relates the name to Dār al-Murābiṭīn in Sūs, suggesting that the Almoravid movement was under the direct influence of this centre of learning. Whatever the case, the Almoravids were strict adherents of the Malikite school of law as it developed in Ifrīqīyah since its introduction to the Maghrib in the 9th century.

The Almoravids began the invasion of Morocco after consolidating their control over Sijilmāssah in 1056. When Ibn Yāsīn was killed in 1059 in an attack on the heretical Barghawāṭa tribal confederation on the Moroccan coast, the military and religious leadership of the Almoravids passed to the chief of the Lamtūnah tribe, Abū Bakr ibn ʿUmar. The latter returned to Mauretania in 1060 to fight against rebels challenging his authority. Command of the Almoravids in southern Morocco was then assumed by Abū Bakr's cousin, Yūsuf ibn Tāshufīn (Tāshfīn), under whose leadership the Almoravids conquered most of the Maghrib and Muslim Spain. By 1082 Almoravid rule extended as far east as Algiers. After the collapse of the Andalusian Umayyads in 1031, Muslim Spain became divided into a number of small Muslim principalities whose rulers were unable to hold out against Christian military advances. Upon request of the Spanish Muslims, the Almoravids sent their army into Spain in 1086. By 1110, four years after Ibn Tāshufīn's death, the Almoravids had become masters of the whole of Muslim Spain. The capital of their expanded empire was Marrakech, which Ibn Tāshufīn had started to build in 1070.

Almoravid conquest of Muslim Spain

In the Almoravid empire the Ṣanhājah tribes of Mauretania constituted a ruling class, distinguished from the rest of the population by the litham (face muffler) that their men wore. The Lamtūnah tribe formed the aristocracy of this ruling class and occupied the empire's important administrative and military posts. Strict adherence to the Malikite version of Islāmic law provided the religious legitimization for the authority of this tribal caste. The *fuqahāʾ* (experts on Islāmic law) supervised both the administration of justice by the qadis and the work of the provincial governors, and they acted as advisers to the rulers. The empire's simple system of government, in which military commanders acted as administrators, was rendered especially stifling by the narrow legalism of the *fuqahāʾ*. Mystical tendencies and new religious ideas reaching the Maghrib from Muslim Spain and the Arab east that the *fuqahāʾ* feared might undermine their authority were fought with the backing of the state.

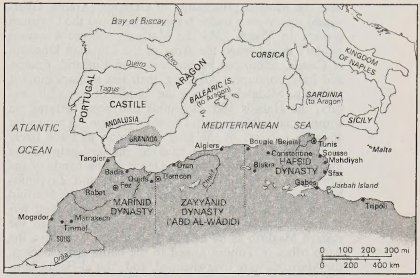
The Almohad revolt

Out of religious opposition to the Islām of the Almoravid jurists developed the revolutionary movement of the Almohads (Al-Muwaḥḥidūn)—*i.e.,* the adherents of *tawḥīd,* the belief in the oneness and uniqueness of God—and led to the downfall of the Almoravids. The founder of the movement was Muḥammad ibn Tūmart, a Berber belonging to the Maṣmūdah tribe of the High Atlas region of Morocco. After returning from a pilgrimage to Mecca in 1117, he preached in public against equating Islām with the provisions of one of the four schools of Islāmic law, calling for a return to its original sources—namely, the Qurʾān (Koran) and the traditions of the Prophet. He also condemned the literal interpretation of the Qurʾān endorsed by the Almoravid *fuqahāʾ,* on grounds that it undermined *tawḥīd* by misleading the faithful to believe that God had human attributes. Ibn Tūmart fled from Marrakech in 1122 when he realized that he would be put to death if he did not cease in his criticism of the state's official religious dogma. After settling with some people of his tribe in the village of Tinmallal in 1124, he started to organize a religious community of Maṣmūdah tribesmen, who became united not only because of their sense of tribal solidarity but also because of their belief in Ibn Tūmart as the *mahdi* (divinely guided redeemer). After Ibn Tūmart's death in 1130, the movement and the conquest of the Almoravid empire continued under his trusted lieutenant, ʿAbd al-Muʾmin, a Berber from the Qūmiya tribe living in the region of Tlemcen.

Beginning in 1133, ʿAbd al-Muʾmin succeeded in establishing his authority in all the High and Middle Atlas mountains. From about 1139 he invaded northern Morocco and then western Algeria. After becoming master of this region in 1145, he advanced into the main centres of Almoravid authority in Morocco, conquering Fez in 1146 and Marrakech in 1147. Muslim Spain passed under Almohad rule between 1148 and 1172. Prior to completing the conquest of Spain, however, the Almohads had advanced into the eastern Maghrib, where the Normans of Sicily, profiting from Zirid weakness, had occupied several positions on the Tunisian coast. Between 1152 and 1160 the Almohads were able to conquer the whole of the eastern Maghrib, including Tripolitania. For the first

and last time in its history, the entire Maghrib was unified under one central indigenous authority.

Like the Almoravid empire, that of the Almohads was a Berber tribal state, in which the Maṣmūdah tribes, previously united in the community of Tinmallal, constituted the ruling class. Unlike the Almoravids, however, the Almohads did not have a clear religious orientation. They rejected the idea of equating the holy law with any of its established schools, but, for practical reasons, the Almohad judges based their judgments on the provisions of the already established Malikite school. Moreover, the belief of the common people in Ibn Tūmart as the *mahdī* was slowly being superseded by the spread of Ṣūfism (Islāmic mysticism) and the veneration of Ṣūfī holy men. Ṣūfism had a prominent representative during the Almohad period in the person of Shu'ayb Abū Madyan al-Ghawth (d. 1197). At the Almohad court, however, the sciences and philosophy were cultivated. The philosopher Ibn Rushd (Averroës) wrote his famous commentaries on Aristotle when at the court of the Almohad caliph Abū Ya'qūb Yūsuf (1163–84). These diverse developments meant that Almohad doctrine could not unite even the ruling class, whose coherence was undermined still more when 'Abd al-Mu'min appointed his son as heir-apparent in 1154, thus making his family, which did not belong to the Maṣmūdah tribe, the ruling dynasty. Through this act, 'Abd al-Mu'min bypassed Abū Ḥafṣ 'Umar, the Maṣmūdah chief who gave protection to Ibn Tūmart in the High Atlas during his period of exile and whom the other Maṣmūdah chiefs expected to succeed 'Abd al-Mu'min. The opposition of the Maṣmūdah was dealt with by putting a number of their chiefs to death and by giving the Ḥafṣids (*i.e.*, the family of Abū Ḥafṣ 'Umar) a position in the state hierarchy second only to the ruling dynasty. Nevertheless, the ruling family constantly had to contend with the opposition of the Maṣmūdah chiefs.



The spread of Ṣūfism

Tension within the ruling class finally led to an open split when the Almohads attempted to reestablish their authority over the eastern Maghrib, after the Banū Ghāniya, the family that last ruled Muslim Spain in the name of the Almoravids and that after 1148 retained control of the Balearic Islands, had taken control there. The Banū Ghāniya invaded eastern Algeria in 1184 and, with local Arab tribal support, brought Almohad authority in the region to an end. In 1203 they took control of Tunisia as well. The Almohad caliph An-Nāṣir (Muḥammad ibn Abī Yūsuf Ya'qūb) restored the empire's authority in the region with several large military campaigns from 1205 to 1207. Before returning to Marrakech, he appointed a Ḥafṣid to govern the reconquered eastern Maghrib. The Ḥafṣids were able to squelch the ongoing rebellion of the Banū Ghāniya in 1227 and to establish control over Ifrīqīyah, thus emerging as virtual rulers of the region. When the Almohad caliph Al-Ma'mun formally renounced the Almohad doctrine in 1229, the Ḥafṣids declared themselves independent of him.

Decline of the Almohads

At the time of the Ḥafṣid secession, the control of the Almohads over western Algeria also had weakened, and they were no longer able to restrain the nomadic Zanātah tribes living in the south from moving with their herds to the rich pasturelands of the north. A group of these Zanātah, the Banū Marīn, advanced through northern Algeria into Morocco during the 1240s. Having captured Fez in 1248, they emerged as rulers of northern Morocco. It was only a matter of time before they brought Almohad rule to an end with the conquest of Marrakech in 1269. In the 1230s another group of Zanātah Berbers, the Banū 'Abd al-Wād, had taken control of the region of Tlemcen in western Algeria. The state they founded there was overrun several times in the 13th and 14th centuries by the Marīnids. Nevertheless, its ruling dynasty, the Banū Zayyān (Zayyānids), was able to maintain its authority in Tlemcen until the beginning of the 16th century.

Political fragmentation and the triumph of Islāmic culture (*c.* 1250–*c.* 1500). After the collapse of Almohad rule, the Maghrib became divided into three Muslim states, each ruled by a Berber dynasty: the Ḥafṣids, whose territory included Tunisia, eastern Algeria, and Tripolitania; the Marīnids, ruling over Morocco; and the Zayyānids,

whose capital was in Tlemcen, ruling over most of western Algeria, when this region was not occupied by the Marīnids. Both the rigorist legalistic doctrine of the Almoravids and the more enlightened religious orientation of the Almohads had proved to be unsuitable as foundations for durable political authority. Furthermore, the rulers themselves were unsuitable to act as custodians of the faith. Islāmic culture came of age in the Maghrib only after the rulers gave up attempting to identify their authority with a single religious doctrine and allowed religious life to develop freely through the interplay of religious ideas and social forces in relative independence from the state. The Maghribi rulers subsequently legitimized their authority by cultivating relations of trust and cooperation with the leading religious scholars of the time. Their capital cities became, consequently, the foremost centres of learning in their realms and were adorned not only with exquisite mosques but also with sumptuous madrasahs, residential colleges built and financed by the rulers. The Malikite school of law was again recognized. Its scholars were held in great esteem and granted various privileges by the rulers, but they were not allowed to determine the conduct of government.

Flowering of Islāmic culture

From the 12th century Ṣūfism had spread widely in the Maghrib. Ṣūfi holy men were venerated in both the towns and the countryside. Although in the towns their influence tended to be overshadowed by that of the legal scholars and the organs of the state, in the countryside they constituted the main custodians of Islāmic norms. Often allied with tribal chiefs, and sometimes having their own communities, these religious leaders contributed toward the establishment of order and stability by using their moral authority to uphold religious norms and arbitrate conflicts. They could perform these functions and gain influence over the tribal societies because the rulers' administrative authority extended little beyond their capital cities and garrison towns, and they, as well as the urban scholars, considered tribal society to be of marginal importance. Indeed, the tribes exercised direct influence on political life only when they became involved in conflicts for power within the ruling family or when their warriors took part in wars against a foreign enemy.

Relations between the three Maghribi states were greatly influenced by the pressures that the Christian states of the Iberian Peninsula exerted on them from the middle of the 13th century. The Ḥafṣids claimed to be the heirs of Almohad religious authority, but after the first independent Ḥafṣid ruler, Abū Zakarīyyā' (1228–49), they gave up attempting to substantiate this claim, either by pressing forward the conquest of the western Maghrib or by helping the Muslims of Spain militarily. The Marīnids inherited both the heartland of the former Almohad state in Morocco and its confrontation with the Christians in Spain, but, because of political instability, they were never able to take the initiative in the war against the Christians. Through their military outposts in southern Spain, they merely tried to check attacks on Morocco itself and to

Military pressures from the Iberian Peninsula

help the Muslim principality of Granada (Arabic: Gharnāṭah) survive as a buffer between them and the Christian powers. In March 1344 the Marīnids suffered a serious military defeat when the army of the Christian kingdom of Castile, reinforced by warriors from England, France, and Italy, conquered Algeciras, their last military outpost in Spain. Meanwhile, since the middle of the 13th century, the Ḥafṣids and Zayyānids had been carrying on commercial relations with Christian Aragon. In return for allowing subjects of the king of Aragon to trade freely in their dominions, they received military help in the form of Catalan mercenaries. Defeat at the hands of the Christians, at a time when the Ḥafṣids and Zayyānids had friendly relations with Aragon, prompted the Marīnid sultan Abū al-Ḥasan ʿAlī (1331–51) to invade their territories. Between 1346 and 1347, his army overran the eastern Maghrib as far east as Tripolitania, but when the Arab tribes of Tunisia joined in the battle against them, the Marīnids were overwhelmed, and Abū al-Ḥasan himself had to flee by sea from Tunis. His son and successor, Abū ʿInān, also invaded the eastern Maghrib in 1356–57, but he too had to withdraw from Tunisia because of Arab tribal resistance.

Political life in the Maghrib from the middle of the 14th to the end of the 15th century was dominated by the preoccupation of the ruling dynasties with internecine conflicts, which in the case of the Ḥafṣids was complicated by the domination of many parts of their territories by Arab tribes. These conflicts led to the division of the Ḥafṣid state between 1348 and 1370 into two parts, one ruled from Tunis and the other from Bejaïa (Bougie), with the ruler of each part being supported by a different Arab tribal group. After its reunification in 1370 by Sultan Abū al-ʿAbbās, the Ḥafṣid state enjoyed periods of relative stability interspersed with ones of strife. Political instability did not, however, prevent the development of learning in the towns. The greatest intellectual figure of the Maghrib before the modern period, the historian and sociologist Ibn Khaldūn, was born and educated at this time in Tunis. Conflicts for power within the Zayyānid state enabled the Marīnids to establish indirect control over Tlemcen in the second half of the 14th century, but, being preoccupied with strife within their own dominions, they were not able to realize their long-held ambition of bringing the whole of the Maghrib under their rule.

The Maghrib from about 1500 to 1830. Between 1471 and 1510 the line of confrontation between the Muslims of the Maghrib and the Christians of the Iberian Peninsula shifted from Spain to the Maghrib itself. The Portuguese occupied a number of positions on the Moroccan coast between 1471 and 1505, which included Tangier in the north and Agadir in the south. The Spaniards conquered Granada, the last Muslim stronghold on the peninsula, in 1492, and between 1505 and 1510 they began establishing garrison posts along the Maghribī coast. The most important of these were at Oran (Wahrān) and Bejaïa in Algeria and Tripoli in Libya. The strong religious reaction in the Maghrib to Christian colonial intrusion enabled the Saʿdī dynasty of sharīfs to capture power in Morocco in 1549 and paved the way for the establishment of Ottoman rule later in the rest of the Maghrib.

Spanish and Portuguese outposts in the Maghrib

Morocco under sharīfian dynasties. As a reaction to the Portuguese presence in Agadir, the tribes in southern Morocco were organized by the sharīfian Saʿdī family—with the active support of Ṣūfī leaders—into a militant religious movement directed against both the Portuguese presence and Morocco's own rulers, the Waṭṭāsids. The latter was a branch of the Marīnid dynasty that had usurped power in Fez in 1472 and pursued a policy of coexistence with the Portuguese. After occupying Marrakech in 1525 and consolidating their authority in southern Morocco, the Saʿdīs conquered Agadir in 1541. By 1550 they had forced the Portuguese to evacuate the rest of their positions on the Moroccan coast and conquered the Waṭṭāsid capital of Fez. The Saʿdīs consolidated their rule in Morocco thereafter and, by later defending the territory against Ottoman expansion from Algeria, gave it a national identity distinct from the rest of the Maghrib. Their authority was legitimized by their descent from the Prophet, but the dynasty's mainstay was the support it received from the settled agricultural and commercial communities, as well as the possession and use of firearms by its troops. The dynasty reached the zenith of its power during the reign of Aḥmad al-Manṣūr (1578–1603) who, with the help of Spanish and Turkish mercenaries, built Morocco's first professional army. With this force at his command, al-Manṣūr imposed his will on the whole country, besides defending it against the Turks and, in 1591, conquering the West African state of Songhai (now Mali). However, conflict for power after his death resulted in the division of the country into several principalities that lasted until the country was reunited through another sharīfian family, that of the ʿAlawites.

The ʿAlawites, who rule Morocco to this day, came to power with the help of Arab tribes that had moved into Morocco in large numbers during the Almohad period. The founder of the dynasty, Mawlāy ar-Rashīd, mobilized these tribes against the powerful Berber principality of the Dilāʾiyya that had dominated the Middle Atlas and parts of northern Morocco since the 1640s. Mawlāy ar-Rashīd's half brother, Mawlāy Ismāʿīl, succeeded in reunifying Morocco with the help of a professional army of ʿAbīds (blacks) recruited from the descendants of the many slaves who were brought back to Morocco after the conquest of Songhai. After Mawlāy Ismāʿīl's death, however, conflict over succession between his sons, who are said to have numbered about 500, complicated by the intrigues of the ʿAbīd officers, ushered in a period of chaos and economic decline that lasted nearly 50 years. Following the dynasty's recovery during the reign of Sultan Muḥammad ibn ʿAbd Allāh (1757–90) and continuing under Sultan Mawlāy Sulaymān (1792–1822), Morocco enjoyed a period of relative stability that was disturbed on a large scale only by conflicts between the ruling dynasty and tribes recognizing the authority of Ṣūfī leaders. The economy of Morocco also started to recover in this period, and the state's external trade expanded. The occupation of Algeria by the French after 1830, together with European political and economic infiltration of Morocco thereafter, however, created new challenges with which the state's traditional political system could not adequately cope.

Ottoman rule in the Maghrib. The Ottoman Turks occupied Egypt in 1517. Shortly afterward they became involved in the confrontation between Muslims and Christians in the Maghrib through the exploits of two Muslim privateers, ʿArūj and his brother Khayr ad-Dīn Barbarossa, who occupied Algiers in 1516 and made it a base for operations against the Spaniards. After ʿArūj was killed in 1518 in an attack on Tlemcen, Khayr ad-Dīn offered submission to the Ottoman sultan in return for military help, which subsequently enabled him to gain control over most of the Maghrib.

Barbarossa's submission to Ottoman control

Algeria was the first country of the Maghrib to be ruled by the Ottoman Turks. Administered at first by governors sent from Istanbul, the Ottoman regency of Algiers was transformed into a sort of military republic when the troops stationed there rebelled against the Ottoman governor in 1689 and installed one of their officers as ruler, giving him the title of dey (maternal uncle). The Ottoman troops thus emerged as a ruling caste that periodically renewed itself with fresh recruits from various parts of the Mediterranean region. The deys, chosen from within this caste, governed Algeria independently from the Ottoman government. They retained religious ties to the Ottoman sultan, however, by recognizing him as caliph and by making the Hanafite school of law—the official school of the Ottoman empire—the official school of law in Algeria as well. Piracy provided the ruling caste with its main source of revenue. Generated largely from the money received for ransoming Christian captives and from the price of peace levied on obliging Christian countries, such income remained forthcoming until the middle of the 18th century. Local inhabitants accepted the rule of the deys because the taxes they had to pay them were light and because their own leaders were allowed a large degree of autonomy in managing the affairs of their communities. Furthermore, the deys were careful to cultivate the good will of the influential Ṣūfī personalities in the countryside. From the

middle of the 18th century, the balance of power in the Mediterranean started to turn in favour of the European powers. Thereafter, the revenue that the deys derived from piracy declined. The heavy taxes that they subsequently had to impose on the Algerians led to conflicts with the tribal communities led by Ṣūfī leaders, which ultimately weakened the regime of the deys on the eve of the French invasion of Algeria in 1830.

Ottoman domination in Tunisia

The Ottoman Turks occupied Tunis in 1534 but were forced by Spanish troops to evacuate it the following year. Thereafter, the Ḥafṣids ruled Tunisia under Spanish protection until the Ottoman Turks reconquered the country in 1574. In 1591 the Ottoman troops stationed in Tunis rebelled against the governor sent from Istanbul and established a regime headed by deys chosen by the troops, which was similar to the dey-ruled regime that appeared in Algeria a little later. In Tunisia the regime of the deys was transformed from within through the importance that the bey, the officer responsible for maintaining order in the countryside and for collecting taxes, came to have in it. In 1705 the bey, Ḥusayn ibn ʿAlī, effectively usurped the power of the dey when, with the help of Tunisian tribal warriors, he repulsed the invasion of Tunisia by the army of Algiers. In this way the Ḥusaynid dynasty of beys, which ruled the country until the monarchy was abolished in 1957, came into being. While recognizing the religious authority of the Ottoman sultan as caliph, the Ḥusaynids ruled Tunisia independently from the Ottoman government. They officially adopted the Hanafite school of law but governed the country through local Malikite notables and allowed Malikite religious scholars to manage the religious and legal affairs of their communities, while also bestowing favours on them. In common with other Maghribi states at the time, piracy was an important source of revenue. It was supplemented, however, by trade in the country's products, which the beys controlled through monopolies sold mostly to Jews at high prices.

The Ottoman Turks conquered Tripoli in 1551 from the Knights of St. John of Malta. The Ottoman province that they established was governed from Tripoli and included the whole of present-day Libya. In 1711 the province underwent a change similar to the one that Tunisia had experienced in 1705, when the chief of the cavalry, Aḥmad Karamanlī, usurped power and established his own dynasty. The Karamanlīs ruled Libya until 1835 when, in the wake of a tribal rebellion supported by the British, direct Ottoman rule was reimposed there. From the middle of the 16th century Libya became active in the lucrative trans-Saharan trade that crossed its territory. In the Karamanlī period it also became an important centre of piracy. After Napoleon's occupation of Malta in 1798, Libya was opened to European trade, and it consequently became involved in the rivalry between the British and the French for supremacy both in the Mediterranean region and in West Africa.

At the time when European colonial expansion in the Maghrib began with the French occupation of Algiers in 1830, the region was divided into four political entities. Morocco, ruled by the ʿAlawite dynasty, was a sovereign country. Algeria, Tunisia, and Libya were autonomous states that recognized the religious authority of the Ottoman sultān. The French occupation of Algeria had direct and serious consequences for the authority of the rulers of Tunisia and Morocco and, indirectly, for the authority of the rulers of Libya as well. (J.M.A.-N.)

NORTH AFRICA AFTER 1830

European pressures on the North African regimes

Advent of European colonialism. The French capture of Algiers in 1830, followed by the Ottoman reoccupation of Tripoli in 1835, rudely interrupted the attempts of North Africa's rulers to follow the example of Muḥammad ʿAlī, the pasha of Egypt, and increase their power along European lines. Of the four powers in North Africa at the beginning of the 19th century, only Tunis and Morocco survived as independent states into the second half of the century to encounter the heavy pressures that Europe then brought to bear on the region for free trade and legal reform, measures originally leveled against the Ottoman Empire and Egypt. Between the death of Tunisia's ambitious reformer, Aḥmad Bey, in 1855 and the dismissal of its talented, reform-minded prime minister, Khayr ad-Dīn, in 1877, Tunis responded to these pressures with the ʿAhd al-Amān, or Fundamental Pact, in 1856 and the short-lived constitution of 1860, the first in the Arab world. The Fundamental Pact guaranteed the equality before the law of all subjects—Muslim, Christian, and Jew—while the constitution provided for a consultative assembly and the administration of justice. The constitution was suspended in 1864, but its chief proponent, Khayr ad-Dīn, came to power in 1869 as president of the International Financial Commission, a group appointed to handle the country's foreign debt, and as prime minister in 1873. At Khayr ad-Dīn's departure in 1877, Tunisia was internally strong but very weak internationally.

The sultan of Morocco, by contrast, was trapped between the European demands for free trade, conceded in 1856, and an unruly tribal population resistant to the imposition of central government. Although defeated by France at the battle of Isly in 1844 and by Spain at Tetuan (Tétouan) in 1860, Morocco was nevertheless able to rely on the support of Great Britain in its dealings with Europe. As a result, although Morocco's immigrant Europeans in this period conducted themselves with impunity under the protection of their consuls, the sultans Muḥammad and Hassan, who ruled Morocco from 1859 to 1894, maintained the country's independence and gradually extended a network of caids (*qāʾids*) or district governors, into the far south of the country. At the beginning of the 20th century—with the fall of Tunisia to French control in 1881—Morocco was the sole exception to colonial rule in North Africa.

France's conquest of Algeria

In 1835 Libya reverted to the status of a provincial backwater of the Ottoman Empire. The French meanwhile took almost 20 years to complete their conquest of the former Turkish territory of Algiers—from the bey of Constantine in the east and from the Arab hero Abdelkader (ʿAbd al-Qādir) in the west—and another 20 years to replace the army with a civilian administration, following the fall of the French Second Empire in 1870. The incorporation of Algeria into metropolitan France was a triumph for the territory's European settlers, achieved at the expense of the native Muslim population, who were denied political rights and were administratively repressed and economically deprived. Immigration from France, Italy, and Spain brought the Europeans in Algeria to about a sixth of the total population in 1900, a proportion that subsequently fell to about a tenth at the outbreak of the Algerian Revolution in 1954. Most Europeans remained in the cities, of which the two largest, Algiers and Oran, had European majorities. The economy of Algeria came to rest on the large-scale production of wine and wheat for export to France, while the majority of the country's Muslims grew ever more impoverished. The injustices of the system were widely condemned in France, and attempts were made by the French to avoid the same mistakes in colonizing Tunisia and Morocco.

A French protectorate was eventually imposed on Tunisia in 1881–83, after the British withdrew their objections to French expansion in North Africa at the Congress of Berlin in 1878. The French preserved the administration of the bey of Tunis, although under French supervision, an indirect form of rule they later applied to Morocco as well. The Moroccan protectorate itself was established only in 1912, after the conclusion of the Entente Cordiale between France and Britain in 1904, a treaty that settled a number of hostilities between the two countries, and the cession of the Cameroons to Germany in 1911. Both acts together left France free to divide the country with Spain, which took over the Rif Mountains in the north and the border region with the Spanish Sahara in the south. Pacification of the Moroccan interior was achieved with a minimum of force by French Field Marshal Louis-Hubert-Gonzalve Lyautey until his efforts were interrupted by the Rif War, waged by the Moroccan nationalist Abd el-Krim (Muḥammad ibn ʿAbd al-Karīm al-Khaṭṭābī) and his forces between 1921 and 1926, an event that delayed total pacification of the country until 1934. Libya was similarly invaded by Italy in 1911, but the prolonged resistance of the Sanūsiyah brotherhood in Cyrenaica denied the Ital-

Guerrilla resistance to colonialism

ian Fascists control of the country until 1931, when they captured and executed the brilliant Sanūsī guerrilla leader ʿUmar al-Mukhtār. By 1939, however, the colonization of Morocco, Tunisia, and Libya by French and Italian settlers was well advanced.

Nationalist movements. World War II brought major changes to North Africa, promoting the cause of national independence. A reaction to years of colonialism had set in that was erupting into strong nationalist tendencies in each of the four countries of the region. The Sanūsī leader Sīdī Muḥammad Idrīs al-Mahdī as-Sanūsī, exiled in Cairo during the war, was restored to power in Cyrenaica by the British and became King Idris I of a united Libya in 1951. Tunisian nationalism formally emerged with the influential Young Tunisians in 1907. It developed further with the founding of the Destour ("Constitution") Party in 1920 and the Neo-Destour Party under Habib Bourguiba in 1934. In Morocco the strong nationalist movement of the 1930s culminated in the foundation of the Independence (Istiqlāl) Party in 1943. In Algeria the French refusal of demands by the reform-minded Young Algerians for French citizenship cleared the way for the radical separatist movement of Messali Hadj Sheik Abd al-Hamid and the Arab Islāmic nationalist movement of Ben Badis. After the war the French were on the defensive, conceding independence to Tunisia and Morocco in 1956 in order to concentrate their efforts on Algeria, where a full-scale rebellion led by the National Liberation Front (FLN) broke out in 1954. This prolonged and costly "savage war of peace" led to Algerian independence in 1962 and, afterward, to the mass exodus of Algeria's European population.

The discovery of oil in Libya in the 1950s presaged further transformations there. The Libyan monarchy was overthrown by a military coup in 1969 and replaced by the popular republicanism of Colonel Muammar al-Qaddafi, whose adventurous Arab nationalism, which he has espoused since coming to power, has fluctuated in intensity with the price of oil. Oil also came to dominate the economy of Algeria, where agriculture was neglected in favour of a program of industrialization based upon the country's huge oil and gas reserves. This policy, however, has been disappointing, and popular disillusionment has called into question the legitimacy of the one-party presidential regime of the FLN in alliance with the army, which has governed Algeria since independence. In Tunisia, the pro-Western Bourguiba survived as president until 1987 when he was deposed by his prime minister, Zine el-Abidine Ben Ali, after having discredited his regime by his inflexible autocracy. Tunisia's heavy economic reliance on tourism since the mid-1960s, moreover, has been a questionable and precarious substitute for an emphasis on agricultural exports to the European Community (EC). Like Tunisia, Morocco has almost no oil, but it does possess greater reserves of phosphates and a more prosperous agriculture. The Moroccan monarchy of kings Muḥammad and Hassan has dominated the country since independence. Although allowing for a variety of parties in the legislature and considerable freedom of speech in the press and media, the monarchy has retained firm control of the government. In 1976 Morocco annexed part of the former Spanish territory of Western Sahara, after which it became involved in a guerrilla war with Polisario, an indigenous nationalist organization based in Algeria. The war became a major obstacle to North African unity, which is regarded as the region's best answer to its exclusion from the EC. Underlying all the political and economic problems of the region is the rapid population growth in Morocco, Algeria, and Tunisia since the 1950s, which threatens to destabilize the conservative regimes in all three countries. (M.Br.)

Western Sahara

THE COUNTRIES OF NORTH AFRICA

Algeria

Algeria is an independent republic in the Maghrib. Its official name is Al-Jumhūriyah al-Jazāʾirīyah ad-Dīmuqrāṭiyah ash-Shaʿbīyah (Democratic and Popular Republic of Algeria). With an area of 919,595 square miles (2,381,741 square kilometres), it is the second largest country in Africa and the 11th largest country in the world. Nearly nine-tenths of the national territory, however, consist of six Saharan *wilāyāt* (*départements* or provinces) in the south.

PHYSICAL AND HUMAN GEOGRAPHY

The country is bounded to the east by Tunisia and Libya; to the south by Niger, Mali, and Mauritania; to the west by Morocco and Western Sahara; and to the north by the Mediterranean Sea.

Algeria is a country of vastness; the Mediterranean to the north separates it from Europe but at the same time opens a thousand doors to it, while in the south the Sahara links it to Africa. History, language, customs, and Islām make it an integral part of the Arab world. Algeria's struggle for liberation, which lasted from 1954 to 1962, has gained it a significant place among the "nonaligned" nations. For the first two decades of independence, Algeria was firmly part of the socialist Third World. During the 1980s its economy was increasingly opened up to privatization and liberalization measures, and multiparty democracy commenced in 1989.

The land. *Relief.* Most of the population of Algeria lives in the northern part of the country—the Tell—which is the richer and the better-watered sector. The remainder of the country, the Saharan region, is uninhabited desert, with the exception of several oases. The Saharan region conceals rich mineral resources and, above all, oil and gas. Each of the country's two physical regions results from a different geologic evolution. The main features of structure and relief have been produced by the collision of the African and Eurasian tectonic plates. This has formed the geologically young and crumpled mountain chains in the north, with the solid and ancient platform of basement rock, horizontal and uniform, forming the south. The first of these areas is the mountainous Atlas region, consisting of two large mountain chains that run roughly parallel from east to west and that are separated by high plateaus. The second region consists of the Sahara desert.

From north to south there are five different zones, all running from east to west. The first zone is formed by intermittent coastal folded massifs; the second is formed by the coastal plains that separate and extend south of the coastal massifs; the third zone consists of the chain of the Tell Atlas (Atlas Tellien) mountains; the fourth zone consists of the High Plateaus (Hauts Plateaux); and the fifth consists of another chain of mountains, the Saharan Atlas (Atlas Saharien).

The north

The coastal ridges and massifs are indented with numerous bays and are often separated from each other by plains—such as the plains of Oran and Annaba—that extend inland. In the same way, the Tell Atlas is not continuous. In the west it forms two distinct ranges separated by interior plains. Thus the plains of Maghnia separate the Tlemcen Mountains to the south from the Trara Mountains to the northwest. Similarly the plains of Sidi Bel Abbes and Mascara are nestled between hill ranges to the north and south. The Dahra Massif forms a long range extending from the mouth of the Chelif river in the west to Mount Chenoua in the east; it is separated from the Ouarsenis Massif to the south by the plains of the Chelif valley.

The relief as a whole, therefore, does not constitute a barrier to communications in the western Tell. However, this is not the case in the central Tell, where the Blida Atlas merges with the Titteri Mountains and the mountainous block of the Great Kabylie joins with the Biban and Hodna mountains to make north-south communications more difficult. Only the valley of the Wadi Soummam permits communication with the port of Bejaïa.

Mountain barriers

Farther east, from Bejaïa to Annaba, one mountain bar-

rier follows another to separate the Plains of Constantine from the sea. The lands south of the plains are dominated by the Hodna, Aurès, and Nemencha mountains. The plains themselves, which have long been used for growing cereals, have a distinct local topography and do not present the same features as the Algero-Oranian High Plateaus, which extend westward from the Hodna Mountains into Morocco. The latter are broken by sebkhas (lake beds encrusted with salt) and are much less favourable to agriculture because of their lower rainfall.

To the south of the Algero-Oranian High Plateaus and the Plains of Constantine runs the second mountain chain, the Saharan Atlas, which is formed of a series of ranges trending southwest to northeast. These decline in altitude from the west where Mount Aissa attains an elevation of 7,336 feet (2,235 metres) in the Ksour Mountains to lower summits in the Amour and Oulad Naïl mountains. Higher summits are again found in the Aurès Mountains, where the highest peak in northern Algeria, Mount Chelia (7,638 feet), is located.

The south

The Algerian Sahara may be divided roughly into two depressions of different altitude, separated from one another by a central north-south rise called the M'zab (Mzab). Each zone is covered by a vast sheet of sand dunes called an erg. The Great Eastern Erg (Grand Erg Oriental), which has an average altitude of 1,300 to 2,000 feet, and the Great Western Erg (Grand Erg Occidental) decline in elevation northward from the foot of the Ahaggar (Hoggar) Mountains to below sea level in places south of the Aurès Mountains. The Ahaggar Mountains in the southern Sahara rise to majestic summits, the highest, Mount Tahat, reaching 9,573 feet in altitude.

Only the northern Tell ranges, lying along a tectonic plate boundary, experience much seismic activity. Severe earthquakes there have twice destroyed the town of Chlef (El-Asnam), in 1954 and 1980. An earthquake in 1989 did much damage in the zone between the Chenoua massif and Algiers.

Drainage. Most of the rivers of the Tell Atlas are short and undergo large variations in flow. The largest river is the Chelif, which rises in the High Plateau. It crosses the Tell Atlas and flows through an east-west trough to reach the sea east of Mostaganem. The Chelif is so intensively exploited for irrigation and drinking water that it has ceased to flow in its lower reaches during the summer months. South of the Tell Atlas only ephemeral rivers (wadis) are found, and much surface runoff ends in saline chotts within inland depressions. Several Sharan watercourses, in particular those flowing off the Ahaggar uplands, occupy valleys formed largely during past pluvial periods in the Pleistocene Epoch (1,600,000 to 10,000 years ago). Some southward-flowing wadis feed the water tables beneath the Saharan surface, and desert oases occur in locations where the water, under hydrostatic pressure, rises to the surface in artesian wells or springs.

Soils. With its wide variations of relief and geology, Algeria has a diverse mixture of soils. Recent vegetation clearance and erosion have limited the area of fertile brown soils to those uplands where evergreen oak forests are still found. Mediterranean red soils occupy the lower altitudes in much of the northern Tell, while farther south increasing aridity results in immature soils that have undergone little chemical weathering or organic matter accumulation. In the desert areas soil development is further impeded by strong and nearly constant wind erosion. An ambitious project since the 1970s has sought to create a "green barrier" against Saharan encroachment northward by reforesting a narrow strip up to 12 miles in width and some 1,000 miles in length.

Climate. Climate, more than relief, is the country's major geographic factor. The amount of rainfall, and above all its distribution through the year, as well as the timing and magnitude of the sirocco, a dry, desiccating wind that emanates seasonally from the Sahara (often with gale force), constitute the principal elements upon which agriculture and many other activities depend.

Algeria's coastal zone and northern mountains have a typical Mediterranean climate, with warm dry summers and mild rainy winters. Algiers, for example, has afternoon temperatures in July of 83° F (28° C), which drop to about 70° F (21° C) at night, while in January daily temperatures range between 59° and 49° F (15° and 9° C). Eighty percent of the city's 30 inches (760 millimetres) of annual precipitation falls between October and March, and July and August are usually rainless. Total annual rainfall increases along the coast as one proceeds from west to east but diminishes rapidly from the coast southward into the interior. The greatest amount of rainfall is experienced in the mountainous regions of the eastern littoral, which are directly exposed to the humid winds that blow inland from the Mediterranean. From a point about 50 miles west of Algiers to the Tunisian frontier, annual rainfall exceeds 23 inches, and in certain places—for example in the Great Kabylie, Little Kabylie, and Edough regions—reaches about 40 inches. West of this location, however, a considerable part of the Chelif Plains, and the plains of the littoral and the region immediately to the south of it in the vicinity of Oran, are insufficiently watered, receiving less than 23 inches. As soon as one crosses the Atlas ranges to the south, however, rainfall diminishes rapidly, except in the Aurès and in a section of the Amour Mountains, which still receive about 16 inches.

Mediterranean climate

This east-west boundary roughly separates the two principal agricultural zones of the country. In the first, dry farming is generally possible and commercially profitable. Fine forests and an abundant vegetation also are found. In the second zone the cultivation of cereal crops is possible only with irrigation. Instead, pastoral activities are predominant, and the forests disappear.

Algeria's relief, which parallels the coastline, limits the southward penetration of the Mediterranean climate. The plains and hills in the region immediately to the south of the coastal mountains still receive sufficient rainfall but have a much drier atmosphere, and temperatures show

Travelers passing through a valley of the Aurès Mountains in northern Algeria.
Victor Englebert

more variation in range. The High Plateau, on the other hand, is characterized by great daily and annual extremes of temperature, hot summers and cold winters, and insufficient rainfall. Summer temperatures are typically above 100° F (38° C) in the afternoon and drop to about 50° F (10° C) at night. In winter the daily range is from about 60° F (16° C) during the day to about 28° F (– 2° C) at night. Annual rainfall varies between 4 and 16 inches.

On the southern border of the Saharan Atlas, the Sahara proper begins. The demarcation coincides with a diminution of the rainfall to less than four inches a year. The landscape and the type of plant life differ greatly from those in the north. Life and activity are limited to a few privileged locations. Daily and annual temperature ranges are even more extreme than on the High Plateau, and the rains, more than in the north, are marked by their great irregularity. Three years may pass without rainfall in the Tademaït region, and as many as five years on the Ahaggar Plateau.

Plant and animal life. Natural vegetation patterns generally follow the country's north-south climatic gradient, with accompanying altitudinal variations in the highland areas. All vegetation in Algeria, where some seasonal aridity occurs everywhere, is characteristically drought-resistant. Forests cover only about 2 percent of the entire land area and are found primarily in the less-accessible mountain regions, where remnants of evergreen forests remain on the moister slopes. Dominated by holm oak, cork oak, conifers, and juniper, the forests today have only limited patches of valuable cedar. Much of the entire Tell region in the north was once covered with woodland, but most of this has been replaced by a poor maquis scrubland consisting of evergreen hard-leaved shrubs and low trees. Often aromatic, maquis shrubs include laurel, rosemary, and thyme. On limestone and poorer soils, however, maquis degenerates into garigue, a low-growing shrub association of gorse, lavender, and sage.

Maquis scrubland

Farther south, increasing aridity reduces the vegetation to a discontinuous type of steppe (treeless plains) dominated by esparto grass. A richer association containing Barbary fig and date palm is still found along the wadis, however. In the desert proper, plant life is very dispersed and consists of tufts of several kinds of grass, various robust species that need almost no water such as drinn and cramcram, several shrubs (which are always stunted and are sometimes spiny), ethels, acacia, and jujube trees, as well as some more varied species that are found in the beds of wadis with underground water or in mountainous regions.

The animal life of the northern mountains includes wild mouflons, Barbary deer, wild boars, and Barbary apes. A multitude of migratory birds pass through the country, including storks and flamingos. In the Sahara gazelles, fennecs, hyenas, and jackals can be found together with many smaller mammals, such as gerbils and desert hare. Insect life is abundant and is most spectacularly manifested in the region's periodic outbreaks of massive locust swarms. Scorpions are common in the arid and semiarid regions.

Settlement patterns. Algeria's population density is highest in the plains and coastal mountains of the northern Tell region. This coincides with the areas of higher, more reliable rainfall. Density declines southward so that much of the southern High Plateau and Saharan Atlas regions are very sparsely populated, while farther south large stretches of the Sahara are virtually uninhabited. Traditionally, rural settlement in Algeria consisted of widely scattered hamlets and isolated dwellings, with nomads in parts of the Sahara and its fringes. Concentrated village settlements were sometimes found at oases and in certain upland regions, such as in the Aurès Mountains and in the Great Kabylie region, the latter being a Berber stronghold renowned for its hilltop villages and traditional way of life.

Rural settlement patterns

French settlers coming to Algeria in the latter half of the 19th century built several hundred "villages of colonization" in the countryside. Often geometric in layout, these settlements replicated French villages and house designs and often provided important service centres in areas of dispersed rural settlement.

The Algerian War of Independence (1954–62) destroyed nearly 8,000 villages and hamlets and displaced some three million people. Many of the displaced were relocated to several thousand new resettlement centres, while others were moved to towns. Most of these centres continued to exist after the war, becoming regular villages as they acquired service functions. In the 1970s another wave of rural settlement was engendered by the government's agrarian reform program, as about 400 "socialist villages" were constructed. By the 1980s, however, this program was abandoned in favour of promoting privately funded settlement efforts.

Urbanization increased greatly under French rule as service centres were created in rural areas and European suburbs and new public buildings were added to the larger cities. Port and industrial activities also accelerated the development of certain coastal towns, such as Annaba (Bône), Skikda (Philippeville), and Mostaganem. During and after the War of Independence, rural exodus to many towns changed them from mainly European settlements to overcrowded Algerian cities. The departure of some one million Europeans after the war made many dwellings available but, because of the subsequent rapid urban growth rate (and even with considerable new construction), did little to alleviate overcrowding in the cities. In the late 20th century, one-half of the population lived in urban areas, of which the largest were located along the coast.

The people. *Ethnic composition.* Some 80 percent of the country's population consider themselves to be ethnically Arab, though most Algerians are descendents of ancient Berber groups who mixed with various invading peoples from the Arab Middle East, southern Europe, and sub-Saharan Africa. Arab invasions in the 8th and 11th centuries brought only limited numbers of new people to the region but resulted in the extensive Arabization and Islāmization of the indigenous Berber population. About 20 percent of Algerians now consider themselves to be Berber, of whom the Kabyle Berbers, occupying the mountainous area east of Algiers, form the largest group. Other Berber groups are the Shawia (Chaouïa), who live primarily in the Aurès Mountains; the M'zabites, a sedentary group descended from the 19th-century Ibāḍite followers of ʿAbd ar-Raḥman ibn Rustam, who inhabit the northern edge of the desert; and the Tuareg nomads of the Saharan Ahaggar region. Nearly all the European settlers, mainly French, Italian, and Maltese nationals, who formed a sizable minority in the colonial period, have departed.

Linguistic composition. Arabic is the first language of the majority of the population and is understood by most others. It is also the country's official language. Berber, in several geographic dialects, is spoken by Algeria's ethnic Berbers, though most Berbers also tend to be bilingual in Arabic.

Algeria's official policy of "Arabization" since independence, which aims to promote indigenous Arabic and Islāmic cultural values throughout society, has resulted in the replacement of French by Arabic as the national medium and, in particular, as the primary language of instruction in primary and secondary schools. Arabization has met with strong resistance among some Berber groups, who fear domination by the Arabic-speaking majority.

Official policy of "Arabization"

Religions. Most Algerians, both Arab and Berber, are Sunnite Muslims of the Malikite (Māliki) sect. A source of unity and cultural identity, Islām provides valuable links with the wider Islāmic world as well. In the struggle against French rule, Islām became an integral part of Algerian nationalism. A distinctive North African aspect of the religion, stemming from pre-Islāmic Berber practices, is the important role played by marabouts, or saintly individuals who possessed special spiritual powers. Venerated locally as mystics and teachers, marabouts gave rise to brotherhoods with their own rituals and rites and were of particular appeal to rural folk who lacked the education to assimilate Qur'ānic teachings directly. Because of the disdain for established authority that maraboutism engendered, Islāmic reformers and state bodies have historically sought to restrict its growth and influence.

While the independent Algerian government has confirmed the country's Islāmic heritage, its policies have often encouraged secular developments. In reaction, Islāmic fundamentalism has been increasing in strength since the

late 1970s. Muslim radicals have periodically clashed with left-wing students and emancipated womens' groups, while fundamentalist imams (prayer leaders) have gained control of many of the country's major mosques.

Demographic trends. Algeria's annual rate of population growth has been high—often above 3 percent—throughout much of the latter half of the 20th century, but by the late 1980s there were signs of demographic transition as growth overall, and birth rates in particular, began to decline. With a youthful population in which one-half are 18 years of age or younger and improved infant mortality rates, however, death rates have also declined and partly offset the effects of the lower birth rates. Most fertility decline has occurred in the cities, where the government's limited family planning program is focused. Life expectancy is about 65 years for men and 67 years for women.

Emigration of Algerians to Europe, once a viable alternative for the country's unemployed, has declined in the late 20th century as France has restricted further immigration, but decades of such migration have left a large Algerian community scattered throughout many of the cities of France, Belgium, and other western European countries. In the desert region, the effects of drought and government policies promoting sedentarization have acted to reduce Saharan nomadism sharply in the 20th century. A growing number of Algeria's famed Tuareg nomads, for example, now lead sedentary lives around oases such as Djanet and Tamanghasset (Tamanrasset), while others cling irresolutely to a precarious and ever more obviously fading way of life.

Decline of nomadism

The economy. Algeria's economy is dominated by its export trade in oil and natural gas. Until 1962 the economy was largely rural-based and complementary to that of France. Since independence, however, production of oil and especially natural gas has come into its own, and industrialization has proceeded rapidly. A series of nationalizations and national plans transformed Algeria into a centrally planned economy with a state socialist system, but, with efforts to privatize parts of the economy taking place in the 1980s, its socialist orientation has been modified somewhat. Standards of living have risen to those of an intermediately developed country, but lower levels of self-sufficiency in food production and an increasingly serious international debt problem pose major obstacles to continued rapid development.

Resources. Extensive deposits of sulfur-free light crude oil were discovered in the Algerian Sahara in the mid-1950s. Production began in 1958, concentrated in three main fields: Hassi Messaoud in the northeastern part of the Sahara, Zarzaitine-Edjeleh along the Libyan border, and El-Borma on the Tunisian border. Reserves in the late 20th century were estimated to be more than nine billion barrels.

Oil and natural gas

Deposits of natural gas were first discovered at Hassi R'Mel in 1956, and since then discoveries have also been made at several other fields. With proven reserves of some 106 trillion cubic feet (3 trillion cubic metres), Algeria ranks seventh in the world in terms of total gas reserves. The gas has a methane content of almost 85 percent and also contains ethane, propane, and helium. Gas liquefaction plants at Arzew and Skikda and a trans-Mediterranean pipeline to Italy via Tunisia permit exports of Algerian gas.

Extensive deposits of high-grade iron ore are worked at Ouenza, and major deposits of medium-grade ore exist at Gara Djebilet near Tindouf.

Deposits of nonferrous metal ores are smaller and more scattered. These include sizable deposits of zinc and lead at El-Abed near Tlemcen and of mercury ore at Azzaba. Intensive prospecting for minerals in the Ahaggar Mountains has been carried out, and traces of tin, nickel, cobalt, chrome, and uranium have been found. Development of the Ahaggar uranium deposits began in the early 1980s.

Phosphate deposits of relatively inferior grade are mined south of Tébessa at Djebel Onk. Sizable kaolin deposits at Djebel Debbagh and large reserves of marble and onyx have been found.

Agriculture. Algeria's intensively cultivated land is largely restricted to the coastal plains and valleys that were colonized by French settlers who established vineyards, orchards, citrus groves, and market gardens. The best farms were located in the well-watered fertile plains around Bejaïa and Annaba in the east, in the Mitidja Plain south of Algiers, and beyond Oran from Sidi Bel Abbes to Tlemcen. The Médéa and Mascara plateaus are also rich vineyard areas. In the drier High Plateau, notably around Constantine, and in the Sersou Plateau to the west, cereals are grown. Also in the west there is an extensive area of esparto grass growing naturally on the region's steppe plains.

Because of aridity, however, more than four-fifths of the country's surface area is uncultivable, and most of the remaining agricultural land is suitable only for pasture. The rest is tilled or devoted to vineyards and orchards. Winter grains (wheat, barley, and oats) are grown on the largest area of arable land. Cotton, tobacco, olives, and dates are important, and sorghum, millet, corn (maize), rye, rice, and truck vegetable crops are also grown. The climate is ill-suited to extensive stock raising, but there are some scattered herds of cattle, goats, and sheep.

Irregular rainfall has long been a threat to agriculture and has also limited hydroelectric development. Dam construction and irrigation projects have added some stability to crop production, but Algeria's meagre water resources are under increasing pressure from urban-industrial demands as well as from the country's growing agricultural needs. At independence Algeria possessed some 20 sizable dams, and an active construction program nearly doubled that number by the late 1980s, adding substantially to the country's total irrigated acreage.

Water resources

Since independence agriculture has been the neglected sector of Algeria's economy, suffering from underinvestment, poor organization, and successive restructuring. As a result, cereal production has undergone large annual fluctuations, orchard and industrial crops have largely stagnated, and viticulture has declined markedly. Wine production, once the mainstay of colonial agriculture and exports, is now low, a tenth of its 1950s levels, and is increasingly deemed culturally inappropriate. Only market gardening and livestock production have shown significant growth. As a result, Algeria has changed from being a food-exporting nation in the 1950s to having a serious food dependency in the late 20th century, as up to 75 percent of food needs are imported.

Forestry and fishing. Algeria's limited forested area has relegated forestry to a position of only minor importance in the country's economy. Furthermore, as the forested area has decreased rapidly since the 1950s, adding to the country's serious problem of soil erosion, government efforts have been aimed at preserving and expanding the remaining forested area. Some cork from the cork oak forests in the higher elevations of the Tell Atlas is processed domestically, however.

The fishing industry is largely underdeveloped, landing only about one-half of its estimated potential catch. Refrigeration and canning facilities, necessary for transporting the catch inland, are limited. The government has given the industry increasing attention in its recent development plans, however.

Industry. The country's main mining centres are at Ouenza and Djebel Onk near the eastern border with Tunisia and at El-Abed in the west. Nearly all of the country's substantial output of high-grade iron ore from the opencut works at Ouenza is used to supply Algeria's own steel industry. Similarly, about one-third of Djebel Onk's phosphate production supplies the Annaba fertilizer complex, while the remainder is exported. El-Abed is Algeria's largest zinc and lead mine, producing most of the nation's output of zinc and lead.

Before independence the manufacturing sector was mainly confined to food processing, textiles, cigarettes, and clothing. Since 1967, however, the main emphasis has been put on heavy industry. The state steel corporation, for example, completed its large El-Hadjar steelworks complex at Annaba in the early 1970s and has constructed a zinc electrolysis plant near the El-Abed mine at Ghazaouet. Much of the steel produced for domestic consump-

Steel production

tion is allocated for machine tools, tractors, agricultural equipment, buses, trucks, and automobiles. Paralleling the Annaba steel complex is the vast Skikda petrochemical works, which includes a gas liquefaction plant, an ethylene factory, liquid petroleum gas separation facilities, a plastics factory, and a benzene refinery. Other gas liquefaction plants are at Bejaïa and Arzew, the latter also being the site of a nitrogenous fertilizer factory, an oil refinery, and a liquid petroleum gas separation plant. A complex at Sétif is composed of methanol and plastics factories, while a further major project in the heavy industry sector is the phosphate fertilizer factory at Annaba.

Most of these industrial developments were by large state-run companies. In the 1980s these were restructured into smaller state-run units and encouraged to pursue joint ventures with private concerns. Also in the 1980s, more emphasis was placed on lighter manufacturing projects.

Following the discovery of oil in the mid-1950s, the main prospecting and producing companies were two French groups, CFP-A (Compagnie Française des Pétroles-Algérie) and ERAP (Entreprise de Recherches et d'Activités Pétrolières). They were later followed by some of the international oil companies. In the late 1960s and early 1970s all French and international oil companies operating in Algeria were nationalized and amalgamated into the state-owned Algerian oil concern, Sonatrach (Société Nationale de Transport et de Commercialisation des Hydrocarbures), which had been set up in 1963–64. Sonatrach extended its activities into exploitation and production on its own account with some success. Much of this development was accomplished with Soviet assistance and more recently by setting up a series of joint service companies with American specialist help.

Pipelines

Four pipelines transport oil from the oil fields to the Mediterranean. The Trans-Mediterranean natural gas pipeline from Tunisia to Sicily and Naples was completed in 1981, boosting substantially the sales of Algerian natural gas to Europe. Exports of natural gas promise to be more important for the economy than sales of oil.

Finance and trade. The Banque d'Algérie, an independent central bank established in 1963, issues the Algerian dinar, the national currency. The government restructured the commercial banking system in the mid-1980s, increasing the number of state-owned commercial banks in the country. The state also opened the financial market to private banks, including some foreign ones, in the 1990s. A law enacted in 1995 lifted government price controls on a variety of commodities. Price subsidies on various basic products have been gradually phased out, in line with Algeria's restructuring agreements with the International Monetary Fund.

Virtually all of Algeria's foreign exchange earnings are derived from the export of petroleum and natural gas products, both of which are refined domestically at an increasing rate. Other exports include phosphates, vegetables, dates, tobacco, and leather goods. The major imports are capital goods and semifinished products, consisting mostly of industrial equipment and consumer goods, followed closely by foodstuffs. About two-thirds of all trade is with countries of the European Union, followed by the United States.

Algerian trade with France dropped from four-fifths of the total trade in 1961 to about one-fifth in the late 20th century. French imports of Algerian agricultural products, especially wine, were severely restricted after independence. Algerians in France formerly remitted substantial sums of money annually to relatives in Algeria; this was partly responsible for Algeria's healthy balance-of-payments position. By the mid-1990s, however, the annual balance of payments was often negative, and Algeria had a high level of external debt.

Transportation. Fast and frequent rail service was established between Oran, Algiers, and Constantine by the late 20th century. The main rail line parallels the coast and extends from the Moroccan to the Tunisian border. Several standard-gauge lines branch from the main line to port cities and to some interior towns, and a few narrow-gauge lines cross the High Plateau to the Algerian Sahara. Two trans-Saharan roads have been built: one paved route from El-Goléa to Tamanghasset and then south to Niger, the other from El-Goléa to Adrar and then on to Mali. A state bus company and several private companies provide reliable intercity bus services.

The principal ports are Algiers, Oran, Annaba, Bejaïa, Bettioua, Mostaganem, and Ténès, in addition to the primarily petroleum and natural gas ports at Arzew and Skikda. Algeria's merchant fleet has grown into a major world shipping line. Administered by the Algerian National Navigation Company, the fleet includes more than 150 vessels, including oil tankers and specialized liquid natural gas tankers. Air Algérie, the state airline, operates flights to many foreign countries and provides daily domestic flights between the country's major cities and towns. There are international airports at Algiers, Annaba, Constantine, Oran, Tlemcen, and Ghardaïa.

Administration and social conditions. *Government.* Algeria was dominated for the first three decades following independence by the National Liberation Front (Front de Libération Nationale; FLN), until 1989 the sole legal political party. New electoral laws passed in that year made the country a multiparty state. The newest constitution, adopted in 1996, provides for a strong executive branch headed by a president, who may be elected, by universal suffrage, for two five-year terms. The president, who is chief of state, appoints numerous state officials, including a wide range of civilian and military leaders, provincial governors, and the prime minister, who acts as head of the government. The prime minister nominates a government for the president's approval, thus completing the executive, and presents a program to the lower house of the nation's bicameral legislature for ratification.

Constitution of 1996

Once the government is in place, the head of government presents draft legislation, which is debated first in the country's lower house, the National People's Assembly (Majlis al-Sha'bī al-Waṭanī), composed of 380 deputies elected for five-year terms by universal adult suffrage. Debate then passes to the upper house, the Council of the Nation (Majlis al-Ummah), consisting of 144 members serving six-year terms, one-third of whom are appointed by the president. The remaining two-thirds are elected indirectly by a secret ballot of local and district legislatures. The legislature meets twice per year, each session lasting no less than four months. It is empowered to draft and ratify legislation on a wide variety of issues, including matters of civil and criminal law, personal status, state finance, and the exploitation of natural resources.

The constitution of 1996 also established a Constitutional Council (Majlis Dustūrī) to oversee elections and referenda, rule on issues of the constitutionality of treaties, negotiations, and amendments, and, when called on by the president, issue opinions on the constitutionality of laws. The Council is appointed jointly by the executive, legislative, and judicial branches.

Below the national level the country is divided into 48 *wilāyāt* (provinces), each with its own elected assembly (Assemblée Populaire de Wilaya; APW), executive council, and governor. The provinces are in turn divided into 227 *dā'irāt* (administrative districts) and then into more than 1,500 *baladīyāt* (communes), each one having its own assembly (Assemblée Populaire Communale) to run local affairs.

Justice. The judiciary consists of three levels. At the first level is the tribunal, to which civil and commercial litigation is submitted and which takes action in penal cases of the first instance. At the second level is the provincial court, which consists of a three-judge panel that hears all cases and functions as a court of appeal for the tribunals and for the administrative jurisdictions of the first instance. At the third and highest level is the Supreme Court, which is the final court of appeal and of appeals against the decisions of the lower courts. In 1975 the Court of State Security, composed of magistrates and high-ranking army officers, was created to handle cases involving state security. The Council of State acts as an administrative equivalent to the Supreme Court, hearing cases not ordinarily reviewed by that body; and the Tribunal of Conflicts was instituted to regulate any jurisdictional disputes that might arise between the other two high courts.

Arabization of learning

Education. Particular attention has been given to replacing French with Arabic as the language of instruction and emphasizing scientific and technical studies. Education in Arabic is officially compulsory for all children between 6 and 15 years of age, and most children of primary-school age and half of all secondary-school-age children are enrolled. Girls and children residing in rural areas have remained underrepresented in the classroom, although much progress for both groups has been made since independence. The literacy rate is about three-fourths for men but less than half for women. The educational system has experienced much difficulty trying to accommodate the increasing number of school-age children. The scarcity of qualified Arabic teachers has been ameliorated by the recruitment of teachers from other Arab countries. Arabic replaced French as the language of instruction at all institutes of higher learning in 2000. Berber discontent over the policy of Arabization, however, has prompted the government to restore Berber language and literature studies at a number of universities. The major institutions include Islāmic universities in Algiers and Constantine, several regional university centres, and a number of technical colleges.

Health and welfare. Because of the country's relatively young population and pressing medical needs, the health care system is oriented toward preventive medicine rather than treatment. Instead of building expensive hospitals, Algeria emphasizes smaller clinics and health centres and maintains a comprehensive vaccination program. Medical care, including medication, is provided by the state without charge, although those earning middle and higher incomes pay a part of their medical fees on a proportional scale. There is an increasing trend toward private health care. In an effort to extend health care to everyone, the government requires all newly qualified physicians, dentists, and pharmacists to work in public health for at least five years. Most medical personnel and facilities, however, remain concentrated in the north, especially in the large cities. Remote mountain locations and much of the Sahara are nearly devoid of modern facilities. Tuberculosis, hepatitis, measles, typhoid fever, cholera, and dysentery are the principal health problems, often brought about by inadequate sanitation facilities and lack of safe drinking water.

Housing. Algeria's chronic housing shortage contributed to health problems throughout much of the latter half of the 20th century. Continuous rural-urban migration and unchecked population growth allowed urban shantytowns to proliferate. The government, whose spending priorities had been focused largely on heavy industry since independence, did little to relieve the housing shortage until the mid-1980s. At that time, however, development plans began emphasizing investment in social infrastructure and services. More construction of affordable government-subsidized housing units has since taken place, including a large prefabricated housing construction program to tackle the most urgent housing needs. Foreign companies—including some from Yugoslavia—were increasingly granted large construction contracts. Algeria also benefited from soft loans throughout the 1990s from the World Bank, the European Union, and other Arab countries to promote its construction sector. State companies were privatized, and joint ventures with European and American companies finally began to address some of the country's housing needs.

Cultural life. Algerian culture and society were profoundly affected by 130 years of colonial rule, by the bitter independence struggle, and by the subsequent broad mobilization policies of postindependence regimes. A transient, nearly rootless society has emerged, whose cultural continuity has been deeply undermined. Seemingly, only deep religious faith and belief in the nation's populist ideology have prevented complete social disintegration. There has been a contradiction, however, between the government's various populist policies, which have called for the radical modernization of society as well as the cultivation of the country's Arab-Islāmic heritage and traditional family structure. Although Algeria's cities have become centres for this cultural confrontation, even in remote areas of the countryside the state has taken roles traditionally filled by the extended family or clan. Algerians have thus been caught between a tradition that no longer commands their total loyalty and a modernism that is attractive yet fails to satisfy their psychological and spiritual needs.

Role of religion

Daily life. Despite efforts to modernize Algerian society, the pull of traditional values remains strong. Whether in the city or countryside, the daily life of the average Algerian is permeated with the atmosphere of Islām, which has become identified with the concept of an autonomous Algerian people and of resistance to what many Algerians perceive as a continued Western imperialism. Practiced largely as a set of social prescriptions and ethical attitudes, Islām in Algeria has more characteristically been identified with supporting traditional values than serving a revolutionary ideology.

Algerians enjoy association football (soccer), handball, volleyball, and athletics. Algerian athletes have participated in the Olympic Games since 1964. They have won medals in boxing, but their major success has been in the area of long-distance running. Noureddine Morceli won the men's 1,500-metre event at the 1996 Summer Olympics and has held numerous world running records. Another runner, Hassiba Boulmerka, won several world championships and a gold medal in the women's 1,500-metre run at the 1992 Summer Games, becoming the first African or Arab woman to win an Olympic track-and-field event.

Algerian cuisine, like that of most North African countries, is heavily influenced by Arab, Berber, Turkish, and French culinary traditions. Couscous, a semolina-based pasta customarily served with a meat and vegetable stew, is the traditional staple. Mutton, lamb, and poultry are still the meat dishes of choice; favourite desserts rely heavily on native-grown figs, dates, and almonds and locally produced honey; and couscous and unleavened breads complete virtually every meal. As is the case in the Middle East, strong, sweet Turkish-style coffee is the beverage of choice at social gatherings, and mint tea is a favourite.

The arts. Various types of music are native to Algeria. One of the most popular, originating in the western part of the country, is *raï* (from Arabic *raʾy*), which combines varying instrumentation with simple poetic lyrics. Both men and women are very free to express themselves in this style. One especially popular Algerian singer of *raï*, Khaled, has exported this music to Europe and the United States, but he and other popular musicians have been targets of Islāmic extremists. *Wahrani* (the music of Oran), another style, blends *raï* with classical Algerian music of the Arab-Andalusian tradition.

Literature

Algeria has produced many important writers. Some, such as Albert Camus and Jean Sénac, are French, although their work was influenced by the many years they spent in Algeria. The writing of Henri Kréa reflects the two worlds he inhabited as the son of a French father and an Algerian mother. 'Abd al-Hamid Benhadugah is the father of modern Arabic literature in Algeria, while Jean Amrouche is considered the foremost poet of the first generation of North African writers who wrote in French. The work of Mouloud Feraoun reflects Berber life. Mohammed Dib, Malek Haddad, Mourad Bourboune, Rachid Boudjedra, and Assia Djebar have all written about contemporary life in Algeria, with Djebar reflecting on this from a woman's perspective.

Press and broadcasting. Daily newspapers are published in both Arabic and French in Algiers, Oran, and Constantine. Several weeklies and a host of magazines are also published in the country. The number and range of newspapers increased during the 1990s, despite frequent violent attacks directed against journalists by Islāmic extremists. Radiodiffusion Télévision Algérienne operates as a broadcasting institution under the Ministry of Information and Culture. Its three radio channels offer programming in Arabic, Kabyle, and, on its international channel, a mixture of French, English, and Spanish. The television network—with two channels—transmits to most of the country. The number of satellite dishes has increased, and many Algerians are now able to receive European stations.

(A.K.Ch./K.Su.)

see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR.

HISTORY

Algerian history before Ottoman rule reveals a country of which the western part was often closely associated with Morocco and the eastern part with Tunisia. Few extensive or long-lived Muslim dynasties originated or were based in Algeria. Geographically, Algeria is a difficult country to rule, with the Tell and Saharan Atlas mountain chains impeding easy north-south communication and the few good natural harbours having access to limited hinterlands. That a significant minority of Algerians were native Berber speakers (and many remain so to this day) indicates the greater resistance to Arabization in Algeria as contrasted with neighbouring Tunisia, not to mention Libya and Egypt. Nor was Ottoman Algeria in the early years of the 19th century nearly so developed in its "nationalization" of politics and government as Tunisia.

Never an easy country to rule or to hold together, Algeria is today very much a nation-state. Much of the present-day sense of nationhood is the result of Algeria's history since 1830. Apologists for French rule in Algeria were wont to assert that France made Algeria. They were, at best, half right. It was the dialectic of colonial confrontation between the two communities on opposite sides of the Mediterranean that fostered Algerian nationalism. Modern Algeria must be viewed in light of its century and a half of colonial rule and confrontation with the West to be understood.

The 19th century. It is customary to begin the story of the French conquest of Algeria in April 1827 when the dey of Algiers angrily struck the French consul with a fly whisk. Three years later the French conquest of Algeria began. In those intervening years, the French government had attempted several tactics to establish control over the region: they tried unsuccessfully to induce Muḥammad ʿAlī, the pasha of Egypt, to send his army against the Deylik (Muḥammad ʿAlī was willing but only provided he kept full control of Algeria), and they instituted a naval blockade against Algeria that was ultimately found to be ineffective. Finally, in early 1830, they decided to invade the country.

The government of the dey, temporizing in the traditional way of confronting European demands and trusting that intervention from other European powers or from Istanbul might save the day, proved no match for the French army that landed on July 5, 1830—Ḥusayn, the last dey of Algiers, surrendered. He and other top officials accepted the French offer of exile. Their departure marked the end of a three-century-long period of Algerian history as an autonomous province of the Ottoman Empire. Only one important Ottoman Algerian leader, Aḥmad Bey, managed to hold out a few years longer, but he ruled from Constantine, an interior city far removed from Algiers and the sea, which France easily controlled.

The French invasion

The French government had decided to invade in the belief that a quick victory abroad might earn it sufficient popularity at home to win the coming elections. Instead, only days after the French victory in Algeria, the July Revolution in France forced the reactionary King Charles X from the throne and ushered in the rule of Louis-Philippe as king of France.

In Algeria a period of vacillation ensued. Although those who achieved the July Revolution in France had cynically dismissed the campaign in Algeria as foreign adventurism to cover oppression at home, they were reluctant to simply withdraw. Various alternatives were considered, including an early ill-fated plan to establish princes of the Tunisian beylical family in parts of Algeria as rulers under French patronage. Efforts to rule through local clients proved equally ineffective, the French realizing too late that such an option might have been better achieved by recruiting the officers of the defeated dey. Another idea was to hold only coastal areas that could be secured easily and economically by French naval power. These first few years of colonial rule were characterized as well by numerous changes of French command. Even in these early years of French indecisiveness a number of French settlers began to arrive. They would soon constitute an ever-growing interest group bent on seeing that France remained in Algeria.

Algerian resistance

There also were efforts to reach settlements with the two principal resistance leaders who emerged after 1830, Aḥmad Bey in Constantine and a native tribal and Ṣūfī brotherhood leader, Abdelkader (ʿAbd al-Qādir ibn Muḥyi ad-Dīn), in western Algeria. Aḥmad Bey repulsed a French attempt on Constantine in 1836, but was driven from the city the following year. The French signed two different agreements with Abdelkader (1834 and 1837), but after the French moved through territory claimed by him later, he countered with a major attack in 1839, driving the French back to Algiers and the coast.

France decided thereafter on all-out war. Led by General (later Marshal) Thomas-Robert Bugeaud, the campaign of conquest eventually brought one-third of the total French army strength (more than 100,000 men) to Algeria and lasted until Abdelkader, using hit-and-run tactics of tribal combat, was forced to surrender in 1847. Earlier Abdelkader, seeking refuge and recruits in Morocco, had forced a reluctant Sultan Abd ar-Rahman to take a stand against French incursions. This resulted in the disastrous defeat of Moroccan forces at the Battle of Isly in 1844.

Abdelkader, exiled to France, was later permitted to settle with his family in Damascus, Syria, where he and his followers saved the lives of many Christians during the 1860 massacres there. Respected even by his opponents, Abdelkader became, and has remained, the personification of Algerian national resistance to foreign domination.

(L.C.Br.)

Abdelkader's defeat marked the end of what might be called resistance on a national scale, but smaller operations continued, such as the occupation of the Saharan oases (Zaatcha in 1849, Nara in 1850, and Ouargla in 1852). The eastern Kabylie region was subdued only in 1857, while the final great Kabylie rising of Muḥammad al-Moqrānī was suppressed in 1871. The Saharan regions of Touat and Gourara, theretofore Moroccan spheres of influence, were occupied in 1900; the Tindouf area, previously regarded as Moroccan rather than Algerian, was only attached to the latter region after the French occupation of the Anti-Atlas in 1934.

Pattern of French rule

French Algeria. The manner in which French rule was established in Algeria during the years 1830–47 laid the groundwork for a pattern of rule that French Algeria would thereafter maintain in its essentials. It was characterized by a tradition of violence and mutual incomprehension between rulers and ruled, by the relative absence of well-established native interlocutors between the French rulers and the great mass of the population, and by an ever-growing French settler population (the colons) demanding the privileges of a ruling minority in the name of French democracy. That Algeria eventually became juridically a part of France added to the power of the colons, who sent delegates to the French parliament. From the late 19th century until the end of French rule, the settlers accounted for roughly 10 percent of the total population.

Settler domination of Algeria was not, however, secured until the fall of Napoleon III in 1870 and the rise of the Third Republic in France. Until then, Algeria remained largely under military administration. The governor-general of Algeria (a title first given to Bugeaud in 1845, replacing the earlier title "governor-general of the French possessions in Africa") was almost invariably a military officer until the 1880s, and most Algerians—but not the settlers—were subject to rule by military officers organized in the famous Arab Bureaus (Bureaux Arabes), whose members (officers with an intimate knowledge of local affairs and of the language of the people), having no direct financial interest in the colony, often sympathized with the outlook of the people they administered rather than with the demands of the European colonists. The seeming paradox of French Algeria was that despotic and military rule offered the native Algerians a better situation than did civilian and democratic government.

A large-scale confiscation of cultivable land, following the crushing of resistance, made colonization possible. Settler colonization was of mixed European origin (mainly Spanish in and around Oran; French, Italian, and Maltese

European-Muslim relations

in the centre and east). For long the presence of the non-French settlers was officially regarded with alarm; but, with time, the influence of French education, of the Muslim environment, and of the Algerian climate created in the non-French a European-Algerian, subnational sentiment. This would probably have resulted, in time, in a movement to create an independent state if Algeria had been situated farther away from Paris and if the settlers had not feared the potential strength of the Muslim majority.

On the overthrow of Louis-Philippe's regime in 1848, the settlers succeeded in having the territory declared French and the three former Turkish provinces converted into departments on the French model, while colonization was developed with renewed energy. On the establishment of the French Second Empire in 1852, responsibility for Algeria was at first transferred from Algiers to a minister in Paris. Soon, however, the emperor reversed this disposition. While expressing the hope that an increased number of settlers would forever keep Algeria French, he also declared that France's first duty was to the three million Arabs. With considerable accuracy he declared that Algeria was "not a French province but an Arab country, a European colony, and a French camp."

This attitude aroused certain hopes in Arab minds, but they were destroyed by the emperor's downfall in 1870. The French defeat in the Franco-German War gave impetus to the last great Kabylie rising (1871) under Muḥammad al-Moqrānī. Its suppression by French forces was followed by the sequestration of another 11 million acres (4.5 million hectares) of land and the imposition of an indemnity of 36.5 million francs; these measures together provided land for refugees from Alsace and capital with which to exploit the land.

During the 50 years that followed, the European population felt free to establish political, economic, and social domination over the country and its native inhabitants. At the same time, new communications, the installation of hospitals and medical services, and modern education—dispensed to a very limited extent and in French to the Muslims, while generally available to the Europeans—created a minority of better-off Algerians.

For Algerians, service in the army and in the factories of France during World War I was another eye-opening experience. When peace returned, some 70,000 Algerians remained in France, and by living with extreme economy they were able to support many thousands of their relations in Algeria.

Three rival tendencies

Nationalist movement. The development of Algerian nationalism can be described in terms of three separate tendencies. First, there was the small group of Algerians who had gained access to French education and earned their living in the modernized French sector. Many of this group, called "assimilationists," were prepared to consider permanent union with France, provided the rights of Frenchmen were extended to native Algerians. Such was the case with the loosely organized "Young Algerians" in the period before World War I, or even to a considerable extent with Khaled Ben Hachemi ("Emir Khaled"), the grandson of Abdelkader, in the 1920s, or with Ferhat Abbas, who later became first premier of the Provisional Government of the Republic of Algeria, as late as the 1930s. All of this group were prepared to accept gradualist, reformist tactics, eschewing illegal actions. They were the Algerian equivalents of the political class who led their countries to independence in most former European colonial territories. They had no such chance in Algeria, for their roots in Algerian society were too shallow and the colons of French Algeria resisted even small reformist measures that might have led, however slowly, to piecemeal liberation.

The second tendency was a Muslim reformist group inspired by the religious Salafiya movement founded earlier in Egypt by Sheikh Muḥammad ʿAbduh. Organized in 1931 as the Association of Algerian Muslim Ulama (AUMA) under the leadership of Sheikh Abd al-Hamid ben Badis, this group was not a political party as such. As religious reformers primarily, they were instead important in engendering among the masses of Algerians a strong sense of Muslim Algerian nationality. They also stymied any possible effort on the part of the assimilationist tendency to move toward more accommodating positions with France in the hope of gaining some concessions.

The third tendency was more proletarian and radical in orientation. It took organizational form among Algerian workers in France in the 1920s under the leadership of Messali Hadj, later gaining wide support in Algeria as well. Preaching a nationalism without nuance, Messali Hadj brought a message that was bound to appeal to Algerians who fully realized their deprivation vis-à-vis the minority French community. Messali Hadj's message, or for that matter the more muted message of Ben Badis, could have been resisted by the gradualist reformers, led since the early 1930s by Ferhat Abbas, only if they had been able to show that step-by-step decolonization was possible. This they were never able to demonstrate. Several efforts to liberalize the treatment of native Algerians promoted by French reformist groups in collaboration with the Algerian reformists both before and after World War I, during the 1930s, and after World War II all proved to be too little and too late.

Failure of reformism

At the time of the Popular Front government in France (1936–37), for example, the Blum-Viollette proposal (so named for the French premier and the former governor-general of Algeria) would have provided for a very small number of Algerians to obtain full French citizenship without being obliged to relinquish their right to be judged by Muslim law on matters of personal status (*e.g.*, marriage, inheritance, divorce, and child custody). This had long been the sticking point shrewdly exploited by the settler population. To all but a few Algerians, abandoning the right to have personal status judged by Muslim law was tantamount to apostasy. Blum-Viollette was thus a potential breakthrough. The small number of Algerians (including the educated, veterans of French military service, and other narrowly defined groups) brought into full French citizenship could then have been gradually increased in later years. Colon opposition to the measure was so fierce that the project was never even brought to a vote in the French Chamber of Deputies. The characteristics of colonial rule in Algeria virtually ruled out any nationalist option other than one based on organized violence. The group that inherited this mission, the National Liberation Front (FLN), not surprisingly grew out of Messali Hadj's organization, later absorbing many adherents of the other two nationalist tendencies. (L.C.Br.)

World War II and the independence movement. World War II brought with it the collapse of France and, in 1942, the Anglo-American occupation of North Africa. The occupation forces were to some extent automatically agents of emancipation, while broadcasts in Arabic both from Allied and Axis stations began to compete, with promises of a brave new world for formerly subject peoples. The effect was heightened by the promise of the emancipation of Syria and Lebanon, given in June 1941 by the Free French and backed by the British authorities in the Middle East.

The Algerian Manifesto

In December 1942 the former assimilationist leader Ferhat Abbas drafted an Algerian Manifesto for presentation to the Allied as well as to French authorities, seeking recognition of the political autonomy of Algeria as a sovereign nation. In December 1943 General Charles de Gaulle declared that, because of loyalty shown, France was under an obligation to the Muslims of North Africa, and in March 1944 French citizenship was extended to certain categories of Muslims. This was by then, however, far from enough to satisfy Muslim opinion. A display of Algerian nationalist flags at Sétif in May 1945 led to an unorganized rising, in which 84 European settlers were massacred. The suppression that followed was indiscriminate, and it resulted, according to a French committee of inquiry, in not fewer than 1,800 deaths.

On Sept. 20, 1947, a statute of Algeria was finally voted by the French Assembly, defining the country as "a group of departments endowed with a civic personality, financial autonomy, and a special organization." The statute created an Algerian Assembly of 120 deputies, elected in equal numbers by two electoral colleges—one composed of 370,000 Europeans and 60,000 assimilated Muslims

and the other of 1,300,000 Muslims. After lengthy debates the statute was passed by a small majority, with 15 Muslim members abstaining. Muslims were at last to be considered as full French citizens with the right to keep their personal Qur'ânic status and were granted the right to work in France without further formalities. The military territories of the south were to be abolished, and Arabic was to be taught in schools at all levels.

Unfortunately, the implementation of this law was poor and the subsequent elections were "managed" by the administration, while most of the reforms laid down by the statute remained a dead letter. In spite of this, Algeria remained quiet. The principal change had been the fact that some 350,000 Algerian workers—five times as many as in the post-World War I period—were able to establish themselves in France and remit money to Algeria.

The Algerian War. Signs of the approaching storm, however, were only too apparent. In 1950 the French police discovered that a robbery of the Oran post office had been the work of the nationalist Special Organization (OS), an offshoot of the party led by Messali Hadj, which had taken the name of the Movement for the Triumph of Democratic Liberties (MTLD). The leader in the robbery was Ahmed Ben Bella, who had been highly commended during the fighting in Italy with the Free French. In 1952 Ferhat Abbas, when tried for a trivial offense, was defended by three lawyers—one Muslim, one Christian, and one Jewish; they combined to deliver an impressive attack on the administration. About the same time, Ahmed Mezerna, acting head of the MTLD, took the unprecedented step of personally seeking support in Egypt. The head of the Association of Algerian Muslim Ulama toured the Arab East and secured scholarships from the Arab governments for Algerians who wished to pursue their studies in Arabic.

The storm burst on the night of Oct. 31, 1954. It was organized by a few young men who, dissatisfied with Messali Hadj's leadership, had decided that justice for Algeria could only be realized by open rebellion. The movement took the title of the National Liberation Front (FLN) and issued a leaflet stating that its aim was the restoration of a sovereign Algerian state. It advocated social democracy within an Islâmic framework and citizenship for any resident in Algeria, with the same rights and duties as other citizens. A preamble recognized that Algeria had fallen behind the other Arab states in emancipating itself socially and nationally, but it claimed that this could be remedied by a difficult and prolonged struggle. Two weapons would be used—guerrilla warfare at home and diplomatic activity abroad, particularly at the United Nations, where the support of the Arab countries and other states would be invaluable. The FLN military objective was to make the position of the administration untenable by sudden raids, ambushes, and sabotage.

The National Liberation Front

Though the first outbreak, which occurred in the region of Batna and the Aurès, was ineffective militarily, it led to the arrest of some 2,000 members of the MTLD, who had not in fact been in favour of open rebellion. In mid-February 1955 Jacques Soustelle arrived in Algiers as governor-general; in June he announced a new plan, which, however, was once again to prove too little and too late. On August 20 a new rising at Ain Abid and at the mine of Al-Alia near Philippeville (now Skikda) degenerated into another massacre of Europeans, followed by summary executions of Muslims. In January 1956 the electoral victory of the Republican Front in France and the premiership of Guy Mollet led to the appointment of the moderate and experienced General Georges Catroux as governor-general. When Mollet personally visited Algiers, however, to prepare the way for the new governor-general, he was bombarded with tomatoes by the European populace. Yielding to this pressure, he allowed Catroux to withdraw and named in his place the pugnacious Socialist Robert Lacoste as resident minister. Lacoste's policy was described as pacification, but was in fact forcible suppression.

French forces sent to Algeria

A French army of 500,000 men was sent to Algeria to counter the control that the rebels had managed to establish in the more out-of-the-way portions of the country while collecting money for their cause and taking reprisals against fellow Muslims who would not cooperate with them. By May the rebels had won over the majority of previously noncommitted political leaders, and Ferhat Abbas and Tawfiq al-Madani, of the Association of Algerian Muslim Ulama, had joined FLN leaders in Cairo.

Externally, the major event of 1956 was the French decision to grant full independence to Morocco and Tunisia and to concentrate on retaining "French Algeria." The rulers of the newly independent states—the Moroccan sultan and Premier Habib Bourguiba of Tunisia—hoping also to find an acceptable solution to the Algerian problem, prepared to hold a meeting in Tunis with five principal Algerian leaders who had been guests of the sultan in Rabat. French intelligence officers, however, managed to divert to Algiers the plane chartered by the Moroccan government to fly the Algerians to Tunis. The Algerian leaders were then arrested and confined in prison in France for the next six years. Far from decapitating the rising, this act provoked an outbreak in Meknès that cost the lives of 40 French settlers before the newly independent Moroccan government could restore order.

In the next year, 1957, the rebels attempted to paralyze the administration of Algiers by terrorism. This was defeated by French parachute troops, who used torture to extract information. The French also cut Algeria off from independent Tunisia and Morocco by barbed wire fences, illuminated at night by searchlights; this separated the resistance bands within Algeria from some 30,000 Algerian armed forces who occupied positions between the fortified fences and the actual frontiers of Tunisia and Morocco, from which they drew supplies. These troops had the advantage of a friendly people and government as a base; they could not, however, penetrate into Algeria proper but could only harass the French line.

Provoked by these assaults, the French air force in February 1958 bombed the Tunisian frontier village of Sâqiyat Sîdi Yûsuf, killing a number of civilians, including children from the local school. This led to an Anglo-American mediation mission, which negotiated the withdrawal of French troops from various districts of Tunisia and their concentration in the naval base of Bizerte (Banzart).

A meeting—the Maghrib Unity Congress—was held in Tangier from April 27 to 30 under the auspices of the Moroccan and Tunisian nationalist parties and the Algerian FLN. It recommended the establishment of an Algerian government in exile and of a permanent secretariat to promote Maghrib unity. The latter proposition had little permanent result, but a government—the Provisional Government of the Algerian Republic (GPRA)—was set up on September 19.

By then, however, conditions had been radically changed by events of May 13, 1958; these began as a typical settler rising—thousands of European Algerians sacked the offices of the governor-general and, with the tacit approval of the army officers, called for the integration of Algeria with France and for the return of de Gaulle to power. The Muslims were clearly taken aback, but soon there was a relatively friendly mixing of Muslim demonstrators with the Europeans and a general hope of better times to come. In the crisis caused by this rising, de Gaulle returned to power in France.

Changes under de Gaulle

On June 4 de Gaulle visited Algiers amid scenes of great enthusiasm. He gave no clear indication, however, that he shared the settlers' enthusiasm for integration, which, in their minds, meant the submergence of the native Algerians in an enlarged France. All Muslims, however, were now granted the full rights of French citizenship, and on October 30 de Gaulle announced in Constantine a plan to provide adequate schools and medical services for the Muslim population, to create employment for the vastly increasing Muslim masses, and to introduce Muslims into the higher ranks of the public services.

In September 1959, de Gaulle, in anticipation of the opening of the United Nations General Assembly, declared publicly that the Algerians had the right to determine their own future. From this time it gradually became clear that he was prepared to go even to the length of granting independence if peace could not be secured on any other terms. The agitation of the Europeans now became extreme.

On Jan. 24, 1960, a fresh settler rising collapsed after nine days from lack of military support. A year later, however, as the prospect of negotiations with the GPRA became more probable, there was another rising, this time organized by four generals, of whom two—Raoul Salan and Maurice Challe—had previously been commanders in chief in Algeria. De Gaulle remained unshaken, and the rising, lacking substantial support from the army, collapsed after only three days.

In May 1961, negotiations were opened in France with representatives of the GPRA. This body had by now long been recognized by the Arab and communist states, from which it received aid, though it had never been able to establish itself on Algerian soil. Negotiations were broken off in July, after which the veteran Ferhat Abbas was replaced as premier by the much younger Ben Youssef Ben Khedda. Settler opposition was meanwhile organized by a body calling itself the Secret Army Organization (OAS), which began to employ terrorism as brutal as that sometimes used by the rebels.

Independence for Algeria

On March 8, 1962, negotiations were resumed, and on the 18th agreement was finally reached. Algeria would thenceforth be independent, provided only that a referendum, to be held in Algeria by a provisional government, confirmed the desire for it. In case of approval, French aid would continue; Europeans could depart, remain as foreigners, or take Algerian citizenship, as they preferred. This announcement produced a violent outburst of terrorism and attempted resistance by the OAS; but in May the terror subsided as its futility became obvious. On July 1, 1962, the referendum in Algeria recorded some 6,000,000 votes in favour and only 16,000 against. After three days of unbounded Muslim rejoicing, the GPRA entered Algiers in triumph, while the departure of the Europeans assumed mass proportions.

Meanwhile, however, the GPRA was itself torn by dissensions, and its authority was challenged by Colonel Houari Boumedienne, who commanded the Algerian army on the Tunisian side. In this he was supported, after some hesitation, by Ben Bella, now released from captivity in France, and by Muḥammad Khidr, secretary general of the FLN. It was not until three months later that the small-scale civil war that ensued was finally settled by the recognition of Ben Bella as premier, Boumedienne as chief of staff, and Khidr as head of the party organization.

Independent Algeria (from 1962). The Europeans who abandoned the country included the overwhelming majority of senior administrators and managerial and technical experts. The chief exception was a group of some 10,000 French schoolteachers who remained, with great courage, often in very isolated posts.

During the six previous years some 10,000 French troops and officers and possibly as many as 250,000 Muslims had lost their lives in the fighting; scores of villages had been destroyed, and 2,000,000 peasants had been moved to new sites. Nevertheless, many public services such as the post office and the railways continued to work remarkably well. On farms and in factories, however, management had largely vanished. Production fell, while unemployment and underemployment reached extreme levels.

Ben Bella's personal style of government and his reckless promises of support for revolutionary movements were not conducive to orderly administration. On the other hand, the revenue from the extensive oil and natural gas fields that had recently been discovered and exploited in the Sahara was of very great assistance.

A serious problem was presented in April 1963 by the resignation of Muḥammad Khidr and by his subsequent departure abroad, taking with him the funds of the FLN. He was later assassinated in Madrid. Little by little, the gradual elimination of other dissident leaders appeared to leave control securely in the hands of Ben Bella and the army under Boumedienne. What appeared to be Ben Bella's plans for a complete political takeover, removing Boumedienne and his supporters, were foiled on June 19, 1965, when Boumedienne and the army moved first. Ben Bella's erratic political style and poor administrative record made his removal acceptable to Algerians, but the Boumedienne regime began with little popular support.

Boumedienne's coup

In the following years Boumedienne moved undramatically but effectively to consolidate his power, with army loyalty remaining the basic element. Efforts to reorganize the FLN met with some success. The cautious and deliberate Boumedienne approach was seen in constitutional developments; communal elections were held in 1967, provincial (*wilāyah*) elections in 1969. Elections for the National Assembly, however, did not take place until 1977. In the previous November, a new constitution had been adopted following wide public debate and referenda.

On Dec. 27, 1978, Boumedienne died. Colonel Chadli Bendjedid, nominated by the FLN to succeed him, was confirmed as president in a referendum in February 1979. The release of Ben Bella later that year from house arrest indicated that the new president felt confident in his authority and served as a symbol that, 17 years after independence, many old disputes were no longer relevant.

Independent Algeria was committed to a socialist, centrally directed economy and society. The mass exodus of the French at the time of independence left the new government with vast abandoned lands. These and the remaining French estates (all French land being nationalized by 1963) were turned into state farms run by workers' committees. In 1971 Boumedienne had inaugurated an agrarian reform aimed at breaking up larger Algerian-owned farms and creating small holdings organized into cooperatives. Subsequent steps continued to break up large holdings and redistribute land to landless peasants.

Agrarian reform

Economic plans stressed developing a state-run industrial core, and Algeria's important oil and gas industry came to be controlled by a government company, Sonatrach. Algeria's economic difficulties were eased by the export of oil and gas as well as by the remittances from the nearly 850,000 Algerians living abroad (mostly in France). In 1976 Algeria signed a trade agreement with the European Community (EC); yet unemployment and underemployment have remained major problems.

In October 1988 serious riots in Algiers, Annaba, and Oran (leaving an unofficially estimated 500 dead) rocked the regime. Bendjedid, reelected for his third five-year term as president in December 1988, moved to liberalize the system and challenge the FLN political monopoly. The new constitution, approved in February 1988, initiated political plurality and dropped all references to socialism. In the 1990 local elections the Muslim fundamentalist Islāmic Salvation Front (Front Islamique du Salut; FIS), led by Abbasi al-Madani, captured clear majorities in the provincial and municipal councils, winning roughly double the number of seats taken by the FLN. The first round of balloting for the National Assembly, held in December 1991, produced an even more striking victory for the FIS, which won 188 seats, just 28 short of a simple majority and 99 short of the two-thirds majority needed to amend the constitution. There seemed little doubt that the FIS would achieve a majority in the second balloting scheduled for Jan. 15, 1992. Instead, the Algerian government and army intervened on January 12 to cancel the elections, President Bendjedid having resigned the previous day. Mohammed Boudiaf, a former FLN dissident, was sworn in as president of a ruling Supreme State Council. Boudiaf was assassinated five months later on June 29 by an alleged FIS gunman while giving a speech in Annaba, as dissension between fundamentalists and the government continued unabated.

In the realm of foreign relations, Algeria's policy is revolutionary in word but pragmatic in deed. Immediately after independence Algeria was a haven for Third World guerrilla and revolutionary movements, but this has largely passed. Algerian spokesmen continue to press for strong positions on the Palestine problem, decolonization in Africa, and economic ties between the developed and underdeveloped worlds, but at the same time the government has supported commercial ventures with private American companies. In addition, the Algerian government played a major role in mediating the release, in January 1981, of U.S. hostages held in Iran.

Relations with Morocco

With neighbouring Morocco, relations have not been smooth. A short border war that broke out in the autumn of 1963 (the area in dispute being rich in iron-ore deposits)

was brought to a halt through intervention of the Organization of African Unity. The rapprochement achieved in 1969–70 later broke down again over Morocco's efforts to absorb Western Sahara (formerly Spanish Sahara). Algeria supported the Popular Front for the Liberation of Saguia el Hamra and Río de Oro (Polisario Front) in resisting Morocco. Then in May 1987 Bendjedid and Morocco's King Hassan met to resolve differences. Subsequent progress toward a possible resolution of the Western Sahara issue has eased tensions between the two states significantly, and diplomatic relations were restored in 1988. (N.B./L.C.Br.)

Fighting between government forces and Islāmic extremist groups continued unabated through the 1990s under successive government-backed administrations, with civilians often being randomly targeted for vicious attacks by both sides. In April 1999 Abdelaziz Bouteflika, the former foreign minister under Boumedienne, ran for president unopposed, as other candidates withdrew following rumours that the elections were rigged. Bouteflika assured the international community that the elections were legitimate and vowed to work with other political parties. More violence ensued, however, and the number of killed, missing, and injured continued to rise. From the mid-1990s the government and various Islāmic groups attempted several times to clear up political differences between them and end the violence, but at the outset of the 21st century the civil war continued to rage and had by then claimed the lives of some 100,000 civilians and numerous political figures. (Ed.)

For later developments in the history of Algeria, see the BRITANNICA BOOK OF THE YEAR.

Libya

The Socialist People's Libyan Arab Jamahiriya (in Arabic, Al-Jamāhīrīyah al-ʿArabīyah al-Lībīyah ash-Shaʿbīyah al-Ishtirākīyah) is an independent socialist state of North Africa. It is bounded by the Mediterranean Sea on the north, Egypt on the east, The Sudan on the southeast, Niger and Chad on the south, and Tunisia and Algeria on the west. Largely composed of the Sahara, it covers an area of 678,400 square miles (1,757,000 square kilometres) and is one-fourth the size of the conterminous United States and almost twice the size of Egypt. The population is concentrated along the coast, where the de facto capital, Tripoli (Ṭarābulus), and Banghāzī (Benghazi), the de jure capital, are located.

PHYSICAL AND HUMAN GEOGRAPHY

Before the discovery of oil in the 1950s, Libya was poor in natural resources and severely limited by the climatic conditions of the Sahara. The country was almost entirely dependent upon foreign aid and the import of commodities necessary for the maintenance of its economy. Petroleum dramatically changed this situation, and Libya became one of the richest countries of the Middle East and Africa. The government controls the economy and has attempted to develop agriculture and industry with the wealth derived from its huge oil revenues. It has also established a welfare state, which provides medical care and education.

The land. *Relief.* Libya is underlain by basement rocks of Precambrian age (from 3.8? billion to 540 million years ago) that are mantled with marine and wind-borne deposits. The major physical features are the Nafūsah Plateau and the Al-Jifārah (Gefara) Plain in the northwest, the Akhḍar Mountains in the northeast, and the Saharan plateau occupying much of the rest of the country.

The Al-Jifārah Plain covers about 10,000 square miles of Libya's northwestern corner. It rises from sea level to about 1,000 feet (300 metres) at the foothills of the Nafūsah Plateau. Composed of sand dunes, salt marshes, and steppe, the plain contains most of Libya's population and its largest city—Tripoli. The Nafūsah Plateau is a limestone massif that stretches for about 212 miles (340 kilometres) from Miṣrātah on the Gulf of Sidra to the Tunisian border at Nālūt. West of Tarhūnah it rises steeply from the Al-Jifārah Plain, reaching altitudes between 2,000 and 3,000 feet.

In the country's northeastern corner, the Akhḍar Mountains stretch for about 100 miles along the coast between Al-Marj and Darnah. The limestone mountains rise steeply from the coast to about 2,000 feet and then stretch about 20 miles inland, attaining their highest altitudes of about 3,000 feet.

The desert and the plateaus

The Saharan plateau covers some 90 percent of Libya and is itself about one-half covered by sand deserts, making it truly a desert land. Al-Ḥarūj al-Aswad is a hilly basaltic plateau in central Libya. Covered with angular stone fragments and boulders, it rises to about 2,600 feet and is crowned by volcanic peaks. The Al-Ḥamrāʾ Plateau lies south of the Nafūsah Plateau. It contains bare rock outcrops and rises to 2,700 feet. An arm of the Tibesti Mountains stretches northward from the main massif in Chad. In the Fezzan region of the southwest a series of long depressions and basins contain wadis (dry riverbeds) and oasis settlements. Mobile sand dunes that reach heights of 300 feet are found in the Fezzan's Marzūq desert and in the Libyan Desert of the east, which extends across the border into Egypt. The country's highest elevations are at Bikkū Bittī peak (Picco Bette), rising to 7,500 feet (2,286 metres) on the Libya-Chad border, and at Mount Al-ʿUwaynāt, with an elevation of 6,345 feet (1,934 metres) on the Libya-Sudan-Egypt border.

Drainage. There are no perennial rivers in Libya. The numerous wadis that drain the uplands are filled by flash floods during the rains and quickly dry up or are reduced to a trickle. The largest wadi systems are the Wadi Zamzam and Wadi Bayy al-Kabīr, both of which reach the western coast of the Gulf of Sidra. Other large wadis drain the interior basins of Surt, Zalṭan, and the Fezzan. There is also, however, extensive underground water. Numerous oases are watered by wells and springs, and artesian wells tap large deep fossil aquifers in the Fezzan and southeastern Libya. Along the coastal strip there are several salt flats, or sebkhas, formed by the ponding and evaporation of water behind coastal dunes. Principal salt flats are those of Tāwurghāʾ, Zuwārah, and the Banghāzī Plain.

Soils. The gray-brown soils of the Al-Jifārah Plain and the Nafūsah Plateau are fertile, although they have become saline from overirrigation. In the east, the soils of the Barce plain—which stretches between the Akhḍar Mountains and the sea—are light and fertile. Rich alluvial soils are found in the coastal deltas and valleys of large wadis. The rest of the country is covered by wind-eroded sand or stony desert. The soils in these areas are poorly developed and contain little organic material. On the margins of the Sahara, the soils are seriously depleted from cultivation and overgrazing.

Climate. The climate over most of the country is that of the hot, arid Sahara, but it is moderated along the coastal littoral by the Mediterranean Sea. The Saharan influence is stronger in summer. From October to March, prevailing westerly winds bring cyclonic storms and rains across northern Libya. A narrow band of semiarid steppe extends inland from the Mediterranean climate of the Al-Jifārah Plain, the Nafūsah Plateau, and the Akhḍar Mountains. The desert climate of the Sahara reaches the coast in the Surt Desert along the southern fringes of the Gulf of Sidra. Periodic droughts, often lasting several years, are common in the steppe and desert climates.

Mediterranean climate is characterized by a cool rainy winter season and a hot dry summer. The warmest months are July and August, when Banghāzī and Tripoli, in the Mediterranean zone, experience average monthly temperatures of 72° to 85° F (22° to 29° C) and 62° to 86° F (17° to 30° C), respectively. The coolest months are January and February; Banghāzī has winter monthly temperatures of 50° to 63° F (10° to 17° C), and Tripoli has 47° to 61° F (8° to 16° C). Al-ʿAzīzīyah on the Al-Jifārah Plain has recorded the world's highest shade temperature, about 136° F (58° C). Banghāzī receives an annual average rainfall of 10 inches (250 millimetres), and Tripoli receives 15 inches.

The amount of annual precipitation declines, and its variability increases, inland from the coast. Most of the rainfall occurs in only a few days between November and January. Steppe climate has less than four inches of rainfall annually, and Saharan desert climate has less than one inch. In the Sahara, 200 consecutive rainless days in a year have been recorded in many areas, and the world's

highest degree of aridity occurs at Sabhā, which averages only 0.4 inch of rainfall annually. The average January temperature at Sabhā is 52° F (11° C), and in July it is 88° F (31° C). Large daily ranges about these averages occur, however. The dry climate is exacerbated by the *ghibli*, a hot, arid wind that blows from the south several times a year, affecting the entire country. It is preceded by a short lull in the prevailing winds, which is followed by the full force of the *ghibli*. The wind carries large quantities of sand dust, which turns the sky red and reduces visibility to less than 60 feet. The heat of the wind is increased by a rapid drop of relative humidity, which can fall from 80 to 10 percent within hours.

The effect of the *ghibli* wind

Plant and animal life. In years of good rainfall the coastal plains are covered with herbaceous vegetation and annual grasses; the most noticeable plants are the asphodel (an herb of the lily family) and jubule. The northern area of the Akhḍar Mountains—where the influence of the Mediterranean is most apparent—supports low and relatively dense forest (or maquis) of juniper and lentisc. Annual plants are abundant and include species such as brome grass, canary grass, bluegrass, and rye grass. The forest becomes more scattered and stunted south of the mountain crest, and annual plants are less frequent. The Nafūsah Plateau has less plant life, and the natural vegetation of grassland lies between barren hills.

In the semiarid steppes vegetation is sparse; isolated drought-resistant plants grow in generally barren pockets. The species most commonly found are saltwort (a plant used in making soda ash) and spurge flax (a shrubby plant), while goosefoot, wormwood, and asphodel also are widespread. Annual grasses grow in the rainy season, and leguminous plants appear in years of good rainfall. Although rainfall is extremely low in the true desert zone and the vegetation cover is scant, some of the plants of the semiarid region penetrate into the occasional wadi valley, and date palms are grown in the southern oases.

Wild animals include desert rodents, such as the desert hare and the jerboa; hyenas; foxes, such as the fennec and the red fox; jackals; skunks; gazelles; and wildcats. The poisonous adder and krait are among the reptiles that inhabit the scattered oases and water holes. Native birds include the wild ringdove, the partridge, the lark, and the prairie hen. Eagles, hawks, and vultures are common.

Settlement patterns. Libya is divided into three regions—the western region (formerly Tripolitania province), the eastern region (formerly Cyrenaica province), and the southern region (formerly Fezzan province). Two-thirds of the population lives in the western region, the majority in Tripoli and other cities along the coast and on the Nafūsah Plateau. About 20 percent of the people live in the eastern region, primarily in Banghāzi and other coastal cities. The remainder of the population is concentrated in oasis towns in the southern region.

Libya's three regions

The vast majority of the rural population lives in coastal oases and is engaged in farming based on irrigation; plots of land are generally held in individual ownership and are often small. On the Nafūsah Plateau, where water is less readily available, a sophisticated agrarian system based on olive- and fruit-tree cultivation and associated livestock raising has evolved. In the eastern region, however, the traditional economy was based on nomadic and seminomadic pastoralism. Arable farming has largely been an adjunct of the pastoral system, with shifting dry-land cultivation rarely entailing sedentary farming. Land ownership is no longer exclusively tribal, but the system of tenancy contrasts sharply with that of ownership in the west. In southern Libya, isolated irrigated farming at the oases represents a third traditional economic system.

The most common mode of life in rural Libya is sedentary cultivation. In the traditional oases most farmers rely on irrigation, and water is raised from shallow wells either by the animal-powered *dalū* (a goatskin bag drawn by rope over a pulley) or, increasingly, by electric or diesel pumps. Landholdings in the oases are small and fragmented; the average five to seven acres (two to three hectares) per farm are generally divided into three or four separate units. On the coastal lowlands farmers normally live on their land and often have rights to graze stock and undertake shifting grain cultivation on communally held land. In both the east and the west, Arab farmers occupy large, formerly European estates, in which individual units range from 12 to 600 acres (5 to 250 hectares).

Pastoral nomadism is practiced in the arid and semiarid regions, particularly in the Akhḍar Mountains and surrounding steppe lands in the eastern region. Nomadic groups subsist primarily on their herds of sheep, goats, and camels, but also participate in the shifting cultivation of cereals. The Bedouins move south as soon as pasture appears in the fall and remain there until the ephemeral grasslands die and necessitate the return to the northern hill lands.

The village was originally an institution alien to Libya's tribal organization. Since the first Turkish occupation in the 16th century, towns and villages were developed by occupying powers mainly as military posts or administrative centres. Many village sites have been occupied for centuries; smaller settlements often began as collecting centres for the nomadic tribes during their summer residence in the oases or hill pastures. Berbers in the west, however, are thought to have retained a more or less continuous thread of settlement in their fortified nucleated villages in the western Nafūsah Plateau. In the southern oases, the villages served both as defense posts for the scattered communities and as watering and provisioning points on the trans-Saharan caravan routes. Modern development has led to the expansion of villages into towns and has fostered internal migration of the rural population from the land to the centres of settlement.

Urban settlement

The two main cities are Tripoli and Banghāzi. They contain more than one-third of the country's entire urban population and about one-fourth of the total population. Tripoli, with a metropolitan population of more than one million people, is the de facto political capital and the most important economic centre. Banghāzi, with half a million people, is the primary city in the eastern region. The modern cities have developed around the old city centres (medinas) with satellite towns and villages in surrounding oases. Shantytowns housing recent rural-to-urban migrants are also found near the two cities, and, although low-income housing is under construction, these areas present problems of sanitation and water supply.

Besides Tripoli and Banghāzi, there are 12 large towns. In the west Gharyān, Al-Khums, Miṣrātah, Tājūrā', Sūq al-Jum'ah, Janzūr, and Az-Zāwiyah are the major centres. In the east Ajdābiyā, Al-Marj, Al-Baydā', Darnah, and Tobruk (Ṭubruq) are of the same rank. These cities are primarily regional administrative and commercial centres with some light industry. Several have petroleum refineries and petrochemical industries.

The people. *Ethnic composition.* Almost all Libyans speak Arabic, the country's official language, and adhere to the Sunnite branch of Islām. They claim descent from the Bedouin Arab tribes of the Banū Hilāl and the Banū Sulaym, who invaded the Maghrib in the 11th century. In the eastern region the influence of the Sanūsīyah, a 19th-century militant Islāmic brotherhood, remains strong. Most of the Jewish and Italian minorities, long established in Tripolitania (the western region), left the country after the government seized their properties in 1970. Small numbers of Roman Catholic and Coptic Christians remain. The government's embrace of Arab nationalism has reduced Western influences, although English is still widely used as a second language in international business and politics. Nearly one-fifth of Libya's total population in the late 20th century was composed of foreign workers temporarily residing in the country. The tribe (*qabīlah*) was for long the basis of the social order in Libya, and eight out of every nine persons once resided in tribal domains.

The Berbers were the major original inhabitants of Libya. The main groups were the Luata, the Nefusa, and the Adassa. The Berbers lived in coastal oases and practiced sedentary agriculture. Most of them have been assimilated into Arab society except in the Nafūsah Plateau region, Awjilah, Hūn, Socra, and Zuwārah. The Berbers speak their own Hamitic language but have adopted the Arabic alphabet. Many are bilingual in Berber and Arabic; most are Muslims.

Origins of the Arab population

The Arab invasions began in the 7th century. The initial Arab incursions were essentially military and had little effect upon the composition of the population. The Banū Hilāl invasion of 1049 and succeeding attacks of the Banū Sulaym later in the 11th century, however, brought migrations of large pastoral nomadic tribes from the eastern Arabian peninsula.

The Banū Sulaym were composed of four main groups—the Banū Hebib, the 'Awf, the Debbab, and the Zegb. The Hebib settled in Cyrenaica, while the others went into Tripolitania. After the establishment of tribal groups, Libya underwent a period of disorder and tribal feuding, which was augmented by the incursion of other Arab adventurers from Egypt. Toward the close of the period of anarchy, the Debbab group took control of much of Tripolitania. By the 20th century about 97 percent of Libya's inhabitants were Arabic-speaking Muslims of mixed Arab and Berber descent.

Several other social groups exist alongside the tribal unit. They are the sharīfs (holy tribes), who came originally from the Fezzan; the marabouts (dervishes who are credited with supernatural powers), who infiltrated from Saguia el Hamra in what is now Western Sahara; and the Koulouglis, who are descended from the Janissaries (elite Turkish soldiers) and the Berber and Christian slave women with whom they interbred.

The sharīfs claim direct descent from the Prophet Muḥammad. Their alleged blood relationship with the Prophet gives them a powerful standing in Muslim society, where they are looked upon as holy men with divine powers of foresight. Extensive tracts of land are found under sharif control in all the oases of western Libya. Marabout tribes are descended from holy men who also claimed relation to Muḥammad. They founded their religious devotions upon an ascetic life manifested in their existence as hermits. In areas where their teachings and way of life made them acceptable to the local inhabitants, they settled and founded tribes pledged to the pure way of life.

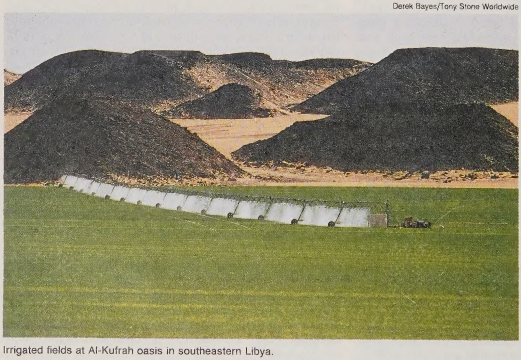
Minority population groups

The Koulouglis have served since Turkish times as a secretarial class in several areas and are often concentrated in and around villages and towns. They speak Arabic and practice Islām.

The trans-Saharan slave trade, which continued during Turkish times, introduced black Africans and their cultures into many of the tribes, especially in the Fezzan and in Tripolitania. Their languages are those of the central Sahara and the eastern Sudan; most also speak Arabic and have adopted Islām.

Small groups of Tuareg tribespeople are found in the southwest, especially at the Ghadāmis and Ghāt oases. Traditionally nomadic, they are gradually assuming a sedentary life-style. Isolated Teda (Tubu) communities of the southeast are slowly gravitating toward the north and the Al-Kufrah oasis in search of employment.

Demographic trends. Libya has one of the highest rates of population growth in Africa, averaging more than 3 percent annually for much of the second half of the 20th century. The huge influx of foreign workers into the country since the 1960s accounts for part of this rapid growth, but Libya's annual rate of natural increase (birth rate minus death rate) has also been one of the highest averages in Africa for much of the late 20th century. Death rates have declined to near the world average, but birth rates remain high. Almost one-half of the population is 15 years of age or less despite high rates of infant mortality—the highest in North Africa—portending continued high birth rates and rapid growth well into the 21st century.



The economy. Oil revenues are Libya's main source of income. During the 1980s, oil accounted for two-thirds of the national income and nearly 99 percent of export earnings, although it employed less than 10 percent of the labour force. The government exerts strong control over the economy. The petroleum industry was nationalized in the 1970s; state trade unions and industrial organizations run most other industries and utilities. To reduce the country's heavy dependence on oil, economic policy has emphasized agricultural and industrial development. Declining oil revenues during the 1980s, however, led to frequent revisions and delays in planned developments. In 1988, domestic reforms liberalized economic policy and encouraged private enterprise.

Libya's per capita income is the highest in Africa, but its population is relatively small. A shortage of labour has led to a large number of foreign workers—mostly from other North African countries, western Africa, and the Middle East—in agriculture and industry. Since the mid-1980s, however, Libya has attempted to reduce the number of foreign workers because of the huge drain that their remittances to their respective countries has caused on Libya's reserves of foreign exchange.

Resources. Petroleum is Libya's most important mineral resource. First discovered in 1956 near the Algerian border, it has since been located mainly in the Surt Basin. The major oil fields are Zaltan, Āmāl, and Intiṣār A in the vicinity of Banghāzī; the Dahra field is located near Miṣrātah, and the Sarir field is near Darnah. Deposits have been located near Ghadāmis on the western border, Murzuq in the southwest, and the Al-Kufrah oasis in the southeast. Exploration for new deposits has concentrated on the western region and offshore, where a large field was discovered northwest of Tripoli in 1988. Libya's proven oil reserves represent almost half of Africa's, or about 2 percent of the world's. Libyan crude oil is low in sulfur content and therefore causes less corrosion and less pollution than most crude oils. The deposits are associated with natural gas.

The first pipeline was constructed from the Zaltan field to Marsā al-Burayqah in 1961. Since then additional lines

Derek Bayes/Tony Stone Worldwide

Irrigated fields at Al-Kufrah oasis in southeastern Libya.

have been built from Dahra to As-Sidrah and to Ra's al-Unūf, and other pipelines connect the Tobruk field to Marsā al-Ḥarīqah and the Intiṣār A field to Az-Zuwaytīnah. Refineries are located at Az-Zāwiyah, Miṣrātah, Ra's al-Unūf, and Tobruk. A natural-gas pipeline runs parallel to the oil pipeline from Zaltan. The gas liquefaction plant at Marsā al-Burayqah is the world's largest.

Libya is usually among the world's dozen largest producers of oil. Sales to Europe were enhanced by the closure of the Suez Canal between 1967 and 1975. During the 1980s, however, production and revenues declined because of an increased supply of oil on the world market. Libya has concluded barter agreements with some European and African countries to exchange petroleum for goods and services. Only a small percentage of the Libyan labour force is employed by the oil industry, along with a few thousand foreign workers.

Other mineral resources are limited. There are important deposits of natron (hydrated sodium carbonate) in the Fezzan and of potash in the Surt Desert near Marādah. The iron ore deposits at Shāṭī', although low in iron content, supply the iron-steel complex at Miṣrātah. Marine salt is produced in Tripolitania, where there are also small deposits of gypsum, manganese, and lignite coal. Sulfur has been found in the Surt Desert, and there are scattered deposits of chalk, limestone, and marble that are quarried for the growing construction trade.

The arid climate supports few biological resources except for the grasslands of the Akhḍar Mountains and the Nafūsah Plateau, which are valuable for grazing. There are no hydroelectric resources, and oil represents the only domestic means of producing electricity thermally.

Agriculture, forestry, and fishing. Agriculture is limited by the environment and by shortages of labour. Only about 1 percent of the total land area is cultivated, mostly on the Al-Jifārah and Barce plains, and about one-tenth of that is irrigated. An additional 8 percent of the land is in pasture. Agricultural development by land reclamation and irrigation is a government priority. The largest projects are at the Al-Kufrah oasis, Tāwurghā', and Sarir, on the Al-Jifārah Plain, and in the Akhḍar Mountains. The Great Man Made River project, under construction during the late 20th century, is the most ambitious. Pipelines will carry water from wells in the southern Sahara to Tripoli, Surt, Banghāzi, Tobruk, and the Al-Kufrah oasis.

Cereals are the major crops throughout the country. Barley is the chief cereal grown because it adapts well to different climates and soils. Wheat is grown primarily on the eastern and western plateaus, and sorghum is raised in the Fezzan. Olive plantations were introduced by the Italians on the Al-Jifārah Plain and on the Nafūsah Plateau, and there are smaller olive groves in the east. Orchards of almonds, citrus fruit, apricots, and figs occur on small and large farms and on small, crowded plots in the oases. Dates are the principal crop of the southern oases. Grapes, broad beans, and peanuts also are grown. Tobacco is raised in Tripolitania.

Animal husbandry is important in Cyrenaica, where the herds are raised on communal grazing lands. Livestock includes sheep, goats, cattle, camels, horses, mules, and donkeys. Animals are raised for their milk, meat, and hides or for their services as a means of transportation. Cattle often serve as draft animals. A small amount of milk is produced commercially, and commercial poultry farms are developing around the larger cities.

Less than 1 percent of the land is in forests. Before the 1950s the only wooded area in Libya was the region of scrub brush in the Akhḍar Mountains. Since then, the government has launched a massive afforestation program. Between 1957 and 1964, 27 million acacia, eucalyptus, cypress, cedar, and pine trees were planted in Tripolitania.

There is little demand in Libya for fish, and most fishing is carried out off the Tripolitanian coast by Libyan, Tunisian, Greek, and Maltese fishermen. The catch includes tuna, sardines, and red mullet. Sponge beds are also important. The sponges are harvested mainly by Greeks who are licensed by the Libyan government.

Industry. Industrial development is limited. Most factories are located in Tripoli and Banghāzi and are managed by Arabs. The industrial work force is small: many of the factories employ fewer than 100 persons. A majority of the factories are engaged in the manufacture of processed food, beverages, cement, leather goods, and textiles. The government has monopolies for the processing of tobacco, salt, and esparto grass. There are also oil-related industries, which produce steel drums, tanks, and pipe fittings; and petrochemical plants are located near refineries.

The production of electricity for public consumption is a government monopoly. There are also private plants, such as the 25,000-kilowatt facility built by an oil company at Marsā al-Burayqah. The total installed capacity, all thermal plants powered by oil, grew more than sevenfold during the 1970s.

Finance and trade. Financial services are headed by the Central Bank of Libya, which supervises the banking system, regulates credit and interest policies, and promotes the transformation of foreign banks into Libyan institutions. The Libyan Arab Foreign Bank has made some investments, primarily in Italy.

Since 1963 Libya has usually enjoyed a favourable balance of trade. Almost all its exports are represented by crude petroleum, but agricultural products and hides and skins also are exported. Imports consist of equipment for the oil and construction industries, farm machinery, consumer goods, and agricultural products. Most of the country's imports are purchased from Italy, Germany, the United Kingdom, France, and Japan. Exports, almost all petroleum, usually go to Italy, Germany, Spain, France, Greece, and Turkey. Foreign trade

Transportation. The main road is the 1,100-mile national coastal highway between the borders of Tunisia and Egypt. The Sabhā road runs from the coastal highway at Al-Qaddāḥiyah south and southwest to Ghāt near the Algerian border. Other national roads run from Tripoli to Ghāt and Sabhā and from Ajdābiyā to Al-Kufrah. About half the roads are paved. The two railroads that served Tripoli and Banghāzi were closed in the late 1960s.

Tripoli is the main port, and Tripoli and Banghāzi together handle most of the country's maritime trade. Tripoli handles the bulk of the imports, particularly those associated with the oil industry and the booming trade in consumer goods. Tobruk is the third most important port.

Petroleum is shipped from As-Sidrah, Marsā al-Burayqah, Tobruk, and Az-Zuwaytīnah. Miṣrātah, Zuwārah, and Al-Khums have been developed as fishing ports. Libya's merchant fleet is modest, and most oil is shipped in foreign vessels.

International airports include those at Tripoli and at Baninah, outside of Banghāzi. Domestic airfields include those at Sabhā, Al-Bayḍā', Ghadāmis, and Ghāt. The Libyan Arab Airlines and foreign airlines operate domestic flights and services to countries in the Middle East and North Africa and to several nations in Europe. There are also domestic flights operated by the oil companies.

Administration and social conditions. *Government.* In September 1969 the monarchy of Idris I was overthrown and the constitution suspended in a military coup d'état. In 1977 the 12-member Revolutionary Command Council formed after the coup was replaced by the General Secretariat of the General People's Congress (GPC) with Colonel Muammar al-Qaddafi as secretary-general. He resigned the post in 1979 but remained in effect ruler of the country and head of the revolution. A General People's Committee has replaced the original revolutionary cabinet, the Council of Ministers; each of the committee's members is the secretary of a department. In 1988 all but 2 of the 19 secretariats were moved from Tripoli, most of them to Surt. The General People's Congress serves as a parliament.

The country is divided into 25 *baladīyāt* (municipalities), which in turn are subdivided into zones. The citizens of each zone are members of the Basic Popular Congress (BPC), each headed by an appointed revolutionary or leadership committee. Citizens are also members of the Arab Socialist Union (ASU), the mass political organization and only legal political party. In the late 1980s, sweeping domestic reforms replaced the army and police forces with the Jamahiri Guards.

Justice. The judicial system consists of the Supreme Court, located in Tripoli, with five chambers of five justices each; it is the final court of appeal. The regional courts of appeal, located in Tripoli, Banghāzī, and Sabhā, each with three justices, hear appeals from the courts of first instance and the summary courts, the basic judicial unit, each with one justice per court. Separate religious courts were abolished in 1973, and all judicial courts base their rulings on Libyan law, founded on the basis of the Sharī'ah (Islāmic law). In 1989 the People's Courts, which try political detainees, and the People's Prosecution Bureau replaced the revolutionary courts.

Education. Public education is free and primary education is compulsory for both boys and girls. Arabic is the language of instruction at all levels. The school system is composed of a six-year primary level, a three-year intermediate and vocational level, and a three-year secondary and advanced vocational level. There are also Qur'ānic schools, which are financed by the government. About three-fourths of the adult population is literate. In order to increase the literacy rate the government has also sponsored an adult educational program.

Higher education is offered by the state institutions of the University of Libya, subdivided in 1973 into Al-Fateh University (Tripoli) and Garyounis University (Banghāzi). Advanced religious training is obtained at a branch of the university at Al-Bayḍā'. Libyan students also study abroad in Egypt, Europe, and the United States.

Health and welfare. The chief health problems are typhoid, leishmaniasis, rabies, meningitis, and schistosomiasis (a parasitic infestation of the liver or intestines). The incidence of malaria has declined, but gastroenteritis and tetanus remain major diseases.

Medical and hospital care and medicines are free. Most care is available in hospitals and at outpatient or specialized-care facilities or clinics.

Schools for medicine and dentistry opened in the 1970s, but the rapid expansion of facilities necessitated the continued hiring of expatriate staff. The number of medical personnel has been increased sharply. Some graduate medical students study abroad.

The National Social Insurance Institute operates social security programs. Workers covered by government insurance programs receive medical examinations and treatment, maternity benefits, and dental care. There are also old-age pensions and payments for incapacity or death as a result of work-related accidents.

Welfare programs

Cultural life. Cultural differences between the provinces are important. The population of the west is far more cosmopolitan than that of the east and includes a higher proportion of people with Berber, Sudanese African, and Turkish origins. Cyrenaica was profoundly affected by the teachings of the 19th-century Sanūsiyah, an Islāmic brotherhood, which had little influence in the west and south.

Since the 1969 coup, life-styles have been strongly influenced by the revolutionary government's restructuring of national and local government and its efforts to reduce the influence of traditional tribes. The government has also brought women out of traditional seclusion and into the mainstream of the revolutionary socialist society.

Libyan culture centres on folk art and traditions, which are highly influenced by Islām. The traditional arts of weaving, embroidery, metal engraving, and leatherwork rarely depict people or animals because of the Islāmic prohibition against such representation. The dominant geometric and arabesque designs are best presented in the stucco and tiles of the Karamanli and Gurgi mosques of Tripoli. Surviving traditions are represented by festivals, horse races, and folk dances.

Nonreligious literature has developed largely since the 1960s; it is nationalistic in character but reveals Egyptian influences. The arts are supported by the government through the Ministry of Information, the Ministry of Education and National Guidance, and the Al-Fikr Society, a group of intellectuals and professionals.

Cultural institutions

Libraries include the Government Library and the Archives in Tripoli, the Public Library in Banghāzī, and the university libraries. The Department of Antiquities is responsible for the Archaeological Museum, the Leptis Magna Museum of Antiquities, the Natural History Museum, and the Sabratha Museum of Antiquities, all in the western region, and the archaeological sites of Ptolemais and Appolonia in the eastern region. The Sabhā Museum contains exhibits of ancient remains of the former Fezzan region.

The government controls broadcasting and the press. Newspapers and periodicals are published by the Jamahiriya News Agency (JANA), government secretariats, the Press Service, and trade unions. JANA publishes a daily newspaper, *Al-Fajr al-Jadīd* ("New Dawn"), in Tripoli. Radio broadcasts from Tripoli and Banghāzī are in Arabic and English; the national television service broadcasts in Arabic, with limited hours in English, Italian, and French. Three publishers of general and academic books are located in Tripoli. (Mu.B./G.L.F.)

For statistical data on the land and people of Libya, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR.

HISTORY

The present borders of Libya contain a huge territory the size of the U.S. states of Texas, Oklahoma, Louisiana, and Mississippi combined. Largely desert with some limited potential for urban and sedentary life in its northwestern and northeastern corners, Libya has never been populous nor a power centre. Like its neighbour Algeria, Libya's very name is a neologism, created by the conquering Italians early in the 20th century. Like Algeria, much of Libya's earlier history—not only in the Islāmic period but even before—reveals that both the western and eastern provinces were more closely linked with neighbouring territory, with Tunisia and Egypt respectively. Even during most of the Ottoman times the country was divided into two parts, one linked to Tripoli in the west and the other to Banghāzī in the east.

Libya thus owes its present unity as a state less to earlier history or geographic constants than to several recent factors: the unifying effect of the Sanūsiyah movement since the 19th century; Italian colonialism from 1911 until after World War II; an early independence by default, since the great powers could agree on no other solution; and the discovery of oil in commerical quantities in the late 1950s. Yet, the Sanūsīyah is based largely in the eastern region of Cyrenaica and has never really penetrated the more populous western region of Tripolitania. Italian colonization was brief and brutal. Moreover, most of the hard-earned gains in infrastructure implanted in the colonial period were destroyed by contending armies during World War II. Sudden oil wealth has been both a boon and a curse as changes to the political and social fabric, as well as to the economy, have accelerated. This difficult legacy of disparate elements and forces helps to explain the unique character of modern Libya. (L.C.Br.)

Ottoman rule. Part of the Ottoman Empire from the early 16th century, Libya experienced autonomous rule (similar to that in Ottoman Algeria and Tunisia) under the Karamanli dynasty from 1711 to 1835. In the latter year the Ottomans took advantage of a dispute over the succession and local disorder to reestablish direct administration. For the next 77 years the area was administered by officials from Istanbul and shared in the limited modernization common to the rest of the empire. In Libya the most significant event of the period was the creation (1837) of the Sanūsiyah (Sennusiyah), an Islāmic order, or fraternity, that preached a puritanical form of Islām, giving the people instruction and material assistance and so creating in them an added sense of unity. The first Sanūsī *zāwiyah,* or lodge, in Libya was established in 1843 near the ruins of Cyrene in eastern Cyrenaica. The order spread principally in that province but also found adherents in the south. The Grand Sanūsī, as the founder came to be called, moved his headquarters to the oasis of Jaghbūb near the Egyptian frontier, and in 1895 his son and successor, Sidī Muḥammad Idrīs al-Mahdī, transferred it farther south into the Sahara to the oasis of Al-Kufrah. Though the Ottomans welcomed the order's opposition to the spread of French influence northward from Chad and Tibesti, they regarded with suspicion the political in-

The Sanūsiyah

fluence it exerted within Cyrenaica. In 1908 the Young Turk revolution gave a new impulse to reform; in 1911, however, the Italians, with banking and other interests in the country, launched an invasion of Libya.

The Ottomans sued for peace in 1912, but Italy found it more difficult to subdue the local population. Resistance to the Italian occupation continued throughout World War I. After the war Italy considered coming to terms with nationalist forces in Tripolitania and with the Sanūsīyah, who were strong in Cyrenaica. These negotiations foundered, however, and the arrival of a strong governor, Giuseppe Volpi, in Libya and a Fascist government in Italy (1922) inaugurated an Italian policy of thorough colonization. The coastal areas of Tripolitania were subdued by 1923, but in Cyrenaica Sanūsī resistance, led by 'Umar al-Mukhtār, was maintained until his capture and execution in 1931.

Italian colonization. In the 1920s and '30s the Italian government expended large sums for developing towns, roads, and agricultural colonies for Italian settlers. The most ambitious effort was the program of Italian immigration called "demographic colonization," launched by Benito Mussolini in 1935. As a result of these efforts, some 150,000 Italian settlers were established in Libya (about 18 percent of that country's total population) by the outbreak of World War II.

These colonizing efforts and the resulting economic development of Libya were largely destroyed during the North Africa campaigns of 1941–43. Cyrenaica changed hands three times, and by the end of 1942 all of the Italian settlers had been withdrawn. Cyrenaica largely reverted to pastoralism. Somewhat more of the economic and administrative development achieved by Italy survived in Tripolitania; however, Libya by 1945 was impoverished, underpopulated, and also divided into regions—Tripolitania and Cyrenaica—of differing political, economic, and religious traditions.

Libyan independence

Independence. The future of Libya gave rise to long discussions after the war. In view of the contribution to the fighting made by a volunteer Sanūsī force, the British foreign minister pledged in 1942 that the Sanūsis would not again be subjected to Italian rule. During the discussions, which lasted four years, suggestions included an Italian trusteeship, a United Nations trusteeship, a Soviet mandate for Tripolitania, and various compromises. Finally, in November 1949, the UN General Assembly voted that Libya should become a united and independent kingdom no later than Jan. 1, 1952.

A constitution creating a federal state with a separate parliament for each province was drawn up, and the pro-British head of the Sanūsīyah, Sidi Muḥammad Idrīs al-Mahdī as-Sanūsī, was chosen king by a national assembly in 1950. On Dec. 24, 1951, King Idrīs I declared the country independent. Political parties were prohibited, and the king's authority was fundamental. Though not themselves Sanūsīs, the Tripolitanians accepted the monarchy largely in order to profit by the British promise that the Sanūsis would not again be subjected to Italian rule. King Idrīs showed a marked preference for living in Cyrenaica, where he built a new capital on the site of the Sanūsī *zāwiyah* at Al-Bayḍā'. Though Libya joined the Arab League in 1953 and in 1956 refused British troops permission to land for the Suez Canal expedition, during that time the government in general adopted a pro-Western point of view in international affairs.

The discovery of oil. In 1959 Libya changed abruptly from a pauper state, dependent on international aid and the rent from U.S. and British air bases, to an oil-rich monarchy. The discovery of major petroleum deposits in both Tripolitania and Cyrenaica assured the country of income on a vast scale. Soon after the discovery there was an enormous expansion of all government services and also of construction projects, and a corresponding rise in the economic standard and the cost of living.

On Sept. 1, 1969, a group of young army officers led by Colonel Muammar al-Qaddafi deposed the king and made Libya a republic. The new regime, passionately pan-Arab, broke the monarchy's close ties to Britain and the United States and also began an assertive policy that led to higher oil prices and to 51 percent Libyan participation in oil company activities and in some cases to outright nationalization.

Plans for Arab unity

Qaddafi's regime. Equally assertive in plans for Arab unity, Libya obtained at least the formal beginnings of unity with Egypt, The Sudan, and Tunisia, but these and other such plans failed as differences arose among the governments concerned. Qaddafi's Libya maintained a strong interventionist orientation on the Palestine issue and in support of other guerrilla and revolutionary organizations in Africa and the Middle East, all of which provoked considerable antipathy from the established governments that were threatened by such groups. In July–August 1977 hostilities broke out between Libya and Egypt, and as a result many Egyptians working in Libya were obliged to return home. Indeed, in spite of expressed concern for Arab unity, the regime's relations with most Arab countries were poor. Qaddafi signed a treaty of union with Morocco's King Hassan II in August 1984, but Hassan abrogated the treaty in August 1986.

The regime, under Qaddafi's ideological guidance, continued to introduce innovations. On March 2, 1977, the General People's Congress declared that Libya was to be known as the People's Socialist Libyan Arab Jamahiriya (the latter term is a neologism meaning "government through the masses"). By 1981, however, a drop on the world market in the demand and price for oil was beginning to hamper Qaddafi's efforts to play a strong regional role. Ambitious efforts to radically change Libya's economy and society slowed, and there were signs of domestic discontent. Libyan opposition movements launched sporadic attacks against Qaddafi and his military supporters but met with arrest and execution. (N.B./L.C.Br.)

Libya's relationship with the United States, which had been an important trading partner, deteriorated in the early 1980s as the U.S. government increasingly protested Qaddafi's support of Palestinian Arab terrorists. An escalating series of retaliatory trade restrictions and military skirmishes culminated in a U.S. bombing raid of Tripoli and Banghāzī in April 1986. U.S. claims that Libya was producing chemical warfare materials have been another source of tension since 1988. Libya has sought throughout the 1970s and '80s to dominate neighbouring Chad or at least to control the mineral-rich Aozou strip situated near the disputed border of the two states. These efforts have produced intermittent warfare in Chad and confrontation with both France and the United States. In 1987 Libyan forces were humiliatingly bested by the more mobile troops of Chad. Diplomatic ties with Chad were restored in October 1988. Libya denied involvement in a December 1990 coup in Chad. (L.C.Br.)

For later developments in the history of Libya, see the BRITANNICA BOOK OF THE YEAR.

Morocco

Morocco (official name Kingdom of Morocco, Arabic: Al-Mamlakah al-Maghribīyah), is situated in northwestern Africa directly across the narrow Strait of Gibraltar from Spain. It is the only African country with coastal exposure to both the Atlantic Ocean and the Mediterranean Sea. Because of its lack of natural harbours, its rugged mountainous interior, and its distance throughout its history from imperial centres in the east, Morocco remained relatively isolated until the early 20th century. This enabled it to preserve a proud traditional character, which is a rich blend of Berber, Arab-Islāmic, and African cultures. Those traits have been joined by a more recent infusion of European cultural elements—a legacy of the colonial period (1912–56) when Morocco was a protectorate of France and Spain. Morocco gained independence in 1956 and has been a constitutional monarchy since 1962. Soon after independence, the Moroccan government began to press a historical claim to the Spanish Sahara (now Western Sahara) directly to its south. In 1975, when Spain withdrew from this region, Morocco annexed the northern half and then added the remainder in 1979—despite protests over the annexations from the international community and from nationalist groups inside the territory.

With the Western Sahara's 97,344 square miles (252,120 square kilometres), Morocco occupies a total area of 274,461 square miles (710,850 square kilometres). Key sectors of the Moroccan economy include agriculture, mining, tourism, and light manufacturing.

Casablanca is Morocco's largest city, primary seaport, and commercial and industrial hub. Rabat is the capital and second largest city.

PHYSICAL AND HUMAN GEOGRAPHY

The land. *Relief.* Most of Morocco lies at high altitudes; the average elevation above sea level is about 2,600 feet (800 metres). Two chains of mountains, one, called the Rif, along the northern coast and the other, the Atlas, in the centre, divide eastern Morocco from Atlantic Morocco. These two parts of the country are connected by the narrow Taza Gap in the northeast as well as by roads that follow older traditional routes. The Atlas and Rif mountains were formed during the Tertiary Period (66.4 to 1.6 million years ago) by the folding and uplifting of sediment that had accumulated in the Tethys Sea, which, at that time, bordered the northern coast of the continent of Africa.

The Rif Mountains are geologically part of the cordilleras (mountain chains) reaching southward from the Iberian Peninsula of Europe, from which Africa was separated only after the Tertiary. The crescent-shaped range rises abruptly from a narrow Mediterranean coastal plain. Most of the limestone peaks in the Rif Mountains surpass 4,900 feet and rise to 8,058 feet (2,456 metres) at Mount Tidirhine.

The Atlas Mountains

The Atlas Mountains comprise three distinct chains. The High Atlas (Haut Atlas), 460 miles (740 kilometres) long, begins as small hills at the edge of the Atlantic, rises rapidly to more than 6,500 feet, and reaches its highest point at Mount Toubkal, which is 13,665 feet (4,165 metres) in elevation. The Middle Atlas (Moyen Atlas) trends away from the High Atlas in a northerly direction, rising to 10,958 feet (3,340 metres) at its crest. The Anti-Atlas extends southwestward from the High Atlas to the Atlantic.

(A.La./W.D.Sw.)

East of the Rif and Atlas mountains is the Moulouya basin, a semiarid lowland created by the eroding force of the Moulouya River. Farther east are the High Plateaus (Hauts Plateaux) of eastern Morocco, extensions of landforms in neighbouring Algeria, which lie roughly between 3,900 and 4,250 feet in elevation. The arid regions to the south and southeast of the Atlas are known collectively as the Sahara, the Arabic word for "deserts." The narrow transitional band is referred to as the pre-Sahara.

Atlantic Morocco consists of plains formed of relatively fine sediments and plateaus of coarser deposits. The Sebou basin, which lies in the northwest between the Rif Mountains and a line running roughly from Rabat to Fès, is a vast alluvial plain. Its agricultural heart is known as the Rharb Plain. South of the Rabat-Fès line, between the Atlas and the Atlantic Ocean, are a series of high plains known collectively as the Moroccan Plateau. These include the Saïs Plain near Fès and Meknès, the Tadla Plain to the northeast of Marrakech, the Haouz Plain west of Marrakech, and the broad Chaouïa, Doukkala, and Abda plains south of Casablanca. Between the High Atlas and Anti-Atlas ranges is the Sous valley, formed by the river of the same name. Morocco's coastline is regular and has few natural harbours. Before modern ports were constructed, sandbars and rocky reefs offshore made navigation difficult.

Drainage. Morocco's mountains capture significant amounts of rain and snow on their windward slopes from storms coming in off the North Atlantic and give rise to numerous perennial watercourses. Indeed, the country has the most extensive stream network in North Africa. Most streams arise either on the western slopes of the Atlas Mountains or on the southern slopes of the Rif Mountains and flow westward into the Atlantic Ocean. The Sebou is approximately 280 miles long and has the largest volume of any Moroccan river. With its tributaries, it accounts for roughly 45 percent of Morocco's surface water resources. The Oum er-Rbia is Morocco's longest river, approximately 345 miles in length. The Moulouya is the only major river flowing into the Mediterranean Sea; it originates on the eastern slopes of the Middle Atlas approximately 320 miles from its mouth, which lies near the Algerian frontier. The northern slopes of the Rif are drained by several short streams that also empty into the Mediterranean. Several minor streams originate on the dry eastern slopes of the High Atlas and flow into the Sahara: the Guir, the Rheris, the Ziz, the Dadès, and the Drâa. Although their volume is small, they have cut impressive gorges. Since the 1930s Morocco's streams have progressively been dammed for irrigation, hydroelectricity, and flood control.

Traditional soil names

Soils. A traditional classification system is usually used to characterize Morocco's major soil types. A dark clay-marl soil known as *tirs* is found on the Chaouïa, Doukkala, and Abda plains. It produces good yields of wheat and barley when precipitation is sufficient and can retain enough moisture to support summer pasture. Another major soil type is *hamri*, a light reddish siliceous soil found throughout the Saïs Plain surrounding Meknès and Fès. It supports productive vineyards and can also produce good cereal yields; it has poor moisture retention, however. *Dhess* is the main soil type of the Sebou basin. A silt-rich alluvial soil, it provides the foundation for much of Morocco's modern irrigated agriculture. Other major soil types, less suitable for agriculture, are *rmel*, a sandy soil found in the Mamora Forest region east of Rabat and along much of the northern coast, and *haroucha*, a rocky soil found throughout Morocco's semiarid regions.

Climate. Most of Morocco north of the Western Sahara, particularly along the coasts, experiences a typical Mediterranean climate, with mild wet winters and hot dry summers. The rainy season generally extends from October to April. Torrential downpours occasionally produce devastating floods, but overall several factors act to reduce the country's rainfall. Morocco is on the southern margins of the mid-latitude tract of frontal storm systems that regularly traverse the North Atlantic. As a result, rainfall levels are relatively low and gradually decrease from north to south. High-pressure ridges, moreover, periodically develop offshore during the rainy season, shifting storms to the north. If these ridges persist for extended periods, drought results. The cold Canary Current off the western shores also induces atmospheric stability and further decreases the potential for precipitation.

In the broad coastal lowlands, average annual rainfall diminishes progressively from about 32 inches (800 millimetres) on the northern Rharb Plain to less than 8 inches in the Sous valley. Farther south, beyond the Anti-Atlas, semiarid conditions quickly fade into desert. Elevation strongly influences this prevailing pattern, however, with significantly higher amounts of precipitation occurring in the mountains. The central Rif, for example, receives more than 80 inches of precipitation annually, and even the High Atlas, much farther south, receives some 30 inches. Above approximately 6,500 feet, snow is common, and the snowpack lingers in the highest elevations until late spring or early summer. Morocco's mountains create a significant rain shadow—directly east of the mountains, in the lee of the prevailing winds, desert conditions begin abruptly.

In the lowlands near the coast, summer heat is reduced by cool onshore breezes. Average daily summer temperatures in the coastal cities range from 64° to 82° F (18° to 28° C). In the interior, however, daily highs frequently exceed 95° F (35° C). In late spring or summer, the *chergui*—a hot dusty wind from the Sahara—can sweep over the mountains into the lowlands, penetrating even to coastal cities. Temperatures rise dramatically, often exceeding 105° F (41° C). If crops have not been harvested, damage can be extensive from the hot desiccating effects of the *chergui*. In winter, the marine influence again moderates temperatures in the coastal regions. Average daily winter temperatures range from 46° to 63° F (8° to 17° C). Away from the coast, temperatures drop significantly—occasionally below the freezing point.

The *chergui*, a local wind

Plant and animal life. Outside the desert areas, the vegetation of Morocco resembles that of the Iberian Peninsula. In the more humid mountainous areas, there are still

extensive forests, with cork oak, evergreen oak, and deciduous oak on the lower slopes and fir and cedar at higher elevations, particularly in the Middle Atlas. In drier mountain areas open forests of thuya, juniper, and Aleppo and maritime pine are common. East of Rabat is the extensive cork oak Mamora Forest. Eucalyptus, originally from Australia, was introduced by French authorities during the colonial period for reforestation. Since independence, the Moroccan government has established several large plantations of this tree surrounding the Mamora Forest. In the rugged highlands south of Essaouira, vast open forests of argan (Morocco ironwood) are found. This tree, which is unique to southwestern Morocco, has a hard fruit that produces a prized cooking oil.

In Morocco, as is common throughout the western Mediterranean region, centuries of human activity have considerably altered the natural vegetation. On many lower mountain slopes, cutting, grazing, and burning have produced an often dense cover of maquis, or scrub growth, characterized by various associations of wild olive, mastic tree, kermes oak, arbutus, heather, myrtle, artemisia, cytisus, broom, and rosemary. In the arid interior plains, the dwarf palm, jujube tree, esparto grass, and Barbary fig (introduced from the Americas by way of Spain in the 16th century) cover vast areas. East of the mountains, desert begins abruptly and there is little vegetation. The date palm was introduced to Morocco at a very early period and is extensively cultivated in the desert oases.

Demise of large game animals

Large game has been progressively eliminated in Morocco since Roman times, when lions and elephants were still abundant. Both have long since disappeared. The gazelle is still seen occasionally in the south, as are the mouflon (a wild sheep) and fennec (a type of fox) in the Atlas region. With government protection, the macaco (a type of monkey, often called the Barbary ape) now flourishes in the forests of the Middle Atlas. However, the richest fauna in Morocco today is the birdlife. Large migratory birds that sojourn in Morocco include the stork, which picturesquely builds its nests on city ramparts and mosque rooftops, and the flamingo, pelican, and cattle egret.

Settlement patterns. Settlement patterns in Morocco correspond loosely to the three major environmental zones: the coastal plains and plateaus, the highland areas of the Rif and Atlas mountains, and the desert south of the Atlas.

The coastal plains and plateaus contain three-fourths of the country's population, including most of its cities, and virtually all of its modern commercial agriculture. This is the Arabic-speaking part of Morocco. It has been the home of settled farmers and seminomadic tribes for many centuries. Most of the rural population in this region lives in villages of single-story cubical adobe or tamped-earth houses. The main form of agriculture is rain-fed cereal production, with wheat and barley as the main winter crops. This is supplemented by stock raising and summer gardens producing pulses (legumes) and fresh vegetables.

The highland areas of the Rif and Atlas contain about a fifth of the Moroccan population and are the bastion of Berber culture. Villages have a distinctive defensive aspect and are commonly perched on hillsides or hilltops. Dwellings are tightly clustered, are often multistoried, and are built of stone, adobe, or tamped earth. Level land is rare, and terraces are constructed to create arable fields along the nearby valley walls. The main subsistence crops are barley as a winter crop and corn (maize) and fresh vegetables as summer crops. Many villages specialize in cash cropping of a nut or fruit well-adapted to the local microclimate, such as olives, almonds, walnuts, figs, apples, cherries, apricots, or plums. Stock raising of sheep or goats often supplements village agriculture. Some groups practice transhumance, migrating with their flocks or herds to summer pastures at higher elevations or winter pastures at lower elevations, living in dark-coloured *khaymas* (tents) woven of goat hair.

The pre-Saharan and Saharan areas south of the Atlas contain less than 5 percent of Morocco's population. A large proportion of the population is of mixed black African descent, and many groups speak Berber. Virtually all settlement is in oases. Most oases are created artificially either by diversion of water from streams or by importation of water from often distant mountains via underground tunnels (*qanāts*). Dates are the main crop, grown as both a subsistence and a cash crop. In the date palm understory, alfalfa, corn, wheat, and barley, as well as fresh vegetables and other crops, are grown. Much settlement in this region is in highly distinctive fortresslike *ksour* (castles) made of adobe. Formerly, nomadic camel herding was an important economic activity in the Saharan zone. However, government policies, desert warfare, multiyear droughts, and other extenuating factors have caused this way of life to disappear almost completely.

Oasis settlements

Date palms and cultivated fields at the village of Tinrhir on the southern slopes of the High Atlas Mountains in the pre-Saharan region of Morocco.

Although approximately half the Moroccan population lives in urban areas, most Moroccan cities retain at least some of their traditional character and charm. During the period of the French protectorate, colonial authorities purposely attempted to preserve existing urban centres, which were usually surrounded by defensive ramparts. Rather than adapting these centres to accommodate new infrastructure for administration and economic development, they established *nouvelles villes* ("new towns") alongside them. In addition, they shifted the focus of political and economic life from the interior of Morocco—where it had long revolved around the royal cities of Fès, Meknès, and Marrakech—to the Atlantic coast. Casablanca was transformed from a sleepy coastal village into a bustling metropolis. Rabat became the capital and centre of administration. By the 1930s, bidonvilles ("tin can cities"), or shantytowns, were beginning to develop around major urban areas and have since become extensive. For many years the government tried to discourage these spontaneous settlements. More recently, however, it has been providing bidonvilles with electricity, piped water, and other facilities and encouraging residents to improve their structures. (W.D.Sw.)

The people. The population of Morocco is Arab and

Arabs and Berbers

Berber in origin, though the main difference between the two groups today is primarily linguistic. The Berber language, although greatly influenced by Arabic, has been preserved in the mountainous regions, which have long been areas of refuge. Berber-speaking inhabitants are divided into three ethnolinguistic groups: the Rif people (also called Riffi or Riffians) of the Rif Mountains, the Tamazight of the Middle Atlas, and the Shluh of the High Atlas and the Sous valley. With improved communications and the ongoing rural exodus to the towns, Arabic-Berber bilingualism has become common: today, in the late 20th century, the proportion of monolingual Berbers does not exceed 25 percent. The remainder of the Moroccan population primarily speaks Arabic (with French as an important secondary language) and is composed mainly of Arabized Berbers, descendants of Bedouin Arabs (who moved to Morocco with the armies of Islām in the 7th century or with the invading Hilāl tribe in the 11th and 12th centuries), and descendants of refugees from Spain. These latter were a mixture of Arab, Berber, and Iberian who fled from the Reconquista, the Christian reconquest of the Iberian Peninsula, which culminated in 1492.

Trade and cultural relations with black Africa since the European Middle Ages have resulted in the gradual growth of a significant black minority, living chiefly in the southern oases or in the royal towns, particularly Marrakech and Meknès. The Jewish minority—a considerable community until Jewish emigration to Israel began in 1948—consists of small Berber-speaking groups whose origins are obscure and of Arabic-speaking groups who arrived from Spain and other Mediterranean countries at various periods of history. However, the majority of the Moroccan population has a common culture and religion. Most Moroccans are Sunnite Muslims of the Malikite order.

Morocco's population growth rate remains high, though it appeared to be declining somewhat during the 1980s and was well below average for countries in the Middle East and North African region. Nonetheless, more than one-half of the population was under the age of 20 in the late 20th century, assuring high birth rates and continued high population growth for years to come. The opportunity to emigrate to western European countries traditionally offered a partial solution to Morocco's population explosion. By the early 1980s some 600,000 Moroccan workers and merchants had established themselves in western Europe, notably in France, Belgium, The Netherlands, and West Germany. Soon thereafter, however, the European labour market became closed to new workers, and Morocco's population problem was only slightly relieved by the open labour markets of some Arab nations, among them Iraq, Saudi Arabia, and Libya. (A.La./W.D.Sw.)

Patterns of emigration

The economy. As is true in most former colonies, the Moroccan economy remains heavily dependent on exports of raw materials. It is also characterized by a dichotomy between a large traditional sector and a smaller modern export-oriented sector. Altogether, the modern economy accounts for as much as 70 percent of the gross domestic product (GDP), even though it provides only about 30 percent of employment.

Viewed globally, the primary sector (agriculture, mining, fishing, and forestry) accounts for about 50 percent of the labour force and 25 percent of GDP; the secondary sector (industry and manufacturing, traditional handicrafts, and construction) for about 15 percent of the labour force and 25 percent of GDP; and the tertiary sector (commerce, administration, transportation, and service activities) for the remaining 35 percent of the labour force and 50 percent of GDP. Not included in these statistics is a large "informal" economy of street vendors, maids, nonlicensed tourist guides, porters, night watchmen, errand boys, and other underemployed and poorly paid individuals.

The large "informal" economy

The three leading exports in order of importance are phosphates and phosphate products, agricultural produce (primarily citrus fruits and market vegetables), and textiles. Tourism and remittances from Moroccan workers abroad are each roughly equal to phosphate exports as sources of foreign exchange. Major imports are semimanufactures and industrial equipment, crude oil, and food commodities.

Since the mid-1980s, under pressure from international lenders, the Moroccan government has been undertaking privatization and other economic reforms. Measures have included the selling of state-owned enterprises, currency devaluation, and changes in pricing policy to encourage local production.

Resources. Morocco is endowed with numerous exploitable resources. With approximately 21 million acres (8.5 million hectares) of arable land, 3 million of which are irrigable, and its generally temperate Mediterranean climate, Morocco's agricultural potential is matched by few other Arab or African countries. It also possesses some two-thirds of the world's reserves of phosphates, used for the manufacture of fertilizers and many other products. World prices for phosphates, however, have been low since the late 1970s. Other minerals include iron ore and coal, mined for Morocco's domestic use, and manganese, lead, and zinc, which are exported in small quantities. The fishing grounds in the Canary Current off Morocco's west coast are exceptionally rich in sardines, bonito, and tuna. However, the country still lacks the modern fleets and processing facilities to benefit fully from these marine resources.

Morocco's sandy beaches, sunshine, diverse environments, and well-preserved traditional culture give it outstanding potential for tourism, which it has already developed to a large degree. Its forests, covering about one-tenth of its total land area excluding Western Sahara, have substantial commercial value. Morocco is able to satisfy much of its timber needs by harvesting the high-elevation forests in the Middle and High Atlas. Its eucalyptus plantations enable it to be self-sufficient in charcoal which is used extensively for cooking fuel. Eucalyptus also provides the raw material for the country's paper and cellulose industry. Paper pulp is a valuable export. Cork from the country's plentiful cork oak forests is also exported on a significant scale.

A major weakness in the country's resource inventory is its shortage of energy resources. Oil exploration has proved to be disappointing. The country possesses some natural gas reserves, however, which have been tapped, and its hydroelectric potential, about half of which has been developed, is considerable. Nonetheless, Morocco must cover roughly four-fifths of its growing energy needs through imports. The principal energy import is crude oil, which Morocco refines domestically at several different facilities. (W.D.Sw.)

Agriculture. Morocco is one of the few Arab countries that has the potential to achieve self-sufficiency in food production. In a normal year Morocco produces two-thirds of the grains (chiefly wheat, barley, and corn [maize]) needed for self-sufficiency. The country exports citrus fruit and early vegetables to the European market; its wine industry is well developed, and production of industrial crops (cotton, sugarcane, sugar beets, and sunflowers) is being expanded. New crops such as tea, tobacco, and soybeans have passed the experimental stage, and the fertile Rharb Plain has proved to be favourable to their cultivation. The country is actively developing its irrigation potential. Plans call for permanent irrigation of well over 2.5 million acres. Livestock raising, particularly of sheep and cattle, is widespread. Morocco fills its own meat requirements and is attempting to become self-sufficient in dairy products. (A.La./W.D.Sw.)

Agricultural development and production

Industry. Industry accounts for about one-fourth of the GDP and is steadily growing in importance in the economy. Two particularly important components of the country's industrial makeup are the processing of raw materials for export and the manufacture of consumer goods for the domestic market. Many operations date back to the colonial period. Until the 1980s, government involvement was dominant, and the major focus was on import substitution. By the late 1980s, however, heavy emphasis was being placed on export-oriented industry, privatization of state operations, and new private investment, including foreign investment. The most important industrial activity is the transforming of phosphate ore into fertilizers and phosphoric acid for export. Food processing for export (canning of fish, fresh vegetables, and fruit) as well as for

Phosphate industries

domestic needs (flour milling, sugar refining, and so forth) is also important. A growing earner of foreign exchange is textile and clothes manufacturing using domestically produced cotton and wool. Refining of imported crude oil and production of cement for construction are other major industrial activities. Morocco's iron and steel industry is small but provides for a significant share of the country's domestic needs.

Finance and trade. Morocco's central bank, the Bank al-Maghrib, plays a preeminent role in the country's banking system. It issues currency, maintains Morocco's foreign currency reserves, controls the credit supply, oversees the government's specialized lending organizations, and regulates the commercial banking industry. Since the mid-1980s, with privatization and structural economic reforms under way, the central bank has had the difficult task of trying to encourage private investment and development while discouraging imports. Privatization has stimulated stock market activity: shares of large former state-owned operations are increasingly being traded on the Casablanca stock exchange. Government attempts to stimulate exports and control imports have not been particularly successful, however. Exports regularly cover only about half the value of imports, resulting in a chronic trade deficit that has proved resistant to change. The main imports are capital goods for industrial development, semimanufactures, crude oil, and food commodities (wheat, barley, flour, sugar, and raw materials to produce cooking oil). Countries of the European Community (EC), particularly France, are the main sources for imports, although Morocco has an impressively long list of trade partners. Major exports are phosphates and phosphate products, agricultural produce (particularly citrus fruits and market vegetables), and textiles and clothing. The EC again forms the main market. The EC market for Morocco's agricultural exports is likely to progressively diminish, however, because of increasing competition from EC members, such as Spain and Portugal, which produce many of the same crops.

Trade with the EC

Transportation and communications. Morocco's road network effectively integrates the country's diverse regions. Established during the colonial period, the network has been well maintained and gradually expanded ever since. The railway system connects the principal urban centres of the north, and new rail links, together with improved roads, are being established to El-Aaiún (Laâyoune) in Western Sahara. Morocco has some 20 ports along its lengthy coastline. Casablanca alone accounts for about one-half of all port tonnage. Other major ports include Safi, Mohammedia, Agadir, Nador, Tangier, Kenitra, and Jorf Lasfar. Nine airports capable of accommodating large aircraft service the country; the principal international airport is located near Casablanca. The state-owned Royal Air Maroc (RAM) airline provides regular service to Europe, North America, the Middle East, and western Africa. In the late 1980s and early 1990s the government undertook a major expansion and modernization of the telecommunications system. This nearly quadrupled the number of internal lines and greatly improved international communications.

Administration and social conditions. *Government.* Morocco has been a constitutional monarchy since 1962, with the king ostensibly ruling in conjunction with a parliament. King Hassan II, who was enthroned following his father's death in 1961, represents the latest monarch in a dynasty that extends back to 1666. In addition, he is the country's spiritual leader and traces his roots back to the Prophet Muḥammad. King Hassan has more inherent legitimacy than most heads of state, and this has been a major source of stability. However, despite the constitution, parliament, and presence of opposition parties, the king wields far more political power than do most rulers.

Although the parliament does have limited legislative power, its primary function is to discuss and ratify initiatives proposed by the king and his advisors. Two-thirds of the members of parliament are elected by universal suffrage (male and female citizens 21 years of age and older), and the remaining third is elected by a college formed of representatives from provincial and prefectural assemblies, professional bodies, and labour groups. In the event of "national emergencies," the king can disband parliament, and he did so from 1965 to 1977, during which time he ruled by direct decree.

The 15 or so political parties are closely monitored, and leaders are occasionally imprisoned for overstepping unwritten rules. The king has taken steps to win the favour of opposition parties through offering Cabinet appointments and government positions to their leaders. Since 1986, political parties have received state funding. They have failed to attract mass participation and remain primarily political organizations for the better-educated elite. The king's two major bases of support are the direct following of the masses and the well-cultivated loyalty of the security forces, which number well over 200,000 and include the Royal Armed Forces (army, air force, and navy), the National Police Force, the Royal Gendarmerie (mainly responsible for rural security), and the Auxiliary Forces (a reserve national guard).

Since 1977 the king has permitted a closely supervised amount of political expression. Elections have been held, parliament has been convened regularly, and circumspect criticism of social and economic conditions or government policies has been tolerated, though not criticism of the royal family, the institution of the monarchy, or certain key policies such as those dealing with Western Sahara or the Islāmic nature of the state. A significant new development during the 1980s and early 1990s was the emergence of Islāmic fundamentalist groups enjoying wide popular support. These groups are regarded as a political threat and have been closely monitored by the security forces.

The country is subdivided into three levels of government, all directly under the Ministry of the Interior. At the top are 49 (including four in Western Sahara) *wilāyāt* (provinces) and *'amālat* (urban prefectures), each ruled by a governor appointed by the king. Beneath this first-order subdivision are rural *qadawat* (districts) and municipalities, governed by *chefs de cercle* or *super qa'ids*. The third level comprises rural communes and autonomous urban centres, governed respectively by *qā'ids* and *pashas*. Lower-order officials are appointed either by the Ministry of the Interior or by the governors. At each level there are popularly elected bodies whose primary function is to help determine local matters and priorities, such as initiating development projects and deciding budget expenditures. However, they are supervised by the central government's representatives, who implement government policies and exercise considerable power within their administrative territories. (W.D.Sw.)

Structure of local government

Justice. In theory, the Qur'ān is the source of law. In effect the Qur'ānic jurisdiction, exercised by the qadis (Muslim judges who interpret and administer the religious law of Islām), is limited to matters relating to the personal status of Muslims. Rabbinical justice applies to Jews. All other matters, whether they concern Muslims, Jews, or others, are in the hands of the "modern" courts, which apply a code of laws inspired by the French. The various regional and local courts are beneath three courts of appeal and the supreme court, which convenes in Casablanca. All are supervised by the Ministry of Justice.

(A.La./W.D.Sw.)

Education. Morocco allocates approximately one-fourth of its budget to education. Much of this is spent on construction of schools to accommodate the rapidly growing population, more than two-fifths of whom are younger than age 15. Education is mandatory for children between the ages of 7 and 13 years. In urban areas most children in this age group attend school. On a national scale, however, the level of participation drops to about three-fourths. Males account for about 60 percent of the school population. Slightly more than half of the children go on to secondary education, including trade and technical schools. Of these, about 1 in 10 go on to higher education.

Morocco has 6 universities and 21 specialized institutes and polytechnics dispersed at urban centres throughout the country. Its leading institutions include Muḥammad V University in Rabat, the country's largest university, with faculties of arts and letters, science, medicine, law, engineering, education, and Islāmic studies and with branches in Casablanca and Fès; the University of al-Qarawiyin at

Fès, founded in the 9th century and a famous centre for Islāmic studies; and the Hassan II Agriculture and Veterinary Institute in Rabat, which conducts leading social science research in addition to its agricultural specialties.

Health and welfare. Morocco has a relatively favourable ratio of physicians and other trained medical personnel to population. The government has been emphasizing preventive medicine by increasing the number of dispensaries and health centres. An estimated one-half of the rural population, however, still lacks access to these facilities. In addition, only about three-fourths of the urban population and one-fifth of the rural population have access to safe drinking water. Infant mortality rates remain high, and at least one-fourth of the population experiences malnutrition. Certain endemic diseases of the past, such as trachoma, tuberculosis, and cholera, have been largely eliminated. Other diseases, such as hepatitis, remain prevalent, however, and new diseases, such as schistosomiasis (linked to the expansion of irrigation), are becoming more frequent. (W.D.Sw.)

Diseases

Cultural life. *The arts.* Arabic is the national and official language of Morocco; French and Spanish, however, are widely spoken, and English is increasingly used. For several years attempts have been made to revive the Berber culture, and authorities have created an institute of Arab and Berber cultures.

The production of literature has continued to grow and diversify. To the traditional genres—poetry, essays, and historiography—have been added forms inspired by Middle Eastern and Western literary models. French is used in publication of research in the social and natural sciences. Moroccan literature is published in both Arabic and French. Many Moroccan authors and educators also publish in France. Since independence a veritable blossoming has taken place in painting and sculpture, popular music, amateur theatre, and filmmaking. The Ministry of Tourism promotes music and dance. Each year it organizes a folklore festival at Marrakech, a jazz festival at Tangier, a festival of Andalusian music at Saïdia, and an African arts festival at Agadir. An August festival at Asilah, organized by private supporters, transforms the entire town into an immense studio where artists from four continents display their work.

Arts festivals

Broadcasting and the press. Morocco's government-owned radio and television network, Radiodiffusion Télévision Marocaine (RTM), broadcasts throughout the country. Radio broadcasts are in Arabic, French, Berber, Spanish, and English, and television broadcasts are in Arabic and French. In addition, there is a private television network headquartered in Casablanca and a private radio network in Tangier. Both are joint ventures of Moroccan and French investors, and both broadcast countrywide in Arabic and French. Moroccans in the north also receive Spanish radio and television stations. Given the estimated number of receivers in the country by the early 1990s, the potential radio audience was believed to include about 80 percent of the population and the potential television audience nearly 70 percent.

There are 11 daily newspapers in Morocco, 5 in Casablanca and 6 in Rabat. Five are published in Arabic only, four in French only, and two in both languages. Most are organs of political parties; the remainder are government-owned or government-leaning. In addition, there is a rich variety of periodicals representing various professions, trades, intellectual interests, and avocations. (A.La./W.D.Sw.)

For statistical data on the land and people of Morocco, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR.

HISTORY

Literally visible from Europe at the Strait of Gibraltar and linked to Spain politically and culturally from the early Islāmic period until the 15th century, Morocco at the beginning of the 19th century was much less in contact with Europe than perhaps any other Muslim country bordering the Mediterranean. Geography provides a partial answer to this paradox. Morocco is not an easy country for people or ideas to penetrate, especially if those ruling within choose to ward them off—and such was the choice of Morocco's rulers.

Another paradox is that, while Morocco, cut up by mountains and desert and possessing no single predominant city such as Paris in France or Tunis in Tunisia, is a difficult country to hold together, it had begun to develop what can be called a protonationalism early in the Islāmic period. In a way that cannot be matched in any other country of the present-day Arab world, save possibly Egypt, Morocco's history since the rise of Islām can be traced in terms of successive ruling dynasties—from the Idrisids to the ʿAlawites, who still rule. Morocco at times has been the core of imperial structures extending beyond its borders, such as during the Almoravid and Almohad dynasties. It has had a major impact—at times militarily devastating, at times culturally enriching—beyond the Sahara in western Africa. At the same time, Morocco had seldom been absorbed for long in empires centred elsewhere. It resisted the push of the Spanish Reconquista in the 15th and 16th centuries, just as it never became part of the Ottoman Empire that for so long controlled virtually all the rest of the Arab world. At the beginning of the 19th century Morocco was, and wished to remain, self-contained. Yet, the premodern characteristics of a great divide between urban and rural life, of a near-subsistence economy, of cultural differences dividing Arabs from Berbers (perhaps just slightly less than half the population at that time), and of a tradition of resistance to any authority that could not be maintained by force was to make Morocco especially vulnerable to the economic and military advances of its European neighbours across the sea. (L.C.Br.)

Proto-nationalism

Decline of traditional government (1830–1912). During the French invasion of Algeria in 1830, the sultan of Morocco, Moulay (Mawlay) Abd ar-Rahman (1822–59), briefly sent troops to occupy Tlemcen but withdrew them after French protests. The Algerian leader Abdelkader in 1844 took refuge from the French in Morocco. A Moroccan army was sent to the Algerian frontier; the French bombarded Tangier on Aug. 4, 1844, and Essaouira (Mogador) on August 15. Meanwhile, on August 14, the Moroccan army had been totally defeated at Isly, near the frontier town of Oujda. The sultan then promised to intern or expel Abdelkader if he should again enter Moroccan territory. Two years later, when he was again driven into Morocco, the Algerian leader was attacked by Moroccan troops and was forced to surrender to the French.

Immediately after Abd ar-Rahman's death in 1859, a dispute with Spain over the boundaries of the Spanish enclave at Ceuta led to a declaration of war by Madrid and to the Spanish capture of Tétouan in the following year. Peace had to be bought with an indemnity of $20 million, the enlargement of Ceuta's frontiers, and the promise to cede to Spain another enclave—Ifni.

The new sultan, Sidi Muḥammad (1859–73), attempted without any marked success to modernize the Moroccan army. After his death, his son Moulay Hassan I (1873–94) struggled to preserve independence. After his death, his chamberlain, Ba Ahmed (Ahmad ibn Musa), ruled in the name of the young sultan Abd al-Aziz until 1901, when the latter began his direct rule.

Attempts at modernization

Abd al-Aziz surrounded himself with European companions and adopted their customs, scandalizing his subjects, particularly the religious leaders. His attempt to introduce a modern system of land taxation resulted in complete confusion because of a lack of qualified officials. Popular discontent and tribal rebellion became even more common, while a pretender, Bu Hamara (Bū Ḥmāra), established a rival court near Melilla. European powers seized the occasion to extend their own influence. In 1904 Britain gave France a free hand in Morocco in return for a French undertaking not to interfere with British plans in Egypt. Spanish agreement was secured by a French promise that northern Morocco should be treated as a sphere of Spanish influence. Italian interests were satisfied by a French undertaking not to hinder Italian designs on Libya. Possible German claims were ignored, thus enabling the sultan to arrange an international conference at Algeciras, Spain, in 1906 to discuss the whole Moroccan question.

The Algeciras Conference confirmed the integrity of

the sultan's domains but sanctioned French and Spanish policing of Moroccan ports and collection of the customs dues. In 1907–08 the sultan's brother, Moulay Abd al-Hafid, led a rebellion against him, denouncing him for his departure from Muslim ways. Abd al-Aziz took refuge in Tangier. Abd al-Hafid then made an abortive attack on French troops, which had occupied Casablanca in 1907, before proceeding to Fès, where he was duly proclaimed sultan and recognized by the European powers (1909).

The new sultan proved unable to control the country. Disorder increased until, besieged by tribesmen in Fès, he was forced to ask the French to rescue him. When they had done so, he had no choice but to sign the Treaty of Fès (March 30, 1912), by which Morocco became a French protectorate. In return the French guaranteed to maintain the status of the sultan and his successors. Provision was also made to meet the Spanish claim for a special position in the north of the country; Tangier, long the seat of the diplomatic missions, retained a distinctive administration.

The French protectorate (1912–56). In establishing their protectorate over Morocco, the French had behind them the experience of the conquest of Algeria and of their protectorate over Tunisia, and they took the latter as the model for their Moroccan policy. There were, however, important differences. First, the protectorate was established only two years before the outbreak of World War I, which was to bring with it a new attitude toward colonial rule. Second, Morocco had a tradition of a thousand years of independence; it had been strongly influenced by the civilization of Muslim Spain and had never been subject to Ottoman rule. These circumstances and the proximity of Morocco to Spain created a special relationship between the two countries. Morocco was also unique among North African countries in possessing a coast on the Atlantic, in the rights that various nations derived from the Act of Algeciras, and in the privileges that their diplomatic missions had acquired in Tangier. Thus, the northern tenth of the country, with an Atlantic and a Mediterranean coast, together with the desert province of Tarfaya in the southwest adjoining the Spanish Sahara, was excluded from the French-controlled area and treated as a Spanish protectorate. In the French sector, the French resident general became the real ruler of the country, subject to the approval of the Paris government. He worked through newly created departments manned by French officials. The outward forms of the traditional Moroccan government (*makhzan*) were preserved, though the negligible role that it actually played can be estimated from the fact that the grand vizier on the installation of the protectorate, Muḥammad al-Moqri, still held the same post on the recovery of independence 44 years later, when he was more than 100 years old. As in Tunisia, country districts were administered by *contrôleurs civils,* except in certain areas such as Fès, where it was felt necessary that officers of the rank of general should supervise the administration. In the south certain Berber chiefs (*qā'id*s or caids), of whom the best known was Thami al-Glaoui, were allowed to remain semi-independent.

The protectorate's government

The pre-World War II period. The first resident general, General (later Marshal) L.-H.-G. Lyautey, was a soldier of wide experience in Indochina, Madagascar, and Algeria. He was of aristocratic outlook and possessed a deep appreciation of Moroccan civilization. The character he gave to the administration exerted an influence throughout the period of the protectorate.

Abd al-Hafid could not reconcile himself to the new regime and, after a few months, joined his brother as a French pensioner in Tangier. In his place a more amenable brother, Moulay Yusuf, was recognized as sultan and succeeded in cooperating with the French without losing the respect of his own people. A new administrative capital was created on the Atlantic coast at Rabat. At the same time, a commercial port was developed at Casablanca. By the end of the protectorate, Casablanca was a flourishing city, with nearly a million inhabitants and a substantial industrial establishment. Lyautey's policy was to build new European cities beside or at some distance from the old Moroccan towns, thus preserving the country's ancient monuments. The remarkable rhythm of innovation was little interrupted by World War I. Though the French government had proposed to retire to the coastal area, Lyautey managed to retain control of all of the occupied area.

The development of Casablanca

After the war one major problem was the pacification of the outlying areas in the Atlas Mountains, over which the sultan's government often had had no real control. This was finally completed in 1934. Another problem was the extension of the uprising of Abd el-Krim from the Spanish to the French zone (see below *World War II and the attainment of independence: The Spanish Zone*).

Marshal Lyautey was succeeded by a civilian resident general in 1926. This marked a change to a more conventional colonial regime, accompanied by the extension of official colonization, the growth of European population, and the increasing impact of European thought on the minds of the younger generation, some of whom had by then received a French education.

As early as 1920 Lyautey had submitted a report saying that "a young generation is growing up which is full of life and needs activity. . . . Lacking the outlets which our administration offers only sparingly and in subordinate positions they will find an alternative way out." Only six years after Lyautey's report, young Moroccans both in Rabat, the new administrative capital, and in Fès, the centre of traditional Arab learning and culture, were meeting, quite independently of one another, to discuss demands for reforms within the terms of the protectorate treaty. They asked for more schools, a new judicial system, and the abolition of the regime of the Berber caids in the south; for study missions in France and in the Arab East; and for the cessation of official colonization—objectives that would be fully secured only when the protectorate ended in 1956.

On the death of Moulay Yusuf (1927) the French chose as his successor his younger son, Sidi Muḥammad (Muḥammad V). Chosen in part for his retiring disposition, this sultan was in time to reveal diplomatic skill and determination. Another significant event was the attempt to use the differences between Arabs and Berbers to counterbalance the Arab character of the sultan's government. This led to the issue of the 1930 Berber Decree, a crude French effort to divide Berbers and Arabs. The result was just the opposite of French intentions; it provoked a Moroccan nationalist reaction and forced the administration to modify its proposals. In 1933 the nationalists initiated a new national day called the Fête du Trône (Throne Day) to mark the anniversary of the sultan's accession. When he visited Fès in the following year, he received a tumultuous welcome, accompanied by anti-French demonstrations that caused the authorities to terminate the visit abruptly. This episode was soon followed by the organization of political parties of nationalist sentiment. These events coincided with the completion of the occupation of southern Morocco, which brought with it the Spanish occupation of Ifni. In 1937 rioting occurred in Meknès, where French settlers were suspected of diverting part of the town water supply to irrigate their own lands at the expense of the Muslim cultivators. In the ensuing repression, Muḥammad 'Allāl al-Fāsi, the main nationalist leader, was banished to Gabon in French Equatorial Africa, where he spent the following nine years.

The Berber Decree of 1930

World War II and the attainment of independence. At the outbreak of World War II in 1939, the sultan issued a call for cooperation with the French, and a large Moroccan contingent, mainly Berbers, served with distinction in France. The collapse of the protecting power in 1940 and the installation of the Vichy regime produced an entirely new situation. The sultan marked his independence by refusing to approve anti-Jewish legislation. When the Anglo-American landings took place in 1942, he refused to comply with the suggestion of the resident general, Auguste Noguès, that he retire to the interior. In 1943 the sultan was influenced by his meeting with United States President Franklin D. Roosevelt, who came to Morocco for the Casablanca Conference and was unsympathetic to continued French presence there. The majority of the people were equally affected by contact with the U.S. and British troops, who put them in touch with the outside

The Allied invasion

world to an unprecedented degree. Among the people at large, the effect of the newly introduced radio broadcasts in Arabic with which the combatants, Allied and Nazi alike, sought to attract Arab listeners to their side, was considerable. Amid these circumstances, the nationalist movement took the new title of Independence Party (Ḥizb al-Istiqlāl). In January 1944 they submitted to the sultan and the Allied (including the French) authorities a memorandum asking for independence under a constitutional regime. The nationalist leaders, including Ahmad Balafrej, secretary general of the Istiqlāl, were immediately arrested on an improbable charge of collaboration with the Nazis. This caused rioting in Fès and elsewhere in which some 30 or more demonstrators were killed. In the situation thus created, the initiative passed to the sultan, who in 1947 persuaded a new and reforming resident general, Eirik Labonne, to gain the French government's permission for him to make an official state visit to Tangier, passing through the Spanish Zone on the way. The journey became a triumphal procession; when the sultan finally made his speech in Tangier, it was under the emotion of his stirring reception in the Spanish Zone and Tangier. While emphasizing the links of Morocco with the Arab world of the East, he omitted the expected flattering reference to the French protectorate.

The regime of General Juin

The result was the replacement of Labonne by General (later Marshal) Alphonse Juin, of Algerian settler origin. With long experience in North African affairs, Juin expressed sympathy for the patriotic nationalist sentiments of young Moroccans and promised to comply with their wish for the creation of elected municipalities in the large cities. At the same time he roused opposition by proposing to introduce French citizens as members of these bodies. The sultan used his one remaining prerogative and refused to countersign the resident general's decrees, lacking which they had no legal validity. A state visit to France in October 1950 and a flattering reception did nothing to modify the sultan's views, and on his return to Morocco he received a wildly enthusiastic welcome.

On December 12 General Juin dismissed a nationalist member from a meeting of the Council of Government, which discussed budget proposals; the 10 remaining nationalist members walked out in protest. Juin began to think of the possibility of utilizing the Berber feudal notables, such as Thami al-Glaoui, to counter the nationalists. Thus, at a palace reception on Dec. 21, 1950, Al-Glaoui told the sultan to his face that he was not the sultan of the Moroccans but of the Istiqlāl and that he was leading the country to catastrophe.

In the face of Sidi Muḥammad's continued refusal to cooperate, Juin surrounded the palace with tribesmen, after having provided a guard of French troops supposedly to protect the sultan against his own outraged people. Faced with this threat, Sidi Muḥammad was constrained to disown "a certain political party," without specifically naming it, but he still withheld his signature from many decrees, including that admitting French citizens as municipal councillors. Juin's action was widely criticized in France, and on Aug. 28, 1951, he was replaced by General Augustin Guillaume. The sultan, on the anniversary of his accession (November 18), declared that he was hoping for an agreement "guaranteeing full sovereignty to Morocco" but (as he added in a subsequent letter addressed to the president of the French Republic) "with the continuation of Franco-Moroccan cooperation." This troubled situation continued until December 1952, when the trade unions in Casablanca decided to organize a protest meeting over the assassination of the Tunisian trade union leader, Ferhat Hashad (Hached), allegedly by French terrorists. A clash with the police followed; hundreds of nationalists were arrested and were held for two years without trial.

In April 1953 the head of a religious confraternity, Abd al-Ḥai al-Kittani, together with a number of Berber notables headed by Al-Glaoui, with the connivance of a number of French officials and settlers, began to work for the deposition of the sultan. The government in Paris, preoccupied with internal affairs, finally demanded that the sultan transfer his legislative powers to a council, composed jointly of Moroccan ministers and French directors, and append his signature to all the blocked legislation. The sultan yielded, but this was not sufficient for his enemies. On Aug. 18, 1953, Al-Glaoui delivered what may be called an ultimatum to the French government. The latter thereupon deported the sultan and his family, appointing in his place the more subservient Moulay Ben Arafa. This did nothing to improve the situation. Sidi Muḥammad at once became a national hero. The authorities in the Spanish Zone, who had not been consulted about the measure, did not conceal their disapproval. The Spanish Zone thus became a refuge for Moroccan nationalists.

The sultan's exile

In November 1954 the French position was further complicated by the outbreak of the Algerian rebellion. In June 1955 the Paris government decided on a complete change of policy and appointed Gilbert Grandval as resident general. His efforts at conciliation were obstructed by the tacit opposition of many officials and the outspoken hostility of the majority of the French settlers, and he was recalled. A conference of representative Moroccans was then summoned to meet in France, and at this conference it was agreed to replace the substitute sultan by a crown council. Sidi Muḥammad gave his approval to the proposal, but it took weeks to persuade the puppet sultan to withdraw to Tangier. Meanwhile, a guerrilla liberation army began to operate against French posts near the Spanish Zone.

On October 26 Al-Glaoui declared publicly that only the restoration of Muḥammad V could restore harmony. The French government agreed to allow the sultan to form a constitutional government for Morocco. In November Sidi Muḥammad returned to Rabat. On March 2, 1956, independence was proclaimed, and the sultan formed a government representative of the various elements of the indigenous population, while the governmental departments formerly headed by Frenchmen became ministries headed by Moroccans.

The Spanish Zone. The Spanish protectorate over Morocco covered about one-tenth of the kingdom, from Larache (El-Araish) on the Atlantic to 30 miles beyond Melilla (already a Spanish possession) on the Mediterranean. This was in the main a mountainous, Berber-speaking area that had often escaped the sultan's control. Spain also received a strip of desert land in the southwest, adjoining Spanish Sahara and known as Tarfaya. In 1934, when the French occupied southern Morocco, the Spanish took Ifni.

Spain appointed a *khalīfah,* or viceroy, chosen from the Moroccan royal family as nominal head of state and provided him with a puppet Moroccan government. This enabled Spain to conduct affairs independently of the French Zone while nominally preserving Moroccan unity. Tangier, though it had a Spanish-speaking population of 40,000, received a special international administration, under a *mandub,* or resident, theoretically appointed by the sultan, actually by the French. In 1940, after the defeat of France, Spanish troops occupied Tangier, but they withdrew again in 1945 after the Allied victory.

The Spanish Zone surrounded the ports of Ceuta and Melilla, which Spain had held for centuries, and included the iron mines of the Rif Mountains. As capital, the Spanish selected Tétouan. As in the French Zone, European-staffed departments were created; the country districts were administered by *interventores,* corresponding to the French *contrôleurs civils.* The first area to be occupied was that on the plain, facing the Atlantic, with the towns of Larache, Alcazarquivir (Ksar el-Kebir; Al-Qsar al-Kabir), and Asilah. That area was the stronghold of the former Moroccan governor Ahmad al-Raisuni (Raisuli), half patriot and half brigand. The Spanish government found it difficult to tolerate his independence, and in March 1913 he retired into a refuge in the mountains, where he held out until captured by another Moroccan leader, Abd el-Krim, 12 years later.

Abd el-Krim was a Berber and a good Arabic scholar who had a knowledge of both the Arabic and Spanish languages and ways of life. Imprisoned after World War I, he later went to Ajdir in the Rif Mountains to plan an uprising. In July 1921 he destroyed a Spanish force sent against him and then established the Republic of the Rif, which endured for five years. It was only when French

The Republic of the Rif

and Spanish forces, numbering more than 250,000 fully equipped men, combined that Abd el-Krim was then finally overwhelmed. In May 1926 he surrendered to the French and was exiled.

The remainder of the period of the Spanish protectorate was relatively calm. Thus, in 1936, General Francisco Franco was able to launch his attack on the Spanish Republic from Morocco and to enroll a large number of Moroccan volunteers, who served him loyally in the Spanish Civil War. Though the Spanish had fewer resources than the French, their subsequent regime was in some respects more liberal and less subject to racial discrimination. Instruction in the schools was in Arabic rather than in Spanish, and Moroccan students were encouraged to go to Egypt for a Muslim education. There was no attempt to set Berber against Arab as in the French Zone, though this may have been prevented by the introduction of Muslim law by Abd el-Krim himself. After the end of the Republic of the Rif, there was little cooperation between the two protecting powers. Their disagreement reached a new height when in 1953 the French, without consulting the Spanish, deposed and deported the sultan. The Spanish high commissioner did not recognize this action, and Muḥammad V was still regarded in the Spanish Zone as the sovereign. Nationalists, moreover, for the first time were given departmental office, and the zone served as a refuge for those who had to leave the French area.

In 1956, however, when the French decided to grant independence to Morocco, the Spanish authorities were taken by surprise and hesitated before following suit. A corresponding agreement was nevertheless reached on April 7, 1956, and was marked by a visit of the sultan to Spain. The Spanish protectorate was thus brought to an end without the troubles that marked the termination of foreign control in the French Zone. With the end of the Spanish protectorate and the withdrawal of the Spanish high commissioner, the Moroccan *khalīfah,* and other officials from Tétouan, the city again became a quiet, provincial capital. The introduction of the Moroccan franc to replace the peseta as currency, however, caused a great rise in the cost of living, and difficulties were also brought on by the introduction of French-speaking Moroccan officials. In 1958–59 these changes gave rise to disorders in the Rif. Tangier, too, lost much of the superficial brilliance that it had developed as a separate zone, as by degrees its special status was modified and its privileges were withdrawn. As in the former French Zone, there ensued a great drop in the number of European and Jewish inhabitants. The southern protectorate area of Tarfaya was handed back to Morocco in 1958. Ifni, in return for which the Spaniards had vainly hoped to gain a recognition of their right to Melilla and Ceuta, was finally handed over unconditionally in 1970.

Independence for Morocco

Ceuta, on the Strait of Gibraltar, and Melilla, farther east on the Mediterranean coast, continue to be Spanish *plazas* in Morocco, both with overwhelmingly Spanish populations. In October 1978 the United States turned over to Morocco its last military base in Africa, that at Kenitra.

Independent Morocco. The French protectorate had been successful in developing communications, in adding modern quarters to the cities, and in creating a flourishing agriculture and a modern industry of a colonial type. Most of these activities, however, were managed by Europeans who, by the end of the protectorate, numbered 360,000 in French Morocco. In the constitutional field there had been virtually no development. Though the government was in practice in the hands of the French, the sultan remained in theory an autocrat; and when independence was finally conceded he became so again in fact, subject only to his undertaking to the nationalists to introduce a constitution. By French insistence, the first Cabinet was composed of ministers representing the various groups of Moroccan society, and it included a Jew. Mubarak Bekkai, an army officer who was not a party man, was selected as premier. The sultan (who officially adopted the style of king in August 1957) selected the ministers personally and himself retained control of the army and the police; he did, however, nominate a Consultative Assembly of 60 members. His eldest son, Moulay Hassan, became chief of staff and by degrees successfully integrated the irregular liberation forces into the military after they had promoted a rising against the Spanish in Ifni (1957) and against the French in Mauritania.

In general, the change to Moroccan control, assisted by French advisers, took place smoothly. Relations with France, however, were badly strained because of the continuing Algerian problem, but independent Morocco remained dependent on French technology and finance.

A major political change occurred when the Istiqlāl split into two sections in 1959. The main portion, which was conservative, remained under the leadership of Muḥammad ʿAllāl al-Fāsī, while the smaller radical section, headed by Mehdi Ben Barka, Abdullah Ibrahim, Abd ar-Rahim Bouabid, and others, formed the National Union of Popular Forces (Union Nationale des Forces Populaires, or UNFP). Of these groupings the original Istiqlāl represented the more traditional elements, while the UNFP was formed from the intelligentsia and favoured socialism with republican leanings. Muḥammad V made use of these dissensions to assume the position of an arbiter above party strife. He nevertheless continued the preparations for the creation of a parliament until his unexpected death in 1961. Moulay Hassan succeeded him as Hassan II.

Division in the Istiqlāl

In 1963, when parliamentary elections were finally held, the two halves of the former Istiqlāl formed an opposition, while a party supporting the king's government was created out of miscellaneous elements and known as the Front for the Defense of Constitutional Institutions (FDIC). This included a new, predominantly Berber, rural group opposed to the Istiqlāl. The ensuing near deadlock caused the king to dissolve Parliament after only one year, resuming personal government with himself or his nominee as premier. In 1970 a new constitution was promulgated that provided for a one-house legislature. This did not survive an abortive coup by army elements against the monarchy in July 1971. The following year Hassan announced another constitution, but implementation was largely suspended following a second attempted military coup in August 1972. This latter coup was apparently led by General Muḥammad Oufkir; he had earlier been implicated in the kidnapping (1965) and disappearance in Paris of the exiled Moroccan UNFP leader Mehdi Ben Barka, who had been regarded as a likely candidate for the presidency of a Moroccan republic. Elections held in 1977 brought a landslide victory to the king's supporters. King Hassan's forceful policies to absorb Spanish (Western) Sahara gave him greatly increased popularity in the mid-1970s. This, in addition to his method of mixing efforts to co-opt the political opposition with periods of political repression, served to maintain royal control. By the early 1980s, however, several bad harvests, a sluggish economy, and the continued financial drain of the war in Western Sahara increased domestic strains, of which the violent riots in Casablanca in June 1981 were symptomatic.

Pro-monarchical FDIC

In foreign affairs Morocco sided with the western European powers rather than with the eastern bloc, while sharing the general outlook of Arab states on such questions as that of Palestine. Claiming Mauritania as a sphere of influence, the Moroccan government refused to recognize that country's independence before 1970. Nor would it recognize the eastern frontier where territory had been attached to French Algeria at Morocco's expense. This was of importance because of the vast iron-ore deposits in the region. In 1970 it was agreed that the iron ore would be exploited by both countries under the Algerian flag but exported through a Moroccan port. At the same time, a rapprochement with Mauritania signified an alignment of the three Maghrib states against a Spanish plan to develop the phosphate-rich Spanish Sahara into an independent state associated with Spain.

Subsequent developments in Spanish Sahara again caused tense relations between Morocco and Algeria. From 1974 King Hassan actively campaigned to assert Morocco's claim there (using this nationalist issue also to rally much-needed domestic support). In November 1975, after a United Nations mission had reported that the majority of Saharans wanted independence and that the principle of self-determination should be applied, Hassan responded

The "Green March"

with the "Green March": he called for 200,000 volunteers and sent them unarmed across the border to claim Spanish Sahara. Spain avoided a confrontation and signed an agreement relinquishing Spanish Sahara. The region was given over to joint Moroccan-Mauritanian administration as Western Sahara. By early 1976 the last Spanish troops had departed, leaving Morocco to struggle with the guerrillas of the Popular Front for the Liberation of Saguia el Hamra and Río de Oro (Polisario), actively supported by Algeria and later by Libya.

King Hassan offered a referendum in the area in 1981, but it was rejected by the Polisario leadership as being too much on Moroccan terms. Fighting continued and Morocco was able to secure some two-thirds of the territory within defensive walls by 1986. In the meantime the territory's government-in-exile, the Saharan Arab Democratic Republic, won recognition from an increasing number of foreign governments. The Western Sahara issue remained largely unresolved, despite improving relations with Algeria and repeated UN attempts at mediation.

Later in his career, Hassan actively promoted a program of democratization in Morocco and managed to recast his image as an old-style autocrat, reshaping himself and his country to reflect more progressive values and engaging in a vigorous campaign directed against corrupt public officials. New political freedoms and constitutional reforms enacted in the 1990s culminated in the election of the first opposition government in Morocco in more than 30 years (1997) and the release of thousands of political detainees.

Hassan also guarded his status as religious head of state and carefully nurtured those aspects of his public image that garnered widespread support in the countryside and among the urban poor, thereby checking his main political opponents, Islamic revivalists. Muhammad VI succeeded to the throne upon the death of his father in July 1999.

For later developments in the history of Morocco, see the BRITANNICA BOOK OF THE YEAR.

Tunisia

The Republic of Tunisia (in Arabic Al-Jumhūrīyah at-Tūnisīyah) has an area of 63,378 square miles (164,150 square kilometres). It occupies a position of strategic importance in the Mediterranean, where its situation and case of access have kept it open to virtually every historical influence in the region. It is bounded by Algeria to the west and southwest, Libya to the southeast, and the Mediterranean Sea to the east and north. The capital is Tunis (Tūnis).

PHYSICAL AND HUMAN GEOGRAPHY

With its 750 miles (1,200 kilometres) of coastline, Tunisia has often been compared to the hull of a ship, solidly moored on the continent but also freely washed by the waves; in consequence, its destiny, as its leaders never tire of repeating, is at once Mediterranean and Maghribian. Because the Maghrib constitutes a single geographic entity, the largely undemarcated boundaries separating Tunisia from Libya and from Algeria do not assume the form of any natural barrier but, rather, have been shaped by the vicissitudes of history. Unlike its immediate neighbours, who are petroleum-rich, Tunisia has somewhat meagre resources at its disposal. In addition, its usable territory is limited and its domestic market is restricted, and consequently the problem of promoting economic development is particularly difficult.

Tunisia's strategic situation

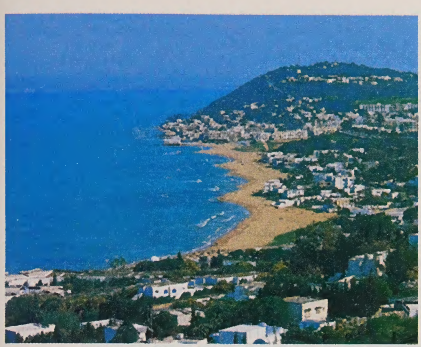
The land. *Relief and drainage.* Tunisia is characterized by moderate relief. The Tunisian Dorsale, or High Tell, a southwest-to-northeast mountain range that is an extension of the Saharan Atlas (Atlas Saharien) of Algeria, tapers off in the direction of the Cape Bon peninsula in the northeast, south of the Gulf of Tunis. The highest mountain, Mount ash-Sha'nabī (Djebel Chambi), located near the centre of the Algerian border, rises to 5,066 feet (1,544 metres), while Mount Zaghwān (Djebel Zaghouan), about 30 miles southwest of Tunis, reaches 4,249 feet (1,295 metres). Between the limestone peaks of the central Tunisian Dorsale and the mountains of the Northern Tell, which include the sandstone ridges of the Kroumirie Mountains in the northwest (reaching altitudes of 3,000 feet) and the Mogod Mountains, running along the deeply indented coastline to the north, lies the Majardah (Medjerda) Valley, formed by a series of ancient lake basins covered with alluvium. Containing the country's only perennially flowing river, which empties into the Gulf of Tunis, this valley was once the granary of ancient Rome and remains to this day the richest grain-producing region of Tunisia.

To the south of the Tunisian Dorsale lies a region of steppes known as the High Steppes in the west and the Low Steppes in the east. These have altitudes ranging from about 600 to 1,500 feet and are crossed by north-south secondary ranges. Farther south there is a series of chott (salty lake) depressions. Large plains border the eastern coasts; south of Sūsah (Sousse) lies the As-Sāḥil (Sahel) plain, and south of Qābis (Gabès) the Al-Jifārah (Gefara) Plain. The extreme south is desert, much of it part of the Great Eastern Erg.

Soils. Tunisia's most fertile soils are found in the well-watered intermontane valleys in the north, where rich sandy clay soils formed from alluvium or soils high in lime content cover the valley bottoms and plains. Aside from these and from the plains of the High Steppe region, where some clay soils of medium fertility may be found, soils in the rest of the country tend to be rocky or sandy in texture. In the dry south, moreover, they are often also saline because of excessive evaporation. The humid coastal plain in the east, running between the Gulfs of Ḥammāmāt and Gabes (Qābis), where Tunisia's thriving olive plantations are found, is the most agriculturally productive of these coarse-textured soil areas.

Climate. Tunisia is situated in the warm temperate zone between the 37th and the 30th parallels of latitude. In the north it has a Mediterranean climate characterized by mild, rainy winters and hot, dry summers with no marked intervening seasons. This changes southward to semiarid conditions on the steppes and to desert in the far south. Saharan influences give rise to the sirocco, a seasonal hot, blasting wind from the south that can have a seriously drying effect on vegetation.

Temperature and rainfall



Temperatures are moderated by the sea, being less extreme at Sūsah on the coast, for example, than at Al-Qayrawān (Kairouan) inland. Temperatures at Sūsah average 44° F (7° C) for the month of January to a high of 89° F (32° C) for the month of August. Comparable temperatures at Al-Qayrawān are 40° F (4° C) in January and 99° F (37° C) in August.

The amount of rainfall varies considerably from north to south. A mean annual rainfall of about 60 inches (1,520 millimetres) occurs in the Kroumirie Mountains in northwestern Tunisia, making it the wettest region in North Africa, as compared with less than 4 inches at Tawzar (Tozeur) in the southwest. Generally, from the middle of autumn to the middle of spring, northern Tunisia receives more than 16 inches of rainfall, and the steppe region receives from 4 to 16 inches. Amounts are also highly irregular from one year to another, and irregularity increases southward toward the desert. Harvests vary as a result, being poor in dry years.

Plant and animal life. The vegetation and animal life of the country are affected by these climatic conditions. From north to south, the cork oak forest of the Kroumirie Mountains, with its fern undergrowth sheltering wild boars, gives way to scrub and steppes covered with esparto grass and populated with small game, and finally to the desert, where hunting is forbidden so as to preserve the remaining gazelles. Scorpions are found in all regions; among dangerous snakes are the horned viper and the cobra. Desert locusts sometimes damage crops in the southern part of the country.

Four demographic regions

Settlement patterns. Tunisia is divided into four natural and demographic regions: the north, which is relatively fertile and well watered; the semiarid central region; As-Sāḥil (the Sahel) in the east central coastal region, which is preeminently olive-growing country; and the south, where, except in the oases, all vegetation disappears. In the central and southern regions, there are still tribes that have preserved a certain cohesion through following a quasi-

La Marsa beach on the Gulf of Tunis, northeastern Tunisia.
Steve Vidler/Leo de Wys, Inc.

nomadic way of life. In the north and east, on the other hand, particularly along the coasts, the population is quite mixed and more dense, the life of the cultivator is more complex, the villages are more crowded, and the cities are larger. City populations have expanded at the expense of the countryside and by the late 20th century had encompassed more than three-fifths of the country's people; about one-ninth of Tunisia's population lives in Tunis alone. Growth has also been significant in the cities of Bizerte, Qābis, Qafṣah, Ṣafāqus, Sūsah, and Jundūbah.

The people. *Ethnic composition.* Tunisia's population is essentially Arab Berber. However, throughout the centuries Tunisia has received various waves of immigration that have included Phoenicians, sub-Saharan Africans, Jews, Romans, Vandals, and Arabs; Muslim refugees from Sicily settled in the As-Sāḥil after their homeland was captured by the Normans in 1091. The most notable immigration, however, was that of the Spanish Moors (Muslims), which began after the fall of Seville, Spain, in 1248 and turned into a veritable exodus in the early 17th century. As a result, 200,000 Spanish Muslims settled in the area of Tunis, in the Majardah valley, and on the Cape Bon peninsula in the north, bringing with them their urban culture and more advanced agricultural and irrigation techniques. From the 16th to the 19th century, the Turks brought their own blend of Asian and European traditions.

Linguistic composition. The cultural Arabization of the country had been completed by the end of the 12th century. Less than 1 percent of the population, in the south, still speaks the Berber language. French, introduced during the protectorate (1881–1956), paradoxically came into wider use after independence because of the spread of education. Although Arabic is the official language of the country, French continues to play an important role in the press, education, and government.

Religion. Muslims constitute virtually all of the population, and Islām in its Malikite Sunnite form is the state religion. Christian and Jewish minorities have declined substantially since independence; non-Muslims numbered more than 300,000 in 1956 and now only about 50,000.

Demographic trends. The population of Tunisia doubled during the last three decades of the 20th century. The country's natural growth rate is less rapid, however, than those of the other North African countries. Emigration has depressed the growth rate, with hundreds of thousands of Tunisians being employed abroad, notably in France and the Middle Eastern countries. Tunisia's relatively favourable demographic situation is reflected in its high life expectancy (among the highest in Africa), higher living standards, declining infant mortality rate, marriages at older ages, and progressive aging of the population.

The economy. Tunisia has a well-diversified economy, although it remains dominated by only a few large sectors. The economy is heavily dependent on mineral exports, especially petroleum and phosphates, and agricultural products. Tourism is also a significant source of revenue and foreign exchange, as are remittances from migrant workers living abroad. While foreign debt has been brought under control, the country suffers from a regional imbalance between the north and As-Sāḥil, which are more fertile and more economically developed, and the arid central and southern regions, which have fewer natural advantages.

Dependence on mineral exports

After a brief experiment with socialism in the 1960s, Tunisia shifted its economic doctrine toward a mixed planned and market economy. However, the economy fell into crisis in the early 1980s, the result of an over-reliance on oil revenues, foreign aid, and labour remittances. In the mid-1980s a comprehensive program was introduced to liberalize the economy, which helped restore Tunisia's international credit standing, stabilize public finances, reduce budget deficits and inflation, improve trade balances, and increase foreign and domestic investments. Public-sector reforms, deregulation, and privatization have also been implemented. By the end of the 1990s, the country's per capita gross national product equaled those of the lesser developed nations of Europe.

There are three large professional organizations: the General Union of Tunisian Workers, the principal trade union; the Tunisian Union of Industry, Commerce and Handicrafts, the main employers' organization; and the National Union of Tunisian Farmers, the principal agricultural union.

Resources. Tunisia's natural resources are limited. The lumber industry is essentially confined to the exploitation of oak and cork from the Kroumirie Mountains of the north, while the esparto grass of the plains is used for the manufacture of quality paper. Until the discovery of petroleum, the principal mineral resource was phosphate; of this, one-third is exported, with the remainder used by domestic chemical industries. Fertilizer is also a chief export.

Petroleum was discovered in the extreme south in 1964 at the Al-Burmah (El-Borma) field. Hydrocarbons are the third most valuable export after textiles and chemicals. As production fell in the 1980s, the government began developing several of the country's smaller oil fields. Nearly a dozen deposits were being exploited by the early 1990s, the largest fields being Al-Burmah and Ad-Dūlāb in southern Tunisia, Sīdī al-Yatā'im (Sidi el-Itayem) north of Ṣafāqis, the Ashtart field in the Gulf of Gabes, and the Tāzirkah field in the Gulf of Ḥammāmāt.

Petroleum reserves

In the early 1990s, Tunisia's petroleum reserves were estimated to be more than two billion barrels, a volume sufficient to maintain the country's low rate of extraction for several decades but insufficient to prevent Tunisia from becoming a net importer of petroleum products. Since then natural gas production has significantly increased, and foreign investment has been encouraged. Major British investments in the Al-Miskar field in the mid-1990s contributed to Tunisia's achieving self-sufficiency in natural gas production. Tunisia receives about 5 percent in royalties on gas that is pumped through a pipeline running through Tunisia, connecting the Algerian gas fields to Sicily.

Agriculture. Some two-thirds of Tunisia is suitable for farming, and more than one-fifth of the working population is employed in agriculture, yet agricultural production is still inadequate to meet the needs of Tunisia's growing population. Cereals, in particular, must be imported, as must meat and dairy products; sheep, goats, and cattle are raised but not in numbers sufficient to supply domestic demand. Low crop yields are partly a result of the division of the property into small, inefficient plots and from outdated farming methods. Climatic variations—periodic droughts and sporadic rainfall—often jeopardize harvests. Much of the country's agricultural investment has focused on irrigation schemes, the construction of wells and dams, and programs to prevent soil erosion and desertification. Nonetheless, Tunisia exports a fair amount of agricultural produce. The principal commodities are citrus fruits, olive oil, grapes, tomatoes, melons, figs, and dates. The fishing industry also contributes to the country's exports.

Industry. The industrialization of Tunisia has encountered two major difficulties. Raw material and power

supplies are inadequate, and the domestic market is limited. Notable and sometimes costly projects, such as the Manzil Bū Ruqaybah (Menzel-Bourguiba) iron-smelting complex, located near Bizerte, however, have been successfully established since independence was achieved in 1956. Existing industries produce foodstuffs, textiles, clothing, construction materials, household articles, and fertilizers. More than half of Tunisia's industry is located in Tunis. In the early 1970s, efforts were made to decentralize and to develop the south economically; for example, the state-owned Industries Chimiques Maghrébines (Maghrib Chemical Industries) complex, which produces phosphoric acid, was opened at Qābis in 1971. Tourism, however, remains Tunisia's leading industry. A vibrant handicraft industry has developed also in its wake. The number of tourists, mainly from western Europe, Libya, and Algeria, has increased steadily since the 1960s.

(M.Ta./J.I.C.)

Trade, finance, and management of the economy.

Importance of primary production

Tunisian overseas trade still reflects the importance of primary production. Exports are dominated by petroleum, fertilizers, and foodstuffs, but clothing has grown in importance. Countries of the European Community account for two-thirds of Tunisia's imports and exports. About a quarter of all trade is with France, with which Tunisia reached an agreement on trade and tariffs following the abolition of a customs union in 1959. The balance of payments is frequently adverse, and in some years this has obliged the government to limit imports.

The strength of the dinar and of the economy has been helped by international confidence in the political stability of Tunisia. The Central Bank of Tunisia performs the functions of an issuing bank. (W.C.B./J.I.C.)

Transportation. The network of roads and of railways is sufficiently dense so that all cities of any importance are linked with the interior regions. Tunisia is connected by both road and rail with Algeria and Morocco but only by road with Tripoli (Ṭarābulus), Libya, and Cairo, since the railway ends at Qābis. Work is being undertaken to modernize and extend the railway network.

The principal ports are Tunis-Ḥalq al-Wādī (La Goulette), which is the outport of Tunis; Ṣafāqis; Bizerte; and Sūsah, as well as the new port of Qābis in the south. An oil pipeline runs from Edjeleh, Alg., to the port of Aṣ-Ṣukhayrah (La Skhira, or Cekhira), on the Gulf of Gabes.

Despite the construction of airports at Al-Munastīr, Jarbah (Djerba), Ṣafāqis, and Tawzar, all of which handle domestic or tourist (charter) flights, international air traffic is directed mainly through Al-ʿUwaynah airport near Tunis.

Administration and social conditions. *Government.* The Tunisian constitution was promulgated in 1959 and amended in 1988; it defines Tunisia as a republic whose religion is Islām and whose official language is Arabic. Legislative power is exercised by the unicameral Chamber of Deputies, which consists of 141 delegates elected for five-year terms by universal suffrage. Executive power is in the hands of the president of the republic, who is head of state and head of the government. He must be a Muslim and is elected for a five-year term by universal suffrage at the same time as the deputies; since 1988 he has been limited to three consecutive terms.

The country is administered by the Cabinet, headed since 1969 by a prime minister. The Cabinet ministers are responsible to the president rather than to the Chamber of Deputies, which, however, holds the power to censure the Cabinet. If such censuring occurs, the president may dismiss the Chamber of Deputies and hold fresh elections. If censured again by the new Chamber, the government must resign.

The Council of State comprises two judicial bodies: an administrative body dealing with legal disputes between individuals and state or public institutions, and a public audit office. The court system consists of magistrate courts at the local level, courts of the first instance, courts of appeal, and a high court in Tunis. Judicial power is exercised by judges whose independence is constitutionally guaranteed.

The constitution guarantees "freedom of opinion, expression, press, publication, assembly, and association" ("under the conditions defined by law"), as well as the right to form trade unions. Despite the introduction of new political parties in November 1981 and permission for a multiparty system in 1988, Tunisia has continued to be governed under a one-party system, that of the Democratic Constitutional Assembly party (originally called the Neo-Destour, to distinguish it from an older Destour Party founded in 1920). The Democratic Constitutional Assembly party, allied with the UGTT, controls the Chamber of Deputies. All Tunisians, including women, who are at least 20 years of age can vote. There is typically a massive turnout for elections, with 90 percent of the registered voters participating.

Local administration

The country is divided into 23 administrative areas called *wilāyāt* (provinces; singular *wilāyah;* French: *gouvernorats*), which are headed by walis (governors). Each province is designated by the name of its chief town and is in turn subdivided into units called *muʿtamadiyāt* (delegations; French: *délégations*), whose number varies according to the province's size. Delegations are administered by a *muʿtamad* and are in turn divided into varying numbers of districts called *manṭaqa turābiyyas.*

Education. Education is free to all students, and scholarships in schools and universities are offered largely on the basis of merit and need. The number of students, schools, and teachers, and the level of literacy have all increased steadily since independence.

This growth has posed problems of financing—education absorbs about one-seventh of the national budget—and of finding enough job opportunities for qualified people. More emphasis has been placed on technical, vocational, teacher, and agricultural training. The large University of Tunis (founded 1960) is the country's major institution of higher education. Two new universities were opened at Al-Munastīr (near Sūsah) and Ṣafāqis in the mid-1980s.

Health and welfare. The living standards of the population in general are modest but rising, with a strong program of social welfare in place and with continuing efforts to advance the role of women through legal equality. The advantages available consist, in addition to the distribution of milk to newborn babies and of school lunches, of free medical care for the destitute and of the extension of the social security system, which provides medical benefits, hospitalization, and maternal and family benefits, to virtually all wage earners. There is also a good network of hospitals and clinics, which has contributed to a relatively low death rate overall and, in particular, to the lowest infant mortality rate on the African continent.

The state of the arts

Cultural life. Tunisia is a country that prides itself on its strong and unique cultural life. It is an Arabic-speaking Muslim country that was deeply imbued with French culture during the 75 years of the protectorate, which ended in 1956. Indications of this are that four of the country's six major daily newspapers are in French and radio programs in French are broadcast regularly. Although Tunisians generally use French in all scientific disciplines, they remain genuinely attached to Arabic in the literary sphere—in poetry, the novel, and the short story. Several literary reviews, the most important of which is *Al-Fikr* ("Thought"), open their pages to youthful talents and stimulate literary output. Modern Tunisian literature, the subject of great debate on radio and television and in the various government-sponsored Houses of Culture (Maisons de la Culture), has made remarkable progress.

Although the Tunisian cinema is still in its infancy, having to its credit no more than a few successful films, contemporary Tunisian painting can already lay claim to a certain tradition. Some of the artists enjoy a genuine local celebrity and also have exhibited abroad. Many have benefited from sales to tourists, but Tunisians have generally been concerned about the influence of tourism upon their social and cultural lives. The music conservatory devotes attention mainly to national traditions but also emphasizes the classical European heritage.

A major effort is in progress to diffuse and decentralize cultural benefits through local libraries, theatres, and museums, and traveling libraries make films and books available to the most remote corners. Television, which naturally plays an important role, likewise covers the en-

tire country; its programs are in Arabic and French and provide information, education, and entertainment.

(M.Ta./J.I.C.)

For statistical data on the land and people of Tunisia, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR.

HISTORY

Tunisia was called Ifriqiyah in the early centuries of the Islāmic period. That name, in turn, comes from the Roman name for Africa. The smallest of the Maghrib states, Tunisia is also the most cohesive. By the beginning of the 19th century virtually all its inhabitants were Arabic speakers. Berber, the earlier language of all the Maghrib, survived in Tunisia in only a few pockets, especially in the extreme south. The vast majority of the population was Muslim, with perhaps 5 percent being Jewish. A single major city, Tunis, dominated the countryside politically and culturally. Tunis itself was located near the site of the earlier Carthage. More easily controlled from within than any other Maghrib country, Tunisia was also more open to the influence of people and ideas coming from abroad. Roman Africa, for example, was the most intensively Christianized portion of North Africa, and Ifriqiyah was later more quickly and more thoroughly Islāmicized.

A small state with limited resources, Tunisia, however, often managed a considerable autonomy within the framework of larger empires ruled from afar. This status was achieved, for example, under the 'Abbāsids in the 9th century and later under the Ottomans. This geographic and historical legacy helped prepare Tunisia for the shocks that it would receive in the 19th century as a land caught between an expanding Europe and a declining Ottoman Empire. Yet, Tunisia proved itself to be as vulnerable economically as it was militarily. (L.C.Br.)

The growth of European influence. In 1830, at the time of the French invasion of Algiers, Tunisia was a province of the Ottoman Empire but autonomous in fact. Because the principal military threat had long come from neighbouring Algeria, the reigning bey of Tunisia, Ḥusayn, cautiously went along with French assurances. Ḥusayn Bey even accepted the idea that Tunisian princes be appointed rulers of Constantine and Oran. It soon became clear that the scheme had no chance of success, however, and it was abandoned.

Then, in 1835, the Ottoman Empire seized the opportunity of a disputed succession in Libya to depose the ruling dynasty there and to reestablish direct Ottoman rule. Thereafter, the vulnerable beylik of Tunis found itself surrounded by two larger powers—France and the Ottomans—both of whom sought hegemony in Tunisia. From that time until the establishment of the French protectorate in 1881, Tunisian rulers sought to keep the larger outside powers in balance while working to strengthen the state from within.

Attempts at reform

Aḥmad Bey, who ruled from 1837 to 1855, was an avowed Westernizer. He brought in Western advisers (mainly French) to help create a modern army and navy and related industries. Conscription was introduced to the great dismay of the peasantry. More acceptable were Aḥmad's steps to better integrate Arabic-speaking native Tunisians into the government, which had long been dominated by Mamlūks and Turks. Aḥmad abolished slavery and took other steps intended to bring Tunisia more in line with Europe, but he also exposed his country to Europe's infinitely greater economic and political power. These governmental innovations imposed upon a stagnant economy increased financial obligations that were met by higher taxes. These, in turn, provoked unrest in the countryside.

The next bey, Muḥammad (1855–59), sought to turn his back on Europe, but this was no longer possible. The execution of a Tunisian Jew for blasphemy brought swift British and French action that forced the bey to issue the Fundamental Pact ('Ahd al-Amān; Sept. 9, 1857), a civil rights charter modeled on the Ottoman rescript of 1839.

The final collapse of the Tunisian beylik came during the reign of Muḥammad aṣ-Ṣadiq (1859–82). By nature disposed to Westernizing reforms, he was, however, too weak either to control his own government or to keep the several European powers at bay. In 1861 the first constitution (*dustūr*) in the Arab world was proclaimed, but this promising step toward representation and responsible government was brought to naught by runaway indebtedness exacerbated by the practice of securing loans from European bankers at exorbitant rates.

When the principal minister, Muṣṭafā Khaznadār (who had served from the earliest days of Aḥmad Bey's reign), attempted to squeeze more taxes out of the hard-pressed Tunisians, the countryside rose in a revolt (1864) that almost overthrew the regime, but a combination of governmental guile and brutality managed to restore order.

Tunisia was bankrupt in 1869, and an international financial commission—with British, French, and Italian representation—was imposed on the country. One last important attempt to strengthen Tunisia from within and thus avoid European domination was made during the reformist ministry of Khayr ad-Dīn (1873–77), one of the most impressive statesmen of the 19th-century Muslim world. Enemies from within the Tunisian government and European consular intrigues, however, forced him from office. All that was needed for France to establish control in Tunisia was the acquiescence of France's principal rival, Britain, and this was obtained at the Congress of Berlin in 1878.

French occupation

The end came in 1881 when the French, on the pretext that some Tunisian tribespeople had moved into Algerian territory, invaded the country and imposed on the bey the Treaty of Kasser Said (Al-Qaṣr as-Sa'id) that sanctioned French military occupation, transferred to France the bey's authority in foreign relations and finance, and provided for the appointment of a French resident minister as intermediary in all matters of common interest. This provoked an uprising in southern Tunisia during which Sousse (Sūsah) was bombarded and captured in July 1881; Kairouan (Al-Qayrawān) was then captured in October, and Gafsa (Qafṣah) and Gabès (Qābis) in November. After the death of the bey Muḥammad aṣ-Ṣadiq, his successor, 'Alī, was constrained to sign an undertaking to introduce such administrative, judicial, and financial reforms as the French government might consider useful. This agreement, known as the Convention of Al-Marsa and signed in 1883, made French control complete.

The protectorate (1881–1956). The arrangement thus arrived at was very different from that in Algeria. The basis was a treaty, not outright conquest. The bey remained in theory an absolute monarch; Tunisian ministers were still appointed, and the framework of the old government machinery was preserved. Tunisians continued to be subjects of the bey. There was no confiscation of land; mosques were not converted into churches; and Arabic remained an official language. Nevertheless, the supreme authority passed in fact into the hands of the French resident general. Under French guidance the finances were soon brought into order, and a modern communications system was established. Though there was none of the wholesale confiscation of land and displacement of population that had occurred in Algeria, the most fertile portions of northern Tunisia, comprising the Majardah Valley and the Cape Bon peninsula, passed largely into the hands of Europeans. Valuable phosphate mines were brought into operation near Gafsa in the south, while the extensive establishment of French and Italian colonists in the Majardah Valley resulted in a considerable export of vegetables.

Young Tunisians

By the 1890s a small Western-trained group—the members of which came to be called "Young Tunisians"—began to push for both Westernizing reforms and greater Tunisian participation in government. Their conduct during the protectorate was necessarily cautious; their major weapon, the newspaper *Le Tunisien*, was founded in 1907 as a French-language publication, an Arabic edition not appearing until 1909. Increased modern-style education was a principal goal. The Young Tunisians sought simultaneously to educate their compatriots and to persuade the more liberal French to help move Tunisia toward modernity. There was no explicit talk of independence.

Even this moderate protonationalism came to grief before French repression in 1911–12. Little nationalist activity

took place during World War I (1914–18), but the postwar period brought the first attempt at mass political organization with the creation of the Destour Party (Constitution Party, so named for the short-lived Tunisian constitution of 1861). In 1920 the Destour Party presented to the bey and to the French government a document that in effect demanded the establishment of a constitutional form of government in which Tunisians would possess equal rights with Europeans. The immediate result was the arrest of 'Abd al-Azīz ath-Tha'alibi, the Destour leader. Two years later, the aged bey, Muḥammad an-Nasir, requested the adoption of the program of the Destour, failing which he threatened to abdicate. The resident general, Lucien Saint, responded by surrounding the bey's palace with troops, with the result that the demand was withdrawn. Saint thereupon introduced repressive measures, together with minor reforms, that pacified Tunisian sentiment and weakened the nationalist movement for several years.

Emergence of Bourguiba

In 1934 a young Tunisian lawyer, Habib Bourguiba, and like-minded colleagues broke with the Destour Party to form a new organization, the Neo-Destour, which aimed at gaining mass support. Under Bourguiba's vigorous leadership the new party supplanted the existing Destour and its old-fashioned leaders. Attempts by the French to suppress the new movement spread its popular appeal. The arrival of the Popular Front government to power in France in 1936 enabled the Neo-Destour to extend its propaganda there also. When the Popular Front government collapsed, renewed repression in Tunisia was followed by civil disobedience; and in 1938 serious disturbances resulted in the arrest of Bourguiba and other leaders of the party, which was officially dissolved.

World War II. On the outbreak of war in 1939, Neo-Destour leaders were deported, still untried, to France. They were released by the Nazis when they occupied Vichy France in 1942 and, since Hitler regarded Tunisia as a sphere of Italian influence, handed over to the Fascist government in Rome. There they were treated with deference, in the hope of eliciting a declaration favourable to the Axis. Bourguiba, however, steadily refused, in spite of the suggestions of some of his companions. In March 1943, after a noncommittal broadcast by him, the Neo-Destour leaders were finally allowed to proceed to Tunis, where the reigning bey, Muḥammad al-Munsif (Moncef), formed a ministry of Destour sympathies.

The assumption of power by the Free French after the Nazi retreat resulted in complete disillusionment. The bey himself was deposed, while Bourguiba escaped imprisonment only by fleeing in disguise to Egypt (1945). He began a vigorous campaign of propaganda for Tunisian independence. In view of the emancipation of the eastern Arab states, and later of the neighbouring, relatively backward Libya, the French felt compelled to make concessions. In 1951 a government with nationalist sympathies was allowed to take office, of which the secretary-general of the Neo-Destour, Salah Ben Youssef, became a member. Bourguiba was allowed to return to Tunisia. When, however, this government wished to establish a Tunisian parliament, the result was further repression. Bourguiba was confined, and most of the ministers were put under arrest. This resulted, for the first time, in outbreaks of terrorism; and nationalist bands began to operate in the mountains, virtually paralyzing the country.

Outbreak of terrorism

In July 1954 the French premier, Pierre Mendès-France, promised to grant complete autonomy to Tunisia, subject to a freely negotiated convention. Bourguiba was released and was able to supervise the negotiations without directly participating. In June 1955 the convention was finally signed by the Tunisian delegates, though it imposed strict limits in the fields of foreign policy, education, defense, and finance, and a mainly Neo-Destour ministry was formed. Salah Ben Youssef denounced the agreement as too restrictive, refused to attend a specially summoned congress unanimously supporting Bourguiba, and organized a brief armed resistance in the south; this was quickly put down, and Ben Youssef fled the country. He was assassinated in 1961.

Independence. Having conceded full independence to Morocco, the French were no longer inclined to resist the same for Tunisia, and an accord was reached on March 20, 1956, for Tunisian independence, with Bourguiba as prime minister. On July 25, 1957, the rule of the beys was abolished and a republic was declared, with Bourguiba assuming the presidency.

Domestic development. The best organized mass political party in the Arab world, the Neo-Destour Party (from 1964 to 1988, the Destourian Socialist Party; from 1988, the Democratic Constitutional Assembly) ensured that independent Tunisia could move quickly with reforms. Advances in education, the liberation of women, and legal reforms were especially impressive. Economic development was less dramatic, but the government creditably gave attention to the more impoverished parts of the country. In 1961 Ahmad Ben Salah took charge of planning and finance (adding the portfolio of education in 1968). His ambitious efforts at forced-pace modernization, especially in agriculture, were foiled, however, by rural and conservative opposition. Expelled from the party in 1969 and imprisoned, he escaped in 1973, to live in exile. His fall brought a move to a more conservative orientation.

In 1975 the Chamber of Deputies unanimously bestowed the presidency for life on the sick and aged Habib Bourguiba. Hedi Nouira, noted for his financial and administrative skills, became prime minister in November 1970. A decade later, in 1980, Muḥammad Mzali replaced the ailing Nouira. This inaugurated an effort to restore dissidents to the party and then, in 1981, to grant amnesty to many who had been jailed for earlier disturbances. Bourguiba was persuaded to accept a multiparty system, but results of the elections of November 1981 were disappointing to those who sought political liberalization. The National Front, an alliance of the Destourian Socialist Party and the trade union movement, swept all 136 parliamentary seats, a result received with cynicism and dismay by the opposition. National elections in 1986 were boycotted by the major opposition parties, and the National Front once again carried the vote. In November 1987, amid widespread unrest and rising Islāmic fundamentalism, Bourguiba was declared mentally unfit to rule and was removed from office. He was succeeded by General Zine el-Abidine Ben Ali, whom he had appointed as prime minister in October 1987. Bourguiba's long rule, widely popular in early years except among traditionalist groups, had later provoked increasing if largely passive opposition among Tunisians. In declining health since at least the early 1970s, Bourguiba was less able to mask his autocratic tendencies by the ample political skills that he had once possessed. The Ben Ali era has not thus far produced the political liberalization expected. In the national elections in 1989 the president gained 99 percent of the vote, and the Democratic Constitutional Assembly won all 141 seats in the legislature. Local elections in 1990, boycotted by opposition parties, were swept by the ruling party as well.

Foreign relations. Three crises in Franco-Tunisian relations were the French bombing raid on the Tunisian village of Sāqiyat Sidī Yūsuf in 1958, during which France claimed the right of pursuit of Algerian rebels; the Bizerte incident of 1961, concerning the continued military use of that port and airfield facility by France; and the suspension of all French aid in 1964–66 after Tunisia abruptly nationalized land held by foreigners. Such difficulties aside, postindependence Tunisian relations with France have been good. Tunisia has also been successful in establishing good relations with the United States and most European states, skillfully building up a multinational pattern of economic and technical aid.

Tunisia's relations with the Arab world have been subject to oscillations. There was a dispute with Egypt and the majority of Arab states when, in 1965, Bourguiba urged a more diplomatic approach toward Israel. Since independence there have also been several periods of tension with Algeria and Libya. Generally, however, Tunisia has been able to increase its standing in the Arab world. When Egypt was expelled from the Arab League for having signed a peace treaty with Israel in 1979, the Arab League moved its headquarters from Cairo to Tunis, where it remained until it was moved back to Cairo in 1990. The Palestine Liberation Organization under Yāsir 'Arafāt opened its

headquarters in Tunis in August 1982 after being forced to leave Beirut. (N.B./L.C.Br.)

Tunisia's decidedly Western orientation after independence bore the strong mark of Bourguiba. His departure from power in 1987, coupled with the rise of Islāmic fundamentalism and increasing Tunisian ties with the Arab world, have produced changes. The Tunisian government, for example, opposed the United States-led coalition of forces against Iraqi President Saddam Hussein's invasion of Kuwait in August 1990, a stand warmly supported by the Tunisian people. This stance created long-standing difficulties in relations with the Gulf states, however. Gen. Zine al-Abidine Ben Ali, Bourgiba's successor, ruled at the head of the Constitutional Democratic Assembly in a virtual one-party government, winning reelection in 1995 and 2000. Some token opposition movements were allowed to exist, but on the whole dissent was suppressed and dissenters imprisoned. (N.B./L.C.Br./Ed.)

For later developments in the history of Tunisia, see the BRITANNICA BOOK OF THE YEAR.

BIBLIOGRAPHY

General works. Broad coverage of all aspects of the region may be found in TREVOR MOSTYN and ALBERT HOURANI (eds.), *The Cambridge Encyclopaedia of the Middle East and North Africa* (1988). An excellent handbook is WILFRID KNAPP, *North West Africa: A Political and Economic Survey,* 3rd ed. (1977); it may be updated by RICHARD LAWLESS and ALLAN FINDLAY (eds.), *North Africa: Contemporary Politics and Economic Development* (1984). *The Middle East and North Africa* (annual) and *Africa Contemporary Record* (annual), contain updated essays on all aspects of the North African countries.

Physical and human geography. *The land:* Good geographic reference books include MONIR S. GIRGIS, *Mediterranean Africa* (1967); GERALD BLAKE, JOHN DEWDNEY, and JONATHAN MITCHELL (eds.), *The Cambridge Atlas of the Middle East and North Africa* (1987); MOSHE BRAVER (ed.), *Atlas of the Middle East* (1988); and J.M. HOUSTON, *The Western Mediterranean World* (1964). Useful works on population are KEITH SUTTON and RICHARD LAWLESS, "Progress in the Human-Geography of the Maghreb," *Progress in Human Geography,* 11(1):60–105 (1987); and ANNE FINDLAY and ALLAN FINDLAY, *The Geographical Interpretation of International Migration: A Case Study of the Maghreb* (1982).

The people: Among the most interesting anthropological studies are DALE F. EICKELMAN, *The Middle East. An Anthropological Approach,* 2nd ed. (1989); LLOYD CABOT BRIGGS, *The Living Races of the Sahara Desert* (1958, reprinted 1969), and *Tribes of the Sahara* (1960); CARLETON S. COON, *Tribes of the Rif* (1931, reprinted 1970); and JEAN DUVIGNAUD, *Change at Shebika: Report from a North African Village* (1970; originally published in French, 1968).

The economy: Works on the economy include AHMED AGHROUT and KEITH SUTTON, "Regional Economic Union in the Maghreb," *The Journal of Modern African Studies,* 28(1):115–139 (1990); and HALIM BARAKAT (ed.), *Contemporary North Africa: Issues of Development and Integration* (1985).

History. *General works:* Overviews are presented by J.D. FAGE and ROLAND OLIVER (eds.), *The Cambridge History of Africa,* 8 vol. (1975–86); UNESCO INTERNATIONAL SCIENTIFIC COMMITTEE FOR THE DRAFTING OF A GENERAL HISTORY OF AFRICA, *General History of Africa* (1981–); ELBAKI HERMASSI, *Leadership and National Development in North Africa: A Comparative Study* (1972); and ABDALLAH LAROUI (ʿABD ALLAH ʿARAWĪ), *The History of the Maghrib: An Interpretive Essay* (1977; originally published in French, 1970).

Ancient North Africa: The monumental work by STÉPHANE GSELL, *Histoire ancienne de l'Afrique du Nord,* 8 vol. (1913–28), remains indispensable as an exhaustive account of the history of the Maghrib to 44 BC. FRANÇOIS DECRET and MHAMED FANTAR, *L'Afrique du Nord dans l'antiquité: histoire et civilisation, des origines au Vᵉ siècle* (1981), provides a scholarly general history of the region. GABRIEL CAMPS, *Berbères: aux marges de l'histoire* (1980), is a controversial, well-illustrated account of Libyan culture (usually described as "Berber" in the book) throughout antiquity. B.H. WARMINGTON, *Carthage,* 2nd ed. rev. (1969), is a standard history of Phoenician Carthage for both specialist and general readers. GILBERT CHARLES PICARD and COLETTE PICARD, *The Life and Death of Carthage,* trans. from French (1968), is accessible and thorough, especially on cultural and religious history.

A. DOREY and D.R. DUDLEY, *Rome Against Carthage* (1971), is an unpretentious but reliable work on the Punic Wars for the general reader. RENÉ CAGNAT, *L'Armée romaine d'Afrique et l'occupation militaire de l'Afrique sous les empereurs* (1892, reissued 1975), in spite of its date, remains the most comprehensive study of the subject. PETER BROWN, *Augustine of Hippo* (1967, reissued 1986), the outstanding biography of St. Augustine, includes a great many impressive details on different aspects of intellectual and social life in late Roman North Africa. W.H.C. FREND, *The Donatist Church: A Movement of Protest in Roman North Africa* (1952, reissued 1985), is the classic interpretation of Donatism as a movement of social and ethnic protest.

CHRISTIAN COURTOIS, *Les Vandals et l'Afrique* (1955, reprinted 1964), is the only comprehensive study of the subject. E.-F. GAUTIER, *Le Passé de l'Afrique du Nord: les siècles obscurs,* new ed. (1964), is a controversial but important interpretation of the period leading up to and following the Arab conquest, with particular emphasis on the Berbers.

RICHARD GEORGE GOODCHILD, *Kyrene und Apollonia* (1971), contains archaeologically based accounts of the best-preserved cities of ancient Cyrenaica. R.G. GOODCHILD, *Libyan Studies,* ed. by JOYCE REYNOLDS (1976), is a selection of specialized studies by the leading authority on the archaeology of modern Libya, with an essay on Cyrenaica.

From the Islāmic conquest to 1830: The entire period is discussed in JAMIL M. ABUN-NASR, *A History of the Maghrib in the Islamic Period* (1987). Information on selected topics may be found in *The Encyclopaedia of Islam,* 4 vol. and supplement (1913–38), and a new edition (1960–) appearing in parts. Works on specific periods include J.F.P. HOPKINS, *Medieval Muslim Government in Barbary until the Sixth Century of the Hijra* (1958); ROGER LE TOURNEAU, *The Almohad Movement in North Africa in the Twelfth and Thirteenth Centuries* (1969), and *Fez in the Age of the Marinides* (1961); GODFREY FISHER, *Barbary Legend: War, Trade, and Piracy in North Africa, 1415–1830* (1957, reprinted 1974); and ANDREW C. HESS, *The Forgotten Frontier: A History of the Sixteenth-century Ibero-African Frontier* (1978).

North Africa after 1830: LUCETTE VALENSI, *On the Eve of Colonialism: North Africa Before the French Conquest* (1977; originally published in French, 1969), offers solid interpretation that dispels old myths. MAGALI MORSY, *North Africa, 1800–1900: A Survey from the Nile Valley to the Atlantic* (1984), is innovative in treating all of northern Africa as a single region. JACQUES BERQUE, *French North Africa: The Maghrib Between Two World Wars* (1967; originally published in French, 1962), is a stimulating but impressionistic account by a leading French scholar. DAVID C. GORDON, *North Africa's French Legacy, 1954–1962* (1962), provides an excellent monograph on the cultural effects of French influence in the region. L. CARL BROWN (ed.), *State and Society in Independent North Africa* (1966), provides general interpretive articles on political, economic, and social issues. Recent political developments are covered by DAVID E. LONG and BERNARD REICH (eds.), *The Government and Politics of the Middle East and North Africa,* 2nd ed. rev. and updated (1986); and RICHARD B. PARKER, *North Africa: Regional Tensions and Strategic Concerns,* rev. and updated ed. (1987). Works on the independence and subsequent history of individual northern African countries may be found in the bibliographies below.

Algeria. *Physical and human geography:* Several comprehensive general works are available including HAROLD D. NELSON (ed.), *Algeria: A Country Study,* 4th ed. (1985); JOHN P. ENTELIS, *Algeria: The Revolution Institutionalized* (1986); JOHN P. ENTELIS and PHILLIP C. NAYLOR (eds.), *State and Society in Algeria* (1992); and RACHID TLEMCANI, *State and Revolution in Algeria* (1986). Population and settlement matters are covered in KEITH SUTTON and M. NACER, "Population Changes in Algeria," *Geography,* 75(4):335–347 (1990); KEITH SUTTON, "The Influence of Military Policy on Algerian Rural Settlement," *Geographical Review,* 71(4):379–394 (1981); and RICHARD I. LAWLESS and GERALD BLAKE, *Tlemcen: Continuity and Change in an Algerian Islamic Town* (1976). Ethnographic introductions include JEREMY KEENAN, *The Tuareg: People of Ahaggar* (1977); and PIERRE BOURDIEU, *The Algerians* (1962; originally published in French, 1958). Economic development is covered in MAHFOUD BENNOUNE, *The Making of Contemporary Algeria, 1830–1987: Colonial Upheavals and Post-Independence Development* (1988). Agricultural change is covered by KAREN PFEIFER, *Agrarian Reform Under State Capitalism in Algeria* (1985); and industrial development in M. BENNOUNE, "The Industrialisation of Algeria: An Overview" in HALIM BARAKAT (ed.), *Contemporary North Africa* (1985), pp. 178–213. DAVID PROCHASKA, *Making Algeria French: Colonialism in Bonê, 1870–1920* (1990), considers colonial politics.

History: CHARLES-ROBERT AGERON, *Modern Algeria: A History from 1830 to the Present* (1989), provides an overall treatment from before 1830 to independence. RAPHAEL DANZIGER, *Abd al-Qadir and the Algerians: Resistance to the French and Internal Consolidation* (1977), is an excellent book on the subject, with a thorough bibliography. DAVID C. GORDON, *The Passing of French Algeria* (1966), emphasizes ideologies. MOSTEFA LACHERAF, *L'Algérie: nation et société,* 2nd ed. (1978), is a

revisionist work by a leading ideologue of the FLN. ALISTAIR HORNE, *A Savage War of Peace: Algeria, 1954–1962,* rev. ed. (1987), is a perceptive interpretive history of these years.

Libya. *Physical and human geography:* For a comprehensive general work, including a discussion of Libya's physical geography, see HAROLD D. NELSON (ed.), *Libya: A Country Study,* 3rd ed. (1979). DOUGLAS L. JOHNSON, *Jabal al-Akhdar, Cyrenaica: An Historical Geography of Settlement and Livelihood* (1973), is also useful. JOHN DAVIS, *Libyan Politics: Tribe and Revolution: An Account of the Zuwaya and Their Government* (1987), is an ethnographic study. FRANK C. WADDAMS, *The Libyan Oil Industry* (1980), focuses on the impact of Libyan oil both on the world market and on Libya's economy. Comprehensive analyses of socioeconomic development and planning are J.A. ALLAN, K.S. MCLACHLAN, and EDITH T. PENROSE (eds.), *Libya: Agriculture and Economic Development* (1973); E.G.H. JOFFÉ and K.S. MCLACHLAN (eds.), *Social & Economic Development of Libya* (1982); M.M. BURU, S.M. GHANEM, and K.S. MCLACHLAN (eds.), *Planning and Development in Modern Libya* (1985); and BICHARA KHADER and BASHIR EL-WIFATI, *The Economic Development of Libya* (1987).

History: E.E. EVANS-PRITCHARD, *The Sanusi of Cyrenaica* (1949, reprinted 1973), offers a seminal historical and anthropological study. The period of Italian colonization is analyzed by CLAUDIO G. SEGRÉ, *Fourth Shore: The Italian Colonization of Libya* (1974); and two articles in *Annals of the Association of American Geographers:* GARY L. FOWLER, "The Italian Colonization of Tripolitania," 62(4):627–640 (1972), and "Decolonization of Rural Libya," 63(4):490–506 (1973). Modern political developments in Libya are analyzed in MAJID KHADDURI, *Modern Libya* (1963, reissued 1968); RUTH FIRST, *Libya: The Elusive Revolution* (1974), a reliable survey; J.A. ALLAN (ed.), *Libya Since Independence* (1982); JOHN K. COOLEY, *Libyan Sandstorm* (1982), on the rise to power of Muammar al-Qaddafi; MARIUS K. DEEB and MARY JANE DEEB, *Libya Since the Revolution* (1982), a dispassionate description stressing internal social and political developments; JOHN WRIGHT, *Libya: A Modern History* (1982), and *Libya, Chad, and the Central Sahara* (1989); LISA ANDERSON, *The State and Social Transformation in Tunisia and Libya, 1830–1980* (1986); and LILLIAN CRAIG HARRIS, *Libya: Qadhafi's Revolution and the Modern State* (1986).

Morocco. *Physical and human geography:* A good general overview is provided by HAROLD D. NELSON, *Morocco: A Country Study,* 5th ed. (1986). The following are outstanding studies of traditional life and socioeconomic change: KENNETH L. BROWN, *People of Salé: Tradition and Change in a Moroccan City, 1830–1930* (1976); DAVID SEDDON, *Moroccan Peasants: A Century of Change in the Eastern Rif, 1870–1970* (1981); CLIFFORD GEERTZ, HILDRED GEERTZ, and LAWRENCE ROSEN, *Meaning and Order in Moroccan Society* (1979), an analysis of traditional economic and family organization; DALE F. ECKELMAN, *Moroccan Islam: Tradition and Society in a Pilgrimage Center* (1976), and *Knowledge and Power in Morocco* (1985), the latter discussing traditional religious education and learning; VANESSA MAHER, *Women and Property in Morocco* (1974); and SUSAN SCHAEFER DAVIS, *Patience and Power: Women's Lives in a Moroccan Village* (1983). Classical analyses of traditional Berber society are found in ERNEST GELLNER, *Saints of the Atlas* (1969); and DAVID MONTGOMERY HART, *The Aith Waryaghar of the Moroccan Rif: An Ethnography and History* (1976). ROBIN BIDWELL, *Morocco Under Colonial Rule: French Administration of Tribal Areas, 1912–1956* (1973), examines colonial rural development policies. I. WILLIAM ZARTMAN (ed.), *The Political Economy of Morocco* (1987), provides valuable insights into many different aspects of contemporary Morocco. The environmental ideals and politics behind colonial and contemporary agricultural development are perceptively analyzed in WILL D. SWEARINGEN, *Moroccan Mirages: Agrarian Dreams and Deceptions, 1912–1986* (1987). A similar analysis focusing on the urban geography of Morocco's capital is JANET L. ABU-LUGHOD, *Rabat: Urban Apartheid in Morocco* (1980).

History: EDMUND BURKE III, *Prelude to Protectorate in Morocco: Precolonial Protest and Resistance, 1860–1912* (1976), gives a solid interpretation of how Morocco came under colonial rule. ALAN SCHAM, *Lyautey in Morocco: Protectorate Administration, 1912–1925* (1970), analyzes the government during this period. DAVID S. WOOLMAN, *Rebels in the Rif: Abd el Krim and the Rif Rebellion* (1968), covers this short-lived revolt. JOHN P. HALSTEAD, *Rebirth of a Nation: The Origins and Rise of Moroccan Nationalism, 1912–1944* (1967), reviews the early nationalists. A thorough case study of decolonization is STÉPHANE BERNARD, *Le Conflit franco-marocain, 1943–1956,* 3 vol. (1963)—vols. 1 and 2 have been translated as *The Franco-Moroccan Conflict, 1943–1956* (1968). Other political studies include JOHN WATERBURY, *The Commander of the Faithful: The Moroccan Political Elite—A Study in Segmented Politics* (1970); and I. WILLIAM ZARTMAN, *Morocco: Problems of New Power* (1964). The origins and evolution of the Western Sahara conflict are competently treated in JOHN DAMIS, *Conflict in Northwest Africa: The Western Sahara Dispute* (1983); and TONY HODGES, *Western Sahara: The Roots of a Desert War* (1983).

Tunisia. *Physical and human geography:* General texts are HAROLD D. NELSON (ed.), *Tunisia: A Country Study,* 3rd ed. (1988); and RUSSELL A. STONE and JOHN SIMMONS (eds.), *Change in Tunisia: Studies in the Social Sciences* (1976). On geography, useful works include WILFRID KNAPP, *Tunisia* (1970); AHMED KASSAB and HAFEDH SÉTHOM, *Géographie de la Tunisie: le pays et les hommes* (1980); MOHAMED FAKHFAKH (ed.), *Atlas de Tunisie* (1979); and HORST MENSCHING, *Tunesien: eine geographische Landeskunde,* 3rd rev. ed. (1979). Other specialized volumes include JAMES ALLMAN, *Social Mobility, Education, and Development in Tunisia* (1979); and GHAZI DUWAJI, *Economic Development in Tunisia* (1967).

History: KENNETH J. PERKINS, *Tunisia: Crossroads of the Islamic and European Worlds* (1986), summarizes history, socioeconomics, and politics from pre-Islāmic times to the mid-1980s. L. CARL BROWN, *The Tunisia of Ahmad Bey, 1837–1855* (1974), studies in detail the beginnings of Westernization. MEZRI BDIRA, *Relations internationales et sous-développement: la Tunisie, 1857–1864* (1978), clarifies the policies of Tunisian leadership during this period. ARNOLD H. GREEN, *The Tunisian Ulama, 1873–1915* (1978), shows well how the religious institutions fitted into society in this period of transformation. LUCETTE VALENSI, *Tunisian Peasants in the Eighteenth and Nineteenth Centuries* (1985; originally published in French, 1977), is a thorough study firmly based on material in Tunisian national archives. DWIGHT L. LING, *Tunisia: From Protectorate to Republic* (1967), provides an overview. CHARLES A. MICAUD, *Tunisia: The Politics of Modernization* (1964), reviews ideological change during the protectorate and the Neo-Destour Party. CLEMENT HENRY MOORE, *Tunisia Since Independence: The Dynamics of One-Party Government* (1965, reprinted 1982), is a thorough political study. Other political studies include LISA ANDERSON, *The State and Social Transformation in Tunisia and Libya, 1830–1980* (1986); and NORMA SALEM, *Habib Bourguiba, Islam, and the Creation of Tunisia* (1984).

(J.I.C./B.H.W./J.M.A.-N./L.C.Br./W.D.Sw./M.Br./G.L.F./K.Su.)

North America

The third largest of the world's continents, North America occupies the northern portion of the landmass generally referred to as the New World, the Western Hemisphere, or simply the Americas. Mainland North America is shaped roughly like a triangle, with its base in the north and apex in the south; associated with the continent is Greenland, the largest island in the world, and such offshore groups as the Arctic Archipelago, the Bahamas, the Greater and Lesser Antilles, the Queen Charlotte Islands, and the Aleutian Islands.

North America is bounded on the north by the Arctic Ocean, on the east by the North Atlantic Ocean, on the south by the Caribbean Sea, and on the west by the North Pacific Ocean. To the northeast, Greenland is separated from Iceland by the Denmark Strait, and to the northwest, Alaska is separated from the Asian mainland by the much narrower Bering Strait; North America's only land connection is to South America at the narrow Isthmus of Panama.

North America has a total area of some 9,418,000 square miles (24,392,000 square kilometres). Its greatest north-south extent exceeds 5,000 miles (8,000 kilometres), and its broadest east-west distance is approximately 4,000 miles. Mount McKinley in Alaska, at 20,320 feet (6,194 metres) above sea level, is the continent's highest point; and Death Valley in California, at 282 feet (86 metres) below sea level, is its lowest. North America's coastline of some 37,000 miles is notable for the great number of indentations, particularly in the northern half.

The name America is derived from that of the Italian merchant and navigator Amerigo Vespucci, one of the earliest European explorers to the New World. Although at first the term America was applied only to the southern half, the designation soon was applied to the entire landmass; those portions that widened out north of the Isthmus of Panama became known as North America, and those that broadened to the south became known as South America. According to some authorities, North America begins not at the Isthmus of Panama but at the narrows of Tehuantepec, with the intervening region called Central America. Under such a definition, part of Mexico must be included in Central America, although that country lies mainly in North America proper. To overcome this anomaly, the whole of Mexico, together with Central and South American countries, also may be grouped under the name Latin America, with the United States and Canada referred to as Anglo-America. This cultural division is a very real one; yet Mexico and Central America (including the Caribbean) are bound to the rest of North America by strong ties of physical geography. Greenland also is culturally divided from, but physically close to, North America.

North America was the first continent to achieve its current approximate size and shape, and it contains some of the oldest rocks on the Earth. Its geologic structure is built around a stable platform of Precambrian rock called the Canadian (Laurentian) Shield. To the southeast of this rose the ancient Appalachian Mountains; and to the west rose the younger and considerably taller Cordilleras, which occupy nearly a third of the continent's land area. In between these two mountain belts are the generally flat regions of the Great Plains in the west and the Central Lowlands in the east.

The continent is richly endowed with natural resources, including great mineral wealth, vast forests, immense quantities of fresh water, and some of the world's most fertile soils. These have allowed North America to become one of the most economically developed regions in the world, and its inhabitants enjoy a high standard of living. North America has the highest average income per person of any continent and a food intake per person considerably greater than the average for Asia. Although it is home to less than 10 percent of the world's population, its per capita consumption of energy is almost six times as great as the average for all the other continents.

North America's first inhabitants are believed to have been ancient Asiatic peoples who migrated from Siberia to North America sometime during the last (Wisconsin) glacial advance. The descendants of these peoples, the various Indian and Eskimo peoples, largely have been supplanted by peoples from the Old World. People of European ancestry constitute the largest group, followed by those of African and of Asian ancestry; in addition there is a large group of Latin Americans, who are of mixed European and Indian ancestry. (J.W.W./Ed.)

This article treats the physical and human geography of North America, followed by discussion of geographic features of special interest. For discussion of individual countries of the continent, see the articles CANADA, MEXICO, and UNITED STATES OF AMERICA. Other North American countries are treated in articles on regions under the titles CENTRAL AMERICA and WEST INDIES. For discussion of major cities of the continent, see specific articles by name—*e.g.*, MEXICO CITY, NEW YORK CITY, and TORONTO. For discussion of the indigenous peoples of the continent, see the articles AMERICAN PEOPLES, NATIVE and PRE-COLUMBIAN CIVILIZATIONS. The principal treatment of North American historical and cultural development is contained in the articles mentioned above and in the article LATIN AMERICA, HISTORY OF. For further discussion of arts and literature, see the articles AMERICAN LITERATURE; AMERICAN PEOPLES, ARTS OF NATIVE; CANADIAN LITERATURE; and LATIN-AMERICAN LITERATURE. For further references, see also the *Index*.

PHYSICAL AND HUMAN GEOGRAPHY

Geologic history

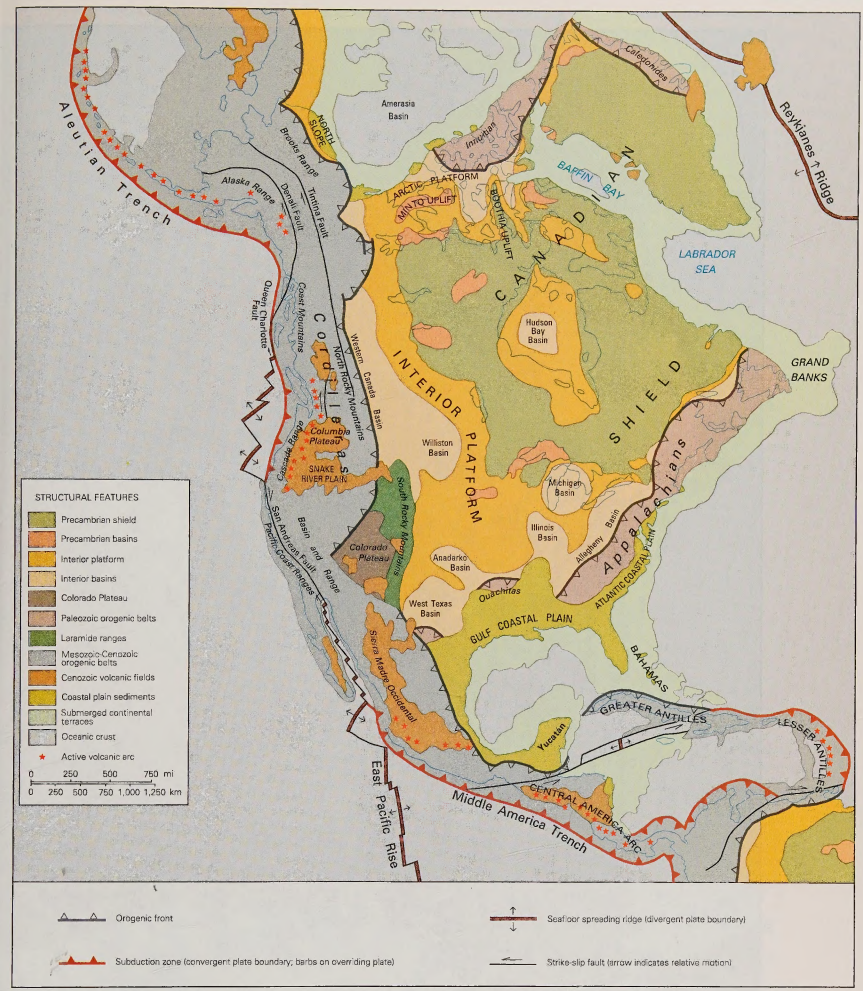
GENERAL CONSIDERATIONS

Continents have collided and broken apart repeatedly over geologic time. When they separate, new ocean basins develop between the diverging pieces through the process of seafloor spreading. Spreading, which originates at oceanic ridges, is compensated (to conserve surface area) by subduction—the process whereby the seafloor flexes and sinks along inclined trajectories into the Earth's interior—at deep-sea trenches. Closure of ocean basins by subduction of the seafloor results in continental collisions.

The material moved laterally from spreading ridges to subduction zones includes plates of rock up to 60 miles (100 kilometres) thick. This rigid outer shell of the Earth is called the lithosphere, as distinct from the underlying hotter and more fluid asthenosphere. The portions of lithospheric plates descending into the asthenosphere at subduction zones are called slabs. The 14 independent lithospheric plates that make up the present surface of the Earth are bounded by an interlinking system of oceanic ridges, subduction zones, and laterally moving fractures known as transform faults. Over geologic time, the system of plate boundaries has continually evolved as new plates have formed, expanded, contracted, and disappeared.

The outermost layer of the lithosphere is called the crust. It is composed of low-density material crystallized from molten rock (magma), produced by partial melting of the lithosphere or asthenosphere. The average thickness of the oceanic crust is about four miles. Oceanic plateaus and seamounts are localized areas of abnormally thick oceanic crust that have resulted from submarine volcanism promoted by hot jets, or plumes, rising from deep within the Earth's interior (*i.e.*, from the mantle). Oceanic crust is transient, being formed at the oceanic ridges and destroyed at the trenches. It has a mean age of about 60 million years.

Continental crust



Continental crust averages 22 miles in thickness, accounting (according to Archimedes' principle of fluid displacement) for its mean surface elevation of about 3 miles above that of the ocean floor. Continental crust is more complex than oceanic crust in its structure and origin and is formed primarily at subduction zones. Lateral growth occurs by the addition of rock scraped off the top of oceanic plates as they are subducted beneath continental margins. Such margins are marked by lines of volcanoes, called volcanic arcs, that manifest additions to the crust resulting from partial melting of the wedge of the asthenosphere situated above the descending slab and below the continental plate (melting is promoted by the release of water from the slab, which lowers the melting point in the wedge). Subduction zones located within ocean basins (where one oceanic plate descends beneath another) also generate volcanic arcs, which are called island arcs. Island arcs consist of materials that tend to be transitional between oceanic and continental crust in both thickness and composition. The first continents appear to have formed by the accretion of island arcs.

Continental crust resists subduction. Consequently, the mean age of the continents is almost two billion years, more than 30 times the average age of the oceanic crust. Thus, continents are the prime repositories of information concerning the Earth's geologic evolution, but understanding their formation requires a knowledge of processes in the ocean basins from which they evolved.

TECTONIC FRAMEWORK

Structural plan. North America is unique among the continents in having stable interior lowlands of great antiquity that are almost completely enclosed by younger orogenic belts (belts of former or actual mountain ranges resulting from crustal deformation related to subduction or continental collision). These lowlands include the Canadian (Laurentian) Shield and an interior platform of crystalline rock that is covered by a veneer of virtually flat-lying sedimentary rock.

The continent's peripheral orogenic belts originated at plate boundaries, and they are of Paleozoic age (540 to 245 million years ago) in the east and Mesozoic to Cenozoic age (245 million years ago to the present day) in the west. These belts are partly covered, and locally breached, by coastal plain sediments of the Arctic Ocean in the north, the Gulf of Mexico in the south, and relatively young volcanic fields in the west. A gap in the Paleozoic orogenic belts between the Appalachian Mountains of Newfoundland and the East Greenland Caledonides is a consequence of seafloor spreading at the mid-Atlantic Reykjanes Ridge, which caused a small portion of the system (the Rockall Bank in the North Atlantic and northwestern Britain) to drift eastward.

Structural features of North America.
Adapted from Paul F. Hoffman, Geological Survey of Canada

The Canadian Shield. The Canadian Shield is the principal area of North America where rocks of Precambrian age (*i.e.,* those that are more than about 540 million years old) arch to the surface. The shield was rifted apart between Canada and Greenland by abortive seafloor spreading in the Labrador Sea and in Baffin Bay between 90 and 40 million years ago. The Greenland Shield is now largely ice-covered. During the past 2.5 million years, the Canadian Shield also has provided centres of ice accumulation from which continental ice sheets advanced southward repeatedly.

The shield is an aggregate of at least four discrete continents that were fused together between about 2.0 and 1.8 billion years ago. Three of the constituent continents behaved as relatively rigid dies, called cratons, that indented and pervasively deformed the remaining continent

during their mutual aggregation; the Slave craton lies to the northwest, the Nain craton to the northeast, and the Superior craton to the south of the intervening nonrigid Churchill province, which may be composite in origin. The structural grain of the cratons is truncated at their margins, suggesting that they originated by the fragmentation of larger continents that formed more than 2.6 billion years ago. Small remnant basins of essentially flat-lying Precambrian sedimentary rocks are arbitrarily included in the shield because of their age, although they have more in common structurally with the interior platform and basins.

Interior platform and basins. Nearly horizontal strata of sedimentary rocks overlie Precambrian crust that extends beyond the limits of the Canadian Shield. The sedimentary cover is less than a mile thick on the platform, but it increases to about 2.5 miles in the Hudson Bay, Michigan, Williston, and Illinois basins and up to 4 miles and more in troughs adjacent to the peripheral orogenic belts. The sedimentary rocks provide sensitive records of differential basement subsidence, the geomorphic evolution of the peripheral orogenic belts, fluctuations of sea level, and climatic changes related in part to latitudinal continental drift.

Paleozoic orogenic belts. Erosional remnants of ancient mountain ranges occur along the eastern, northern, and southern margins of the continent. The mountains were created mainly between 400 and 300 million years ago, when North America collided with other continents to form the ancient supercontinent of Pangaea. The Ouachita Orogen (mountain chain) formed when the south-facing margin of North America collided with South America, the Appalachian Orogen when the southeast-facing margin collided with northwestern Africa, the Caledonian Orogen when the northeast-facing margin collided with northwestern Europe, and the Franklinian Orogen when the Arctic margin collided with crust that now underlies the Barents shelf off northern Europe and Alaska north of the Brooks Range. The portions of the orogenic belts next to the continental interior are composed mainly of folded sedimentary rocks indigenous to North America. The parts closer to the modern oceans are more diverse and include rock masses that originated outside the continent. A striking observation from paleogeographic reconstructions is that the present-day ocean basins opened along lines close to the lines of closure of the preceding Paleozoic oceans.

Passive continental terraces. Sediments younger than 200 million years are draped across the rifted eastern, northern, and southern margins of the continent. The rifted margins formed when the Atlantic and Arctic oceans and the Gulf of Mexico began to open. Rivers transported great quantities of sediment to the Gulf of Mexico and the Arctic Ocean. In both areas the resulting sediments are now pierced from below by fingerlike masses of salt, called salt domes, that often are many miles in diameter. In the Arctic, sediments older than about 40 million years were crumpled during the counterclockwise rotation of Greenland as it drifted away from northeastern Canada. Sediments deposited along the Atlantic margins of North America lie mostly underwater.

Mesozoic and Cenozoic orogenic belts. The youngest mountain ranges formed along the western margin of the continent (the Cordilleras) and around the Caribbean Sea.

Formation of the Cordilleras

The development of the Cordilleras occurred mainly after the Atlantic Ocean began to open and North America started drifting westward over the floor of the Pacific Ocean, about 180 million years ago. As a result, sedimentary and volcanic rocks were sheared off the Pacific Plate that was being subducted and were accreted to the leading (western) edge of the continent. Simultaneously, volcanic arcs formed inland of the continental margin. For about 30 million years North America has been overriding the East Pacific Rise, a centre of seafloor spreading, resulting in a fundamental segmentation of the Cordilleras. As the seafloor west of the spreading axis moves sideways (northward) relative to North America, those segments of the continental margin that have crossed the spreading ridge (*i.e.*, California and northwestern Canada) are characterized by faults (the San Andreas and Queen Charlotte) with right-lateral displacements and by the absence of trenches or volcanic arcs.

The present Caribbean Sea floor originated as a submarine plateau in the eastern Pacific basin. For about 80 million years, it has progressively penetrated the gap formed earlier by the separation of the North and South American plates. As the two plates (including the western Atlantic) drifted westward, subduction and arc volcanism occurred along the eastern margin of the Caribbean, and the northern and southern margins of the Caribbean were sheared and dismembered. Arc volcanism in Central America is related to subduction of the Pacific Ocean floor at the Middle America Trench off the region's Pacific coast; it is mirrored by subduction of the Atlantic floor beneath the Lesser Antilles volcanic arc.

Cenozoic volcanic fields. Volcanism in the Cenozoic Era (*i.e.*, in the past 66.4 million years) is related to subduction-zone processes, mantle plumes, and crustal stretching. Volcanic arcs occur in the Lesser Antilles, Central America, Mexico, the Cascade Range, the Gulf of Alaska, and the Aleutian Islands. Vast areas of Mexico, New Mexico, and Colorado east of the main volcanic arc were blanketed by volcanic ash flows between 38 and 28 million years ago. Lines (or tracks) of volcanic activity that become older from east to west may emanate from melting sites, or hot spots, beneath the drifting continental plate. The Anahim volcanic belt of central British Columbia and the Snake River lava plain of Idaho are examples of such tracks. The Yellowstone caldera marks the active eastern end of the Snake River track. The Columbia Plateau basalts of Oregon and Washington, which are 14 to 17 million years old, resemble lava floods associated with the establishment of mantle plumes. Flood basalts in coastal and offshore eastern Greenland are related to the separation of Greenland and northwestern Europe under the influence of the Iceland mantle plume about 68 million years ago. Lavas in coastal areas of western Greenland are related to the separation of Greenland from Baffin Island. The Basin and Range Province, a vast area of crustal stretching in the western United States, contains numerous relatively small volcanic fields, mostly less than about 15 million years in age.

TECTONIC EVOLUTION

Chronological summary

North America is an ancient continent in several respects. It contains the oldest rocks found on the Earth, its interior has been stable for the longest period of time, and it was the first continent to achieve approximately its present size and shape. Although its known geologic history spans almost four billion years, two ages stand out as turning points. The first was about 1.8 billion years ago, when several continental fragments coalesced to form the stable crust underlying the Canadian Shield and northern interior platform. The second occurred about 600 million years ago, when fragmentation of ancestral North America created the continental margins along which the peripheral orogenic belts developed. It was then that the present size and shape of the continent was determined.

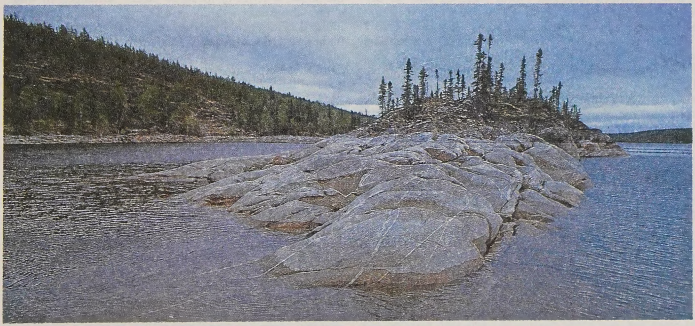
Precambrian time. *4.0 to 3.0 billion years ago.* The oldest rocks in North America (and in the world) occur in the Canadian Shield. Their ages have been calculated from precisely measured ratios of the steady radioactive decay of trace amounts of uranium and lead isotopes in the mineral zircon. Rocks at least 3.8 (and possibly up to 3.96) billion years old (Acasta gneiss) occur southeast of Great Bear Lake in the northwestern corner of the shield. In the northeastern part of the shield, rocks as old as 3.8 billion years are found on the formerly contiguous coasts of western Greenland and Labrador. Rocks in the Minnesota River valley, near the southern limit of the shield southwest of Lake Superior, range in age up to 3.66 billion years. There are many occurrences of rocks between 3.5 and 3.0 billion years old, but, like the older rocks, none are known to be more than a few tens of square miles in extent. The compositional range of the old rocks is essentially the same as that of much younger rocks, implying similar processes of formation.

3.0 to 2.6 billion years ago. The interval between 3.0 and 2.6 billion years ago was one of rapid crustal growth

in North America, during which most of the Canadian Shield and the crust beneath the northern Great Plains was formed. In any given region, relatively thin primeval oceanic crust evolved into thick continental crust over a period of about 50 million years. The repeated melting and resolidification of this crust led to progressive vertical differentiation as lighter components separated from heavier ones and were distributed at the top. As the thickened crust emerged above sea level, it was stripped by erosion and redeposited in adjacent depressions as detrital sediment. As exposed in the Canadian Shield, the thickened crust consists of multifarious granitic intrusions and subordinate enclaves of folded and faulted volcanic and sedimentary rocks. The enclaves, known as "greenstone belts," contain minable concentrations of gold, silver, copper, zinc, and lead. Regional geologic mapping and isotope dating indicate that the processes of crustal thickening tended to occur incrementally in zones a few tens of miles wide and many hundreds of miles long. The overall process of crustal transformation has much in common with activity associated with plate convergence, where oceanic volcanic arcs and derived sedimentary rocks are accreted onto the leading edge of the overriding plate and later are intruded by magmas generated in the mantle above the subducted plate.

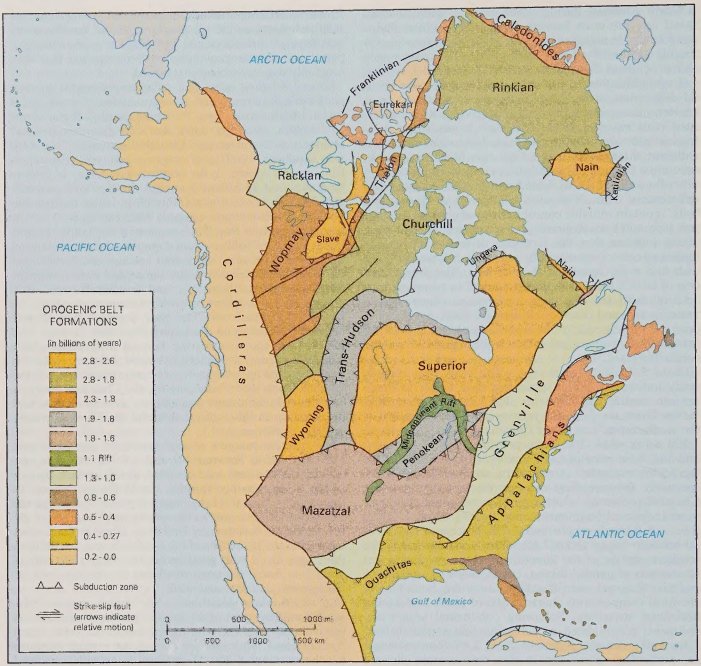
Continental breakup

2.6 to 2.0 billion years ago. The crust that had already formed 2.6 billion years ago soon began to break up into continental fragments. The largest of these fragments forms the Superior province, which is located in the south-central part of the Canadian Shield and is some 1,500 miles wide. The Slave province (300 miles wide) and the Nain province (500 miles wide) are located in the northwestern and northeastern parts of the shield, respectively. Between these three provinces is the sprawling Churchill province—which may be a composite of four or more individual fragments named the Wyoming, Hearne, Rae, and Burwell subprovinces. The process of continental breakup began about 2.45 billion years ago along the southern margin of the Superior province, producing extensive sets of parallel dikes (vertical sheets of crystallized intrusive magma) and rift valleys containing lavas having chemical compositions characteristic of plates undergoing horizontal stretching. Following continental separation, sediments accumulated on subsiding continental shelves. (The shelf sediments deposited about 2.4 billion years ago are particularly significant in that they contain discrete layers strewn with boulders dropped from shelf ice, implying that seawater then had a temperature range similar to that of the present.) Continental fragmentation continued episodically until about two billion years ago. Because it is difficult to track the drift of continental fragments of such antiquity, it is not known how many parent continents are represented by the fragments now located in North America. Striking similarities between contemporaneous shelf sediments on the southern margins of the Wyoming and Superior provinces and between the crust of the Superior and Hearne provinces, however, suggest that they originally may have been juxtaposed.



2.0 to 1.8 billion years ago. The continental fragments constituting interior North America coalesced between 2.0 and 1.8 billion years ago. The amalgamation began about 1.97 billion years ago, when the Slave province collided obliquely with the western Churchill province. The collision produced the Thelon orogenic belt, which stretches from central Alberta to the northwestern corner of Greenland. About 1.85 billion years ago the Superior province collided with the southern Churchill province to form the bowlike Trans-Hudson orogenic belt, the crest of which underlies Hudson Bay. The zonation of the Trans-Hudson belt is typical of collision zones: granitic rocks representing the eroded roots of a continental volcanic arc occur along the Churchill province margin, the medial zone comprises relics of oceanic island arcs, and the Superior province margin is characterized by shelf sediments overthrust by slivers of oceanic crust. The Nain province had already collided obliquely with the eastern Churchill province 1.82 billion years ago, forming the Torngat Mountains, which parallel the coast of northern Labrador. All three collisions were preceded by subduction of oceanic plates beneath the Churchill province. Consequently, the Churchill province experienced much more magmatism, metamorphism, and deformation in this interval than did the Slave, Superior, or Nain provinces.

Accretion of volcanic island arcs



The external margins of the composite protocontinent also were active between 1.9 and 1.8 billion years ago. Volcanic island arcs were accreted to the western margin of the Slave province forming the Wopmay Orogen, to the southern margin of the Superior province forming the Penokean Orogen, and to the southeastern margin of the Nain province forming the Ketilidian Orogen. Thus, what is now the stable interior of the continent was, 1.85 billion years ago, laced with great mountain ranges; 50 million years later found the crust of all but the southern part of the interior platform coalesced.

1.8 to 1.6 billion years ago. The buried crust underlying the southern part of the interior platform was accreted immediately after the continental fragments to the north had coalesced. This younger crust in the interior platform has been sampled by oil drilling. It extends westward beneath the Colorado Plateau of western Colorado and eastern Utah and the surrounding Cordilleras and eastward into parts of the younger Grenville and Appalachian orogenic belts. This crust is much like that formed earlier in the shield: diverse granitic bodies intrude altered and deformed volcanic and derived sedimentary rocks. The rocks are believed to have originated in oceanic volcanic

island arcs between 1.8 and 1.7 billion years ago. They were accreted piecemeal to the protocontinent to the north and then subjected to regional northwest-southeast compression between 1.69 and 1.64 billion years ago. This event, called the Mazatzal orogeny, may be related to a collision between ancestral North America and an unknown continent to the south, and it concluded the main accretionary stage of North America.

1.6 to 1.3 billion years ago. Hundreds of granitic and subordinate basaltic magma bodies were emplaced in a broad zone from southeastern California to the coast of Labrador from about 1.6 to 1.3 billion years ago. The magmas were generated by repeated partial melting in the crust and mantle over a period of 250 million years. In Labrador, where the magmas are best exposed, they form subcircular intrusive bodies, called batholiths, that are up to 95 miles in diameter and 6 miles thick. The magmatism was most profuse in the new crust of the southern interior platform, which was blanketed by up to 4 miles of volcanic ash flows derived from the partial melting of the lower crust.

Magmatism seems not to have been induced by deformation of the continental plate but may have been a consequence of hot mantle upwelling beneath the plate. (A similar style of magmatism occurred from 300 to 150 million years ago in new crust near the active southern margin of the supercontinent Pangaea. Heat buildup beneath the stationary supercontinent induced a large-scale upwelling from the mantle that ultimately contributed to supercontinental breakup. By analogy, North America may have been part of an earlier supercontinent between 1.6 and 1.3 billion years ago.)

A thick sedimentary prism exposed in the northwestern corner of the Canadian Shield and the adjacent Cordilleras may mark a contemporaneous continental margin. To the south, a series of localized basins developed in what is now the Rocky Mountains. The Belt basin, centred in Idaho and western Montana, contains large base-metal ore bodies embedded in sediments up to 12 miles thick. It originated as an enclosed basin floored by highly stretched continental crust or trapped oceanic crust, which is analogous to the structure found in the present-day Black Sea. The Belt basin

1.3 billion to 950 million years ago. The interval between 1.3 billion and 950 million years ago began with continental rifting and culminated in the Grenville orogeny along the southeastern margin of the continent. Northwest-trending dikes were abruptly intruded across the entire northwestern half of the Canadian Shield 1.27 billion years ago. The dikes radiate from the northwestern corner of the shield, which was flooded by mantle-derived lava. Lava fields and fault-bounded sedimentary basins also formed in northern Baffin Island and in northeastern and northwestern Greenland. These deposits signify rifting that may have accompanied the opening of an ocean basin to the northwest. The closure of that basin may be recorded by southeast-directed thrust faulting in some of the same deposits. In the southeastern shield, from the Great Lakes to southern Greenland, rift-related magmatism began about 1.33 billion years ago and continued episodically for about 230 million years, when mantle-

derived lava up to 16 miles thick flooded the 800-mile-long Midcontinent Rift that arcs through Lake Superior. The short time span and large volume of magma effused suggest that hot mantle plume heads impinged on the base of the North American Plate in northwestern Canada and Lake Superior about 1.27 and 1.10 billion years ago, respectively.

The Midcontinent Rift developed contemporaneously with northwest-directed crustal-scale thrusting in the Grenville orogenic belt. The belt is exposed principally along the southeastern margin of the Canadian Shield, but inliers occur in the Appalachians, East Greenland Caledonides, Texas, and Mexico. It has been traced at depth across the eastern and southern fringes of the interior platform. Thrusting occurred mainly between 1.16 and 1.05 billion years ago and caused a doubling in the thickness of the crust, the rise of great mountains, and the exhumation of rocks altered under midcrustal conditions of elevated temperature and pressure. Sediment eroded from the Grenville orogenic belt was carried away by rivers and deposited in what is now the western Arctic platform and the northern Canadian Cordillera. The northwestern part of the Grenville belt consists of crust that belonged to the continent before thrusting began; the southeastern part comprises slices of crust formed offshore between 1.5 and 1.3 billion years ago and accreted to the continent at the time of Grenvillian thrusting. The orogenic belt presumably records collisions between eastern North America and other continents and belongs to a contemporaneous system of orogenic belts that is represented on other continents. The collisions may be related to the amalgamation of a new supercontinent.

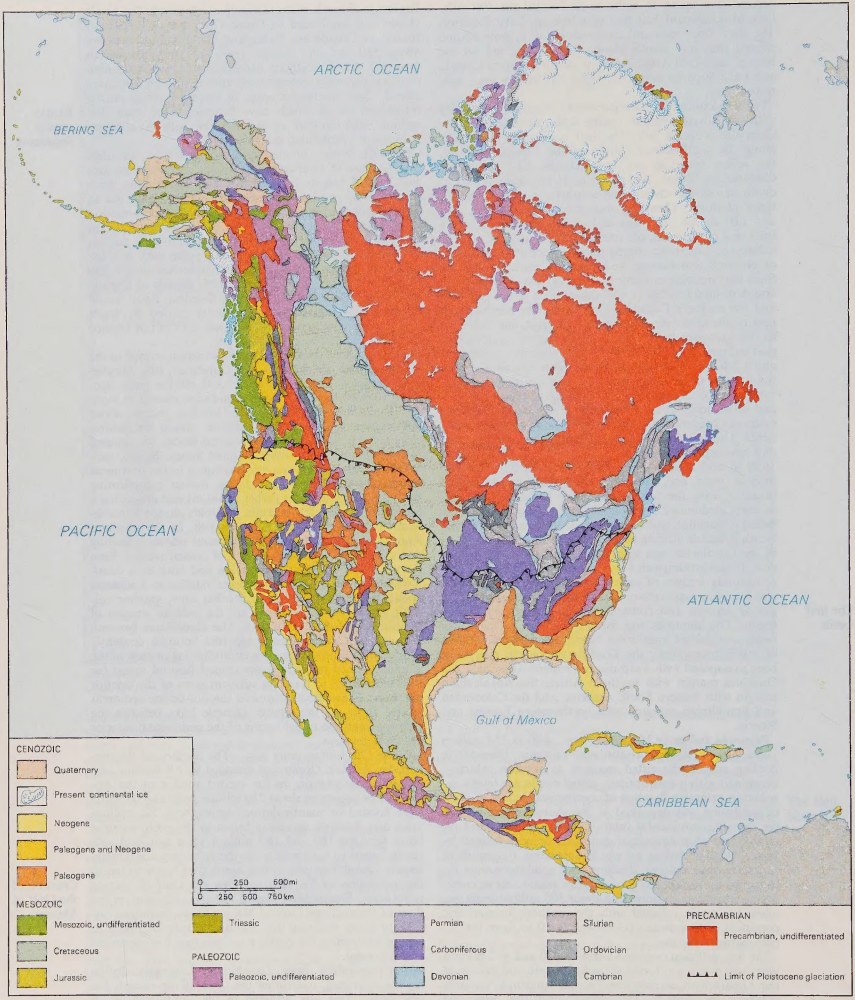
950 to 600 million years ago. Between 950 and 600 million years ago, renewed rifting led to continental breakup along the north-facing (Franklinian), northeast-facing (Caledonian), southeast-facing (Appalachian), south-facing (Ouachita), and west-facing (Cordilleran) margins of North America. Rifting began about 780 million years ago in the Cordilleras and somewhat later on the other margins. It was accompanied by deposition of thick, laterally continuous wedges of sediment and sporadic volcanism and intrusive magmatism. The sediments typically include glacial deposits and contain the first soft-bodied animal fossils. The identities and former positions of the continents that drifted away from North America are subjects of much speculation: the Cordilleran margin may have been juxtaposed with Australia and eastern Antarctica, the Ouachita margin with southern Africa, the Appalachian margin with western South America, and the Caledonian and Franklinian margins with northwestern Europe and Siberia.

The first fossils

Paleozoic and early Mesozoic time. *600 to 250 million years ago.* Following continental breakup, lithospheric cooling caused the rifted margins to subside, which—combined with a concomitant global rise in sea level—resulted in extensive flooding of continental shelves. A sheet of sandstone was deposited as the shoreline was pushed far into the continental interior. As sources of sand retreated, the then-equatorial continent became framed by broad, shallow shelves on which limestones thousands of feet thick accumulated. Shallow-shelf conditions were interrupted by the accretion of volcanic island arcs or continental fragments, culminating about 300 million years ago when Laurentia collided with the southern hemispheric continent of Gondwana (Gondwanaland) to form the supercontinent Pangaea.

The first collision occurred between 470 and 460 million years ago, when a volcanic arc collided with and deformed the Appalachian margin (the Taconic orogeny). Younger volcanic arcs, some built on strips of crust that originated on the northwestern margin of Gondwana, then drifted northward and were accreted to the Appalachian margin between 450 and 410 million years ago (the Acadian orogeny). Simultaneously, the continent Baltica (consisting of the Baltic Shield and the Russian platform) collided with Laurentia to form the Caledonian orogenic belt of eastern Greenland and Norway. In the northern continental interior, a zone of crustal shortening of Caledonian age (420 to 400 million years ago) extends from the Boothia Peninsula of north-central Canada northward to the Arctic Ocean and southward to Hudson Bay. The Franklinian margin of Canada and Greenland was deformed between about 380 and 360 million years ago (the Ellesmerian orogeny), when northern extensions of the Caledonian orogenic belt were sheared westward to northern Ellesmere Island; these extensions occur as so-called exotic crustal fragments, all of which have histories more than 380 million years old that are incompatible with the adjacent indigenous Franklinian margin.

Exotic crustal fragments



The early history of the Cordilleras is difficult to interpret because of later dismemberment, but volcanic arcs that formed mainly between 380 and 360 million years ago were accreted to the continent from California to Alaska immediately thereafter. The resulting deformation (the Antler orogeny) was close in age to the Ellesmerian orogeny in the Arctic. The arcs formed on or near ancient continental crust (2.0 to 2.4 billion years old), but the origin of the material in these arcs is uncertain. By 330 million years ago, the northern Arctic islands of Canada had begun to subside; the resulting Sverdrup Basin would be the major repository of sediment carried by rivers draining the continental interior until the Gulf of Mexico formed some 150 million years later.

In the southern Appalachians, deformation related to the amalgamation of Laurentia and Gondwana (the Alleghenian orogeny) also began about 330 million years ago. Relative northward motion of Gondwana caused its western promontory to override the Ouachita margin about 305 million years ago. The collision caused discontinuous crustal deformation (the ancestral Rocky Mountains) throughout the southwestern United States. By 290 million years ago, Gondwana was impinging to the northwest against the southern Appalachians, further complicating structures formed by the earlier collisions and producing a broad belt of new thrust faults and folds along the northwestern periphery of the orogenic belt. In the northern Appalachians broadly contemporaneous sideways faulting was caused by the lateral escape of crustal wedges from the area of continental indentation and later by a counterclockwise rotation of Gondwana relative to Laurentia about 270 million years ago. By that time, another volcanic island arc had formed off the western margin of Laurentia and was accreted to the Cordilleras between 260 and 240 million years ago (the Sonoma orogeny). Mountains resulting from crustal thickening in each of the aforementioned collision zones caused flexural moats (or foreland basins) to form on adjacent parts of the interior platform. These moats captured interior-bound sediment eroded from the mountains. Genetic links between the collisions and the ovoid basins of the continental interior are more tenuous.

250 to 120 million years ago. The opening of the present-day Atlantic Ocean was presaged by rift faulting and related sedimentation on the eroded surface of the Appalachians beginning about 230 million years ago. The rifts were flooded by mantle-derived lavas about 201 million years ago. Seafloor spreading began in the proto-Atlantic basin between 180 and 160 million years ago, and sediment began to accumulate on the subsiding continental terrace. Simultaneously, rifting along the Ouachitas led to the separation of Yucatán, creating the Gulf of Mexico in its wake. Evaporation caused salt to precipitate on the floor of the enclosed Gulf of Mexico basin. Sediment carried by rivers draining the continental interior began to fill the basin from the north, a process that has continued to the present.

Creation of the Gulf of Mexico

After separating from Gondwana, Laurentia drifted rapidly westward, overriding the floor of the eastern Pacific basin. This was reflected in the Cordilleras by an upsurge in arc magmatism on the continental margin between 180 and 140 million years ago. Thrust faulting and folding crumpled the sedimentary rocks to the east (the Sevier orogeny). In addition, former offshore island arcs and other oceanic crustal fragments were accreted to the advancing continental margin. The central part of the Cordilleras in Canada and Alaska was accreted piecemeal, also between 180 and 140 million years ago, but there is disagreement as to whether the western part was accreted

Geologic structure of North America.

in the same interval or between 110 and 70 million years ago (the two parts are separated by the deeply eroded granitic batholiths exposed in the Coast Mountains of British Columbia).

Late Mesozoic and Cenozoic time. *120 to 30 million years ago.* After the abortive opening of the Gulf of Mexico, South America drifted away from Yucatán, creating a proto-Caribbean gulf that opened eastward into the Atlantic and was separated from the Pacific basin by an east-dipping subduction zone and related volcanic arc near the present location of Central America. Sometime between 80 and 60 million years ago, a large submarine plateau composed of unusually thick oceanic crust (possibly formed in the Pacific basin during initiation about 90 million years ago of a hot spot now located beneath the Galápagos Islands) arrived at the subduction zone oppo-

site the proto-Caribbean gulf. Because the oceanic plateau was too buoyant to be subducted, it began to override the proto-Caribbean gulf, carrying the Antilles volcanic arc on its prow. The plateau—which now floors the Caribbean Sea—continued its penetration into the westward-drifting North and South American plates until the volcanic arc on its northeastern margin (the Greater Antilles) collided with the Bahamas limestone platform sometime between 60 and 35 million years ago. This collision initiated a reorganization of Caribbean tectonics. The collision zone, notably the island of Cuba, was sheared off the Caribbean Plate and became fixed to the North American Plate. An east-dipping subduction zone was reestablished beneath Central America, detaching the Caribbean Plate from the Pacific. Continued subduction of the central Atlantic lithosphere beneath the eastern part of the Caribbean Plate gave rise to the Lesser Antilles volcanic arc.

Continental separation

Meanwhile, seafloor spreading in the Atlantic basin moved northward: continental separation occurred at about 120 and 100 million years ago on the eastern and northern margins, respectively, of the Grand Banks of Newfoundland; about 90 million years ago in the Labrador Sea; and about 70 million years ago in Baffin Bay and eastern Greenland. Continental breakup in the northern North Atlantic about 70 million years ago was accompanied by voluminous volcanism related to inception of a mantle plume from a hot spot now centred beneath Iceland. Spreading in the Labrador Sea and in Baffin Bay resulted in the counterclockwise rotation of Greenland around an axis near Devon Island in the Canadian Arctic islands. To the northwest, the rotation of Greenland caused widespread folding and faulting of sediments in the Sverdrup Basin between 70 and 35 million years ago (the Eurekan orogeny). In the western Arctic, far northern Alaska was relocated from its former position adjacent to the Arctic margin of Canada. There is disagreement as to whether the relocation was accomplished through a counterclockwise rotation or a left-lateral shearing of Arctic Alaska relative to Arctic Canada. Separation of the two began about 92 million years ago and created the oceanic Amerasia basin in its wake.

North America continued to override the Pacific basin, but tectonic activity in the Cordilleras varied in space and time according to the age, angle, obliquity, and relative velocity of the oceanic plates being subducted beneath the continental margin. From 120 to about 80 million years ago, the relative eastward motion of the Pacific floor resulted in crustal accretion and arc magmatism along the western continental margin. Thereafter, the inception of a new oceanic spreading ridge resulted in subduction with a strong northward component of motion in Canada and Alaska. Consequently, the main locus of accretion and arc magmatism shifted to southern Alaska, and strips of previously accreted crust were displaced northward along the western margin of Canada.

In the western United States, a broad region of crustal shortening developed as far east as the Rocky Mountains between 80 and 50 million years ago (the Laramide orogeny). Simultaneously, arc magmatism ceased near the coast but migrated up to 600 miles to the east. These effects are attributed to changes in the angle of the subducting slab, which became shallower, coincident with increased subduction velocity and the hypothesized subduction of a buoyant oceanic plateau. A sharp decrease in subduction velocity in the northwestern United States and adjacent Canada between 60 and 50 million years ago coincided with an end to thrusting in the Rocky Mountains and an episode of crustal extension and melting to the west. In the southwestern United States and Mexico, crustal stretching and melting triggered extensive volcanism between 40 and 30 million years ago and may have been caused by the collapse or thermal dissipation of the low-angle slab. In general, crustal extension was most evident in areas of earlier crustal thickening, a relationship which suggests that overthickened crust was susceptible to gravitational collapse when plate convergence slowed.

30 to 2.5 million years ago. About 30 million years ago North America began to override the East Pacific Rise, an oceanic spreading ridge. This activity placed a progressively longer segment of the coast in contact with the plate west of the ridge. The western plate—which contains the Pacific Coast Ranges of California—has been moving to the northwest relative to North America along the San Andreas Fault system. Active subduction and arc volcanism have been limited to the regions south (the Sierra Madre Occidental) and north (the Cascade Range) of the San Andreas system, which now extends from the Gulf of California in Mexico to Cape Mendocino in northern California. (An analogous gap in subduction and arc volcanism between northern Vancouver Island and the Gulf of Alaska is related to the Queen Charlotte Fault system.) To the east, crustal stretching and related volcanism has continued to shape the distinctive topography of the Basin and Range Province. The Colorado Plateau, however, has resisted the stretching that has occurred on three sides of it. East of the Cascade Range, a great flood of mantle-derived (basaltic) lava formed the Columbia Plateau between 17 and 14 million years ago. Subsequently, the locus of magmatism migrated eastward, forming the Snake River basin and the active Yellowstone volcanic centre. This and other lesser volcanic tracks across the Cordilleras may be products of stationary mantle plumes overridden by the drifting continent. Uplift rates have increased in the past few million years in many parts of western North America, notably in the Sierra Nevada, the Colorado Plateau, the Coast Mountains, the Rocky Mountains, and the Great Plains, but the underlying causes are not well understood.

Plate movement along the San Andreas Fault

The past 2.5 million years. Continental ice sheets developed abruptly 2.5 million years ago in North America, a date based on the appearance of ice-rafted debris in ocean-sediment cores. As glaciation began much earlier in Antarctica (37 million years ago), it is suspected that a specific causal factor—presumably involving a change in ocean-atmosphere circulation—was involved in addition to the overall global cooling trend related to the emergence of greater continental landmass over the past 70 million years. Proposed causes include establishment of the Isthmus of Panama and the increase of plateau uplifts in the western United States and Central Asia. From 2.5 until about 1.0 million years ago, the ice sheets did not reach as far south as the Great Lakes. According to oxygen-isotope records from ocean-sediment cores (the isotopic ratios are correlated with glacial ice volume), glaciation waxed and waned with a 41,000-year rhythm that corresponded to the variation in the proximity of the Earth's orbit to the Sun (the obliquity cycle), the effect of which is greater at higher latitudes. Almost 700,000 years ago, the maximum extent of the ice sheets reached the Great Lakes. It is then thought that glacial periodicity came to be governed primarily by the 100,000-year orbital-eccentricity cycle, although the 23,000- and 19,000-year precessional cycles also came into play—the climatic effect of the latter being stronger at lower latitudes. (For an explanation of these and related matters, see GEOCHRONOLOGY: *Pleistocene Epoch: Cause of the climatic changes and glaciations.*)

Glacial periodicity

At the time of the last glacial maximum (about 18,000 years ago), ice sheets had spread from centres located (in descending order of size) southeast and northwest of Hudson Bay, Greenland, the Canadian Cordillera, Baffin Island, and Newfoundland. The last glacial recession took place from 13,000 to 6,000 years ago but was interrupted by a sharp advance between 11,000 and 10,000 years ago (called the Younger Dryas event) that was most evident around the North Atlantic. The advance coincided with an apparent temporary diversion of glacial meltwater from the Mississippi River to the St. Lawrence drainage system. It has been postulated that this discharge of cold, fresh water disrupted the Atlantic Ocean circulation system that warms the North Atlantic. A more recent cooling episode, the so-called Little Ice Age between about AD 1450 and 1850, has had no satisfactory explanation. The repeated glaciations scoured the Canadian Shield and deposited topsoil in the continental interior, which in modern times has aided farming in the southern portion of North America and geologic research in the northern part; what the north lacks in soil, however, it makes up for in fresh water. (P.F.H.)

The land

Although the geologic processes that shaped the North American continent have been so important that the 19th-century American historian Frederick Jackson Turner once contended that the life of America flowed down the arteries of its geology, the continent nevertheless has been altered considerably by climate and drainage and, to some extent, by soils and vegetation. The resultant physiographic regions dominate the contemporary geography of the continent.

RELIEF

The central shield. The central shield consists of a low plateau (averaging 1,400 feet in elevation) that is tilted at its edges and sinks down to Hudson Bay at its centre. It has a rough surface of old worn mountains and domes that rise above flat, geologically ancient basins. The shield represents an area that has undergone extensive erosion and sculpting by ice and weathering processes. The southern edge has the mountainous Algomans and Laurentians (more than 2,000 feet) and rises to above 5,000 feet in the great dome of the Adirondacks. The eastern edge is somewhat higher, rising to nearly 6,000 feet in the Torngats and more than 7,000 feet in Baffin Island; in Greenland, too, it tilts up to more than 6,000 feet. The western rim is much lower, reaching only about 600 feet in parts. The Snare and Nonacho ranges west of Hudson Bay lift the edge of the plateau to nearly 2,000 feet. Faulting broke the northern rim into a series of prongs, extending into southeastern Ellesmere Island and across Victoria Island, with sea-drowned channels and low sedimentary basins in between forming the Canadian Arctic Archipelago.

The entire shield was under successive ice sheets during the Pleistocene Epoch (1,600,000 to 10,000 years ago), and its high eastern rim still contains relics of these glacial advances and retreats. Ice-cut valleys in the higher areas, ice-plucked basins everywhere, and ice-deposited ridges known as eskers and drumlins point to a major centre of ice accumulation and dispersion over central Labrador, still noted for its heavy snow cover. Greenland also was a main centre of glacial advance and retreat, while Keewatin in western Canada was an important secondary focus. After most of the ice had melted and its tremendous weight had been lifted from the crust, portions of the shield began to rise, leaving traces of former beaches along the coasts of Greenland, Baffin Island, Labrador, and the Gulf of St. Lawrence; these provided narrow but vital benches for human settlement. Ice-cut rock basins have left countless lakes, and parts of the surface of the central shield are almost more water than land.

Relics of glaciation

The marginal mountains. *The Appalachians.* Erosion also profoundly altered the marginal mountains. The Appalachians have been planed down to such an extent that their crest lines are smooth-topped for hundreds of miles. Several levels at which summits accord with each other in height indicate a series of uplifts followed by planations. In Canada the highest level lies at about 4,000 feet, in the flattops of the Shickshocks (French: Chic-Chocs); another exists at 2,000 feet on Mount Carleton; and lower ones lie at roughly 1,100 and 600 feet in the Acadian ranges. In New England, mountains like Mounts Washington and Monadnock, which are composed of highly resistant rock, rise above a broad mass of ridges at just above the 2,000-foot level; these ridges, in turn, rise above the 1,100-foot-high New England Upland. Pleistocene glaciation deepened and straightened the valleys, strewing their sides and parts of the coast with debris. Portions of sea-

Physiographic regions of North America.

buried end moraines, which mark the limit of the tonguing glaciers, form offshore banks east of Newfoundland, Nova Scotia, and New England. The unglaciated Appalachian Mountains—*i.e.*, those located south of the Susquehanna River—have striking accordances of long flat-topped summits at altitudes of about 2,500 feet and broad terraces at 500 to 600 feet. The Ridge and Valley section's pattern of drainage consists of short, deep gaps across the ridges and long parallel stretches in between. East of the Blue Ridge extends the Piedmont Upland, terminating abruptly in the fall line, where its rivers plunge down to the Atlantic Coastal Plain over rapids or falls. The Hudson-Mohawk gap represents a major break between the northern and the southern Appalachians and affords a natural point of entry to the interior of the continent.

The Cordilleras. Taking up about a third of North America, the Cordilleras completely dominate Alaska and Central America and swell out widely in the U.S. Rocky Mountains.

The six zones of the Canadian Cordilleras

In Canada the Cordilleras consist of six well-marked zones: the 10,000- to 12,000-foot-high Rocky Mountains, continuing north into the Brooks Range of Alaska; the Rocky Mountain Trench, a profound fault feature forming the headwaters of the Columbia, Fraser, Peace, and Yukon rivers; the interior uplands and old fold mountains from the Selkirk and Okanogan ranges in the south to the Cassiar Mountains and the Yukon Plateau in the north, mostly lying at altitudes of about 2,400 feet but with ridges above 8,000 feet; the Coast Mountains, extending north into the Alaska Range and including lofty volcanoes in the north; the Inside Passage from Puget Sound to Alaska, which is possibly a downfaulted zone flooded by the sea; and a structurally complex outer island arc, running from Vancouver Island to the Aleutians. The magnificent scenery of the northern Rocky Mountains, including U-shaped valleys often extending westward into sea-drowned fjords, has resulted from frequent glaciation, and some areas still nurse sizable glaciers.

In the United States the Rockies, typified by flat or gently folded rocks, sweep south from Canada into northern Montana as the Lewis Range. They then change to a group of domes or long anticlines with "parks" or broad basins between them. This park-and-dome area is characterized by the "peeling back" of younger rocks from the cores of much older, primary rocks at the heart of the anticlines. The southern Rockies have striking volcanic peaks. West of the Rockies and east of the Pacific coast ranges is a vast region of intermontane plateaus, extending from eastern Washington state to northern Mexico. The immense lava tablelands of the central Columbia–Snake River basin are known as the Columbia Plateau. To the south lie the Basin and Range Province and the Colorado Plateau. The former, extending from southern Oregon and Idaho to northern Mexico, apparently is the result of the splitting of a broad central plateau by a great number of fault ridges, the slopes of which plunge under basins partly filled with debris worn from the ridges. The region includes all of the continent's major deserts. The Colorado Plateau is a massive feature with a series of relatively flat-bedded ridges, made steplike by faulting action and intruded by domes of igneous rocks. Its slow rate of uplift was matched by the steady downcutting of the Colorado River, producing, in the Grand Canyon, one of the most spectacular gorges in the world. Westward rise the mountains of the Sierra Nevada, which reach to nearly 15,000 feet, are intensively folded and faulted, and continue north in the Cascade Range, which is marked by some of North America's most beautiful volcanic cones. Seaward of this mountain zone is a line of depressions marked by Puget Sound, the Central Valley of California, and the Gulf of California. These are separated by knots of volcanoes, as in the Klamath Mountains, and enclosed by the ranges along the Pacific coast, including the Olympic Mountains of Washington. This whole area has been profoundly faulted. Along some of the faults, notably the San Andreas, earthquake shocks occur, and occasionally these have produced devastating results.

In Mexico the folded ranges of the Sierra Madre to the west and east of the central Mexican Plateau terminate in the grandeur of a mass of high volcanoes of 15,000 to 17,000 feet located to the south of the fertile lake-filled basins of Guadalajara and Mexico City. The Balsas River basin then makes a distinct break. To the south the Sierra Madre del Sur and the mountains of Guatemala and Honduras exhibit a west-east trend. This structural region includes a sweep of fold mountains of from 4,000 to 6,000 feet, with Caribbean extensions in Jamaica, southern Cuba, the island of Hispaniola, and Puerto Rico. These mountains swing southward through the West Indies, a chain of volcanic islands fringed with coral reefs or limestone plateaus. Another arc, of two lines of fold mountains on either side of a trench through western Nicaragua, dominates Central America and links it with the folds of western Colombia, in South America.

The structural break at the Sierra Madre del Sur

The lowlands. Long irregular ridges of coarse morainic deposits mark the outer limits of the advance of the Cordilleran ice sheets, which swept down preexisting river valleys in the Rockies, and the larger, thicker continental sheets, which advanced south out of Canada. The long, tonguing loops of end moraines of the continental ice sheet are prominent features north of the Missouri and Ohio rivers—some running for hundreds of miles and standing 300 or 400 feet above the plains. Several glacial advances—perhaps as many as 10 or more—successively covered the lowlands with glacial drift. Four of these have been named for the extent of their southern advances: the Nebraskan crossed the Missouri River; the Kansan extended as far as the lower Missouri and the Ohio rivers; the Illinoian overlay these older areas as far as southern Illinois; and the Wisconsin heaped its moraines over the prairies of southern Canada and the plains of the Great Lakes and the Ohio, Mohawk, and Hudson rivers (see also below *Drainage*). Evidence of deposits from other major advances may be buried beneath the drift from later glaciers.

In the ice-free areas, lowlands are river-molded. Streams debouching from the Rockies have spread sands, occasionally whipped up into sand hills, well beyond their banks; those funneling into the Mississippi River have created a vast alluvial plain running out into the Mississippi delta.

© Richard Alexander Cooke III

Esker, narrow ridge of gravel and sand left by a retreating glacier, winding through the Keewatin district near the Thelon River in the Northwest Territories.

In addition, the Coastal Plain is marked by lines of sand hills, which are the relics of stranded beaches that eroded as the plains were lifted slowly out of the seas in post-glacial times.

Detailed discussion of the Alaskan mountains, Appalachian Mountains, Great Plains, North American Desert, Pacific coast ranges, Rocky Mountains, Sierra Madre, and Sierra Nevada can be found in *North American geographic features of special interest* at the end of this article.

DRAINAGE

Drainage conditions and water supply are affected markedly by climate, though they also reflect topography. North America has one of the longest rivers in the world (the Mississippi) and also a drainage system with one of the greatest water capacities (the St. Lawrence–Great Lakes system). It is a continent of immense rivers—largely because of their vast drainage area in the long and broad plains between the central shield and the marginal mountains. Rivers that rise in the Canadian Shield, the Appalachians, or the Cordilleras and flow into the Interior Lowlands must travel a great distance to reach the sea. The Great Lakes–St. Lawrence system on the east and the Mackenzie River on the west drain much of the outer edges of the shield. The Nelson River takes advantage of the low saddle in the shield to carry out the gathered waters of the Saskatchewan and the Red rivers by way of Lake Winnipeg to Hudson Bay, which also has fairly long rivers draining into it from the uptilted edges of the shield. The vast Missouri-Mississippi-Ohio system receives waters from the Cordilleras, the Canadian Shield, and the Appalachians to unite the Central and Gulf lowlands in the heartland of the continent. From the Rocky Mountains, long rivers like the Colorado, Columbia, Fraser, and Yukon flow west to the Pacific. Fed by perpetual snowpacks and ice, they are particularly valuable as sources of water in the arid Southwest.

There is a marked east-west asymmetry to North America's drainage: the chief continental divide, along the Rockies, is well to the west, thus shedding the longest rivers to the east. The longest tributaries—the Peace into the Mackenzie, the Saskatchewan into the Nelson, and the Missouri into the Mississippi—are all west of the main streams. The chief gulfs—Hudson Bay, the Gulf of St. Lawrence, and the Gulf of Mexico—taking the discharge of many of the rivers, are on the east. All these factors helped the European settlers move from their Atlantic bases into the heart of North America by facilitating travel. Considerable north-south disparity also exists in North America's drainage pattern: there are no rivers or lakes south of the Rio Grande that approach the size of those found to the more humid north.

Lakes. Lakes abound in North America. Most of them are products of glaciation, which has had a vast effect on the continental drainage pattern—notably by widening the passes through the northern Appalachians and the Cordilleras and by forming big lakes in ice-deepened basins. The Great Lakes proper have a fascinating history, as Lakes Superior and Huron were vast synclinal depressions even in Precambrian times. In the place of the present eastern lower Great Lakes (Erie and Ontario), a scarp-and-vale topography existed, with the high front of the Niagara limestone scarp separating vales of shale to the west and east. The glaciers picked out the vales and synclines and greatly deepened them into ice-cut basins, where water gathered; as the ice melted away, the Great Lakes formed. While the ice front of the glaciers was blocking the St. Lawrence outlet, the early lakes drained southward into the Mississippi-Ohio, the Susquehanna, and the Mohawk-Hudson systems. When the ice retreated from the Gulf of St. Lawrence, the lakes sought the lower outlet through the St. Lawrence River, decreasing the level of the Great Lakes and leaving beaches around them that stand out as raised beaches, or strandlines. The land, depressed under the enormous weight of the ice, has been rising since, lifting the old beaches above the present diminished bodies of water. Similar strandlines follow the Gulf of St. Lawrence, once under glacial Lake Champlain; Lake Winnipeg, once part of the immense glacial Lake Agassiz; and Lake Athabasca and Great Slave and Great Bear lakes, which also are the relics of once deeper and larger glacial lakes. The western lakes were formed by ice blocking the free drainage of water to Hudson Bay or the Beaufort Sea. Farther south, in the Great Basin, a pluvial (rainy) period of climate during the Pleistocene, matching the ice age in the north, gave rise to the enormous Lakes Lahontan and Bonneville. The Great Salt Lake is a relic of Lake Bonneville, the ancient strandlines of which are up to 1,000 feet above the present shoreline. Similarly, present-day Lake Chapala in Mexico represents only a small portion of the large body of water that accumulated on the Mexican Plateau and whose level fluctuated during several pluvial periods. The contribution of all these—and many more—lakes to the drainage of North America has been outstanding. Much of the Canadian Shield is so riddled with lakes and swamps as to form an amphibious landscape.

The Great Lakes

Rivers. The river regimes of North America exhibit great variety. Northward-flowing rivers, like the Yukon, Mackenzie, Red, and Nelson and the rivers of eastern Canada, freeze in winter. Because their upper courses then thaw before the lower sections are free of ice, their lower (northern) reaches frequently flood, especially if the thaw is late enough to coincide with early summer rains. The St. Lawrence runs high in spring and early summer; the winter precipitation falls on a frozen surface and serves mainly to heighten runoff during the spring thaw.

The Mississippi system also is frequently swollen in spring as melting snows in the upper parts of the drainage basin are added to runoff from spring rains in the southern Great Plains and southeastern states; flooding can then become a major hazard. River water is kept high by the rains that tropical gulf air and local convection storms bring until midsummer. A marked falloff then occurs, giving way to full flow in late autumn and winter as polar continental air reactivates mid-continental storm tracks. Most other eastern rivers have two periods of high water, occurring in early summer and late winter.

The Mississippi system

In the American Southwest, winter is the main period of flooding, as rivers dwindle appreciably in summer. The northern Pacific region, by contrast, has rain in all seasons, though with a winter maximum. In the southern tropical regions, rivers have a much more regular regime, running full throughout the year, except in the dry rain-shadow areas leeward of the mountains.

Detailed discussion of the Colorado River, Columbia River, Great Lakes, Mackenzie River, Mississippi River, Panama Canal, Rio Grande, St. Lawrence River and Seaway, and Yukon River can be found in *North American geographic features of special interest* at the end of this article.

SOILS

Before 1960, climate was the main basis used for categorizing soils, with a division first into humid and arid groups and then into subgroups according to the way in which temperature and moisture acted together to produce different horizons (layers) in the soil. Since then, soil classification has come to depend on the unique characteristics of soils and their horizons. The current system of soil classification, called soil taxonomy, involves hierarchical groupings of soils based on types of horizons, temperature, colour, drainage or wetness, chemistry, and mineralogy. Eleven major categories of soils have been identified, all of which can be found in various parts of North America. Most of these still can be placed into two broad groupings that reflect their general vegetation cover: forest soils and grassland and desert soils; some soil categories, however, cannot be placed into either grouping.

Eleven major categories

Forest soils. The forest soils are the most widespread in North America and typically occur in humid regions.

Spodosols. The cool temperate climatic zone is characterized by spodosols, which typically form on sandy materials under coniferous or mixed coniferous and deciduous forest. They are easily recognized by a leached, acid, grayish white horizon near the surface. Relatively infertile because of deep leaching of otherwise nutrient-poor sands,

Soils of North America.

spodosols are best left to forest or to crops that prefer acid conditions, such as potatoes. They extend under the boreal forest (taiga) from Alaska to Newfoundland.

Andisols. Only since about 1989 have andisols been recognized as a distinct soil category; before then they were considered to be a subcategory of inceptisols. Andisols are formed in volcanic ash and are found throughout the tectonically active belt of the Cascades and north into Canada. There, layers of ash have accumulated and formed these highly fertile, though easily eroded, black soils.

Alfisols. Alfisols are found in the warm-summer subregion of the cool temperate zone, primarily in the Laurentian mixed-forest vegetation region. They are characterized by an upper horizon leached of iron and aluminum compounds, humus, and clay. These materials accumulate in the subsoil, where they form a reddish, clayey subsoil. Alfisols are the moderately fertile, grayish brown soils so typical of the glaciated parts of the northeastern United States; large parts of the dairy regions of Wisconsin and New York are centred on these soils.

Ultisols. Bright red and yellowish red ultisols occur south of the glaciated areas, extending southward from the lower Ohio valley and Chesapeake Bay to the Gulf Coastal Plain. They correspond to the area of the southeastern mesothermal climate, which has a long growing season and rainfall of up to 60 inches per year. Deep leaching and great age have resulted in the loss of many of the essential nutrients from these soils; heavy fertilization is required for such typical crops as tobacco, cotton, and corn (maize). Because many ultisol areas of the southern United States have been in row-crop tillage for several centuries, severe erosion has resulted, further limiting their productivity.

Oxisols. The tropical climates of southern coastal Mexico and Central America, with constantly high temperatures of 65° to 82° F (18° to 28° C) and perennial rainfall of from 80 to 120 inches, have caused intense weathering of rock. The resulting soils, called oxisols, are deep red in colour, are extremely infertile, and may even harden irreversibly into bricklike laterite after being drained and cultivated. In these soils, red iron and aluminum hydroxide and sesquioxide compounds, the residual products of rock decay, have accumulated. Deep and strongly acidic, these lateritic soils support primarily grazing and pastoral activities or swidden agriculture.

Grassland and desert soils. Soils in this group cover an extensive area of North America and generally are found in the drier regions of the continent.

Mollisols. Marking the transition between humid and arid soils, mollisols are found in the open parkland or the tall-grass prairie of the Great Plains or in the humid prairies of the western Central Lowlands. Unlike the forest soils mentioned above, these soils have formed under grassland vegetation and have been heavily influenced by the closely matted roots in the dense sod of the thick-

Formation of mollisols

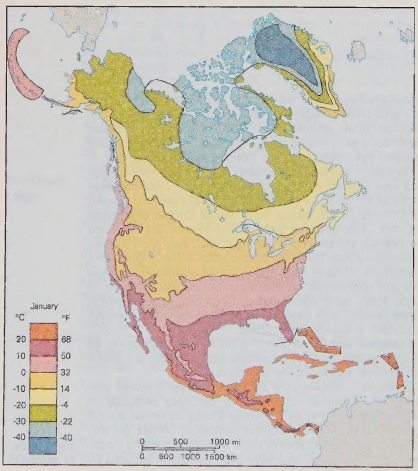
growing grasses. The roots eventually decay underground, turning into humus and giving mollisols a dark brown or black colour. With a short rainy period from April to mid-July followed by considerable evaporation during the dry, sunny summer, whatever leaching occurs is not pronounced. The leached horizon is shallow and passes down to a horizon in which the upward movement of water caused by evaporation from the surface has brought up salts, especially lime, which neutralizes the acidity of the surface soil. Extremely fertile soils of neutral pH, mollisols make up most of the Wheat Belt of the central Great Plains. Farther east, where rainfall is higher, the Corn Belt of Illinois and Iowa also is centred on mollisols.

Vertisols. Vertisols form in materials with a high clay content where there are distinct wet and dry seasons; they are distinguished by the large cracks that form in the surface during dry periods. These soils are limited in North America to small areas of Mexico and Texas. When irrigated, vertisols are highly productive for growing cotton and for use as rangeland.

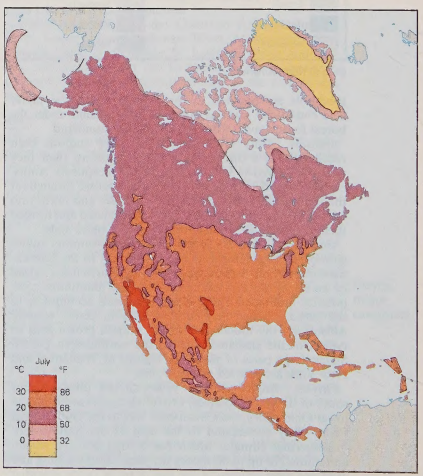
Aridisols. Characterizing the dry climates of the intermontane basins of the United States, most of the Mexican Plateau, and the southwest Pacific Coast, aridisols are found where vegetation is sparse and where, accordingly, little humus has formed at the surface. Leaching is rare and virtually ineffective; strong evaporation leads to the upward movement of alkaline salts through capillary action, which often leaves a skin of white crystals on the surface. Aridisols are too rich in lime and, often, sodium to be fertile unless they are extensively irrigated and the salts are removed.

Other soils. Three soil types are distinguished by their relative youth—*i.e.,* their greater affinity to parent minerals than to the vegetation associated with them—and can be found in most vegetational environments.

Entisols. The very youngest soils are entisols. These soils strongly resemble their geologic parent materials, as there has been insufficient time to alter these materials into soils with strongly developed horizons. Disturbed landscapes also have soils classified as entisols, such as the many square miles of land occupied by freeway medians and urban centres in North America. Such natural landscapes as the Sand Hills of Nebraska also are areas of entisols. Because disturbed or eroded sites or recently deposited materials like river alluvium are common in all landscapes, entisols are found widely scattered throughout North America.



Inceptisols. Inceptisols are slightly more weathered and developed than are entisols; like entisols, inceptisols are not uniquely associated with any particular climatic regime but are widespread across the continent. They are common in the tundra landscapes of northern Canada and Alaska and in the high elevations of the Cordilleras, and they constitute the fertile soils of the Pacific Northwest and of the coasts of British Columbia and Alaska. Many of the soils formed from acid glacial tills in the mountains of New England also are inceptisols.



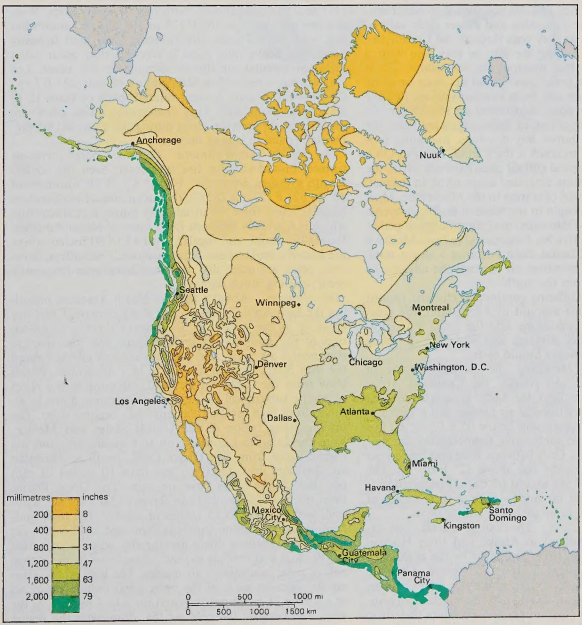
Histosols. Saturated with water for many months of the year, histosols constitute nothing more than deep accumulations of organic materials. They are especially common beneath the coniferous forests of the Great Lakes area and in Canada, where geologically recent glaciation has left many areas of standing water or shallow lakes. The cool climate of these areas also limits decomposition of wood fragments, grasses, sedges, and mosses that may have accumulated in the wet sites. Histosols also are known as peat and muck.

CLIMATE

Climate has had considerable influence on relief—particularly in the extremes of cold or hot and dry or humid landscapes; and, in turn, climate has been affected by relief. The enormous width of the continent in the higher latitudes has led to a great extension of Arctic and cool temperate climates, while the tapering south has greatly reduced the land area under tropical conditions. The Cordilleras of Canada and the United States have wet, windward slopes facing the Pacific and dry, leeward slopes facing the interior. Most storms are driven from west to east by a strong mid-continental air flow called the jet stream, and these storms most often converge on the New England region.

Temperature. While the greater part of North America falls within the temperate zone—a fact that made it attractive to European settlers—large cool-to-cold areas lie in the north and extend as far south as the Ozark Mountains in winter. The continent's northerly position means that Greenland, the Canadian Shield, the Mackenzie Lowlands, and the northern part of the Cordilleras have unusually long and cold winters. Much of this land has permanently

Average temperatures for January (left) and July (right) for North America.



Chilling effect of frozen subsoils and seas

frozen subsoil (permafrost) and is under snow and ice most of the year. The frequently frozen seas interlacing the Canadian Arctic Archipelago, together with innumerable northern lakes, produce an enormous chilling effect on the air above, and the temperatures for these huge regions are 6° to 8° F (3° to 4° C) cooler than the average for their latitude. The North Pacific, warmed by an extension of the Kuroshio (Japan Current), has a positive anomaly of 8° to 10° F (4° to 6° C) warmer than the average for its latitude. Related trends over the northern part of the North Atlantic affect Iceland and Europe rather than North America but still raise the temperatures off the northeast coasts by perhaps 2° F (1° C). The climate thus shows marked contrasts between the maritime and continental areas. Notably warm temperatures extend northward along the west coast from Vancouver Island to Alaska, while a great cold loop extends down the Mackenzie plains and the Canadian Shield over the heart of the continent. The chilling effects of the immense Greenland ice cap drag cold continental conditions southward over the northeast coast at least as far as Newfoundland. The average January temperatures of Annette Island in the Alaskan panhandle, about 34° F (−1° C), of Fort Smith, N.W. Terr., −14° F (−26° C), and of Nain, Labrador, 1° F (−17° C), show the difference between coastal and continental conditions and also between the west and the east coasts; these differences are negligible in the tropical parts of North America.

Precipitation. Most of the continent is humid and provides a good water supply for settlement and development. From mid-California north, the windward sides of mountains along the Pacific coast are bathed with rain- or snow-laden westerlies, giving from 40 to 200 inches (1,000 to 5,000 millimetres) of precipitation per year. Westerlies again reassert themselves east of the Rockies—especially east of the Missouri River and Red River of the North—bringing moderately wet (20 inches) to wet (45 inches) conditions in the central and eastern regions. Two main areas exist where precipitation amounts generally are low. The first is in the far north and northeast, under the influence of extremely cold and relatively dry winds, with a thin dusting of winter snow and a meagre fall of summer rain in the Canadian Arctic Archipelago and Greenland. The other is in the south and southwest, where the mid-latitude high-pressure system produces subsiding and descending air that greatly inhibits rainfall. The high pressure also leads to dry offshore winds from mid-California to southern Mexico. Since these winds blow from the interior out to sea, they carry little moisture, with annual precipitation in that area usually less than 10 inches.

Air masses. The continent's air masses reflect different conditions of temperature and humidity; they include northern and southern components, subdivided into continental (dry) and maritime (moist) types. In the north are found the Arctic air mass, over Greenland and the Canadian Arctic Archipelago; the polar continental, over northern central Canada; the polar Pacific, over Alaska and the northern Pacific shores; and the polar Atlantic, off the Atlantic provinces of Canada and New England. The southern half of the continent is characterized by the subtropical Pacific air mass, off the western United States; the tropical continental mass, over the intermontane basins of the Cordilleras from Utah southward; the tropical gulf, centred in the Gulf of Mexico and the Caribbean; and the tropical Atlantic, off the southeastern United States.

The polar continental, the tropical gulf, and the polar Pacific are the most influential air masses. The polar continental reflects the spread of a negative temperature anomaly over much of the continent. It is a cool-to-cold

Average annual precipitation for North America.

mass of stable air forming an immense dome of high pressure above the Canadian Shield, with winds blowing outward to sweep over Labrador and New England or southward across the Great Lakes and the Great Plains. At its maximum, it extends from the Canadian Arctic Archipelago to the Ozark Mountains. In winter it joins with the Arctic air mass over Greenland to make a formidable body of cold, heavy air that carries subzero weather as far south as the Ohio River valley and may overflow the Appalachians and penetrate into the Rockies. Exceptionally, it can produce killing frosts into the Central Valley of California, the Texas Gulf Coast, and central Florida. In the spring it shrinks northward before the swift advance of the tropical gulf air, which is drawn northward by low pressures developed in the Mississippi River basin as the heart of the continent heats up. This air mass is warm, moist, and unstable; at its height in late July, it extends two enormous loops of warm air, one northwestward up the Mississippi and down the Mackenzie and the other northeastward up the Ohio and down the St. Lawrence. The July average of 60° F (16° C) is then carried north of Edmonton, Alta., in the west and to Quebec in the east. The storm-generating polar Pacific air mass is active from northern California to Alaska, especially in the winter, when its mild, wet air reflects the North Pacific temperature anomalies. When the tropical continental air mass moves to the north and east, it is responsible for extremely hot, droughtlike conditions in the Great Plains in the summer and for mild spells in the Great Lakes region in the fall, the latter period called "Indian summer."

Pacific Coast storm tracks

Storm tracks. Where cyclones (low-pressure cells) develop persistently along the advancing air-mass edges, strong storm tracks occur. Pacific storm tracks thread the Strait of Georgia, Puget Sound, and the Inside Passage to Alaska. In summer they shift north of Prince Rupert; in the depth of winter they migrate southward to San Francisco. Moving up the Columbia and Fraser river valleys, these storms weaken as they pass through the Cordilleras, only to form again on the lee side as they join with a stream of Pacific air that overtops the mountains. These draw in air from the polar continental air mass on their advancing cold sectors and from tropical gulf air in their warm sectors. As the polar continental air mass begins to expand in September, a line of storms tracking from the Mackenzie River to James Bay develops, migrating progressively southward to reach a track from Texas to Ohio in January. As the tropical gulf air mass expands north, the successive tracks become activated again until, in August, the gulf air brings a swirl of storms to the Mackenzie. Most of these storm tracks begin in the western plains, converge on the Great Lakes–Ohio area, and then bunch together in the climatically active St. Lawrence–Hudson–Mohawk zone. The Atlantic Coastal Plain becomes a storm track in winter as tropical maritime air contests the advance of the continental air from the north.

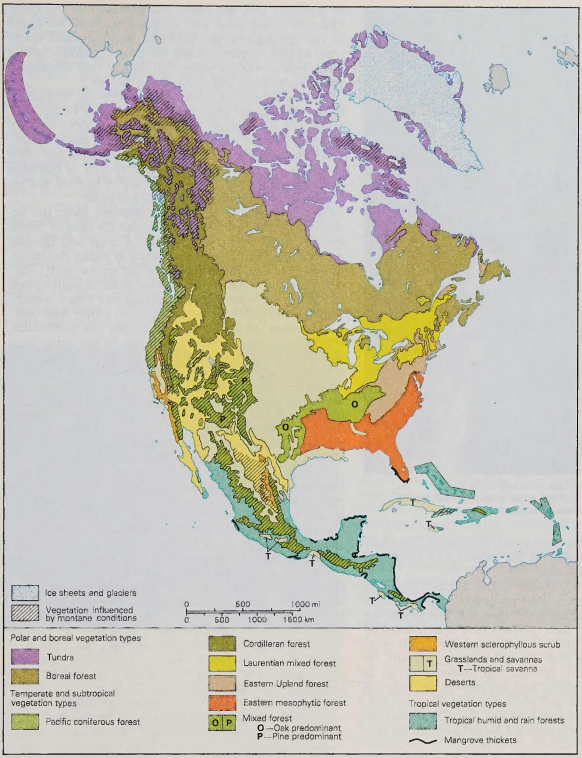
Climatic regions. Differing continental climatic regions reflect the considerable amount of Arctic land, the great spread of temperate conditions, and the small but significant tropical area; dry climates also stand out in strong contrast to the prevailingly humid ones.

The Arctic zone. Including the northern parts of the Canadian Shield and Alaska, the Canadian Arctic Archipelago, and Greenland, the Arctic zone is dominated by Arctic and polar continental air masses and is perennially cold or cool. Temperatures below 0° F (−18° C) last for 5 to 7 months, and subfreezing temperatures can persist for 8 to 10 months. Only between June and September do temperatures frequently rise above 32° F (0° C). The frost-free season does not exceed 60 days. Precipitation is low—especially in the far north—with 2 to 4 inches of summer rain, plus 30 to 60 inches of winter snow.

Zone of long, severe winters

The cool temperate zone. The cool temperate zone extends from Newfoundland to Alaska and from Hudson Bay to the Ohio River. It is dominated by the polar continental air mass. Winters are long and severe. After the period of "Indian summer" that continues into October, temperatures fall quickly and do not rise substantially until April or early May. In January and February they drop to below 32° F (0° C) in the Ohio River valley and below 0° F (−18° C) north of the Great Lakes, with minimum temperatures as low as −20° to −80° F (−29° to −62° C). Winter killing of crops and spring and autumn frosts are a hazard in the Canadian parts of the region, where the frost-free season is from 90 to 120 days. A swift transition occurs with spring; tropical gulf air raises monthly mean temperatures to more than 50° F (10° C) in June and to more than 60° F (16° C) in July. Precipitation is moderate, from 15 to 35 inches; as evaporation is low, however, most precipitation is effective for plant growth. The maximum precipitation occurs in summer to fall, when the James Bay, Alberta, and Wyoming storm tracks are activated and when moist gulf air is in place.

The warm temperate zone. On the southeast coasts of the United States, the warm temperate zone extends to the Mississippi River and over the Gulf Coast; the zone is strongly influenced by the tropical gulf air mass. The long frost-free season exceeds 200 days. The tropical air spreads north in February and dominates the region until November, when polar continental air descends. Winters are mild, with January means of from 40° to 54° F (4° to 12° C). July averages are tropical, being as high as 83° F (28° C).



This warmth and the long growing season allow subtropical crops to be grown. Rainfall is ample (40 to 60 inches) and benefits from the presence of the Colorado and Texas low-pressure systems and from the strong summer movement of tropical maritime air. By then the landmass is intensely heated; and this, combined with the air movement, produces frequent thunderstorms, especially in early summer. Hurricanes are an annual hazard along the Gulf of Mexico and up the lower Mississippi valley.

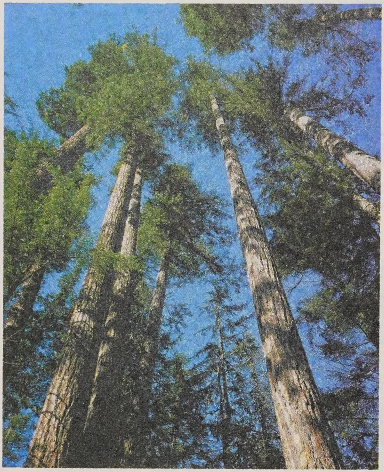
In the American Southwest a Mediterranean type of climate is found. Summers are dry there, since the tropical continental air is dominant. July means of 70° to 80° F (21° to 27° C) are typical, with bright, sunny skies. Winters are mild (45° to 50° F [7° to 10° C]) and somewhat wet, with polar Pacific airs swinging south and bringing occasional heavy rain. Frost is rare but may occur when polar continental air thrusts through to the coast. Los Angeles has a record low temperature of only 23° F (−5° C). Snowfall is rare. Annual rainfall totals of from 15 to 30 inches, along with high evaporation rates, often are insufficient for growing crops during the summer; supplemental irrigation is then necessary.

The tropical humid climate. Central America, with its tropical humid climate, has no winter; even the coldest month averages above 64° F (18° C). With summers of 80° to 82° F (27° to 28° C), the mean annual temperature range is lower than the usual daily range, a characteristic which is markedly different from most of North America. Rainfall is ample and regular, with 45 to 80 inches where the easterly trade winds blow onshore. Lee valleys, however, often are quite dry. Summer hurricanes frequently recur, causing much damage.

Factors in the Southwest's aridity

Dry climates. About a third of North America, including the high Arctic latitudes, has a dry climate. Chief dry areas lie in the American Southwest, where a combination of the mid-latitude high-pressure belt, the tropical continental air mass, and the rain-shadow effects behind the high Sierra Nevada has led to lack of rainfall. Winds blow from the continent outward, discounting the effect of Pacific subtropical air. As the winds move down in altitude from high interior plateaus, they become drier. The intermontane region of the United States and Mexico, from the Columbia River basin to Guadalajara, and the Pacific Coast from San Diego, Calif., south to Mazatlán are therefore arid, receiving less than 10 inches of rain per year. Some years have no rain. The Great Plains, from the South Saskatchewan River to Mexico, are semiarid, with from 8 to 15 inches of rainfall; the high midcontinental jet stream usually is depressed southward over them, strengthening down-moving dry wind from across the Rockies and tending to fend off cyclones from tropical gulf or polar continental air masses. The high Arctic areas are dry because most of the open water (which could act as a source of moisture) is frozen for 6 to 9 months of the year, and because the cold air that dominates the region can hold little moisture.

Vegetation zones of North America.



PLANT AND ANIMAL LIFE

North American vegetation communities and their associated fauna are closely allied to soil, as their habitats, too, reflect the powerful influences of climate. Forests dominate the humid regions and once covered about two-thirds of North America; grassland, scrub, desert vegetation, or tundra typify the dry third of the continent.

Forest communities. *The Pacific coniferous forest.* Offering one of the great spectacles of the continent, the Pacific coniferous forest consists of immense redwoods and firs forming vast cathedral-like groves, where the tall trunks rise hundreds of feet like great pillars to support a canopy of evergreen branches overhead. A long growing season and a heavy, constant supply of moisture have combined to foster the tallest and largest trees found in North American forests; redwoods and western cedar along the north coast of California give way to Douglas fir and western hemlock from Oregon to British Columbia and Sitka spruce in Alaska. In the south red-stemmed arbutuses lend a Mediterranean touch; giant-leaved maple, oak, and ash are common in the middle sector; and birch and aspen are the subdominants in the north. This coastal forest is one of the continent's chief sources of construction timber. It also is a major source of pulp and paper and a home for large numbers of red deer and mountain elk and also of black bear, lynx, and beaver. Fish-eating hawks and eagles abound. North America's greatest runs of salmon are seen there, as the fish swarm upstream to spawn in mountain lakes; while off the Queen Charlotte Islands lies one of the continent's chief halibut fisheries. The meeting of the Kuroshio, a warm current from across the Pacific, with the cool water along the western offshore deeps provides ideal conditions for abundant fish life. The faulted and glaciated coasts with great fjords and perennial rivers attract fish inland and thus facilitate fishing.

Fish-breeding conditions in the offshore deeps

The boreal forest. One of the greatest sweeps of forest in the world, the boreal forest (or taiga) extends in a vast and virtually unbroken sheet of green eastward from the Aleutian Islands through Alaska and northern Canada to the island of Newfoundland. Its conifers are much shorter than those of the Pacific Coast but grow in denser, sometimes almost impenetrable, stands. The boreal forest essentially is the domain of spruce and balsam fir, with various species of pine becoming significant in the west and jack pine and tamarack in the east; interspersed among the conifers are such handy deciduous species as white birch. From Alaska through the Mackenzie plains to Keewatin, white spruce dominates; through eastern Canada and up-

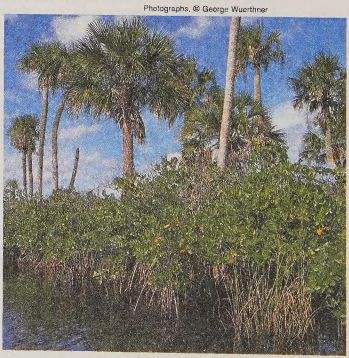
land New England, the black spruce is common, especially on wet soils. The region is the Western Hemisphere's greatest source of pulpwood.

Great herds of caribou shelter in the northern fringes of this forest in the winter. They are preyed upon by packs of timber wolves. Farther south deer, elk, and moose are still common, though their numbers have been reduced by humans. Both black and brown bears are frequently seen, especially in berry patches. Many fur-bearing animals, including martens, mink, beavers, and muskrats, occur, as do squirrels. In the spring pickerel run up the rivers to spawn, and lake trout and whiting live in the cool, deep waters of the innumerable northern lakes. Whitefish are caught in great numbers in Great Slave Lake, but because of pollution they are much less prevalent in the Great Lakes than they once were. Cod and haddock are found in vast numbers on the banks off Newfoundland southward to New England, where the cold Labrador Current mixes with part of the warm Gulf Stream, thus stimulating aquatic conditions and encouraging fish life.

The boreal forest is home to an enormous bird population. Year-round residents include species of jay, owl, raven, and woodpecker, while summer migratory birds include such waterfowl as the common loon, mallard duck, and Canada goose and large flocks of warblers and other songbirds. Summer also brings huge swarms of blackflies and mosquitoes, which are a nuisance to humans but are important as a food source for fish and birds.



The Cordilleran forest. The Cordilleran forest lies between the Pacific coniferous forest and the interior boreal forest. On the west it is made up of cedar and Douglas fir, with Sitka and Engelmann spruce at higher elevations; while, in the east, it has more pine and spruce, with lodgepole pine and white spruce making close, straight-limbed stands. On the intermontane plateaus and ridges, western hemlock and yellow or sugar pine form groves with parkland between. Altitude and aspect dictate tree distribution, with tall and dense fir woods occurring on the wetter faces at lower levels, spruce blanketing the higher slopes, and pine abundant mainly on the drier exposures. At elevations above the tree line, scattered clumps of subalpine firs are found in sheltered areas, these giving way to Alpine tundra at higher altitudes and ultimately to ice and snow on the highest peaks. Animal life is rich there, as this region is the continent's chief game preserve. Species include elk and deer in the fir-spruce forests, antelope in the open parkland, and goats high up in the Alpine pastures. Preying on these are the mountain lion and the occasional pack of wolves. The grizzly bear keeps to higher and less accessible haunts, but the black bear is common in the lower forests. Mountain trout are abundant in streams.

Game animals

The Laurentian mixed forest. Lying in the warm-summer region of the cool temperate zone, the Laurentian mixed forest occurs in the Great Lakes–St. Lawrence, the upper Mississippi–Ohio, and the New England lowland regions. It consists mainly of deciduous hardwoods—beech, maple, oak, and birch—but also has a good deal of coniferous softwood, including pine and the eastern hemlock. White pine and white and red oak once were abundant but have largely been cut for timber. American elm, which formerly was dominant in the moister soils, largely has been killed everywhere by Dutch elm disease. The long, hot, humid days of summer, when tropical gulf air predominates, lead to huge-crowned, large-leaved trees, which shed their cover with the return of winter under

polar continental airs. Rain or snow fall most of the year and thus provide ample moisture for dense growth. Deer are common, especially in areas of partially cleared land where a patchwork of forest and agricultural fields exists; but the moose population has been reduced by overhunting. Wolves, too, largely have been hunted out, a fate that the bear also is suffering, and beavers have been reduced to a small population. Squirrels are still common, but wild mink and marten have become rare. The passenger pigeon that once made this forest its home was hunted to extinction, but numerous other bird species reside there permanently or as summer migrants.

The Eastern Upland forest. Also known as the Acadian forest in Canada, the Eastern Upland forest covers much of the central and southern Appalachians; there, polar continental airs are pronounced, while altitude modifies the tropical maritime winds. The growing season ranges from 90 to 120 days, and winter cold brings subzero temperatures. The forest, therefore, consists of fast-growing evergreen softwood species such as black spruce and balsam fir, along with aspen, alder, birch, and numerous flowering species. Deer are plentiful, as are such small fur-bearing animals as muskrat and squirrel.

The Eastern mesophytic forest. Extending from the mid-Atlantic states to northern Florida, the Eastern mesophytic forest is a mixture of hardwoods and softwoods. On the clays of river bottoms and the coast plain, great-crowned oaks form a tall, dense forest, mixed with hickory, walnut, and yellow poplar on the lower slopes of rivers and with ash and elm on higher slopes. Chestnut and elm at one time were widespread but were virtually eliminated by diseases. With warm summer temperatures and abundant rainfall, many subtropical trees and bushes, such as pawpaws, crape myrtles, magnolias, laburnums, rhododendrons, and mimosas, flourish. Live oaks and gum trees are also distinctive of the area. On the sandy soils left by old stranded shorelines, magnificent stands of loblolly, longleaf, and slash pines form the Southern Pineries, now one of America's major sources of timber and pulpwood. Occasional hurricanes bring torrential rains and high winds to the forest, resulting in the widespread blowdown of trees. The white-tailed (Virginia) deer, black bear, raccoon, and opossum are typical animals. Wild turkey, once plentiful but then made rare through overhunting, have made a comeback.

Mangrove thickets. Ringing southern Florida and the Mexican lowlands facing the Caribbean, mangrove thickets are backed by quick-oak and palms. Ibis fleck the woods with their gleaming white feathers. Water moccasin and other venomous snakes are common in swamps, as are alligators.

The Western sclerophyllous scrub forest. In the hills of southern California and throughout much of the American Southwest the Western sclerophyllous forest occurs. There trees and small shrubs must be adapted both to dry, hot summers when the tropical continental air is dominant and to moist, mild winters when polar Pacific air sweeps down from the north. A thin, short, open scrub of chaparral, or stunted evergreen oak, mixed with yellow pine and sagebrush, is typical. Frequent fires are a natural part of this community, keeping plants widely spaced and giving an impression of openness. Pronghorns, jackrabbits, mountain pumas, coyotes, land turtles, and snakes are common. Hawks are typical, preying on small desert rodents.

Role of fires

The tropical rain forest. Tropical rain forests provide dense covering of all windward slopes in southern Mexico and Central America. The forests consist of such tall, broad-leaved evergreen trees as mahogany, ironwood, and palm, which form a spreading canopy over a lower tier of tree ferns, grape bays, gum trees, rattans, and mangroves laced with lianas and covered with epiphytes. Numerous species of plants are widely scattered in the forest. Wildlife also is varied, with a great number of parrots, cockatoos and nutcrackers, troops of monkeys, and many snakes and iguanas. Leopards are still quite common. Ants, beetles, and flies feed on the decaying vegetation, and bacterial activity is high. This is an environment in which such tropical diseases as yellow fever, malaria, and blackwater fever historically have taken a heavy toll. A dry, tropical scrub of thorn trees, cactus, and sagebrush often replaces forest across a remarkably short distance on leeward slopes and in rain-shadow basins.

Grassland and desert communities. Covering about a third of North America, grassland, desert, and tundra—all virtually treeless environments—are found in the drier and colder regions.

Tropical savannas. Located in patches in subhumid parts of Central America, tropical savannas usually occur at the intermediate levels of the lee slopes of mountains and on plateaus. They are significant in Guatemala and the Yucatán Peninsula of Mexico. Heavy, though short-lived, summer rains bring on a thick rapid growth of tall grasses; cyclones associated with the northeastern trade winds bring enough rain during the rest of the year to maintain a thin cover. Fires and hurricanes are frequent agents that disturb vegetation on the savannas.

Temperate grasslands. The temperate grasslands, or prairies, form a belt between forest and desert, mainly on the Great Plains but also on the mid-slopes of the intermontane basins, above the salty desert flats. At the "break of the plains" on the eastern subhumid margin, invaded by rain-bearing tropical gulf airs in spring and early summer, the grasslands consist of a dense growth of tall grasses, such as big and little bluestem and Indian grass, along with small berry bushes, wild roses, and stunted aspen trees. These are the tall-grass prairies that once were home to most of America's bison, before hunters virtually exterminated the species. "Wet" prairie exists in the middle Mississippi basin, where the annual rainfall exceeds 30 inches; its origin has been attributed to repeated burnings by Plains Indians, either to stampede bison in mass hunts, to burn off trees and thicken the grass to provide pasture, or to expedite travel. Farther west, where rainfall drops below 17 inches (in Texas) or 15 inches (in Alberta), vegetation is less luxuriant, and shortgrass prairie is typical. In the westernmost parts of the plains, grasses are found only in bunches, with areas of generally bare ground and gravel between. The vegetation is made up of bluestem bunchgrass, thin needlegrass, and tough grama and wire grasses, along with patches of cactus, sagebrush, or, farther south, mesquite grass. These regions still pasture many small antelopes, although they mainly have been turned into rangeland for cattle or sheep.

Deserts. Desert vegetation is found in intermontane basins and along arid coasts of the western United States and in northern Mexico. Extensive salt flats and mountains with rocky soils make this a harsh environment for all but the most drought-tolerant plants. Frost and snow are not uncommon in the Great Basin Desert of Nevada, Utah, and Wyoming, which is dominated by sagebrush and by scattered shortgrasses. Creosote bush, saltbush, mesquite, and many species of cactus, including the treelike saguaro, are common in the Sonoran and Chihuahuan deserts of Arizona, New Mexico, and northern Mexico. Animal life is primarily reptilian and tends to be nocturnal.

Tundra. Across northern Canada and on the many islands in the Arctic Ocean lies a vast marshy plain called the tundra. There the growing season is only 45 to 60 days, and frost is possible year-round. Too cold for trees, this community contains only a few plant species, such as sedge, moss, lichen, cotton grass, and heath. In sheltered areas willow and alder shrubs and some dwarf birches are found. Shallow permafrost inhibits infiltration of the already meagre amounts of meltwater and rainfall into the ground. This, coupled with the flatness of the tundra landscape, make for wet, boggy conditions throughout much of the growing season. Biting flies, mosquitoes, and gnats are innumerable. Many species of birds summer in the region; caribou and polar bear are typical mammals.

The human imprint on the landscape. Before the arrival of Europeans in North America, the impact of human activity on the environment seems to have been minimal. The attitude of the European immigrants and their descendants favoured clearing the forests and killing off the wildlife, with the aim of making room for agriculture and urban centres. In a continent that was so vast and at the same time so empty, they also developed the idea

that environmental resources were unlimited and only awaited people to exploit them. It should be remembered that many of these immigrants came from a Europe in which, during the Agricultural and Industrial revolutions, there had been an increasing attack on natural resources, particularly associated with the rise of heavily industrialized cities. When the United States and Canada became industrialized, they used coal, oil, iron, other metals, and wood with extravagance and often with great waste. The waste products of the factories of these nations started to pollute air, land, and water; and, as cities with enormous populations began to appear, most people came to live in an environment sharply modified by human activity.

By the mid-20th century, the people of the United States had killed off about four-fifths of the nation's wildlife, cut more than half of its timber, plowed up nearly all its grassland, and used up two-fifths of its high-grade iron ore; the nation was consuming its oil so fast that, even with its great resources, it began to import enormous quantities from other countries. Soil erosion also became rampant, as agriculture was practiced carelessly or on land with marginal producing capacity. Conscious of the great drain on the resources of the nation and suffering from the increasing ill effects of pollution, the United States began attempts to conserve its reserves of forest, soil, water, fuels, and minerals; and the country has come to lead the world in its conservation programs, particularly in renewing forests and grasslands, conserving soils, and effectively controlling the waters. Canada, too, has an active conservation program and was the first North American country to pass clean-water legislation to help fight the pollution of its lakes and streams. Mexico likewise has initiated an active, though limited, conservation effort. Other environmentally positive actions—such as recycling materials otherwise discarded as solid waste, and energy conversion—have helped in the northern part of the continent to offset the effects of increased population pressure on the land. (J.W.W./R.J.Sc.)

Conservation programs

The people

In global terms, North America long remained a relatively empty and economically undeveloped land until about AD 1500. After that the continent began to receive great numbers of people from the Old World—primarily Europe and Africa—and it underwent a profound transformation. The discussion that follows primarily covers the nonindigenous peoples of mainland North America. The ethnohistory of the North American Indians is treated in more detail in the article AMERICAN INDIANS, and that of the Mesoamerican peoples is discussed in PRE-COLUMBIAN CIVILIZATIONS; for treatment of the peoples in the Caribbean region, see WEST INDIES, THE.

THE NORTH AMERICAN INDIAN HERITAGE

The date of the arrival in North America of the initial wave of peoples from whom the American Indians (or Native Americans) emerged is still a matter of considerable uncertainty. It is relatively certain that they were Asiatic peoples who originated in northeastern Siberia and crossed the Bering Strait (perhaps when it was a land bridge) into Alaska and then gradually dispersed throughout the Americas. The glaciations of the Pleistocene Epoch (1,600,000 to 10,000 years ago) coincided with the evolution of modern humans, and ice sheets blocked ingress into North America for extended periods of time. It was only during the interglacial periods that people ventured into this unpopulated land. Some scholars claim an arrival before the last (Wisconsin) glacial advance, about 60,000 years ago. The latest possible date now seems to be 20,000 years ago, with some pioneers filtering in during a recession in the Wisconsin glaciation.

These prehistoric invaders were Stone Age hunters who led a nomadic life, a pattern that many retained until the coming of Europeans. As they worked their way southward from a narrow, ice-free corridor in what is now the state of Alaska into the broad expanse of the continent—between what are now Florida and California—the various communities tended to fan out and to hunt and forage in comparative isolation. Until they converged in the narrows of southern Mexico and the confined spaces of Central America, there was little of the fierce competition or the close interaction among groups that might have stimulated cultural inventiveness. Although great architectural and scientific advances did occur in Mesoamerica, there was markedly less in the way of metallurgy, transportation networks, and complex commerce than among the contemporary civilizations of Asia, Europe, and sections of Africa. Cities appeared first among the Olmec in the strategic narrows between Mexico and Central America and among the Maya in portions of Guatemala, the Yucatán Peninsula, and Honduras. Subsequently, the Toltec and Aztec created some remarkable cities in the high Mexican Plateau and developed a society whose crafts and general sophistication rivaled those of Europe. These dense populations were based on a productive agriculture that relied heavily on corn (maize), beans, and squash, along with a great variety of other vegetables and fruits, fibres, dyes, and stimulants but almost no livestock.

Cultural achievements

The size of the pre-Columbian aboriginal population of North America remains uncertain, since the widely divergent estimates have been based on inadequate data. Luis de Velasco, a 16th-century viceroy of New Spain (Mexico), put the total for the West Indies, Mexico, and Central America at about 5,000,000; some modern scholars, however, have suggested a figure two to five times larger for the year 1492. The pre-Columbian population of what is now the United States and Canada, with its more widely scattered societies, has been variously estimated at somewhere between 600,000 and 2,000,000. By that time, the Indians there had not yet adopted intensive agriculture or an urban way of life, although the cultivation of corn, beans, and squash supplemented hunting and fishing throughout the Mississippi and Ohio river valleys and in the Great Lakes–St. Lawrence river region, as well as along the Gulf of Mexico and Atlantic Coastal Plain. In those areas, semisedentary peoples had established villages, and, among the Iroquois and the Cherokee, powerful federations of tribes had been formed. Elsewhere, however, on the Great Plains, the Canadian Shield, the northern Appalachians, the Cordilleras, the Great Basin, and the Pacific Coast, hunting, fishing, and gathering constituted the basic economic activity; and, in most instances, extensive territories were needed to feed and support small groups.

The history of the entire aboriginal population of North America after the Spanish conquest has been one of unmitigated tragedy. The combination of susceptibility to Old World diseases, loss of land, and the disruption of cultural and economic patterns caused a drastic reduction in numbers—indeed, the extinction of many communities. It is only since about 1900 that the numbers of some Indian peoples have begun to rebound.

THE EUROPEAN HERITAGE

The European attitudes toward the environment. When European colonizers entered North America, they regarded the continent as a virtual wilderness, one waiting to be settled and developed economically. The indigenous agriculture in what is now the United States and Canada seemed strange and rudimentary to them, and it had made only a slight dent in the vast forests and grasslands. There were no herds or flocks of domesticated grazing animals exploiting the natural pastures, and mineral deposits, water power, and other resources were being ignored by the aborigines. The Europeans saw no reason why they should not claim land they thought could be used to better advantage; and they proceeded to buy out, exterminate, or push out the Indians—when they did not enslave them—and established their supremacy over the land.

The dispossession of the Indians. The process of removing the Indians from their ancestral lands led to bitter disputes. The British tried to end one such problem by setting up the Proclamation Line of 1763 along the Appalachian divide, allowing whites to take over what lay to the east but attempting to reserve what lay to the west as Indian territory. After their independence from Britain, the Americans continued to adopt this ideal of a two-nation state, but in practice the notion soon collapsed as

they pushed the Indian line westward past the Appalachians to the Mississippi River and into the Missouri River valley and other western lands. Nearly all the Indians in the east were displaced to the west and into special zones in Oklahoma, the Great Plains, and the intermontane basins. Even there, their land and their way of life were not respected, as ranchers, railroaders, and homesteaders opened the West to settlement.

The Indian "territories" soon were reduced to isolated "reservations." As a result, most of the Indian population in the United States is now found west of the Mississippi River, usually in drier areas unsuited to productive agriculture. At times the U.S. government has encouraged Indians to leave the reservations and mix with the general population in the large cities of the Midwest and West, a process of acculturation that some—including many younger and ethnically conscious Indians—would claim poses as many dangers to the individual and social well-being of Indians as do the communal misfortunes already brought upon them. Counteracting the forces of assimilation have been increasingly energetic programs to defend and strengthen aboriginal identity.

Canadian reservation system

In Canada the reservation system was adopted at a relatively early date; it protected Indian settlements throughout the east, even in such agriculturally rich areas as the Montreal plain or peninsular Ontario. As the Europeans moved west, care was taken to retain Indians on at least part of their own lands, including such fertile areas as the valley of the Red River of the North and the Fraser River delta. Intermarriage between whites and Indians was much more common than in the United States and produced a sizable community of the French and Indian métis, who in 1869–70 unsuccessfully attempted to set up a separate state in the Canadian prairies.

In both Mexico and Central America, racial admixture has gone much farther. In Mexico, the mestizo population—of mixed Indian and white descent—accounts for some three-fifths of the population, while pure-blooded Indians amount to less than a third, and whites constitute nearly all the rest (a tiny fraction are Mexicans of African descent). European immigration to Mexico and Central America since the original Spanish conquest has been negligible. When Velasco made his tally of 5,000,000 Indians within his jurisdiction, there were only 150,000 Spaniards in the New World.

The policies of the colonizers. *Spanish policy.* Colonial policies strongly affected the evolving human patterns of North America. It often is stated that Spanish interests centred around God and gold—the Christianizing of the Indians and quick wealth from precious metals—but this is an overstatement. The Spanish also were deeply involved in the land, which they developed into huge haciendas (estates) that were worked by tenants or by direct labour in the form of serfs or peons. As a result of this policy, few European settlers were drawn to the lands ruled by Spain, although it did introduce a competent entrepreneurial and professional group into North America—mine owners and operators, proprietors of the haciendas, merchants, administrators, and priests—but few members of the middle and working classes. Little manufacturing was established; and, even though towns were important, they functioned mainly as centres for trade and services. Descendants of the Spanish remain as an elite class in the area colonized by their ancestors.

French policy. The policy of France was much the same, even though the physical conditions of their territories prevented creation of large estates or mining operations. The first Frenchmen on the continent were mostly entrepreneurs interested in the lucrative fur trade who hired Indians to collect and carry furs from the hinterland to the French trading posts. The French opposed, sometimes forcefully, extensive European agricultural settlement. The royal government, however, believed it essential to have a strong European population base in its new holdings. Consequently, it gave large seigneuries, or grants, to landed proprietors who promised to bring in settlers, clear the forest, and develop the country. The seigneurs arrived with the traditional French ideas of tenant farming, a system under which the seigneury was divided into small parcels, each paying rent for the land. Like the Spanish, few of the French wished to live in the New World under Old World conditions. As a consequence, when the British took over from the French in Canada in 1763, there were only about 80,000 French settlers in Acadia and Quebec, whereas the British on the continent then numbered between 2,000,000 and 3,000,000. The French, however, had been there for more than 150 years; and, since their language, religion, school system, and laws were tolerated by the British, the French Canadians were able to retain their identity. The people of French origin now account for about one-fourth of Canada's population and are firmly entrenched in the province of Quebec, with sizable communities in New Brunswick and Ontario and smaller outliers in the western provinces. They form a distinctly Latin element within the Anglo-American realm, and, indeed, many Québécois yearn for an independent French-speaking nation based in Quebec.

The Quebec French community

British policy. British policy promoted, with considerable success, the large-scale settlement of its colonies in North America by freemen seeking land of their own, businessmen trying to found new enterprises, mill owners, craftsmen, professionals, and workers eager to make the most of their own skills, as well as political and religious refugees and landlords intent upon exploiting their grants. The British colonies, therefore, attracted many settlers from the British Isles (including the Irish) with a wide range of competence. The British also opened their colonies to non-British Europeans, notably the Dutch and Swedes and such religious minorities as the French Huguenots and the Mennonites and other dissenting groups from Germany. Under the Hanoverian regime in Britain, many German mercenaries also were settled. In the 19th century the British opened the Canadian west to Germans, Scandinavians, Ukrainians, and Poles on a large scale and later accepted Chinese, East Indians, and other settlers.

U.S. policy. The newly independent United States continued and expanded British colonial immigration policy. Provisions for landownership were even more generous, and—especially after the Southern plantation system and chattel slavery were abolished—opportunities for capitalist manufacturing and trade increased dramatically. The nation welcomed virtually all immigrants from Europe in the belief that the United States would become, at least for whites, the "melting pot" of the world and thus in a sense develop what the historian Frederick Jackson Turner called a "new race of men." A major influx did not materialize until the 1830s, when massive numbers of British, Irish, and Germans began entering, to be joined after the Civil War by streams of Scandinavians and then groups from eastern and southern Europe and the Russian Empire; in addition, small numbers came from the Middle East, China, and Japan.

A decline in immigration from northwestern Europe and concerns over the problems of assimilating so many people from other areas prompted the passage in the 1920s of legislation restricting immigration. Since 1970, however, there has again been a liberalization in immigration policy and a striking change in the demographic makeup of the new immigrants, with large numbers now coming from Latin America, the West Indies, and East and South Asia; significant numbers also come from Europe, Canada, and the Middle East. The number of documented (legal) and undocumented (illegal) immigrants may approach 1 million per year, the great majority of whom are destined for urban centres. In total, somewhat more than 50 million people have migrated to the United States in the span of two centuries, which far outnumbers population movements to any other part of the world.

THE AFRICAN HERITAGE

The slave trade and its consequences

North Americans of African descent originally were brought to the continent involuntarily as slaves. The entire question of the transatlantic slave trade and its turbulent legacy is still fraught with deep emotions—a not unexpected development—since this tragic episode set in motion forces and counterforces that molded much of European and African, as well as North American, society over the course of nearly four centuries. Slaves were not

widely used in Canada or in most sections of New England and the Middle Atlantic states, areas where plantation agriculture never developed, or in Mexico or Central America, where Indian labour could be coerced; but slaves were imported in great numbers to the Caribbean islands and to the Southern states of the United States, where they toiled on tobacco, cotton, sugar, and rice plantations. The importation of slaves to the United States became illegal in 1808, but illicit traffic and natural increase produced a steady growth in the black population. These people lived under conditions that not only were physically difficult but also created social and psychological problems for families and individuals.

The abolition of slavery in 1865 gave blacks, in theory if not in practice, freedom to work and live where they chose. Many, however, saw no alternative to staying on plantations as impoverished tenants or sharecroppers. Economic and technological developments in the 20th century—notably the mechanization of farming—sent large numbers of blacks to the Northern cities, where they became concentrated in ghettos and had to face new problems of racial discrimination in addition to those present in the South. The resulting social and racial polarization struck at the very roots of American society and challenged the validity of its professed egalitarianism. Although the struggle to win full equality made some progress, especially from the 1950s, the cause of black Americans remains far from won. Schooling, housing, social services, and, above all, equitable access to employment opportunity remain major areas of concern. Partly because of this systematic exclusion from the mainstream American society, the African contribution to the life of the nation has given rise to a rich and unique African-American culture.

Black Americans have been the usual and longest-standing victims of racial prejudice in America; but they have not been its only victims. Racism has complicated relationships with peoples from other cultures and continents as well. Hawaii, nevertheless, has become something of a model as a multiracial society; and attitudes on the mainland have matured as the influx of Mexicans, Chinese, Koreans, Southeast and South Asians, and others has continued. The United States increasingly continues to become a polyglot nation. The resulting rich ethnic mix, while generating certain problems, also is one of that nation's greatest assets.

DEMOGRAPHIC PATTERNS

Favourable and unfavourable regions. As an area of late exploitation, North America does not have the high settlement densities of Europe and Asia. The continent's population, however, continues to grow and is concentrated in regions of comparative advantage, such as the coasts, lowlands, and humid and temperate zones. The enormous expanses of the Canadian Shield and of mountainous terrain have discouraged continuous settlement in nearly half of the continent. Settlement is even more problematic in the frost-ridden areas of the Arctic coastal plain and the Mackenzie and Hudson Bay lowlands. Similarly, drought conditions in much of the western parts of the continent limit their use, while the disease-ridden, wet, tropical lowlands of Central America remain relatively empty. Furthermore, some of these sparsely populated areas are becoming emptier, as those who seek better economic and social opportunities move to already crowded regions.

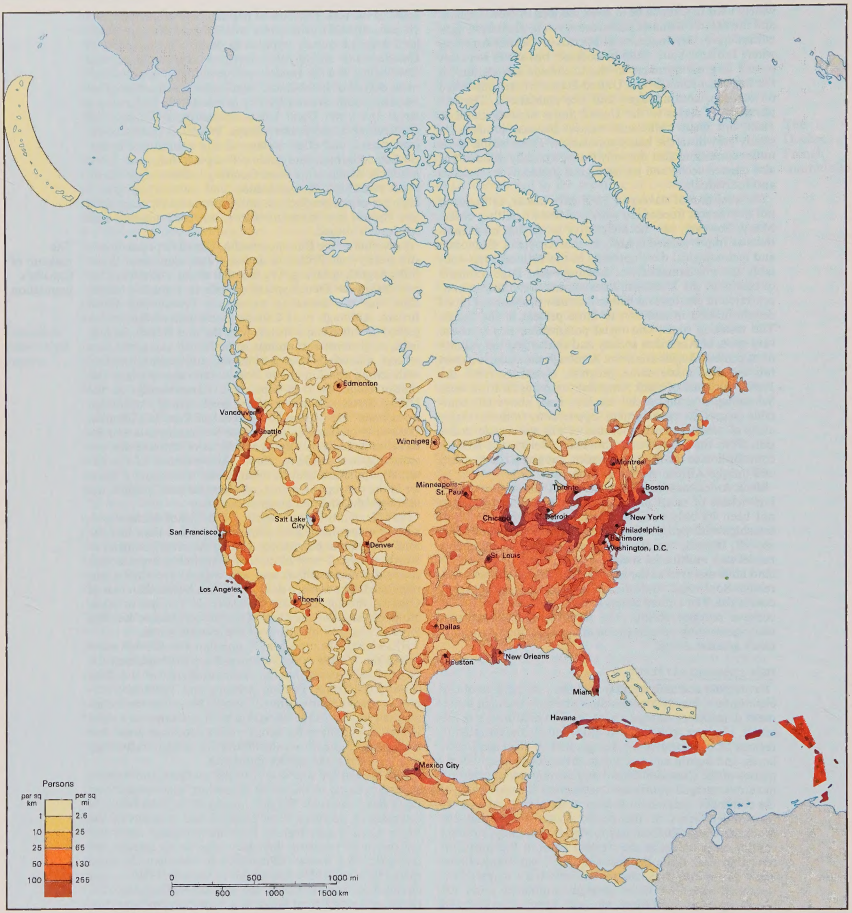
These more densely populated areas include the Atlantic Coastal Plain from Nova Scotia to Florida; the humid, cool temperate belt of southern Canada, with its warm summers; the vast warm temperate zone of the United States centred in the Mississippi-Ohio drainage basin; the mild, moist Pacific Coast from southern British Columbia south to California; and the temperate, yet warm, and well-watered Mexican Plateau and similar portions of Central America. Within these privileged areas, growth is concentrated still further in the large cities, especially those associated with the Atlantic coast from Maine to Virginia, the Hudson-Mohawk gap, the Great Lakes–St. Lawrence system, the Ohio River basin, the middle Mississippi basin, Puget Sound and the Fraser River delta, and the California coast.

Geographic distributions. *The role of Canada.* Canada's share of the total continental population is small (less than 10 percent); and, with some two-fifths of the continent's land area, its overall population density is low. Most of Canada—the shield, the northern Appalachians and Cordilleras, and the tundra and boreal forest zones—is almost devoid of inhabitants. Population is concentrated toward the south, around the Bay of Fundy, the St. Lawrence River and lower Great Lakes, the southern prairies, and the Columbia and Fraser valleys. Wealth is still based on iron, nickel, and other metals; oil and natural gas; hydroelectric resources; and grains, livestock, fish, and forest products. Much of its manufacturing industry depends on these resources. Mechanization and automation give a high per capita production, and it produces far more food and various raw materials than it can consume and thus sells much abroad.

The makeup of Canada's population

A member of the Commonwealth, Canada's population is still nearly half British in ancestry and more than three-fifths English-speaking. The fact that about a quarter of the population is French-speaking reflects Canada's origin from the two founding nations of France and Great Britain. Although most Canadians are native-born, immigration is still a major factor, with the non-British (including U.S. citizens) outnumbering the British among the new settlers. Canada is thus a bilingual, multicultural nation, with strong attachments to Britain and other western European countries. It is dependent, economically, on the United States, the source of the great majority of foreign investment and of some 70 percent of Canada's imports. Ontario is the leading destination for immigrants and internal migrants, but Alberta and British Columbia also are attracting new residents. Some three-quarters of the national population lives in urban areas, with about a quarter in the metropolitan areas of Montreal and Toronto, the leading industrial and business centres.

The role of the United States. The United States dominates the continent, with considerably more than half the total continental population. Unlike the other countries of North America, most of its area is habitable, even though the many mountainous and arid regions are almost unpopulated. The average density is much higher than that of Canada, though still low compared to Europe or Asia. Nonetheless, more than half of the nation's people are clustered in less than one-tenth of the country's area.



Historically, the most heavily populated section has comprised the Middle Atlantic states, New England, and the Great Lakes states; but in the second half of the 20th century California, Florida, Arizona, and Texas have undergone rapid relative growth rates. This influx can be attributed in part to the attraction such amenities as a mild winter climate have for people retiring to those areas, but it also has resulted from the flourishing of high-technology manufacturing and service industries.

Even though the strong shift to the southern and western states has come to dominate migration, other population flows have emerged. Notable among these have been the increases in northern New England and portions of the upper Great Lakes region. Most metropolitan areas still receive more migrants than they lose—both foreign and domestic—but overall urban growth rates have lessened markedly since 1950. Indeed, since the late 1960s a near equilibrium has existed in the exchange of migrants between urban and rural areas, and nonurban environments have become increasingly appealing to many Americans.

The United States has developed its service sector more fully than any other New World nation, with more than two-thirds of its working population thus employed. About one-quarter of all workers are in manufacturing and construction, and the remainder are engaged in primary production, such as farming, mining, fishing, and lumbering. The per capita consumption of material goods in the United States is among the highest in the world.

Immigration

Although only a small fraction of the American population now is foreign-born, immigration is supplying an increasingly large share of the nation's population increase; the birth rate has dropped below the replacement level. Among native-born groups, fertility has been highest among American Indians, Hispanics, blacks, and such religious groups as the Mormons. Less than one-

Population density of North America.

fifth of all black Americans remain in the rural South, as most now live in the larger cities, predominantly in overcrowded inner-city areas. Blacks now constitute the largest single group in most large American cities and represent a majority population in many of them. The inner-city concentration of blacks and Hispanics, one of the more conspicuous features of urban life in North America, has been paralleled by a strong white population shift to the suburbs. About two-thirds of the U.S. population growth has been in metropolitan suburbs, thus often exacerbating the problems of the inner city.

Despite the leveling effects of modern means of communication and travel and the impact of large national and multinational firms, the United States retains much regional diversity in its culture. Even though new regional patterns may emerge—as in southern California or the Hispanic-influenced Southwest—the five principal traditional culture areas of New England, the Midland, the South, the Midwest, and West remain recognizable in a variety of ways. Such cultural complexes are the products of differences in the ethnic identity and social backgrounds of their inhabitants, the date and place of their arrival, and the interaction with physical habitats and historical circumstance that vary from place to place. Perhaps the most closely studied of the relevant phenomena have been the various dialects of a rapidly evolving American English, a language that is clearly distinct from British English and subtly different from Canadian English; and these di-

alects—and subdialects, such as the speech of New York City, New Orleans, or Philadelphia—tend to coincide with other markers of regional identity. Enough also has been learned about the regional aspects of building construction—including barns, fences, farmsteads, cemeteries, and the layouts of towns and villages—to affirm the existence of the older and newer culture areas. A striking 20th-century development has been the emergence of what are called "voluntary regions"—*i.e.,* places to which people of similar tastes or aptitudes tend to gravitate. Some of these regions are relatively large (such as southern Florida, the Ozarks retirement region, or the Kentucky Bluegrass region), but much smaller localities (such as cities in Nevada and Arizona, certain college communities, winter-sport developments in the Rockies, or research complexes in places like North Carolina's Research Triangle) have acquired their unique populations and distinctive ways of life.

American religious diversity

In one major cultural respect the United States has become unique: the sheer number and diversity of its religious denominations. All the world's major religions and sects are represented, and other groups are constantly appearing. Many of these churches were imported from the Old World, but a large number are domestic in origin. Although Protestantism accounts for a large majority of denominations and population, Roman Catholicism is by far the largest single religious community; it accounts for nearly 30 percent of all church members in the United States, but many of its adherents and parishes tend to practice the faith in their own ethnic fashion. There remain significant minorities of Americans professing other faiths—notably Eastern Orthodoxy, Judaism, Islām, and Buddhism—as well as less familiar ones; and, like Protestants and Catholics, these groups often are split along ethnic or doctrinal lines. Certain denominations are closely identified with general culture areas. This is true for the Southern Baptists, the Lutherans of the Upper Midwest, and, most prominently, the Mormons of Utah and portions of neighbouring states. Other denominations that were once localized have become national in scope, such as the Presbyterians who once were clustered in western Pennsylvania and other zones of Scotch-Irish settlement and the Unitarians who were most closely identified with portions of New England.

The role of Mexico, the West Indies, and Central America. The combined areas of Mexico, the West Indies, and Central America have a substantial population, which has been growing rapidly. Although birth rates have been reduced somewhat in Mexico and Costa Rica, overall birth rates remain high, and death rates have dropped to an all-time low; thus, a population explosion has been under way for some time. As in other developing areas, the existing economy can scarcely support the present population, despite the considerable expansion of manufacturing and service industries in Mexico. American capital investment and government aid have been aimed at helping Central America and the Caribbean countries to become self-sufficient; and, although the assistance has been helpful, it also has created problems, such as the massive foreign debts owed by many of these countries. In addition, the impact of such development assistance tends to be concentrated in the capital cities, with little discernible benefit to the rest of the countryside.

If Canada has something approaching the diversity of religions found in the United States, the situation is relatively simple in Mexico and Central America, where the overwhelming majority of inhabitants are at least nominally Roman Catholic or—in the case of many mestizos and aboriginal people—profess a version of Christianity that has become hybridized with preconquest indigenous faiths. As might be expected, the Spanish language also is strongly dominant in these lands, except in those less accessible portions of Mexico and Guatemala where a multiplicity of aboriginal tongues are still spoken. The Spanish spoken in these regions has undergone a transformation from its mother tongue similar to the process that gave rise to American English. Regional dialects have emerged, and the language has been enriched through the adoption of words from indigenous languages.

Dominance of Spanish

The economy

Few episodes in human history have been more remarkable than the economic transformation of North America since about 1700. During the pre-Columbian period, the territories that became the United States and Canada (sometimes called Anglo-America) were areas thinly settled by an aboriginal population that just had begun to practice agriculture on a local scale. In contrast, comparatively old and complex agrarian and urban civilizations had arisen in portions of Mexico and Central America, where relatively elaborate economies and dense populations had developed.

The revolutionary changes occurring after European contact and occupation were the result of an extraordinary combination of circumstances, at least in the United States and Canada. The large numbers of energetic immigrants from a rapidly modernizing western Europe, who brought with them the newest technological advances, encountered a habitat that afforded them ample opportunity to create considerable wealth. Many of the vast regions they encountered were well watered, covered by rich, exploitable forests and productive soils; underlain by considerable mineral resources; and blessed with a climate tolerable to Europeans. Moreover, the configuration of ocean shorelines, rivers, lakes, and landforms rendered feasible the construction of a dense and efficient transportation system for both domestic and foreign commerce. In addition, throughout nearly all of this economic transformation, the huge expanse of the continent north of Mexico has been controlled by two remarkably compatible nations—the United States and Canada—which, in their political orientations, have actively promoted aggressive economic development. The outcome of all of these circumstances has been a level of physical well-being for their citizens that ranks among the highest in the world. Finally, during much of the 20th century the United States has been the world's dominant power in terms of financial resources and economic influence—as well as in agricultural, mineral, and industrial output—and in general it has been the locus of an inordinate share of worldwide production and consumption.

Development in Latin America

Since the time of the Spanish conquest, the economic development in Mexico, Central America, and the Caribbean region—which constitute the northern portion of what often is called Latin America—has been much less pronounced. The failure to attract large numbers of immigrants (aside from African slaves and East Asian labourers in the West Indies), the fragmentation of Central America and the Caribbean into small colonies or sovereign nations, and the perennial political instability throughout the region have all inhibited development. The quantity or quality of natural resources has been less crucial than social and political factors in relegating these lands to peripheral or so-called underdeveloped status within the world economy. (New England, for example, prospered despite distinctly mediocre physical resources.) Whatever economic well-being these Latin American and West Indian countries now enjoy depends to a large extent on the export of minerals and the products of plantations, forests, and the sea and on the infusion of foreign capital and expertise. This has given rise to an economic system in which only a small number of individuals in certain advantaged areas of the region have benefited from the wealth generated by economic development, while the great majority of the region's population has remained impoverished and little affected.

This so-called core-periphery model of development also is evident—though to a lesser extent—in the United States and Canada. Large disparities in social and economic attainment exist between such generally affluent areas as the northeastern Atlantic Seaboard of the United States, the California coast, and the more urbanized areas of Ontario and Quebec and such economically depressed regions as the southern Appalachian Mountains, the lower Mississippi River valley, and Newfoundland. On a smaller scale, notable differentials can be discerned among neighbourhoods in individual cities and among communities within urban areas.

RESOURCES

North America has rich and varied resources. Although it contains less than 10 percent of the world's population, it has an extraordinarily high proportion of the world's resource wealth. It produces a substantial percentage of the world's oil, iron ore, steel, copper, lead, and zinc. With a large percentage of the world's coal and oil output and electrical power production, it possesses the critical elements of modern industry.

Metallic minerals. *The shield.* With a large shield area and mountains strongly intruded by igneous rocks, the continent is well endowed with metals. Its vast interior lowlands and some long stretches of coastal plain are areas of major fossil-fuel formation. Metal-bearing regions include shield structures affected by mountain building or trough development, together with the intensely folded ridges that rose from the eugeosynclines (narrow subsiding troughs that fill with debris) on the periphery. The shield has four main metal-bearing areas: the iron of the Adirondack Mountains and Superior Upland in the United States; the iron-nickel-copper and gold belt of Ontario and Quebec, along the old fold zones north of Lakes Superior and Huron; the iron of the Ungava Peninsula; and the copper, nickel, gold, and uranium of the fault and fold systems of the shield's western rim. Three areas are of special importance: the taconite hematite ores of Mesabi and Ungava, mined with relative ease by opencast, or open-pit, methods; the world's largest deposit of nickel in the norite ore body at Sudbury, Ont.; and the large copper and gold bodies associated with the greenstone intrusions in northern Ontario and Quebec.

The marginal mountains. The Appalachians also are endowed with significant metallic deposits, especially in the median mass between the Caledonian and the Acadian folds, where lead and zinc are found in Newfoundland and New Brunswick; and also in the eastern or outer intensively folded rocks, with iron deposits in Belle Isle (Nfd.), the Trenton (N.J.) prong, and the Birmingham (Ala.) basin.

Deposits in the Cordilleras

The Cordilleras are rich in ores, mainly because of the immense igneous intrusions that underlie many of their structures. The median mass between the Laramie–Rockies and the Sierra Nevada–Cascade systems has major gold, silver, copper, and iron ores in the old plateau of Colorado and Utah. Large lead, zinc, and copper ore bodies occur in the Selkirk Mountains and adjacent ranges of British Columbia. Famous silver, lead, zinc, and gold deposits dot the Cassiar Mountains and upper Yukon River in the north; and, far to the south, the Mexican Plateau holds iron, lead, and silver ores. To the east of this long, north-south line of plateaus lie the Rockies, which were not intensively folded and hence are not as rich in metals

Basic structural regions and principal mineral and hydroelectric sites of North America.

as other mountainous regions of the continent; but the vast intruded mass of the Idaho Batholith and the igneous bodies in the Dome and Peak region were associated with copper, silver, and lead ores of great importance. The Western Cordilleran ore deposits are widespread. They are found linked with intensively folded and intruded rocks of the Sierra Nevada–Cascade–Pacific Coast systems, notably the copper and gold ores of southern and western Alaska. They also include the copper, lead, zinc, and iron ores of the enormous Coast Batholith of British Columbia; the gold, copper, and iron deposits in Arizona and in the Sierra Nevada, where the discovery of gold touched off the famous gold rush of 1849; and the copper, gold, and silver of the Sierra Madre Occidental of Mexico.

Other metallic minerals. With the exception of iron, copper, lead, zinc, nickel, gold, and silver, North America has a mixed endowment of the metals needed for advanced industrial production. Of the various ferroalloy metals that have become essential for industrial and military purposes, only molybdenum is abundantly available, while chromium, manganese, vanadium, tungsten, titanium, cadmium, and cobalt are imported and stockpiled. Domestic reserves of mercury, barites, and uranium may be adequate, but the continent is deficient in tin, platinum, and bauxite (the principal ore of aluminum).

Nonmetallic minerals. The nonmetallic mineral wealth of the continent also is great, particularly in coal, natural gas, and oil. These fuels accumulated as carbon deposits in the lakes and shallow seas of the great lowlands stretching between the shield and the marginal mountains. They also underlie portions of the coastal plains and the continental shelf, particularly in the Atlantic and Arctic oceans.

Coal deposits. Coal deposits were preserved in basins between gentle upwarps in the buried extensions of the shield beneath the Interior Lowlands and also in mildly folded rocks in the miogeosynclines of the inner, less disturbed parts of the Appalachians and Cordilleras. Below the Mississippi-Ohio lowlands and the Great Plains, the outer edge of the shield was depressed and buried, after which it buckled into basins and warps. The Cincinnati Anticline created a vast elongated basin between the middle Ohio River and the Appalachians, in which the western Pennsylvania, West Virginia, and Kentucky coalfields were preserved—probably the single largest coal reserve in the world—together with the Lima (Ohio) oil field. The Kankakee Rise, south of the Great Lakes, has preserved coal and oil in the Michigan (Saginaw) Basin, to the north of it, and the Indiana and Illinois basins, to the south. The last-named basins, also called the Eastern and Western Interior fields, are separated from each other but kept close to the surface by the La Salle Anticline. The Llano uplift similarly has helped to form the Southwest Interior field in Texas.

Coal reserves of the Cincinnati Anticline

An enormous mid-continental arch, the stem of the ancient Y-shaped structure connecting the Canadian Shield with the Colorado Plateau, separates the interior from the western coalfields lying in basins in front of the Rocky Mountains. Seams of bituminous coal occur in the Raton Basin, which is cut off from the Denver Basin by the Las Animas uplift. The huge Williston Basin extends farther north, but it contains rather low-grade coal. Beyond it lies the vast Alberta Basin, with coal exposed in the foothills of the Rockies; this basin also contains one of the largest coal deposits in the world.

Oil and natural gas deposits. The same coal-containing "rises" and basins in the buried shield also have controlled the distribution of oil and natural gas. The Appalachian oil and gas basin, in Pennsylvania on the western flanks of the Appalachians, was the first to be developed. The Illinois, Kansas, and Oklahoma basins lie in the huge quadrilateral formed by the Cincinnati Anticline and mid-continental arch to east and west and by the Kankakee rise and Ozark Dome to north and south. Between the Ozark Mountains and the Sierra Madre Oriental of Mexico are the tremendously productive fields of West and East Texas and the Gulf Coast. Northward, between the mid-continental arch and the Rockies, are found a number of important fields, including the Denver, Big Horn, and western Alberta fields, close to the Rockies, and the Williston, eastern Alberta, and Mackenzie River valley areas, halfway toward the shield. Small fields of oil and gas lie on the flanks of folded mountains within the intermontane zone, as at Paradox, Utah, and San Juan, N.M. The western basins, bordering the Pacific Coast Ranges of California, are of moderate size but very rich. In the extreme north, the Prudhoe Bay basin of Alaska and Mackenzie delta oil have proved that the potentialities of the Arctic shore are real; domes—very much like the salt and sulfur domes of the Gulf Coastal Plain, associated with Louisiana's oil and gas—go with oil on the plains sloping away from the Innuitian fold mountains in the Canadian Arctic Archipelago. Large, though unexploited, oil reserves also occur in the form of oil sands in Alberta and oil shales in Utah and Wyoming.

Arctic oil reserves

Other nonmetallic minerals. In general, North America contains ample supplies of nearly all the more economically important nonmetallic minerals. Few populated places are far from sand and gravel deposits of commercial quality and quantity. Several regions have essentially unlimited amounts of excellent clays for the ceramic industry; limestone for fertilizers, cement, road building, and other uses; and nitrates for farms and the chemical industry. Southeastern Quebec is a principal source of the world's asbestos; the United States—Florida and North Carolina in particular—accounts for a third of the world's phosphate production and dominates the helium market (mainly because of wells in Kansas and Texas); while immense tonnages of borax are mined in California, and North Carolina has substantial mica resources. A fifth of the world's sulfur comes from Texas and Louisiana, areas which together with Ohio, western New York, and lower Ontario account for virtually unlimited amounts of salt. Among the sources of high-quality building stone are Vermont and northern Georgia for marble, Pennsylvania and New York for slate, and southern Indiana for limestone. Mexico and the United States also produce many semiprecious stones, while Mexico is second only to Australia in opals.

Water resources. Considered as a resource, water and waterpower are also abundant, although supplies are rather unevenly distributed. The average rainfall in North America is 30 inches a year, which produces some 15 billion acre-feet of water. About half of this is lost through evapotranspiration, which is direct evaporation plus transpiration from plants. A further sixth is lost through rapid runoff, while yet another sixth percolates down into the groundwater. The amount available from rivers and lakes is thus relatively limited, a fact of growing concern as demand for water grows. It takes 16,000 gallons of water, for example, to produce one ton of steel, while an average steam-generated power plant requires 4,000 cubic feet of water per second. The gap between use and availability is widening, although such measures as tapping artesian water have increased considerably—at least for a time—the overall supply.

The water resources of the continent vary with regions. In northern Alaska, the Canadian North, and Greenland, they are low, mainly because they are locked up in ice most of the year; when the summer melt comes, runoff is high. Central Alaska and mid-northern Canada have a moderate precipitation of from 12 to 15 inches per year, but again much of this is locked up in winter ice. The spring melt leads to extensive flooding, which makes the control of water difficult. Late summers are dry, but evaporation is low. Though rivers dwindle, they generally carry enough water to meet demand.

The Great Plains area also has marked high- and low-water periods, the latter posing serious problems. Most rivers rise in mountains to the west, where usually there are extensive snows. Meltwater gives an early spring flush, and high flow is continued into early summer through storms generated by the tropical gulf air. In late summer and fall, however, the storms cease, and the rivers drop. Streamflow originating within the region may dry up, while bigger rivers may sink into braided channels between bars of sand. Evapotranspiration also exceeds precipitation, a loss not made up again until early winter with the return of polar-front storms. Surface water therefore is scarce for

Water problems in the Great Plains

four to five months and often needs to be supplemented from groundwater.

The intermontane basins stretching from southern British Columbia to central Mexico exhibit a strikingly unequal pattern, with areas of water surplus in the mountains lying adjacent to areas of marked deficit in the basins. Major rivers like the Columbia, Colorado, Rio Grande, and Guadalajara rise in snowy or rainy mountains and supply enough water, especially where their waters are trapped by dams, to serve the basins through which they flow. Lesser rivers, however, often cease flowing and are intermittent or ephemeral. Groundwater supply in areas with artesian wells alleviates the situation.

The eastern parts of southern Canada and the United States have ample water, with rainfall in most months, as the southern movement of polar continental air and the northern expansion of tropical gulf air draw storms regularly across the area. Rainfall is from 30 to 60 inches a year, and evapotranspiration does not exceed precipitation except in late summer. Streamflow is perennial, averaging more than 10 inches in depth per stream each year.

Finally, the tropical areas in the trade-wind belts in Central America are well supplied with water, yet less is available than might be expected owing to swift runoff after heavy rains and high evaporation. Rivers are relatively short and steep and are prone to flash flooding.

Biological resources. The coming of Europeans and their activities over a period of some five centuries have vastly transformed the plant and animal life of North America. Paradoxically, it is the creatures of the ocean—the earliest biological resources to be heavily exploited—that have undergone the least change qualitatively. Because of a favourable conjunction of ocean currents, the waters off Labrador, Newfoundland, Nova Scotia, and New England have maintained rich marine populations; and, despite heavy, often excessive fishing since the late 15th century, such sought-after species as cod and haddock are still available in some abundance. More recently, the waters and estuaries farther south in the Atlantic, Gulf of Mexico, and Caribbean Sea and off the Pacific coast have become economically important for their fish and crustaceans. Overfishing and pollution have reduced considerably the significance of major inland rivers and the Great Lakes, although sport fishing is popular in many of the more sparsely settled areas of the United States and Canada. On the other hand, pond-raised catfish and other species have become increasingly important, and promising experiments have begun in cultivating oysters, crabs, shrimps, and other varieties of seafood.

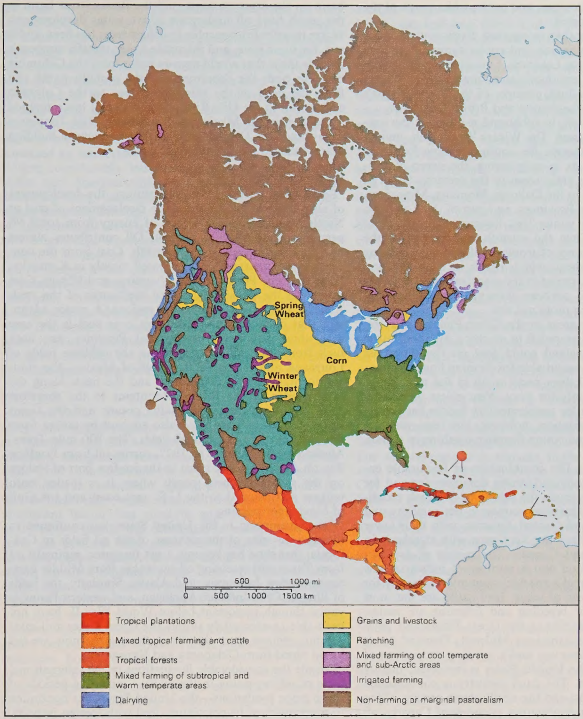
Loss of original vegetation

The most striking changes to North America's flora have been in the magnificent forests that once covered much of the eastern half of the United States and those sections of eastern Canada south of the shield and in the formerly luxuriant grasslands that fanned out westward in a large triangular shape from central Ohio. A combination of extensive clearing for fields and pastures; exploitation for fuel, construction, and industrial uses; and the impact of various introduced pests on species of elm, oak, and chestnut have reduced the original vegetation to only scattered patches of virgin woodland and a few tiny remnants of the original prairies. A similar retreat of forests has occurred in Mexico and Central America because of strong pressure for space and resources by a rapidly expanding population. Change has been less noticeable in the subarctic boreal forest (taiga) of Canada and Alaska because of its remoteness and the thinness and poor quality of the trees, but the southern third of this forest is a major base for pulp and paper industries. The much reduced northern mixed and eastern hardwood forests have lost most of their former value, as the original stands have been replaced by commercially marginal second- and third-growth trees; these woodlands have become attractive, however, for recreational purposes. Some forests of the Pacific Coast and Cordilleras still contain some excellent stands, and, with controlled use, growth usually is rapid enough to produce a steady yield. The Southern Pineries, long neglected by farmers because of sandy soils, have become a major source of timber and pulpwood for the United States. The tropical hardwood forests are also important for timber, but much has been cut down and replaced by banana plantations or poor second growth. Oak and pine forests above 3,300 feet in the *tierra templada* ("temperate land") remain a useful resource.

Early European explorers and settlers in North America were delighted by the abundance and variety of its endemic wildlife; and the various mammals, birds, and fish were important as sources of raw materials as well as food for aborigines and European pioneers. For many years, hunting and fur trapping were dominant activities throughout much of Canada and the wooded tracts of the United States. Excessive exploitation and changes in land-use patterns brought about the near extinction of some species (such as the beaver and bison) and the disappearance of others (such as the once superabundant passenger pigeon), so that the harvesting of wild creatures has become minor in significance. On the other hand, recreational hunting—for deer, bears, turkeys, geese, ducks, and other such controlled populations—is a large industry in many areas of Canada and the United States. It is important to note that the introduction of Old World domesticated animals has changed considerably North America's plant cover, especially where overgrazing has occurred in much of Mexico and the western United States.

MINING, FORESTRY, AND FISHING

Essential though they were to the continent's economic development, three of North America's primary industries—mining, forestry, and fishing—now account for only a small share of total continental economic output and nonagricultural employment. Part of the explanation lies in the depletion of resources, especially within the United States, and an increasingly heavy reliance on imports. The advent of mechanization also has lowered demand for labour while keeping productivity at a high level, at least locally. The relatively minor role of fish in the American diet has kept the domestic fishing industry from flourishing as it might have otherwise, although Japanese, Russian, and Scandinavian vessels intensively exploit the rich North Atlantic and North Pacific fisheries for their home and export markets. The inland and upland concentration of so much of the Mexican and Central American population has inhibited development of marine resources except for export to other lands.



Local fisheries

Despite the relative insignificance of these industries in the total economy, they are crucially important in certain localities. Thus, fishing is still a dominant activity in much of Newfoundland, Labrador, and sections of the Maritime Provinces. Within the Gulf of Mexico and Pacific coast fisheries (from which most of the catch goes into animal feed and industrial products), many coastal towns are economically dependent on their fishing fleets, as is also true for some communities along Chesapeake Bay and the New England coast. Despite drastic reductions in the work force in the bituminous and anthracite fields of the Appalachians, coal still dominates the economy of much of West Virginia and eastern Kentucky, and strip-mining is now a major economic factor in Montana and Wyoming. Oil and gas extraction, which accounts for most American mining employment, is of central importance to the welfare of Texas, Oklahoma, and Louisiana. The fortunes of Alberta rise and fall with the price of petroleum, while the production and export of oil is of great importance to the economy of Mexico. Similarly, the cutting of trees for lumber, plywood, pulpwood, and fuelwood is a major source of income for much of the Pacific Northwest and the Gulf and South Atlantic coastal plains and dominates large portions of Quebec and Ontario. Although Canada remains one of the world's principal exporters of wood and wood products, the United States must import a large share of its overall needs.

AGRICULTURE

The various peoples who developed North America have made it a world economic leader and, in general, a well-used and productive continent. Agriculture, though no longer the principal economic activity (except in some of the southern Latin nations), is still important.

Tropical regions. In tropical areas, the Spaniards made

Agricultural regions of North America.

the most of the strong altitudinal zonation by raising sugarcane in rainy parts of the low *tierra caliente* ("hot land"), wheat and cattle in the middle levels of the *tierra templada* ("temperate land"), and sheep on the upper slopes in the *tierra fría* ("cold land"). Later, orange groves and coffee, cocoa, and banana plantations were established on the coastal plains and wet windward slopes of the tropical areas; and cotton and hemp were grown in the warmer and drier basins of the intermediate zone. These remain important export crops for Central American countries and Mexico, being shipped mainly to the United States and Europe.

Subtropical and warm temperate regions. An enormous extension of fruit, winter vegetable, cotton, and tobacco farming has occurred in the subtropical and warm temperate areas of the United States and northern Mexico. Citrus fruits do well in Florida and the Rio Grande valley of Texas, where the Gulf of Mexico brings warm tropical air with early rain but much late-summer sun. The Central Valley of California—guarded from frosts by the Sierras, with winter rain for growth and prolonged summer sun for ripening—also is a prime area for growing fruit and vegetables. Drought is a challenge, however, and has been met only by extensive irrigation. Winter vegetables are widely grown on the sandy soils of the Gulf Coastal Plain and the southeastern parts of the Atlantic coast, which have a long frost-free season and ample rain. Cotton has proved a success in areas with less than 60 inches of rain and more than 200 days free of frost. Tobacco is concentrated on the sandy soils of old shores and deltas from Virginia to Kentucky. Many tobacco and cotton fields are now alternately planted with rye, corn (maize), soybeans, and winter wheat grown as fodder for cattle or as additional cash crops. These help to maintain the fertility of the soil, which long has been threatened by the practice of monoculture.

Cool temperate, humid regions. Crops of the continent's cool temperate, humid regions include hardy fruits grown on the valley sides of the Appalachians and the Piedmont from Georgia through Virginia, in the Finger Lakes region of New York, in the Niagara Peninsula of Ontario, on the eastern shore of Lake Michigan, and in parts of the Columbia River basin in Washington and British Columbia. In all these areas, aspect, frost, and drainage are important factors.

The Corn, Dairy, and Wheat belts

The zone known as the Corn Belt derived its name from the preponderance of corn grown in the warm-summer region that extends westward from the Ohio River to the lower Missouri River, although soybeans have come to rival corn as the leading field crop. In this region winter snowmelt, rains from the northward springtime surge of tropical gulf air, and early summer convection showers bring on the plants, while strong late-summer sun and high temperatures ripen the cobs and bean pods. Most of

the corn is fed to fatten pigs and cattle, while much of the soybean crop is exported.

The Dairy Belt, another recognized division, makes use of a shorter growing season and cooler summers in New England and the Great Lakes–St. Lawrence region, where clover, timothy hay, and hardy small grains thrive. Dairying also exploits the lush pastures of the Pacific Coast's equable climate in Washington and British Columbia.

West of the Corn Belt, in subhumid regions, lie the continent's vast wheat areas. The Winter Wheat Belt, mainly in Kansas and Oklahoma, lies south of killing frosts. As the polar front retreats in early spring, the sweep of rainstorms brings on the grain sown in the previous fall. The Spring Wheat Belt—in the Dakotas, Montana, Minnesota, the Canadian Prairie Provinces, and part of the Columbia basin—has a severe winter that forces postponement of sowing to spring. Then the warmth and wetness of the sudden northward surge of tropical gulf air quickly bring on the new-sown wheat, which ripens in a usually dry, sunny fall. Wheat farming takes place on an ever larger scale than corn and soybean farming, using more machines and producing more per acre.

Dry regions. Dry areas in the Great Plains and intermontane basins long were left to ranching. Hereford cattle brought in from England could feed on the shortgrass prairies, which were unsuitable for farming homesteaders. Sheep, raised in still drier parts or up in the mountains, have been bred mainly for wool. Near rivers or in artesian areas, irrigation for supplementary fodder has greatly helped ranching. Irrigation, however, has been used increasingly for fruit and cotton farming, resulting in a drain on water supplies.

Livestock raising. The combination of favourable environmental conditions and strong domestic demand for animal products has made the raising of livestock prominent in the North American economy; but quantity and quality in Mexico and Central America, with their lower purchasing power, have not kept pace with standards in the United States and Canada. The raising of domesticated animals for food and a number of industrial raw materials has generated a specific economic geography for each species. In terms of value, beef cattle are the most important, and their breeding and fattening are major, often dominant activities in the Great Plains and adjacent sections of the American Midwest. Demand tends to outrun supply, however, and a growing proportion of beef consumed in the United States is imported, mainly from Latin America. The dairy industry is concentrated in the Upper Midwest and the northeastern section of the United States and neighbouring portions of Canada, all areas that provide the appropriate habitat and are near major markets. The production of hogs and pigs may be widespread, but some three-fifths of North America's commercial output is concentrated in five Midwestern states. Mutton and lamb never have figured significantly in North American diets (although kid meat is highly esteemed in Mexico), and so a relatively small number of sheep are raised primarily for wool; sheep ranching is limited to a few tracts in the Great Plains, the intermontane basins, and California. Since about 1970 the consumption of red meat has declined as awareness of potential health risks associated with it has grown, and there has been a subsequent increase in the consumption of poultry; large-scale poultry production has expanded sharply in Southern states from Arkansas to Maryland, where land and labour for a factory-like industry are cheap and abundant.

Poultry production

WATER DEVELOPMENT

Water development is crucial both to circumvent drought and to prevent flooding. Roughly 50 million acres of irrigated land have been developed in the United States, with large dam projects and conduits in the Columbia and Snake river valleys, the Central and Imperial valleys of California, the Salt and Gila tributaries of the Colorado River, the upper Rio Grande, and the upper Missouri and the upper Platte rivers. In western Canada a vast scheme has been under development on the Bow and South Saskatchewan rivers; while in Mexico the lower Rio Grande (shared with the United States), the Fuerte River basin on the dry west coast, and the Balsas River basin in the south have all undergone active water development. Water transfer from surplus to deficit areas has been under way for some time, and interstate water-transfer proposals include those that would convey water from the Columbia basin to both the Sacramento and Colorado rivers and from the head of the Missouri system to the Colorado and thence to the Gila River. Flood control has remained a problem in the Mississippi River basin. The Tennessee valley and the Ozarks schemes have involved building many dams to redistribute river water.

ENERGY DEVELOPMENT

Fossil fuels. During the 20th century, the development of new fuels caused the dramatic displacement of coal as North America's major source of energy from some 90 percent to less than 25 percent. Oil contributes almost half, and natural gas about a fourth. Coal from the continent's vast reserves is concentrated mainly in Kentucky, West Virginia, Pennsylvania, Wyoming, and Illinois. Coal is sent to the power plants and steelworks of the mid-Atlantic and lower Great Lakes regions. A major advantage that oil and natural gas have over coal is the ease with which they can be transported. Pipelines carry both fuels from their remote sources in the offshore fields of Louisiana and Texas in the Gulf of Mexico, the mid-continental fields of Oklahoma, and the fields along the eastern edge of the Rocky Mountains to the shoreline cities of the Atlantic and Pacific oceans and the Great Lakes. Large amounts of oil also are sent by tanker from the ports close to the gulf oil fields. The 800-mile Trans-Alaska Pipeline, opened in 1977, carries oil from Prudhoe Bay on Alaska's Arctic coast to the ice-free port of Valdez on the state's southern coast, where it is loaded onto tankers and shipped to the U.S. west coast and the Gulf of Mexico for refining.

Oil consumption in the United States has continued to increase. In spite of the richness of the oil fields in California, that state has become a net importer, piping in oil from Texas and receiving oil by tanker from Middle Eastern countries, Indonesia, and Alaska. Similarly, the fields of Illinois, Ohio-Indiana, Michigan, and western Pennsylvania, though important before World War II, have not been able to adequately supply the Great Lakes and mid-Atlantic regions since that time; those areas now are fed by oil piped from Oklahoma and Kansas.

Despite the considerable fluctuations in the international price of oil beginning in the 1970s—including periods of sharp price escalations—the United States has continued to meet much of its petroleum need with foreign imports. In Canada the industrial regions in Vancouver, B.C., and the lower Great Lakes–St. Lawrence area are fed oil and natural gas by pipe from Alberta; and in Mexico, oil is supplied to Mexico City by pipe from the Gulf Coast oil fields around Reynosa and Tampico-Tuxpan, and natural gas is piped to Monterrey from gas fields around Reynosa.

Oil pipelines

Hydroelectricity. Hydroelectric development has been immense in the United States and Canada. The rivers of the Canadian Shield, fed from lakes and falling abruptly over the edge of the plateau, provide many sites, especially in Quebec and Ontario. These are linked to such Great Lakes–St. Lawrence sites as Niagara Falls and International Falls, which, in turn, tie in to a power grid developed from Appalachian rivers. The north-central and northeastern areas are thus well supplied.

The snow-fed rivers from the high Cordilleras, where impounded (as at the Grand Coulee, Hoover, Glen Canyon, Fort Peck, and Garrison dams), also provide an immense amount of power. Yet, in the United States, hydroelectric power represents only a small percentage of the total electricity generated, nearly all the rest coming from coal-, gas-, or oil-fired thermal plants and from nuclear-power stations.

Nuclear and other sources. Since the 1950s the United States has put more than 100 nuclear power plants into operation in more than 30 states—the largest total for any country—while Canada has built close to 20. Nevertheless, nuclear-generated electricity accounts for a relatively modest share of North America's total energy budget:

less than 20 percent of all electricity generated in the United States and only about 1 percent of all the energy the nation consumes. The initial predictions that nuclear technology would assume a much larger role in the energy economy have not been realized for several reasons: costs of construction and operation have been higher than anticipated; it has been difficult to find plant sites that are technically and politically acceptable; plant operation and maintenance have been subject to frequent problems; and the safe, long-term disposal of radioactive wastes has remained an intractable problem.

Other considerably less complicated technologies that utilize such inexhaustable resources as solar and wind power for energy production have been making slow but steady progress, although they supply only a tiny fraction of the continent's energy. Tens of thousands of homes and commercial structures have installed rooftop solar collectors for heating and cooling purposes; and research and development has continued to enhance the efficiency of photoelectric cells that convert sunlight directly into electricity, which has potential for widespread use in the sunnier sections of the continent. More limited geographically is the potential exploitation of geothermal and wind power, but experimental projects in some favoured localities have confirmed the practicality of technologies created to utilize these energy sources.

INDUSTRY

The role of ports in industry

Coastal sites. The industry of North America is its chief contemporary source of wealth. It first developed at Atlantic coast and Mississippi River ports, where raw materials transported from abroad or brought by coastal trade from other colonies could be made into goods for distribution in the interior. Inland products also could be transformed before being exported from such ports, where immigrant labour was plentiful and capital brought in or developed locally was abundant. In many respects the ports still perform these roles. New England ports bring in wool, leather, hardwoods, and metal from abroad and cotton from the Southern states; New York City imports coffee, cacao, sugar, timber, pulp, and oil; the Philadelphia region brings in great quantities of iron from Canada and Venezuela and oil and petroleum coke from the Gulf of Mexico; together these cities manufacture textiles, leather goods, petrochemical products, iron and steel, ships and machines, books, clothes, and foods not only for their own dense populations but also for the interior United States. In spite of the enormous development of the interior, coastal sites (including those on the Great Lakes and Pacific coast) have remained paramount. From Buffalo, N.Y., to Chicago, the movement of coal from the Appalachian and eastern interior fields up to the lakeshore, combined with the shipment of iron ore from Lake Superior and Ungava to the lake ports, has led to a vast and dynamic belt of ironworks and steel mills, transport facilities, and machine-making cities. The Pacific ports of Seattle, Wash., San Francisco, and Los Angeles have developed from an outpouring of forest, fish, farm, mine, and oil-well products, partly shipped abroad and partly sent by the Panama Canal to the eastern United States.

Similarly, Canada imports oil, wool, cotton, leather, and food-based raw materials into the St. Lawrence–Great Lake ports such as Montreal and Toronto and exports iron, nickel, copper and other metal-based goods, wood products, and flour from the eastern ports and from Vancouver. These trade activities have resulted in concentrated population at the gateways in and out of the country. Mexico's gateway district, at Vera Cruz, is also industrialized.

Inland sites. Sites in the interior, however, are not without importance. The first to develop were the fall-line power centres, strung out from the falls of the Merrimac River at the edge of the New England Upland, then southward along the eastern front of the Piedmont, to the Coosa River south of the Appalachians. Later, with the advent of steam and electric power, these sites continued as major textile, pulp and paper, and engineering locations. A major shift inland occurred with the use of coal for power in the eastern and western Pennsylvanian coalfields around Wilkes-Barre and Pittsburgh, in the Birmingham (Ala.) coal and iron fields, and in the Saginaw Bay, Indiana, and Illinois coalfields. Pittsburgh soon used up its local iron ore but was sufficiently near the Great Lakes to bring in Mesabi Range iron ores, which, in combination with the vast amounts of high-quality coking coal at hand, formed the basis for a great iron and steel industry. Except where coking coal is used in the steel plants, the lower-grade Western coal has been used primarily for electricity generation. Oil and natural gas, however, have become the base of active petrochemical industries in areas such as Alberta, Louisiana, Oklahoma, and Texas. Since oil and gas can be easily piped, they have not stimulated the development of industry on a large scale near their sources but have fueled the northeastern and Pacific Coast industrial areas. Modern industry has become less tied to sites where fuel and raw materials are available and more oriented toward the market. Service industries especially have concentrated in the highly populous areas of Boston–New York City–Philadelphia, Pittsburgh-Detroit-Chicago, and San Francisco–Los Angeles. Space-age developments have been supported by science-based industries from Texas through Louisiana to Florida. Industries to meet the immense demand for travel and recreation have sprung up on the major highways and in the tourist areas in the Appalachians, in the Cordilleras, and along the seacoasts. Though industry is more free to disperse—and has done so to a significant degree—it nevertheless continues to centre on areas of existing urban agglomeration. In the United States, industrial concentrations are greatest in the New York–Washington, D.C., Cleveland-Chicago, and Los Angeles regions; in Canada, in the Montreal-Toronto and Vancouver districts; and in Mexico, in the Mexico City basin. The major cities of these regions also are the focus of critical social and economic problems.

Service industries

More generally, automation is everywhere creating a major problem of technological unemployment, met in part by reducing working hours and retiring people earlier. These trends, in turn, have given rise to the problem of the use of leisure time, which has become the target for much of America's fastest-developing industries.

TRADE

North American trade patterns offer noteworthy contrasts. Canada, with a small population but with immense resources and high productivity, has a low home consumption and depends on foreign trade more than any other developed country on the continent. The United States, on the other hand, with a vast internal market and the highest per capita consumption of goods in the world, depends mainly on internal trade, although external trade has risen considerably since World War II and now accounts for about one-fourth of its total trade. Mexico and Central America, by contrast, still have large areas where people live at a subsistence level and produce little more than goods for local trade. Production of certain metals, oil, and tropical crops, however, has expanded rapidly for sale in foreign markets.

The Canadian segment. Canada's internal trade is dominated by the provinces of Ontario and Quebec. Together they account for three-fourths of the nation's manufactured goods, which they ship across Canada in exchange for fish, lumber, and fruit from British Columbia, wheat and meat from the Prairie Provinces, and pulpwood, iron ore, and fish from the Atlantic provinces. Most of Canada's trade abroad consists of raw or semiprocessed materials, including pulp, paper, lumber, iron ore, nickel, lead and zinc, uranium, and asbestos, sent to Britain, the United States, and Japan; and wheat, exported to Britain, China, and Japan. Some oil and natural gas are sold to the United States.

Until World War II, Canada traded mainly with Britain; during that time, the United States still produced a surplus of most of the things Canada raised and thus was not a major customer. Canada, in fact, bought far more from the United States than it sold to it. By the late 20th century, however, the United States had become short of metals, wood, pulp and paper, power, and water and was importing these items from its neighbour on an increas-

ing scale. It has thus replaced Britain as Canada's chief market. The European Economic Community and Japan also are important customers for Canada's metals, wood products, and wheat.

Role of internal trade

The United States segment. Internal trade in the United States is enormous, often surpassing that among sovereign states on other continents. It is dominated by New England's need for fuel, cotton and wool, leather, wood products, and metals; by the mid-Atlantic states' demand for coal, oil, natural gas, iron ore and other metals, and food products; by the Pittsburgh region's need for iron, copper, oil, and gas; by the lower Great Lakes–Lake Michigan area's need for coal, oil, gas, iron, pulp and paper, and wood; and by the Los Angeles–San Francisco region's demand for steel, aluminum, cellulose products, oil, and chemicals.

Most of the other areas of the United States trade their raw materials or semifinished goods to these major manufacturing regions, though of course there are local industrial centres of importance. Trade is concentrated in servicing, or in being served, by such large metropolitan centres as New York City, Los Angeles, Chicago, Houston, and Philadelphia. These cities also handle a great deal of American foreign trade. Southeastern ports send out cotton, tobacco, and wood products; and the mid-Atlantic coast ports send out wheat, corn, meat, and a wide range of manufactured products.

Since the development of the St. Lawrence Seaway, the major cities along the Great Lakes have been directly exporting the steel products, cars, airplanes, agricultural machinery, cereals, and meat for which the northern Midwest is famous. New Orleans continues as an exporter of cotton, corn, and other agricultural products from the vast Mississippi hinterland, although oil and grain now are more important; while trade from Houston's port is based on oil and chemical products. Los Angeles dominates the West, with its sales of aircraft, ships, motion pictures, and chemicals. Seattle is important for its trade in fish and forest products and in aircraft. American imports include a wide variety of products: tropical fruits, woods, fibres, and vegetable extracts, mainly from Latin America, West Africa, and Southeast Asia; oil from Saudi Arabia, Mexico, Nigeria, Indonesia, and Great Britain; tin from Bolivia and Malaysia; wool from Australia and South America; and a wide range of motor vehicles, machines, textiles, instruments, and books from Japan and western Europe.

American trade has a worldwide distribution and impact: of its export total, about one-third goes to western Europe; more than one-fifth to Japan, Southeast Asia, Australia, and New Zealand; almost one-fifth to Canada; one-tenth to Mexico, Central America, and the West Indies; and one-twelfth to South America. Of almost equal importance has been the widespread influence of American foreign aid: while initially this helped American trade by being tied to the use of domestically manufactured equipment, it has become much freer and enables countries to develop their own agriculture or industry in the most satisfactory way.

The Mexican and the Central American segments. The Latin American portion of the continent includes some highly sophisticated regions, along with many as yet undeveloped areas. In Mexico's internal trade the capital region predominates, producing most of the nation's manufactures, which are then distributed through regional cities. Mexico City consumes much of the domestically used oil piped up from the coast, the metals of the Cordilleran mines, the cotton of the irrigated central and western basins, and hemp from Yucatán. Petroleum exports became a steadily growing part of Mexico's external trade following the discovery of vast oil reserves in the Bay of Campeche in 1972. Within a decade, petroleum sales represented by far the greatest portion of Mexican export earnings. The oil exports have given Mexico higher income, but they also have placed the country in danger of becoming overly dependent on a commodity that is subject to market fluctuations. In an effort to avoid the consequences of such dependence, the government has attempted to diversify the country's export economy. This effort has involved expanding Mexico's industrial base, increasing the export of manufactured goods, and augmenting the export of agricultural goods and metals.

Mexican petroleum exports

Imports consist predominantly of manufactured goods and of parts and materials needed for Mexican industries. Machinery, vehicles, and consumer goods are the chief items. The United States has the greatest share of Mexico's foreign trade, providing the greatest portion of the imports and exports. Since 1960, however, more of Mexico's trade has been oriented toward Latin America. Mexico is also trying to send more winter fruits and vegetables, textiles, and leather goods to Canada.

Central America has developed a limited amount of trade. By far the greatest exports are tropical fruits, fibres, and minerals (especially from the Caribbean), which are sent to the United States in exchange for American manufactured goods. Increasingly, virtually the whole of North America is being integrated in its economic development with the growth of the United States.

TRANSPORTATION

Waterways. Industry has been strengthened by the ease of movement in North America. Waterways, widely used by the Indians and early Europeans, are still important. In spite of the barriers of the Canadian Shield and the Appalachians, the routes up the Gulf of St. Lawrence, the Hudson Strait, Chesapeake Bay, and the Gulf of Mexico permitted the swift development of coastal ports and allowed the continental interior to be opened up. The Mississippi-Ohio and the Great Lakes–St. Lawrence waterways drew navigation into the heartland. Connecting these two systems, the Chicago Sanitary and Ship Canal, linking the Illinois River with Lake Michigan, and various Ohio River–Lake Erie canals provided a tremendous network, extended by the Erie Canal to the Mohawk-Hudson waterway and by the Intracoastal Waterway to river ports of the Gulf of Mexico. The St. Lawrence Seaway, which overcame the Lachine and International rapids and Niagara Falls, has made ocean ports of inland cities.

Railways. Railways soon offered the challenge of more direct and speedy access than the waterways. Developed principally from bases along the Atlantic Seaboard, they made the most of gaps through the Appalachians, debouched on the Great Lakes or Ohio River at Buffalo and Chicago and Pittsburgh, and pushed on to the Mississippi River at St. Louis, Mo., and St. Paul–Minneapolis, Minn. Other lines were then laid across the Great Plains and, utilizing passes through the Cordilleras, the railways built terminals at San Francisco, Seattle, and Los Angeles. Most of the Western railways were given large land grants to encourage immigrants to settle along them, while low promotional rates on long-haul traffic developed transcontinental trade. In Canada the transcontinental railways linked up the Maritime Provinces with the St. Lawrence–Great Lakes, and thence, from Montreal and Toronto, they crossed the shield to converge at Winnipeg; there, reinforced by large land grants, they fanned out across the prairies, to be drawn together by the Fraser River down to Vancouver.

Development of Canada's railway system

Mexico overcame difficult grades in building a railway from Vera Cruz to Mexico City and added extensions north and south along the Gulf Coast, with lines into Monterrey and to Mérida. Eventually lines were pushed through the Sierra Madre Occidental at Guadalajara to the Pacific coast.

Railroads had a tremendous impact on urban development. Among the major railroad cities are New York City, Chicago, St. Louis, and Los Angeles in the United States, and Montreal, Winnipeg, and Vancouver in Canada. Mexico City dominates the network in Mexico. Railroads led to the rise of east-west over north-south lines and rapidly displaced most waterways, particularly the Mississippi. The main economic axis in the United States lies along the railway belt from New York to Chicago. Inadequate overall planning in major metropolitan regions has resulted in crucial transportation problems, however, and inner-city rapid-transit systems often have fared no better.

Roads. North America's road network first began to offer serious competition to the railways after World War I. The U.S. government has since financed more than 300,000 miles of transcontinental highways, including

more than 40,000 miles of limited-access, multilane roads. In Canada the Trans-Canada Highway offers a coast-to-coast through route, while from Mexico the Pan-American Highway links the countries of Central America. These highways have enabled trucks to take over short-haul routes from railways, and the railways have concentrated on long-haul, low-cost routes. Truck and train, however, have been integrated in the "piggyback" containerized carriage. The automobile, meanwhile, has displaced commuter trains in many cities, and radial and ring routes have helped draw the cities far out into the countryside. The attendant problems of congestion and pollution have approached the critical stage in many cities.

Air transport. Air transport has taken most of the long-distance passenger traffic from the trains, and airfreight has cut into truck-freighting trade. Intense overall competition is thus a recurrent feature of North American transportation systems. Airways have tended to centre on the larger cities and to magnify their importance, although the rise of the "hub" system of air transport has helped to diversify air routes. Links with Europe and Asia make North America the chief crossways of air routes in the world. The United States alone accounts for some two-fifths of all the world's passenger air traffic, and several of the chief airports in the world are in the United States, including those in Chicago; Dallas–Fort Worth, Texas; Atlanta, Ga.; Los Angeles; Denver, Colo.; San Francisco; New York City; Miami, Fla.; Boston; and Washington, D.C. Montreal and Mexico City are also major air hubs.

NORTH AMERICAN GEOGRAPHIC FEATURES OF SPECIAL INTEREST

Landforms

ALASKAN MOUNTAINS

The mountain ranges of Alaska give their state a rugged and beautiful terrain across its entire expanse. They include the highest peak in North America and are characterized by glaciers, earthquakes, and continuing volcanic activity. Structurally, the ranges are northwestward continuations of the Rocky Mountains and the Pacific mountain system of North America. Still little explored for vast stretches, Alaska's mountains contain, or lie close to, largely untapped mineral resources.

The most northerly of the three major Alaskan mountain groups are the Brooks Range and the Arctic foothills, which extend the Rocky Mountains in an east-west arc from the Canadian border across northern Alaska. Central Alaska is characterized by highlands and basins drained by the great Yukon and Kuskokwim river systems.

Alaska's southern coast and adjoining southeastern panhandle are dominated by an arc of mountain ranges that demark the Gulf of Alaska and make the state's Pacific coast one of the most spectacular on Earth. This Pacific mountain province is subdivided into several groups. The interior Alaska Range merges southwestward into the Aleutian Range and the Aleutian Islands. Separated from the Alaska Range by the Talkeetna and Wrangell mountains, the main mountains of the southern coast lie in the Kenai and Chugach mountains. These heavily glaciated ranges border the Gulf of Alaska, the Chugach Mountains adjoining, to the south and east, the St. Elias Mountains at the Canadian border. The St. Elias Mountains, in turn, merge to the southeast into the mountains of the coastal Boundary Ranges, which, with the mountainous islands of the Alexander Archipelago, constitute the Alaskan panhandle.

Physical features. *Physiography of the northern ranges.* The Arctic northward-sloping foothills, just north of the Brooks Range and along Alaska's Arctic Ocean coast, consist of low east–west-trending ridges and rolling plateaus with irregular isolated hills. They rise from 600 feet (180 metres) in the north to 3,600 feet in the south. Except for the east-flowing upper portion of the Colville River, most drainage is northward. This tundra-covered area, called the North Slope, is underlain by permafrost, a permanently frozen, rock-hard soil; only a shallow surface zone thaws during the short summer, producing a vast number of small ephemeral lakes and ponds. This region is geologically complex, as is the higher Brooks Range to the south, but the layered bedrock is of less-resistant lithologies, some of which are oil-bearing. The rocks in the Arctic foothills consist of sediments that are folded, faulted, and overthrust toward the north.

Brooks Range

The Brooks Range, situated just south of the Arctic foothills, is the highest mountain range within the Arctic Circle. It includes groups of subranges extending some 600 miles (1,000 kilometres) from the Canadian border westward to the Chukchi Sea. Average elevations range from 3,000 to 4,000 feet in the west to 5,000 to 6,000 feet in the east, with a high point of 9,060 feet in Mount Isto. Except for some higher ridges, the entire area has been glaciated and has exceedingly rugged topography. Several small glaciers are still present in the east, fewer in the west. The Brooks Range forms the drainage divide between waters flowing northward across the North Slope into the Arctic Ocean, those flowing westward into Kotzebue Sound, and those flowing southward into the Yukon River drainage system, which empties into the Bering Sea. Several major rivers have eroded headward into the range to form low passes, the best-known being Anaktuvuk Pass, at an elevation of 2,200 feet in the central part of the range. Atigun Pass, at the head of the Dietrich River, connects the oil-producing areas of the North Slope with interior Alaska and the south.

The backbone of the range is composed of sedimentary and metamorphic rocks dating from the early Paleozoic Era (540 million years ago). Younger sedimentary rocks flank the range. The mountains were uplifted by major compressional foldings (orogenies) in the Earth's crust. Folding, faulting, and major overthrusting toward the north during these orogenies were accompanied by erosion and glaciation. Most of the area now is characterized by permafrost.

Physiography of the central ranges. The mountains of central Alaska are lower than the ranges to the north and south. They are drained almost entirely by two river systems, the Yukon and the Kuskokwim. The intricately dissected uplands are divided into three areas: the eastern highlands, the western highlands, and the Seward Peninsula. The great sweep of ranges extends south of the Yukon from the Canadian border to the Bering Sea; north of the river the ranges are discontinuous.

The eastern highlands consist of several separate mountain chains (*e.g.*, the White Mountains), with average elevations of 4,000 to 5,000 feet and a few ridges rising 1,000 to 2,000 feet above these uplands. No glaciers are present in the region, and permafrost is discontinuous, occurring only at the higher elevations. Underlying rocks are highly deformed metamorphic and metasedimentary, with some older volcanic material. The higher parts are commonly composed of small segments of resistant granite that intruded into the other rocks while in a molten state.

The Kuskokwim Mountains

The western highlands are subdivided into several smaller groups, notably the Kuskokwim Mountains. These ranges are somewhat lower and more rolling than the eastern highlands, with ridges trending southwest-northeast. Numerous isolated, nearly circular groups of mountains rise above these ridges. No glaciers are now present, but the Ahklun Mountains at the sector's southwestern extremity are the largest formerly glaciated area in central Alaska.

To the west and north is the upland area of the Seward Peninsula, the western tip of which is some 50 miles from Russia, across the Bering Strait. Much of the peninsula consists of broad, convex hills and ridges with an average elevation of about 2,000 feet surmounted by more rugged

The Alaskan mountain ranges and the Mackenzie and Yukon river basins and their drainage networks.

mountain groups. A few peaks rise above 3,000 feet; the highest, at 4,714 feet, is Mount Osborn in the Kigluaik Mountains in the southwestern part of the peninsula. The entire area is characterized by permafrost.

Physiography of the southern ranges. The Alaska and Aleutian ranges—together with the Talkeetna, Chugach, and Wrangell mountains, the interior part of the St. Elias Mountains, and the Boundary Ranges of southeastern Alaska and flanking interior sectors of northwestern British Columbia—constitute the most massive and spectacular mountain system in North America.

The Alaska and Aleutian ranges extend in a great belt from the Canadian border, at first northwestward and then south- and westward to the Aleutian Islands. The oceanic Aleutians comprise a chain of mountainous volcanic peaks, the crest of a huge submarine ridge 1,500 miles long and 20 to 60 miles wide that rises 11,000 feet above the seafloor. Separating the Bering Sea from the Pacific Ocean, the archipelago stretches in a 1,100-mile-long arc from the Alaska Peninsula to Attu Island at the western end of the chain. With the Aleutian Range on the southeast side of the peninsula, they form a long, narrow belt of storm-whipped, often fog-shrouded peaks for 1,600 miles from Attu to Mount Spurr just west of the city of Anchorage. Some 80 volcanoes have been mapped in this chain, more than half of which have been reported active since 1760. Marine sedimentary rocks and granitic intrusions, as well as volcanic rocks, form this range. Pavlof and Shishaldin volcanoes rival Japan's Mount Fuji in the beauty of their symmetrical cones. In 1912 one of the most spectacular of recent historic eruptions occurred when a volcano in the Aleutian Range erupted, forming the Valley of Ten Thousand Smokes, in what is now Katmai National Park and Preserve. Mount Spurr erupted in 1954 and remains active, as do Mounts Redoubt (1968) and Augustine (1976).

The Alaska Range merges on its western end with the Aleutian Range between Iliamna Lake and Mount Spurr and extends in a great arc some 600 miles to the Canadian border at the southeastern end. This great mountain wall is about 120 miles wide near Mount Spurr and about 60 miles wide in the vicinity of Mount McKinley, gradually narrowing to about 30 miles near the Canadian border. The range is extremely rugged and glaciated. The crest of most of the range averages between 7,000 and 9,000 feet in elevation, with a number of peaks exceeding 10,000 feet. The heavily glaciated massif of Mount McKinley (Denali), at 20,320 feet (6,194 metres), is the highest point in North America. Four great individual mountain masses dominate the Alaska group, divided by a number of low passes and river valleys. Great valley glaciers radiate from these mountain masses, except in the relatively low eastern sectors, where the few glaciers are small. The Alaska Range is the drainage divide for rivers flowing north into the Yukon system and those flowing south into the Gulf of Alaska.

Mount McKinley

Most of the Alaska Range is underlain by large granitic intrusions (batholiths) into sedimentary rocks that have been metamorphosed and deformed. The youngest sedimentary sequences can contain large deposits of coal. Long valleys and low passes follow the course of geologic faults, some extending almost the entire length of the range.

Between the Alaska Range and the coastal ranges lie the Talkeetna Mountains and, to the east of them, the Wrangell Mountains. The Talkeetnas occupy a rugged oval area about 100 miles from north to south and 70 miles from east to west. They consist of a compact group of radial ridges averaging from 6,000 to 8,800 feet in elevation. There are only a few low passes. The higher ridges are sharp-crested, but on the western flank, as elevation decreases, the ridge tops have been rounded and subdued by overriding glaciers during the Pleistocene Epoch (1,600,000 to 10,000 years ago). Small glaciers 5 to 15 miles long are still present at the heads of many valleys in the Talkeetnas.

The Wrangell Mountains, covering an area 100 by 70 miles, lie near the Pacific between the Alaska Range to the north and the Chugach Mountains to the south. The high, glaciated massifs rise more than 10,000 feet above the Copper River basin. Extensive local ice caps cover most of the highest mountains and feed large valley glaciers. This oval-shaped range consists of composite volcanic mountains that rest on metamorphosed sedimentary and igneous rocks. Several peaks are at elevations higher than 12,000 feet; the highest is Mount Bona, at 16,421 feet.

Encircling the Gulf of Alaska, from Kodiak Island in the west to Baranof Island in the southeast, is another arcuate (bow-shaped) mountainous belt, 800 miles long and 20 to 110 miles wide. Mountainous Kodiak Island and the Kenai and Chugach mountains form a rugged barrier along the northeast margin of the Pacific Ocean. The mountains of the Kodiak Island group, at average elevations of 2,000 to 4,000 feet, trend southwest-northeast. Pleistocene glaciation over most of the island produced a highly irregular coastline.

Kodiak Island

The average elevation of the Kenai Mountains is 3,000 to 5,000 feet, whereas the Chugach group to the north and east average 7,000 to 8,000 feet. The highest peaks are in the sharp bend of the arc, where Mount Marcus Baker rises to 13,176 feet. The mountains are extremely rugged and heavily glaciated, resulting in the Sargent and Harding ice fields in the Kenai Mountains (on the Kenai Peninsula) and the Bagley Ice Field in the eastern Chugach Mountains. Numerous long and spectacular glaciers descend from the crests of these mountains. The St. Elias Mountains and the Kenai-Chugach mountain system have the most extensive system of highland and valley glaciers in North America.

The St. Elias Mountains straddle the border between Alaska and Canada. The Alaskan part of the range is topographically continuous with, and geologically similar to, the Chugach Mountains and joins the southeastern panhandle to the rest of the state. The St. Elias chain, composed of many glacier-fed ranges, is one of the highest coastal mountain groups in the world. It is about 200 miles long and has a maximum width of about 100 miles. The chain merges with the Chugach group near the Alaska-Yukon border and with the Wrangells and parts of the Alaska Range to the northwest.

The massive, blocklike St. Elias Mountains rise from a myriad of narrow ridges and spectacular peaks at 8,000–10,000 feet (2,400–3,000 metres) in elevation to numerous ice-armoured summits over 14,000 feet high. Mounts Logan (19,524 feet) and St. Elias (18,008 feet) are the two highest peaks. The St. Elias chain contains the largest ice field in North America, with about half of its glacial cover in Canada and the rest in Alaska. The average elevation of the ice fields blanketing the lower regions is 3,000 to 7,000 feet. Because of difficulty of access and extensive ice cover, the geology is still little known.

At the southern end of the St. Elias Mountains, on a peninsula south of the Alsek River where it enters Dry Bay, rises the unique and spectacular fault-block mountain system of the Fairweather Range. At the southern end of this range is the Brady Icefield, and east of the range is world-renowned Glacier Bay, with its largely receding tidal glaciers. The Chilkat Range, east of Glacier Bay, is flanked by Lynn Canal, the northern extension of Chatham Strait. Together they represent one of the longest and deepest fjords in North America.

Along the north-south axis of this fjord is the trace of a great, inactive fault system known as the Lynn Canal–Chatham Strait trough. West of the St. Elias Mountains and Fairweather Range is the still-active Fairweather Fault, a northward extension of California's coastal San Andreas Fault. This fault system has been the locus of many major earthquakes in Alaska since the 1850s, including the large quake of March 1964.

The mountains of southeastern Alaska tie in the Canadian Coast Mountains to the south and east with the St. Elias range to the north and west. As such, they are a northward continuation of the Pacific mountain system that extends southward into the western United States. The heavily glaciated Boundary Ranges along the Alaska-Canada border extend between the Skagway River at the northern end of Alaska's Inside Passage southward to the Portland Canal southeast of Ketchikan. They rise to 5,000 to 7,000 feet above sea level, with the higher peaks

reaching 10,000 feet. These mountains are underlain by the intruded granitic rocks of the Coast Range Batholith. To the northeast and southeast of Juneau, respectively, are the Juneau and Stikine ice fields that feed numerous valley glaciers, some of which extend to the sea.

Lying to the west of the Boundary Ranges on the mainland is the rugged and scenic island complex of the Alexander Archipelago. The mountains of the archipelago range in elevation from 2,000–3,500 feet in the southern Prince of Wales Mountains to more than 4,000–7,500 feet in the Chilkat Range and the mountains of Admiralty, Baranof, and Chicagof islands. These islands have small glaciers and rugged coastlines indented by fjords.

Climate. On a regional scale the Alaskan mountains span all the climatic zones found in the state. The northern slopes of the Brooks Range fall within the Arctic zone, while its southern slopes and the Alaska, Talkeetna, and Wrangell ranges all fall within the continental zone. Both zones are characterized by long cold winters, short cool summers, moderate summer rainfall, and light snowfall during the winter. The continental zone is generally more arid, with clearer skies and more extreme temperatures.

The Chugach Mountains, the western Aleutian Range, and the Alaska Peninsula fall within the transitional zone. The mountains of the Aleutian Islands and the remaining southern mountains, in particular those of the panhandle, lie within the maritime zone, the climate being influenced by the warm waters of the Kuroshio (Japan Current). These two zones have relatively small temperature variations and much cloudiness and precipitation, although these conditions are all less pronounced in the transitional zone. Mean January temperatures range from −20° F (−29° C) in the Brooks Range to between 14° and 32° F (−10° and 0° C) in the Boundary Ranges of the panhandle. Winter temperatures at or below −50° F (−46° C) are not unusual, however, in the mountains of the interior and at higher elevations in the Boundary Ranges. Mean July temperatures range from about 60° F (16° C) on the lower slopes of the Brooks Range (and lower still at higher elevations) to about 68° F (20° C) in the lower Talkeetnas. With less than 20 inches (500 millimetres) of annual precipitation, the Brooks Range is the driest of the Alaskan ranges, while the coastal mountains from the Copper River delta area southward through the Alexander Archipelago are the wettest, with precipitation sometimes reaching 200 to 300 inches annually.

Plant and animal life. Vegetation at the higher elevations of the mountain ranges, when they are not barren or covered by ice, is usually a ridge type of tundra, or treeless plain. Above the timberline, vegetation consists of lichens, grasses, sedges, and heather. Dwarf species of willow and alder also are found, while extensive grasslands occur in the Aleutians, on the Alaska Peninsula, and on the southern slopes of the Alaska Range. The interior forests, consisting of white spruce and birch or aspen, with mixtures of balsam poplar, occur mostly on the lower slopes of the larger river valleys north of the Alaska Range.

The timberline

The Tongass National Forest encompasses southeastern Alaska, and the Chugach National Forest covers the lower parts of the Chugach, Kenai, and Kodiak mountain areas. Vegetation in the lower elevations is a hemlock-spruce coastal forest. Western hemlock and Sitka spruce extend to about 1,500 feet above sea level, and subalpine species to at least 2,500 feet. The Tongass National Forest is composed largely of western hemlock, with a much smaller proportion of Sitka spruce and a sprinkling of western red cedar, Alaska cedar, and alpine fir. On the continental flank of these ranges, white spruce and lodgepole pine dominate. The Chugach National Forest is predominantly a hemlock forest with some Sitka and white spruce and occasional cottonwood and paper birch.

Several large mammals are native to the Alaskan mountains. Brown and grizzly bears and wolves inhabit the Boundary and St. Elias ranges, the Alaska Range, and the interior. Black bears, absent from the Alaska Peninsula, are found in most of the state. Dall bighorn sheep live high in the mountains from the Kenai Peninsula to the Brooks Range and southeastward in the interior St. Elias and Boundary ranges. Mountain goats are in the Chugach, Kenai, Talkeetna, St. Elias, and Boundary ranges. Moose, though living mostly in the lower elevations, range into high country from the Alaska Peninsula to the Brooks Range. Barren-ground caribou and foxes range over high plateaus and mountain slopes from the Alaska Peninsula to the Arctic. Sitka deer are abundant in southeastern Alaska and in parts of the Prince William Sound region. A number of smaller fur-bearing animals—including lynx, martens, and weasels—are native to all the mountains.

The people and economy. As a marginal environment in a mostly harsh climatic region, the Alaskan mountains have few areas suitable for settlement. Where they occur, settlements are limited to lower elevations or intermontane valleys. Only the coast mountains of southern Alaska and the panhandle support sizable populations. Anchorage is the most populous urban area. Commercial fishing, forestry, some mining, and tourism are the major economic activities in settled coastal areas. The Trans-Alaska oil pipeline, from Prudhoe Bay on the North Slope, crosses the Brooks, Alaska, and Chugach ranges, terminating at the ice-free port of Valdez, east of Anchorage.

Mountain landscapes in the interior have soils underlain by permafrost and only short frost-free periods in summer,

both of which inhibit agriculture. Moreover, solifluction—the downslope flow of waterlogged soil over subsurface permafrost—prohibits building construction and road development in many areas. Inhabited mostly by Alaskan Indians and Eskimos, interior settlements are isolated and depend largely on subsistence-level activities such as hunting, fishing, and fur trapping, with some farming. Arts and crafts are economically important in some areas. The major commercial activities in the mountain interior are metal (zinc, platinum, gold, and silver) and coal mining and forestry. There are some gold and silver mining operations in the mountains of the panhandle.

Mapping

Study and exploration. Alaska has been fully mapped topographically from aerial photographs; the underlying geology of large areas, however, remains incompletely mapped. The U.S. Geological Survey, as part of the general reconnaissance mapping program from the late 19th century to the 1960s, did most of the geologic work, with some fieldwork also by the U.S. Bureau of Mines and the Alaska Department of Geological and Geophysical Surveys. Since 1950, areas of potential mineral and transportation value have been mapped on a more detailed basis by these state and federal agencies. Various university research parties also have contributed to the data, while some local site assessments and geologic mapping have been done by private mining and petroleum companies.

Detailed glaciological studies in the Alaskan mountains began with the Harriman Alaska Expedition (1899), funded by the railroad magnate Edward Henry Harriman. This was followed by expeditions of the National Geographic Society in the early and mid-20th century and field studies by the American Geographical Society, the Office of Naval Research, the Arctic Institute of North America, and the U.S. Geological Survey. The longest continuous glaciological study in the Alaskan mountains has been conducted since 1946 by the Juneau Icefield Research Program in the Coast Mountains. (R.Sc./M.M.M.)

APPALACHIAN MOUNTAINS

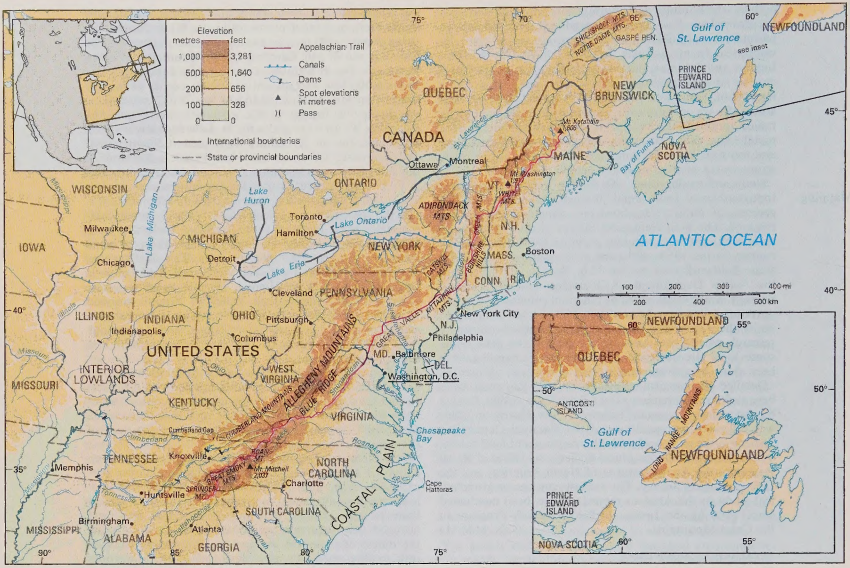
The Appalachian Mountains are one of the great highland systems of North America, the eastern counterpart of the Rocky Mountains. Extending for almost 2,000 miles (3,200 kilometres) from the Canadian province of Newfoundland to central Alabama in the United States, they form a natural barrier between the eastern Coastal Plain and the vast Interior Lowlands of North America. As a result, they have played a vital role in the settlement and development of the entire continent. They combine a heritage of natural beauty and a distinctive regional culture with contemporary problems of economic deprivation and environmental deterioration.

Physical features. *Physiography.* The system may be divided into three large physiographic regions: northern, central, and southern Appalachia. These include such mountains as, in the northern area, the Shickshocks (French: Chic-Chocs) and the Notre Dame ranges in Quebec; the Long Range in Newfoundland; the great monadnock (isolated hill of bedrock) of Mount Katahdin in Maine; the White Mountains of New Hampshire; and Vermont's Green Mountains, which become the Berkshire Hills in Massachusetts, Connecticut, and eastern New York. New York's Catskill Mountains are in central Appalachia, as are the beginnings of the Blue Ridge range in southern Pennsylvania and the Allegheny Mountains, which rise in southwestern New York and cover parts of western Pennsylvania, western Maryland, and eastern Ohio before merging into the third, or southern, region. This area includes the Alleghenies of West Virginia and Virginia; the Blue Ridge range, extending across Virginia and western North Carolina, the northwestern tip of South Carolina, and the northeastern corner of Georgia; the Unaka Mountains in southwestern Virginia, eastern Tennessee, and western North Carolina (of which the Great Smoky Mountains are a part); and the Cumberland Mountains of eastern Kentucky, southwestern West Virginia, southwestern Virginia, eastern Tennessee, and northern Alabama.

Elevations

The highest elevations in the Appalachians are in the northern division, with Maine's Mount Katahdin (5,268 feet [1,606 metres]), New Hampshire's Mount Washington (6,288 feet), and other pinnacles in the White Mountains rising above 5,000 feet, and in the southern region, where peaks of the North Carolina Black Mountains and the Tennessee–North Carolina Great Smoky Mountains rise above 6,000 feet, and the entire system reaches its highest summit on Mount Mitchell (6,684 feet [2,037 metres]).

A distinctive feature of the system is the Great Appalachian Valley. It includes the St. Lawrence River valley in Canada and the Kittatinny, Cumberland, Shenandoah, and Tennessee valleys in the United States; the latter is the site of the world-famous Tennessee Valley Authority (TVA), a government agency for natural resource conservation, power production, and regional development.



In the area known geologically as "New" Appalachia, especially where there are softer limestone rocks that yield to the constant erosion by water, numerous caves are a distinctive feature of the physiography. The chief caverns lie within or border the Great Valley region of Pennsylvania, Maryland, West Virginia, Virginia, and Tennessee. Caverns of the Shenandoah Valley in Virginia provide well-known and dramatic examples of underground passages, rooms, watercourses, formations, and decorations that honeycomb much of the land below central and southern Appalachia.

Geology. The Appalachians are among the oldest mountains on Earth, born of powerful upheavals within the terrestrial crust and sculpted by the ceaseless action of water upon the surface. The two types of rock that characterize the present Appalachian ranges tell much of the story of the mountains' long existence.

First there are the most ancient crystallines. Between about 1.1 billion and 540 million years ago, during Precambrian time, long periods of sedimentation and violent eruptions alternated to create rocks and then subject them to such extreme heat and pressure that they were changed into sequences of metamorphic rocks. Among the oldest of these are the gneisses. Limestone changed into marble, shales became slate and schist, sandstones were transformed into quartzite, and intrusions of magma formed bodies of granite. These ancient rocks antedated most plant or animal life; in addition, the intense pressure and heat destroyed any traces of primitive life—so that the Precambrian crystallines contain no trace of fossils. They make up what is known as "Old" Appalachia in Canada, New England, and a belt east of the Great Valley with the Blue Ridge at its heart. To west the Great Valley, the Valley Ridges, and the Appalachian Plateau (including the Alleghenies) are characterized by the second type of rocks, the Paleozoic sediments. These make up "New" Appalachia—the shales, sandstones, and coals that were created by sediments deposited, stratified, and solidified over a vast range of geologic time. During the Carboniferous Period (360 to 286 million years ago), this long process included the formation of some of the richest coal beds in the world. During the Permian Period, near the end of the Paleozoic Era (*i.e.,* about 250 million years ago), a great mountain folding occurred. This was the Appalachian Revolution, a vast interior crumpling resulting from the stress placed on huge masses of subterranean rock. As parts of the Earth buckled into folds, cracked, and faulted, other parts were uplifted—sometimes in the parallel ridges distinctive of the Appalachians—and thrust faults served to move one rock mass atop another. Thus, the ancient crystallines were lifted in places above more recent sedimentary rock deposits.

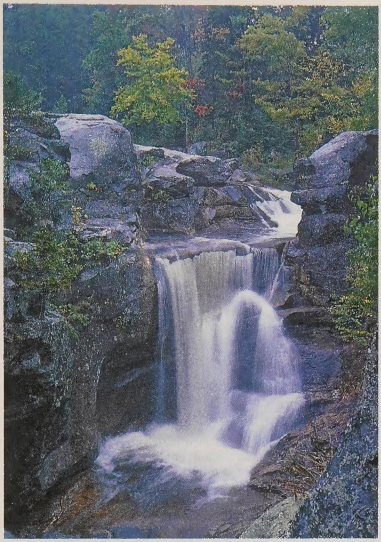
The Appalachian Revolution

In addition to the massive folding of the Appalachian Revolution, however, two other agents—ice and water—have carved the steep ridges and pinnacles and gouged out the deep ravines and valleys of the Appalachians. This building, eroding, uplifting, and shaping of the Appalachians has been a continuous process throughout the ages. Many of the major rivers are older than the mountains. This accounts for the fact that northeast of the New River in Virginia the major Appalachian rivers flow into the Atlantic Ocean, often through dramatic passages called water gaps, while southwest of the New the rivers, with few exceptions, flow to the Ohio River. When the mountains were thrust up, blocking their westward course to

The Appalachian Mountains.

the ancient sea that once covered the American Midwest, these old rivers cut out their own routes, creating those spectacular canyons, gorges, and "narrows" that are part of Appalachian scenery.

The northern Appalachians were also affected by glacial forces. During the Pleistocene Epoch (1.6 million to 10,000 years ago), continental ice sheets flowed down over North America, covering New England but reaching no nearer the southern Appalachians than the Ohio River valley. These moving tongues of ice stripped topsoil, ground and polished certain peaks, and elsewhere scattered rock debris and random boulders, all the while driving plants and animals farther south where they could survive. Thus, the southern Appalachians became the refuge for northern life forms, a giant bed for reseeding when the glaciers retreated and the plants moved slowly north again, leaving behind a rich botanical variety thriving in northern and southern latitudes.



Drainage. The New River, rising on the Blue Ridge in North Carolina, runs northward and then turns westward across the Appalachian Valley and the Alleghenies (where it becomes the Kanawha River) and empties into the Mississippi River basin. The larger mountain streams to the south, dominated by the Tennessee River, follow this example. Exceptions are the rivers rising southeastward on the Blue Ridge, which flow into the Atlantic, and the Chattahoochee, rising in the northeastern corner of Georgia, which runs southwestward into the Gulf of Mexico.

The entire Appalachian system is laced with an intricate network of springs, streams, waterfalls, and rivers. Water is most abundant in the southern Appalachians. Certain areas of the Blue Ridge receive an annual rainfall of 69 inches (1,750 millimetres) during an average year. Elsewhere precipitation is even higher—the western slopes of the Great Smoky Mountains, for example, often receive as much as 90 inches per year—being exceeded in the United States only along the northwest Pacific coast. Much of this rainfall comes in extremely heavy downpours during short periods. Since this region does not have the natural storehouses of numerous lakes and glacial deposits of sand and gravel spread over hills and valleys, such as are found in the northern Appalachian region, sudden rainfalls bring rapid rises and falls in the southern Appalachian stream flows. Under certain conditions (as when the forest cover, which serves as a storage sponge, has been destroyed) destructive floods have characterized much of the hydrologic history of this part of the Appalachians. To contain these floods and harness the might of an entire river system for purposes of navigation, power production, land reclamation, and watershed development, the Tennessee Valley Authority was established in 1933, and it quickly became one of the chief factors influencing the ecology of the Southern Appalachian region. Its system of dams turned a river that rampaged and often destroyed into a river that flows gently and productively. The TVA created a series of spacious reservoirs (the majority of which are in or adjoining the Appalachian region) called "the Great Lakes of the South." These lakes, in turn, have altered the natural and human resources of the region, using Appalachian water power to produce electrical power that has expanded industrial and agricultural and recreational opportunities.

The Tennessee Valley Authority

Waterfalls are common throughout much of the Appalachian system. Most of those in the northern Appalachians, especially from New York to Maine, were created when glacial moraine or debris, scraped from surrounding peaks by the melting ice cap, solidified into shelves along creeks or river valleys over which the water must plunge as over a terrace. Southern Appalachian waterfalls generally were formed by the action of water on alternating layers of soft and hard rock.

Climate. Generally temperate and humid, the climate of the Appalachians presents sharp contrasts. In the Canadian ranges and the Presidential Range of the White Mountains, Arctic and subarctic conditions prevail. Altitudes below 2,000 feet usually have milder weather in the

Screw Auger Falls in the Mahoosuc Range, northern Appalachian Mountains, Maine.

hills of northwestern Georgia and northeastern and north-central Alabama. Snowfall is heaviest in the Shickshocks, Newfoundland's Long Range, and the White Mountains, but Mount Mitchell in North Carolina has recorded more than 100 inches in a single year. Unique in climatic severity is barren, boulder-strewn Mount Washington, which is lashed by some of the world's strongest winds (a gust of 231 miles per hour was recorded there in 1934); temperatures recorded on its summit have never risen above 71° F (22° C). Heavy clouds and haze are common throughout the Appalachians, often frustrating recreational activities and sightseeing but nourishing the abundant plant life and the river system.

Plant and animal life. From Maine to Georgia, the Appalachian Mountain system was once almost totally covered with forest. Today some of the best and most extensive broad-leaved deciduous forests in the world still flourish in the Appalachians and bordering areas, notably in southern Appalachia. To the north are the conifers (red spruce and balsam fir, which grow at the highest elevations and distinguish the Canadian and Maine woods) and the northern hardwoods (sugar maple, buckeye, beech, ash, birch, and red and white oak). Farther south are hickory, poplar, walnut, sycamore, and at one time the important and—before they were destroyed by blight—plentiful chestnuts. All of these, plus other of the 140 species of trees of Appalachia, are found in the southern mountain region. Lofty elevations nurture representatives of the Canadian forest, while the western slopes of the Great Smokies, with their abundant rainfall, produce trees that have reached record maximum height and diameter. Among these are the tulip tree (yellow poplar), buckeye, eastern (Canadian) hemlock, and chestnut oak.

Forests

The interdependent system of southern plant growth known as the "Appalachian forest" is highly complex. It forms one of the great floral provinces of the Earth. There are the trees that bear luxuriant bloom, such as serviceberry, redbud, hawthorn, tulip tree, dogwood, locust, sourwood, and many others. Among the numerous shrubs with particularly showy flowers are the rhododendron, azalea, and mountain laurel. Certain summits of the southern Appalachians are called heath balds—open meadows or grasslands interspersed with thick growths of heath. Roan Mountain in the North Carolina–Tennessee Unakas is one of the most extensive of these, with some 1,200 acres of natural gardens sprawling vivid rose and pink and purple rhododendron across its high pinnacle and down its slopes. It is estimated that, of some 2,000 species of Appalachian flora, perhaps 200 are native and wholly confined to the southern Appalachians. Ferns, mosses, and mushrooms of many species also are part of the complex Appalachian plant life.

Bison, elk, and wolves, once common to the Appalachians, disappeared long ago, although elk subsequently have returned to the northern mountains; caribou and moose are still found in the northernmost corners of the region. Scattered through other areas are the black bear, white-tailed deer, wild boar, fox, raccoon, beaver, and numerous other small animals. All areas of Appalachia, from the Gaspé Peninsula to Georgia, support an abundant birdlife. In the Great Smoky Mountains alone some 200 varieties of game birds and songbirds have been recorded.

The people and economy. *Settlement and expansion.* Various Eastern Woodland Indian groups, including the Pennacook, Mahican, and Susquehanna, inhabited the northern half of the Appalachians for centuries before European settlement. In the southern mountains, the Cherokee were predominant. Warfare and eviction had driven most of the Indian populations from the mountains by the mid-19th century. The so-called Trail of Tears, the forced march of the Cherokee to Oklahoma in the fall and winter of 1838–39, is perhaps the best-known episode of Indian removal.

Obstacles to settlement

The long blue wall of the Appalachians thrust up a mighty barrier to colonial expansion. Exploration and settlement was further discouraged by the size and complexity of the lateral mountain ranges, the rugged courses of many of the streams and rivers, and the ubiquitous dense forest. The central Appalachians, with their more spacious water gaps affording easy passage, attracted the largest number of early settlers. Many of these were Germans and Scotch-Irish who went into the interior of Pennsylvania and subsequently migrated down the Great Appalachian Valley in Virginia and Tennessee. In the New England Appalachians the narrow notches, often blocked by glacial debris, and the steepness of the mountains discouraged early settlement—as did the massive ruggedness of the successive ranges in the southern Appalachians—so that each of these regions remained a wilderness long after the American frontiersman Daniel Boone had forged his pioneer route through the Cumberland Gap. During the French and Indian War (1754–63), trails to the Ohio country and Great Lakes led through central Appalachia, and these, with their scattered lonely forts of the interior, became brutal battlegrounds of border warfare. Indian allies of the British waged bloody skirmishes against Appalachian settlements during the American Revolution (1775–83), but the Appalachian Mountains confined most of that struggle for independence to the Eastern Seaboard.

Economic growth. The diversity that characterizes Appalachian plant and animal life also exists in the system's mineral resources. As the immense stands of timber throughout the Appalachians brought into existence important lumber and wood-pulp industries, so rich coal beds, veins of iron ore, salt springs and licks, and deposits of granite and marble created major American industries in the region. Each of these has been attended by its own peculiar problems, especially in the field of conservation. There is, for instance, pollution of Appalachian waterways by the pulp and chemical industries and the devastation of land and human resources brought on by certain coal-mining operations. Air pollution, especially in the form of acid rain, has taken a toll on Appalachian forests from North Carolina to Canada. The pinnacle of the Appalachians, Mount Mitchell, once called Black Dome because of its blanket of virgin evergreens, is now a ghost forest of dead trees.

Despite the early arrival of the lumber industry and the opening of the coal mines, some areas of Appalachia remained isolated until early in the 20th century, notably those mountain areas of the southern region where rough terrain hindered road building. As a consequence, Southern Appalachian highlanders developed a distinctive culture characterized by handicrafts, ballads, folklore, and mores that reflect both the massive problems and the rich potential of the region.

Recreation and tourism. The Appalachian region has developed into one of the premier recreational areas of North America. One unique feature of a large portion of the system is the 2,100-mile Appalachian Trail. This footpath, stretching from Mount Katahdin in Maine to Springer Mountain in Georgia, provides a hiker's grandstand on the varied ranges of the Appalachians. Overnight shelters are scattered along the way. A noncommercial motor route, the Blue Ridge Parkway, stretches 469 miles from the Shenandoah National Park in northern Virginia to the Great Smoky Mountains National Park and is the most popular area administered by the U.S. National Park Service.

The Appalachian Trail

The springtime profusion of flowering wild azalea, rhododendron, and laurel is a major tourist attraction in the Appalachians, beginning in the south in April and spreading northward. In autumn the pattern is reversed, as the brilliant coloration of the foliage moves from north to south. Motoring, hiking, camping, fishing, skiing, whitewater rafting, and spelunking are encouraged throughout the Appalachians, as are visits to numerous craft centres and historic sites. Famous spas are reminders of more leisurely days in both the northern and southern mountains, while conference facilities and theme parks reflect a growing emphasis on tourism, with its attendant benefits and its problems of environmental stress.

Study and exploration. The ruggedness of the Appalachians, the transverse ranges by which they are crossed, their maze of streams and rivers, and their lack of natural passes created a formidable barrier to early explorers and settlers. The Spanish conquistador Hernando de Soto was probably the first European to enter southern Appalachia, in 1539–40. In 1716 Governor Alexander Spotswood of Virginia led the first organized body of English colonists across the Blue Ridge Mountains. During the 1760s and '70s Daniel Boone became America's frontier folk hero through his exploits in exploring and settling the Blue Ridge and Cumberland Mountain country. Historical figures associated with the opening of northern Appalachia include the French explorer Samuel de Champlain, who sighted the mountains in 1605 as he sailed along the Maine coast; the American Darby Field, who made the first climb up Mount Washington (1642); Timothy Nash, discoverer of the Crawford Notch (1771), which made possible communication between the coast and the Connecticut River valley; and Sir William Logan, first director of Canada's geologic survey, who made a cross section of the geologic formation of the Gaspé Peninsula in 1844 and became the first European to cross the Shickshock Mountains. During the mid-19th century the first extensive scientific studies of Appalachia began when in 1849 the Swiss geographer Arnold Guyot commenced mapping the eastern mountains. Starting with the White Mountains, he spent five years in northern Appalachia, then moved south to the Great Smoky Mountains area. He mapped, measured elevation, and made the first methodical effort to name mountains. The highest peak in the eastern United States was named for another pioneer explorer-scientist, Professor Elisha Mitchell, who fell to his death in 1857 while establishing the fact of this mountain's preeminence. It remained for Horace Kephart, a St. Louis, Mo., librarian turned naturalist who came to the southern mountains in 1904, to bring the isolated and scenic region to national attention. From his writings grew the interest and impetus that led to the establishment of the Great Smoky Mountains National Park. (W.D.)

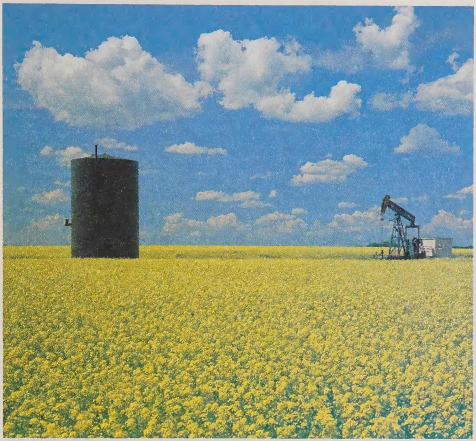
GREAT PLAINS

A major physiographic province of North America, the Great Plains lie between the Rio Grande in the south and the delta of the Mackenzie River at the Arctic Ocean in the north and between the Interior Lowland and the Canadian Shield on the east and the Rocky Mountains on the west. Their length is some 3,000 miles (4,800 kilometres), their width from 300 to 700 miles, and their area approximately 1,125,000 square miles (2,900,000 square kilometres), roughly equivalent to one-third of the United States. Parts of 10 states of the United States (Montana, North Dakota, South Dakota, Wyoming, Nebraska, Kansas, Colorado, Oklahoma, Texas, and New Mexico) and the three Prairie Provinces of Canada (Manitoba, Saskatchewan, and Alberta) and portions of the Northwest Territories are within the Great Plains proper. Some writers have used the 100th west meridian as the eastern boundary, but a more precise one is an eastward-facing escarpment that runs from Texas to North Dakota, generally somewhat east of the 100th meridian. In the Canadian portion the line dividing the Great Plains from the Canadian Shield runs east of the Red River of the North, cuts through Lake Winnipeg, and then curves northwestward, crossing Lake Athabasca, Great Slave Lake, and Great Bear Lake; in the far north, the plains reach the Arctic Ocean in a narrow strip just west of the Mackenzie delta.

Extent of the Great Plains

For map coverage of the Great Plains, see below *Mississippi River*.

Physical features. *Relief and drainage.* Once known as the Great American Desert, the Great Plains are a vast high plateau of semiarid grassland. Their altitude at the base of the Rockies in the United States is between 5,000 and 6,000 feet (1,500 and 1,800 metres) above sea level; this decreases to 1,500 feet at their eastern boundary. The altitudes of the Canadian portion are lower, and near the Arctic Ocean the surface is only slightly above sea level. Some sections, such as the Llano Estacado (Staked Plains) in western Texas and eastern New Mexico, are extremely flat; elsewhere, tree-covered mountains—the Black Hills of South Dakota and the Bear Paw, Big Snowy, and Judith mountains of Montana—rise 1,500 to 2,000 feet above the general level of the plains.



In the United States the Great Plains are drained by the Missouri River and its tributaries (the Yellowstone, Platte, and Kansas) and the Arkansas, which flow eastward from the Rockies in broad, steep-sided, shallow valleys. In Canada the Saskatchewan River and its tributaries constitute the main drainage system.

Soils and climate. The soil groups of the Great Plains are correlated with rainfall and natural grass cover. In the more humid region with heavier grass cover, deep, black soils with much organic matter developed. Sections with less moisture have lighter, shallower soils with less organic matter, while in the most arid regions the soils are even thinner, lighter in colour, and less organic in composition.

The Great Plains have a continental climate. Over much of their expanse, cold winters and warm summers prevail, with low precipitation and humidity, much wind, and sudden changes in temperature. The major source of moisture is the Gulf of Mexico, and the amount falls off both to the north and west. Thus, the southern plains have 15 to 25 inches (380 to 640 millimetres) of rain annually, the northern plains 12 to 15 inches, the eastern margin in Nebraska 25 inches, and the western margin in Montana less than 15 inches. The southern parts of the Canadian Great Plains receive 10 to 20 inches and have a growing season of 70 to 110 days. The growing season averages 240 days in Texas, 120 days at the U.S.-Canadian boundary, and from 70 to 110 days in the Prairie Provinces. A distinctive winter phenomenon of the western Great Plains is the chinook, a warm wind that blows down the eastern slope of the Rocky Mountains and can raise temperatures by as much as 30° to 40° F (17° to 22° C) in a short period.

Plant and animal life. Natural vegetation in the Great Plains is dominated by grasses—tallgrass and medium grass prairie in the east and shortgrass steppes in the west. These grasslands include larger plants such as the yucca and the prickly pear cactus in marginal areas. Much of the natural grass cover, however, has been removed to create agricultural land. Gallery forests are found along the rivers and include hardy xerophytic (drought-tolerant) trees such as box elder and cottonwood. Coniferous evergreens (pri-

Dominance of grasses

Pumping oil from a well in a field of mustard on the Great Plains, in western Saskatchewan, near Maidstone.
© E. Otto/Comstock

marily Ponderosa pine) dominate the mountain islands, such as the Black Hills. Between Edmonton, Alta., and Winnipeg, Man., a transition zone trending northwest-southeast and known as the "Parklands" is found, where the grasslands gradually give way to forest; and north of 54° N latitude coniferous forests dominate the vegetation.

Before European settlement, the Great Plains were the home of immense herds of grazing mammals: the buffalo (bison) and the pronghorn. The buffalo were nearly eliminated, but the pronghorn continued to thrive. Other grassland-adapted animals that thrive together with agriculture include prairie dogs, coyotes, and rattlesnakes. In the northern coniferous forests are found moose, woodland caribou, Canada lynx, and timber wolves.

The people and economy. The Great Plains were sparsely populated until about 1600. Spanish colonists from Mexico had begun occupying the southern plains in the 16th century and had brought with them horses and cattle. The introduction of the horse subsequently gave rise to a flourishing Plains Indian culture. In the mid-19th century, settlers from the eastern United States began to supplant the Indians, the latter being relegated to marginal agricultural areas set aside as reservations. European immigrants also played an important role in settling the plains; by 1910, foreign-born immigrants and their children constituted nearly half the population of the six northern plains states (Montana, North Dakota, South Dakota, Wyoming, Nebraska, and Kansas), with the British, Germans (many of them from Russia), and Scandinavians the leading ethnic groups. The Prairie Provinces were settled by British, German Russians (many of them Mennonites), Ukrainians, and Scandinavians.

Many of the immigrants were religious, thrifty, hard-working people who developed a strong attachment to the land. Kinship and nationality ties drew the plainsmen together, and they would travel long distances to visit and exchange work. Class differentiation was less and the status ladder shorter than in Europe or parts of North America that had been settled longer.

Although there are still few large cities, some three-fifths* of the population is urban. The largest cities are Edmonton and Calgary in Alberta and Denver in Colorado; smaller cities include Saskatoon and Regina in Saskatchewan and Amarillo, Lubbock, and Odessa in Texas. The rural population also has remained sparse.

Life-styles of the plains

Ranchers traditionally enjoyed their remoteness and looked upon their rangeland as the last remaining trace of the Old West, with its vast expanse of plains and untamed wilderness. Not generally a gregarious kind of people, they were highly individualistic in politics. Farmers, more inclined to social interaction, made economic cooperatives strong on the plains. Since the end of World War II, ranchers and farmers alike have valued horsemanship and rodeos as symbols of a tradition and style of life that evolved from the natural habitat.

The need for larger farms and ranches to produce viable economic units has led to a heavy migration from the rural areas. This exodus has been demoralizing for the farmers, ranchers, and businessmen who remained, and it has made survival more difficult for churches, schools, and the rural trading centres. The low density of population has concentrated services increasingly in a few centres, necessitating long trips to attend school and church, to do business, and to find recreation. To meet these difficulties, some farmers have moved into town to live and commuted back to their land to work, a revival of a centuries-old pattern.

Indians on horseback exploited the buffalo herds for some two and a half centuries; but in the 1870s cattle replaced the buffalo, and cowboys replaced the Indians. In the 1880s and '90s farmers began to crowd the ranchers, and wheat began to replace cattle. Settlement came in years of good rains, so the Great Plains were overpopulated in the first rush. A heavy emigration followed the twin blows of drought and economic depression in the 1930s. Many grain farmers left because their farms were too small and more vulnerable to drought than the cattle ranches. Those who stayed built up the size of their holdings, saved against hard times, and added livestock to grain farming. These people were aided considerably by the construction after World War II of numerous dams in the Missouri River basin, which provided flood control, hydroelectric power, and irrigation. In addition, an immense source of groundwater, the Ogallala Aquifer, was tapped for irrigation water for an area extending from Nebraska to the Texas Panhandle.

Thus, the Great Plains have remained basically an agricultural area producing wheat, cotton, sorghum, and hay and raising cattle and sheep. Eight of the leading U.S. wheat states (Kansas, North Dakota, Texas, Montana,

Nebraska, Colorado, Oklahoma, and South Dakota) lie within the Great Plains, and the Prairie Provinces are the leading wheat producers in Canada. Of increasing importance are crops of such oilseeds as sunflower and canola. Livestock accounts for a large percentage of farm income in most of the plains states.

The Great Plains states also produce much mineral wealth, with Texas leading the nation and four other plains states (Oklahoma, New Mexico, Wyoming, and Kansas) ranking high. Four of the plains states have the largest coal reserves in the nation (Wyoming, North Dakota, Montana, and Colorado) but, except for Wyoming, rank low in actual production. Texas leads the United States in production of petroleum and natural gas, and several other plains states are substantial producers. Alberta leads Canada in petroleum and natural gas.

Study and exploration. European knowledge of the Great Plains began with the expedition of the Spanish explorer Francisco Vázquez de Coronado in 1539–41. American interest in the region was sparked by the Louisiana Purchase (1803), which gave rise to the great Lewis and Clark Expedition in 1804–06. Two subsequent expeditions are of note: the first, led by Zebulon Pike (1805–07), explored the Arkansas and Red rivers; and the second, led by Stephen Long (1820), concentrated on the Platte and Arkansas river basins and caused Long to characterize the region as the "Great American Desert." Fur trappers and then settlers traveling through the region on the Oregon, Mormon, and Santa Fe trails completed the basic knowledge of the plains.

Expeditions of Pike and Long

Study of the Great Plains in the 20th century has concentrated on their agricultural and mineral potential, as well as on their natural history. Since World War II more emphasis has been placed on ecological studies of the soils, groundwater, and effects of the use of agricultural chemicals. Research also has been undertaken on the effects of rural depopulation and on the impact the region's natural grass cover—particularly its restoration—may have on global climatic conditions, including the greenhouse effect. (E.B.R./J.L.Di.)

NORTH AMERICAN DESERT

A vast, irregular belt of inhospitable terrain stretches north to south down the western side of the North American continent from southern Oregon and Idaho to northern Mexico, roughly corresponding to the sheltered, and hence rain-starved, intermontane region lying between the soaring barrier of the Rocky Mountains to the east and the fertile coast ranges fringing the Pacific Ocean to the west. Estimates of the size of this region vary from about 500,000 to more than 730,000 square miles (1,300,000 to 1,900,000 square kilometres). The physical geography and human utilization of this huge area exhibit great internal variety, but its overall aridity—associated with an excess of evaporation over precipitation, great temperature extremes, frequent winds, localized storms, and a predominance of starkly eroded sun-beaten landscapes—give it an unquestioned unity. Scientists, in naming this whole ecological complex, or biome, the North American Desert, are merely echoing the legend of a "Great American Desert" established as early as the 1820s by the vivid reportage of an expedition led by the American pioneer explorer and engineer Stephen H. Long.

All forms of life, from lowly plants and insects to people, have had to struggle to survive in the region, and the North American Desert thus has had enormous importance in the development of the continent. Descendants of the earliest inhabitants, the desert-culture Indians, are still found in the area. Their ranks were swollen in the 19th century by tribes thrust westward in the great dispossession that followed the advance of European settlement from the Eastern Seaboard into the continental interior, and the region is now the home of most of the U.S. Indian population. The legacy of much earlier population movements from farther south has lent a distinctly Spanish element to the area, while modern American settlement has added its own contribution in the form of sheep and cattle grazing, military installations, and small but often rapidly expanding oases of mining and manufacturing.

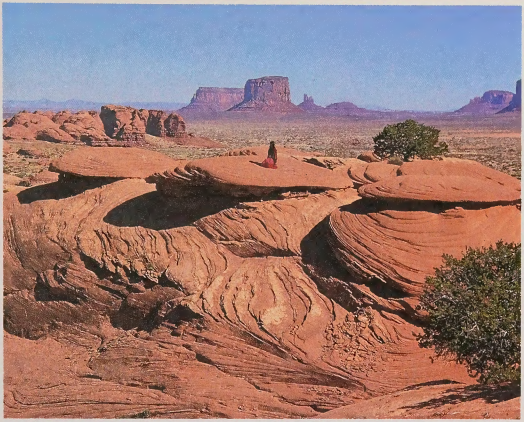
All the peoples of the North American Desert, whatever their origin, have their lives molded by the basic and all-pervading lack of water.

Physical features. *Physiography.* Differences in latitude, elevation, climate, topography, vegetation, soil, and human use have allowed the North American Desert to be subdivided into regions of cold mid-latitude and hot mid-latitude desert. All the continent's major deserts are associated with the intermontane Basin and Range Province of the western United States and northern Mexico.

The basic divisions of the desert

Classified as a cold mid-latitude desert is the Great Basin Desert, which lies in the physiographic Great Basin that covers nearly all of Nevada, western Utah, and portions of surrounding states. It constitutes the largest section of the Basin and Range Province and includes the Great Sandy Desert of southeastern Oregon, the Snake River Plains of southern Idaho, the volcanic Black Rock Desert of northwestern Nevada, and the Great Salt Lake Desert of western Utah. Although they are not usually assigned to the physiographic Great Basin, the Red Desert of southern Wyoming and the Painted Desert of northern Arizona are sometimes considered as extensions of the Great Basin Desert.

To the south the Great Basin Desert merges with the Mojave (Mohave) Desert and the hotter mid-latitude desert regions. In California near the undefined Great Basin–Mojave border are the sun-scorched landscapes of Death Valley; the valley's maximum depth of 282 feet (86 metres) below sea level is the continent's lowest point. The Mojave merges in the southeast with the Sonoran Desert, which covers much of Baja California and runs along the Gulf of California coast to the Mexican state of Sonora. Its subdivisions include the Yuma and Colorado deserts. To the east lies the huge Chihuahuan Desert, extending from southern New Mexico (where the dazzling gypsum dunes of White Sands National Monument are found) and western Texas to the highlands of central Mexico.



Geology. Most of the North American Desert—and all the salty-lake remnants—occupies areas covered by geologically recent Quaternary deposits (*i.e.,* those less than 1.6 million years old) and mountains thrust up and folded by movements in Tertiary time (or about twice as old, with some plains and plateaus consisting of sediments up to 225 million years old).

Through long periods of erosion, the landforms produced from these rocks are characteristically sharp and angular (except in the heavily eroded badlands regions) and contain, in their harsh but breathtaking beauty, some of North America's finest scenery. The action of wind, temperature changes, ephemeral streams, and floods have all been involved in this molding process. The individual deserts are characterized by plateaus, gorges, ravines, and alluvial fans washed out at the feet of mountains. Deserts of the bolson types contain playas (dried-up lake remnants) and mud and salt lakes and flats. Deserts of the hammada type are characterized by extensive rocky surfaces with boulder or gravel coverings, sometimes blackened and wind-scoured, with magnificent buttes, mesas, and other isolated mountain remnants rising high above the flat landscape. Stretches of shifting sands known as ergs—the extensive Algodones Dunes of the Colorado-Yuma desert are a notable example—are found at lower elevations, with the shallow troughs of arroyos carrying intermittent streams from surrounding uplands to be lost in the sands.

The Algodones Dunes

Soils. The soils of the North American Desert have origins similar to those of more humid regions, but they are less enriched by organisms and less leached of constituents. Most belong to the dry-soil order called aridisols, but local variations occur, reflecting differing salt and mineral composition and presence or absence of organic matter. With proper management, the more fertile soils can be productive. The youngest, least developed soils belong to the order known as entisols.

Climate. Regardless of the latitude, longitude, and elevation, a harsh and extreme temperature regime exists in the North American Desert, with a high frequency of cloudless days and intense solar radiation, infrequent and intense storms, winds carrying dust and sand, low relative humidity, and rapid evaporation or sublimation

Sandstone formations rising above the desert floor of Monument Valley Navajo Tribal Park, which straddles the boundary of Utah and Arizona.

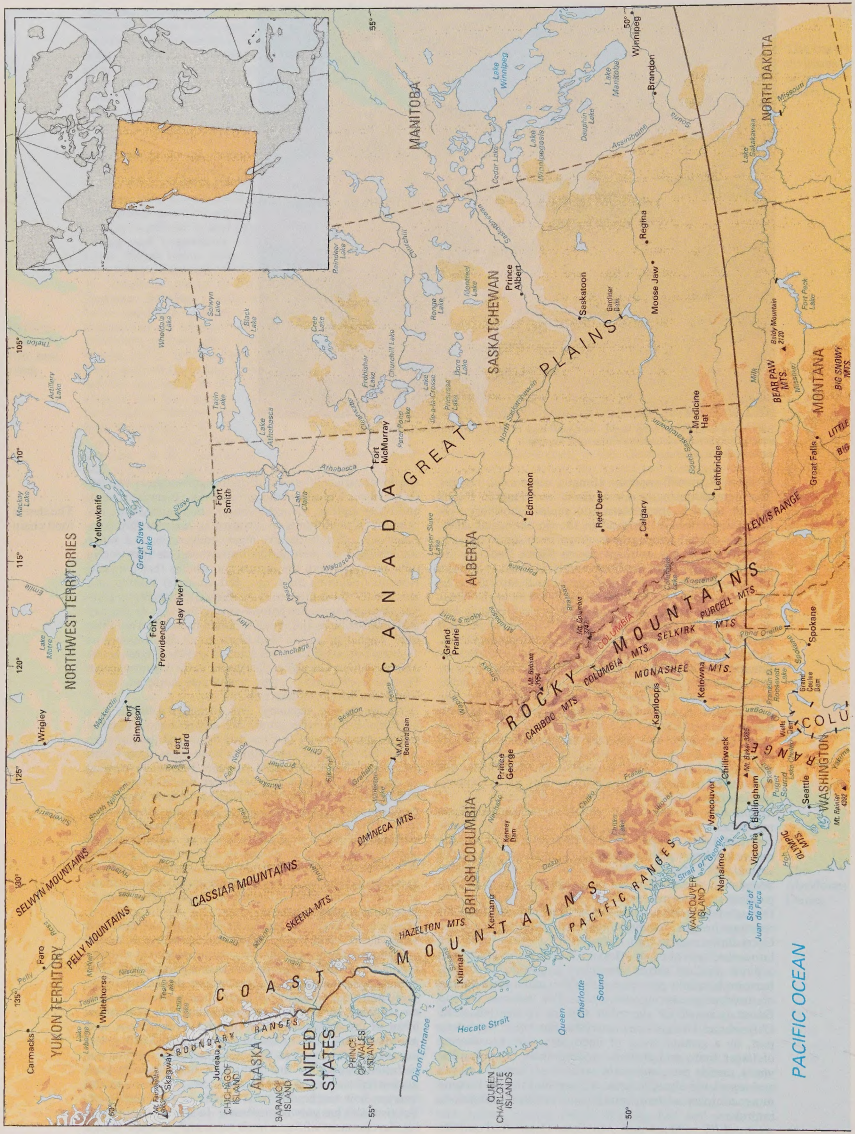
of snow. Regionally specific climatic zones exist, ranging from temperate in the Great Basin and Painted Desert to subtropical in the western Sonoran and northern Chihuahuan sections to tropical in the Sonoran gulf coast. Average annual temperatures range from approximately 49° F (9° C) in the northern deserts (Black Rock) to 73° F (23° C) in the Sonoran Desert and 77° F (25° C) at the bottom of Death Valley. Average annual rainfall varies from 6 to 12 inches (150 to 300 millimetres) in the Great Basin Desert, 2 to 6 inches in the Mojave Desert (a low of 2 inches in Death Valley), 10 to 11 inches in the Red and Painted deserts, 8 to 18 inches in the Sonoran Desert, and 12 to 14 inches in parts of the Chihuahuan Desert. Precipitation may be seasonal and characteristically is erratic, scattered, or intense. Snowfall of 12 to 24 inches occurs in most of the northern deserts, decreasing to only a trace in the Sonoran Desert. Winds are directional, with speeds averaging seven to nine miles per hour. Average relative humidities are generally less than 50 percent (20 percent for Death Valley), but 10 percent or less is not uncommon. The growing season varies from 90 to 140 days in the northern deserts to more than 300 days along the Sonoran gulf coast and in the Baja Peninsula.



Plant life. In the North American Desert, available moisture is the most critical factor for life. Local environmental factors also are significant in determining the nature of desert plant communities and their dependent animal life. Most desert plants are xerophytes (plants adapted to arid conditions) or phraetophytes (plants dependent on a permanent water supply) and survive only through their root systems and adaptive mechanisms for resisting drought. Sagebrush and saltbush characterize the Great Basin region, with Joshua trees, creosote bush, and burroweed typical of the Mojave. The Sonoran Desert has a thorn scrub of shrubs (mesquite, paloverde, ironwood, burrobush, smoke tree, and cat's claw) and a great variety of moisture-preserving succulents. The Arizona Upland Desert is noted for the giant saguaro cactus, while the Chihuahuan Desert is characterized, notably in its eastern part, by a ground cover of open mesquite, a scattering of larger trees, and shrubby undergrowth, including the yucca, prickly pear, and other varieties of cactus. Plant life and associated algae, lichens, mosses, and insects become more complex as temperature and moisture conditions improve.

Animal life. The North American Desert harbours an abundant variety of insects, including grasshoppers that occasionally reach destructive proportions. Lizards, snakes, and other reptiles, the most conspicuous animals, are dependent on plant fluids or devoured animals for moisture. Likewise, desert birds are largely independent of water sources (and are seen almost everywhere), as they derive their moisture from the insects and spiders that they eat. Rodents (including mice, rats, and squirrels), rabbits, and bats are the most numerous mammals; essentially nocturnal, they remain underground during the heat of the day and, like the birds and reptiles, obtain moisture from their food. Higher up in the food chain are such carnivores as coyotes, bobcats, foxes, and skunks; and the largest desert mammal, found at higher elevations, is the bighorn sheep. Protective coloration, often remarkably complex, is an important feature of desert life.

The desert food chain

The people and economy. As ancient dwellings, rock paintings and carvings, and other archaeological remains testify, desert-culture Indians had developed a distinctive way of life within the approximate boundaries of the North American Desert thousands of years before the coming of Europeans. Spanish explorers were the first Europeans to penetrate the southwestern area, and their legacy has molded much of the character of the region. It was only in the 19th century that a great wave of settlement, often attracted by the lure of mineral wealth, swept westward over the whole area on its way to the more fertile regions of the Pacific coast; left behind was a scattering of settlements focused on mineral wealth and irrigated regions and, even more sparsely, in the vast areas given over to sheep and cattle grazing.

Large areas of the contemporary landscape are occupied by Indian reservations, a legacy of America's continental expansion. Military installations, some associated with the testing of nuclear weapons, also take up vast areas. The various types of agriculture encompass dryland farming, sheep and cattle grazing, and more intensive developments on irrigated oases. Mineral exploitation has continued, often to the detriment of the natural environment, and manufacturing industry has become associated with growing urban settlement in the more favoured regions. Air pollution, caused by the burning of fossil fuels in population centres along the Pacific coast as well as in the interior, now reaches the most remote areas of the desert. Tourism also has grown immensely. In spite of the increasing development of dams, reservoirs, and canals, the lack

Physical features of western North America.

of water has remained a severe limitation to agricultural, urban, and industrial expansion.

Study and exploration. The Indians of the region accumulated a rich natural lore during the thousands of years of their adaptation to the desert environment, but it was left to Francisco Vázquez de Coronado and other 16th-century Spanish explorers to provide the first written descriptions of the region, particularly of the southwestern portion. Although Stephen H. Long never saw the true North American Desert, his depiction of the "Great American Desert" fired the American public's imagination. John C. Frémont's mapping of the region in the 1840s foreshadowed a host of reports, often generated by the huge land grants made to railroads and land companies and written by 19th-century surveyor-engineers. In 1878 the geologist John Wesley Powell made a significant report on the arid West, accurately forecasting the detrimental consequences of imposing on arid regions ways of life more appropriate to humid lands. More diversified studies followed—the first arid-lands research laboratory was founded at Tucson, Ariz., in 1903—and contemporary studies have included the important International Biological Program of ecological investigation. (R.E.C.)

Report of Powell

PACIFIC MOUNTAIN SYSTEM

The Pacific mountain system is a general term for the series of mountain ranges that stretches along the Pacific coast of North America from northern British Columbia (Canada) to northwestern Mexico. These ranges may be divided into eight sections. Roughly from north to south they are the Coast Mountains of British Columbia, the mountains of Vancouver Island and the Queen Charlotte Islands, the Cascade Range (itself divided into North, Middle, and South ranges), the Olympic Mountains, the Coast Ranges of Washington and Oregon, the Klamath Mountains, the Coast Ranges of California, and the Transverse Ranges. Although the Sierra Nevada often are considered to be part of this system, they are not included in this discussion (see below *Sierra Nevada*).

Physical features. *Geology.* In general, the movement of tectonic plates has been responsible for the development of the Pacific mountain system. The coastal mountains from the Queen Charlotte Islands southward to southern California have been folded, faulted, and intruded with molten rock as a result of this movement. The most significant activity has been the lateral, northerly movement of the Pacific Plate (west) relative to the North American Plate (east) along transform faults. To the north, in British Columbia, this movement has been along the offshore Queen Charlotte Fault, while in California it has been along the San Andreas Fault. Subduction (crustal sinking) is not currently occurring in these two areas. Seismic activity, particularly in California, is considerable along the transform faults. After Alaska, California is the most earthquake-prone area in North America.

To the west of the coasts of Oregon and Washington the Pacific Plate is spreading along the Gorda and Juan de Fuca oceanic ridges. The Juan de Fuca Plate, east of this spreading centre, is subducting under the North American Plate. The molten mantle rock produced by this subduction is responsible for the major volcanoes in the Cascade Range. All the Cascade composite cones are of the explosive type, their molten rock being high in silica. Until the eruption of Mount St. Helens in 1980, Lassen Peak had been the most recently active volcano (1914–17) in the coterminous 48 United States. The Mount St. Helens eruption, which blew off the top of its cone, was of greater magnitude than any other eruption in the region since the eruption and collapse of Mount Mazama 6,600 years ago, which formed the caldera now occupied by Crater Lake.

Because the subduction process is not continuous—it is impeded as huge quantities of materials accumulate on plate boundaries—enormous stresses develop. The release of these stresses creates shock waves of a larger magnitude than any other known earthquakes (*i.e.,* greater than 9 on the Richter scale). It is thought that for the past 4,000 years such subduction-related earthquakes have occurred at intervals of 300 to 1,000 years.

Earthquakes related to subduction

Physiography. The arrangement of the ranges in the system can be visualized as being in the shape of an extremely elongated H with a closed base. From north to south the west side of the H is made up of the ranges of the Queen Charlotte Islands and Vancouver Island, the Olympic Mountains, and the Washington, Oregon, and California Coast Ranges. From north to south the east side of the H consists of the Canadian Coast Mountains, the Cascade Range, and the Sierra Nevada. The Klamath Mountains of southern Oregon and northern California make up the east-west cross in the centre of the H, while the Transverse Ranges bend eastward from the California Coast Ranges to form the closed base of the H.

Inside the H north of the Klamath Mountains are the drowned inside passage of British Columbia, the Puget Sound Lowland of Washington, and the Willamette Valley of Oregon. Inside the H south of the Klamath Mountains is the Central Valley of California.

Coastal plains are either narrow or nonexistent along the entire north-south extent of the coastal ranges. Offshore a narrow continental shelf drops abruptly into ocean depths. In places waves have cut notches and terraces. More resistant igneous rocks stand as sea cliffs with undercut notches. Softer sedimentary rocks have been eroded to form embayments.

The ranges of Vancouver Island and the Queen Charlotte Islands have been heavily glaciated. Stream valleys have been deepened by glaciers to produce a fjordlike coast, with relatively short streams draining the interior. Southward, across the Strait of Juan de Fuca, the Olympic Mountains rise to almost 8,000 feet (2,440 metres). They consist of folded sedimentary and metamorphic rock and also have been heavily glaciated. Drainage is radial from the highest peaks; among the major streams are the Hoh, Quinault, and Elwha.

The Canadian Coast Mountains and North Cascades differ structurally from the Middle and South Cascades. These northern ranges consist of a dissected upland of late Paleozoic rock (*i.e.,* about 300 million years old) that has been folded, metamorphosed, and intruded by granites. Ridges in the North Cascades rise to elevations between 6,000 and 8,000 feet; above these ridges stand the composite volcanic cones of Glacier Peak and Mount Baker. The Coast Mountains of British Columbia are considerably

Coast Mountains along the Torres Channel, an arm of Atlin Lake, northern British Columbia.

lower, with the highest elevations reaching 3,000 to 4,000 feet in the south. The higher peaks, however, often are glacier-covered. All the ranges have been heavily dissected by running water both before and after the Pleistocene Epoch (1,600,000 to 10,000 years ago). During the Pleistocene they were covered by a cordilleran ice sheet, the glaciers of which occupied and deepened many existing stream valleys. On the east side of the North Cascades, Lake Chelan is in a glacially formed valley, and its deepest points are more than 1,500 feet below the surface. In the Coast Mountains glacial action has produced a spectacular fjord coast. Farther south in southern British Columbia and Washington are deep glacial valleys opening out onto the Fraser River delta and the Puget Sound Lowland.

The Middle Cascades

The Middle Cascades, which extend southward from west-central Washington into Oregon, are an uplifted and faulted region consisting of volcanics of Tertiary and Quaternary age (*i.e.*, from the past 66.4 million years). These volcanics consist of successive layers of tuffs, breccias, and mudflows, covered by basaltic flows. The range can be divided into eastern and western sections, the western being the oldest. Capping the higher, eastern part of the range is a more recent layer of Tertiary and Quaternary andesites and basalts. Elevations reach 4,000 to 6,000 feet, with a number of volcanic peaks—such as Mounts Rainier and Hood—standing high above the general surface relief; Rainier, at 14,410 feet (4,392 metres), is the highest peak in the Pacific mountain system.

The Columbia River cuts through the Middle Cascades in a magnificent gorge. On the southern (Oregon) side are numerous hanging valleys with streams that plunge in spectacular waterfalls into the gorge. Multnomah Falls, at 620 feet, is second in height in the United States only to Yosemite Falls in California. During the latter part of the Pleistocene (10,000–12,000 years ago), a large lake (Lake Missoula) was impounded by an ice dam in western Montana. On several occasions the dam gave way and released enormous quantities of water, which then rapidly drained to the sea. These floods deepened and widened the existing Columbia River valley and are responsible for the present profile of the gorge.

The South Cascades, extending from southern Oregon into northern California, differ from the Middle Cascades in that they were not uplifted. Even so, two of the major volcanoes in the western United States, Lassen Peak and Mount Shasta, surmount the range. The Pit River provides a low-elevation passage across these mountains.

The Klamath Mountains are the oldest of the Pacific coastal mountains, dating to the early Paleozoic Era (*i.e.*, about 500 million years ago). They are extremely complex, probably resulting from the collision of tectonic plates in the Early Triassic Period (245–240 million years ago). Later they were intruded by granite batholiths. The Klamath Mountains have been glaciated in their higher elevations and have been heavily dissected by streams; the major watercourse crossing them is the Rogue River.

Both the Coast and the Transverse ranges were formed by plate collisions. The Washington and Oregon Coast Ranges consist of folded gray mudstones and siltstones oriented in a north-south direction. The major streams are antecedent to the uplift and have been drowned in their lower courses, producing estuaries. In addition to the Columbia[1] these include the Umpqua and Siuslaw rivers. The California Coast Ranges also are made up of folded and faulted sedimentary rocks. The major faults trend northwest-southeast, however, and the rivers tend to follow these lines of weakness. North of San Francisco Bay are the Napa, Russian, Eel, and Klamath rivers, while the Salinas River is the major coastal stream south of the bay. The eastern section of the Transverse Ranges consists of granites and metamorphic rocks, while the western portion resembles the sedimentary structure of the Coast Ranges; streams draining them include the Santa Clara and Santa Ana rivers.

Three most abundant orders

Soils. In the Pacific mountain system are found all of the 11 orders of soils, of which three are most abundant. Inceptisols dominate in the coastal ranges from the Queen Charlotte Islands south to San Francisco Bay and in the Cascade Range. They have weakly differentiated horizons (layers), are little altered from their parent material, and occur where summers are cool. The California Coast Ranges south of San Francisco and the Transverse Ranges have dark-coloured mollisols rich in organic material. Much of the Klamath Mountains area is characterized by ultisols, leached reddish soils that develop where winters are mild and moist and summers are warm and dry.

Climate. The orientation of the Pacific mountains has a profound effect on the climate of the western United States and Canada. Regionally, they act as a barrier to storms from the Pacific Ocean, which especially in winter bring large quantities of precipitation to the western slopes of the ranges. For example, the highest annual precipitation levels in the 48 coterminous states (more than 150 inches [3,800 millimetres]) occur on the southwestern slope of the Olympic Mountains, while the greatest annual precipitation total in Canada (more than 200 inches) occurs along the British Columbia coast north of Vancouver Island. Inland precipitation decreases on the east side of the coastal ranges and increases again on the western slopes of the Cascades, in some places exceeding 100 inches; much of this is in the form of snow. Immediately east of the Cascades the annual precipitation decreases drastically to only 8 inches at Yakima, Wash. In California more than 50 inches falls on the windward side of the Coast Ranges, decreasing to 30 inches in the higher parts of the Transverse Ranges.

Plant life. Climate is the major influence on vegetation type. Conifers predominate and can grow to enormous size, especially on the moister, western slopes. The Sitka spruce is dominant along the coast from southern British Columbia to northern California. The largest standing mid-latitude rain forest in the United States is on the west side of the Olympic Mountains. Inland and up into the Cascades, Douglas fir and western hemlock dominate. They give way at high elevations to trees such as Pacific silver fir and mountain hemlock. On the eastern slopes of the Cascades, ponderosa pine is the major tree.

Along the coast from southern Oregon to the Monterey Peninsula of California, the redwood is dominant, occurring with Sitka spruce, Douglas fir, and hardwoods such as alder. Farther from the coast, the Coast Ranges are characterized by mixed forests of bigleaf maple, madrone, various oaks, and pines and other conifers. On the eastern slopes is an oak-grassland association. In the drier Transverse Ranges is found the bigcone Douglas fir, as well as pines and oaks.

Animal life. The anadromous (river-spawning) salmon is the most distinctive creature of the coastal ranges. Five species—pink, chum, coho, sockeye, and chinook—are found in the streams draining the mountains, each with its own distinctive range and environmental conditions. The pink and chum spawn in coastal streams near the ocean, while the sockeye usually spawns in upstream lakes. The chinook (or king) favours large rivers such as the Columbia and Sacramento and travels hundreds of miles inland. The coho also favours larger rivers. The American shad, another anadromous fish and originally native to the Atlantic coast, was introduced in the late 19th century and has adapted to streams of the Pacific coast.

Mammals

The larger land mammals include Roosevelt elk in the coastal ranges from British Columbia to northern California and black bears in the coastal ranges and Cascades. Three species of deer are found: mule deer on the eastern slopes of the Cascades, black-tailed deer in the coastal and Cascade ranges, and, locally in the Coast Ranges of Oregon, white-tailed deer. Three members of the cat family—lynx, bobcat, and mountain lion—are found throughout the Pacific mountain system. The beaver, a mainstay of the 18th- and 19th-century fur trade, is found as far south as northern California.

The people. The Pacific mountain region had a large American Indian population before the arrival of white explorers and settlers. Hunting, the gathering of berries, roots, and nuts, and fishing were the major economic activities. Trade and barter were common among tribes, especially in the north, where peoples from the interior traded hides, meat, and roots for salmon caught by the coastal peoples.

The Spanish were the first Europeans in the region. They moved northward, establishing missions throughout California to just north of San Francisco Bay. The first whites in the northern areas were fur trappers and traders. These early contacts had profound effects on the lives of the native peoples. Many of the California Indians were put on missions, where they became farmers and pastoralists. The fur trade introduced a number of useful manufactured goods, notably firearms and blankets. Contact with whites, however, introduced such European diseases as smallpox, scarlet fever, and measles, for which the Indians had little immunity: much of the Indian population was wiped out in a short period of time.

From the 1830s an increasing flood of whites poured into the region, many of them farmers who settled in the Fraser River valley, Puget Sound Lowland, and Willamette Valley. By the end of the 19th century, the region's modern settlement pattern had been established, with most of the Indians on reservations and the economy dominated by the logging and lumber industry.

The economy. *Resource exploitation.* The abundant precipitation and deep, weathered soils of the coastal ranges from the Queen Charlotte Islands through the Klamath Mountains and into northern California produce the largest softwood lumber trees in the world. The completion of railroads into the region in the 1880s, giving it access to other parts of the country, made possible the large-scale commercial exploitation of these forests. The opening of the Panama Canal in 1914 stimulated the movement of lumber by ship. Wholesale cutting of these lands ensued. The coastal ranges, most of which were privately owned, were virtually cleared of their old-growth (virgin) forests. The Canadian Coast Mountains and the Cascade Range were the last areas to be logged, because their greater inaccessibility made it more difficult to cut and transport the timber.

Mining and the extraction of oil and natural gas are of some economic importance. Sand and gravel are now the major minerals mined.

Although the Columbia River basin is the main focus of hydroelectric development in the region, the abundant precipitation, large drop in elevation, and deep, wide glacial valleys for water storage also have made possible hydroelectric development in the Canadian Coast Mountains and North Cascades. Two notable schemes are the harnessing of the Skagit River northeast of Seattle, Wash., and the generating station at Kemano, on the coast of British Columbia, that supplies power for an aluminum smelter at nearby Kitimat.

Hydroelectric schemes

Agriculture and fishing. Agriculture is important in some of the valleys within the ranges. From southern British Columbia to northern California, dairying and egg production are leading activities. Some of California's most important vineyards are in the Coast Ranges near San Francisco, notably the Napa and Sonoma valleys to the north. The Salinas Valley south of San Francisco and the Central Valley to the east are two of the leading vegetable-producing areas in the United States.

Fishing once was a major activity along the entire Pacific coast. Salmon fishing was dominant from British Columbia to northern California, while tuna and sardines were important in southern California. Overfishing, pollution, and (for the anadromous salmon) the destruction of the natural spawning habitat have seriously depleted fish stocks and reduced the importance of commercial fishing. Salmon farming has become significant, however, especially in British Columbia.

Recreation. The Pacific mountain system is one of North America's great playgrounds. Large numbers of tourists and outdoors enthusiasts are attracted to the region's magnificent scenery and its varied, year-round recreational opportunities. More than a dozen national parks, monuments, and recreation areas are scattered throughout the ranges, as well as dozens of provincial, state, and county parks. Some of North America's best Nordic and Alpine skiing facilities are found in the region, often in close proximity to large urban areas.

Environmental concerns. The almost rainless summers in all but the most northerly part of the region make fire a constant threat. Although some fires are started by natural causes (mainly lightning), many are caused by human carelessness, as, for example, with the great Tillamook Burn in Oregon in 1933.

The logging practice of clear-cutting left millions of acres of denuded mountainsides. Exposed hillsides were subject to heavy erosion, and one result was the deposition of sediment on the gravel spawning beds used by salmon. The removal of forest cover also eliminated habitat for many species, although as ground cover was reestablished it provided grazing for such large mammals as deer and elk. Reforestation often was successful on more accessible, privately owned lands in the coastal ranges, but such efforts frequently met with difficulty in areas (often public lands) with poorer soils and steeper, more rugged terrain.

Beginning in the late 19th century, concerns about timber depletion led to the creation of government-protected lands. These formed the core of the present-day system of crown lands in Canada and national forests in the United States and the government supervision of logging. A growing environmental movement was instrumental in the enactment of increasingly stringent logging regulations; those that restricted habitat destruction, such as the old-growth forests inhabited by the northern spotted owl, sparked a bitter dispute between environmentalists and logging interests.

Logging regulations

Study and exploration. Juan Rodríguez Cabrillo, a Portuguese explorer in the service of Spain, probably was the first European to explore the coast of California. He is thought to have sailed north in 1542, and his pilot, Bartolomé Ferrelo, may have reached as far as the present southern border of Oregon. Sir Francis Drake sailed the coast in 1579 and may have landed in Oregon. Juan Pérez landed on the west coast of Vancouver Island in 1774, and the following year Bruno Hezeta reached the Washington coast and claimed the area for Spain. Captain James Cook charted the coast from Oregon to the Arctic in 1778.

The first overland explorer was Alexander Mackenzie, who in 1793 traveled westward until he reached the British Columbia coast. In 1805 the Lewis and Clark Expedition reached the Pacific Ocean after following the Columbia River. The last of the great overland treks was by the Canadian explorer Simon Fraser, who followed the river later named for him and reached its mouth (near present-day Vancouver, B.C.) in 1808.

The first geologic studies of the ranges were carried out in the late 19th century. The great San Francisco earthquake of 1906 precipitated a thorough investigation of the California Coast Ranges. Present-day scientific research focuses on restoring wild stocks of salmon, finding evidence of the periodicity and magnitude of subduction-caused earthquakes, and improving methods of forest management.

(J.G.A.)

ROCKY MOUNTAINS

The Rocky Mountains form the backbone of the great upland system that dominates the western North American continent. Generally, the ranges included in the Rockies stretch from northern Alberta and British Columbia southward to New Mexico, a distance of some 3,000 miles (4,800 kilometres). In places the system is 300 or more miles wide. Limits are mostly arbitrary, especially in the far northwest, where mountain systems such as the Brooks Range of Alaska are sometimes included. The Rockies are bordered on the east by the Great Plains and on the west by the Interior Plateau and Coast Mountains of Canada and the Columbia Plateau and Basin and Range Province of the United States.

The Rocky Mountains include at least 100 separate ranges, which are generally divided into four broad groupings: the Canadian Rockies and Northern Rockies of Montana and northeastern Idaho; the Middle Rockies of Wyoming, Utah, and southeastern Idaho; the Southern Rockies, mainly in Colorado and New Mexico; and the Colorado Plateau in the Four Corners region of Utah, Colorado, New Mexico, and Arizona. These four subdivisions differ from each other in terms of geology (origin, ages, and types of rocks) and physiography (landforms, drainage, and soils), yet they share the physical attributes

Four broad groupings

of high elevations (many peaks exceeding 13,000 feet [4,000 metres]), great local relief (typically 5,000 to 7,000 feet in vertical difference between the base and summit of ranges), shallow soils, considerable mineral wealth, spectacular scenery from past glaciation and volcanic activity, and common trends in climate, biogeography, culture, economy, and exploration.

For map coverage of the Rocky Mountains, see above *North American Desert.*

Physical features. *Physiography.* The Canadian Rockies include the Mackenzie and Selwyn mountains of the Yukon and Northwest Territories (sometimes called the Arctic Rockies) and the ranges of western Alberta and eastern British Columbia. The Northern Rockies include the Lewis and Bitterroot ranges of western Montana and northeastern Idaho. These ranges formed along the eastern edge of a region of accumulated carbonate sediment some 17 miles thick. This structural depression, known as the Rocky Mountain Geosyncline, eventually extended from Alaska to the Gulf of Mexico and became a continuous seaway during the Cretaceous Period (144 to 66.4 million years ago). The ranges of the Canadian and Northern Rockies were created when thick sheets of limestones were thrust eastward over younger rocks during the mountain-building episode called the Laramide Orogeny (65 to 35 million years ago). Some of these thrust sheets have moved 20 to 30 miles to their present positions. The western margin of the Canadian Rockies and Northern Rockies is marked by the Rocky Mountain Trench, a graben (straight, flat-bottomed valley) up to 3,000 feet deep and several miles wide that has been glaciated and partially filled with deposits from glacial meltwaters.

The Columbia Icefield is situated on the continental divide in the Canadian Rockies at elevations of 10,000 to 13,000 feet above sea level. It includes the large Athabasca Glacier, which is nearly five miles long and about a mile wide. Glaciers in this ice field, while continuing to move, are thinning and retreating. The Canadian Rockies are about equally divided between drainage to the east (Atlantic and Arctic oceans) and west (Pacific Ocean).

The Middle Rockies

The Middle Rockies include the Bighorn and Wind River ranges in Wyoming, the Wasatch Range of southeastern Idaho and northern Utah, and the Uinta Mountains of northeastern Utah; the Absaroka Range, extending from northwestern Wyoming into Montana, serves as a link between the Northern and Middle Rockies. While the massive deposition of carbonates was occurring in the Canadian and Northern Rockies from the late Precambrian to the early Mesozoic, a considerably smaller quantity of clastic sediments was accumulating in the Middle Rockies. Mountain building there resulted from compressional folding and high-angle faulting, except for the low-angle thrust-faulting in southwestern Wyoming and southeastern Idaho. The granitic core of the anticlinal mountains often has been upfaulted, and many ranges are flanked by Paleozoic sedimentary rocks (*e.g.,* shales, siltstones, and sandstones) that have been eroded into hogback ridges. Most mountain building in the Middle Rockies occurred during the Laramide Orogeny, but the mountains of the spectacular Teton Range attained their height less than 10 million years ago by moving more than 20,000 vertical feet relative to the floor of Jackson Hole along an east-dipping fault.

The Bighorn, Wind River, and Uinta ranges all form sharp ridge lines that rise above surrounding basins. The Wind River Range supports a large area of glaciers, including the Dinwoody Glacier. These glaciers, however, are retreating fairly rapidly.

Geologic events in the Middle Rockies strongly influenced the direction of stream courses. A special feature of late Cenozoic time (*i.e.,* the past 10 million years) was the creation of rivers that flowed from basin floors into canyons across adjacent mountains and onto the adjacent plains. This phenomenon resulted from superposition of the streams. The stream courses were initially established in the Late Miocene Epoch (11.2 to 5.3 million years ago), when the basins were largely filled by Tertiary deposits (*i.e.,* those between 1.6 and 66.4 million years old) that locally extended across lower segments of mountain axes. During the subsequent regional excavation of the basin fills—which began about five million years ago—the streams maintained their courses across the mountains and cut transverse canyons.

The Yellowstone-Absaroka region of northwestern Wyoming is a distinctive subdivision of the Middle Rockies. A large magma chamber beneath the area has filled several times and caused the surface to bulge, only to then empty in a series of volcanic eruptions of basaltic and rhyolitic lava and ash. Three such cycles have occurred in the past two million years, the most recent of which occurred about 600,000 years ago. The magma chamber is currently filling again, and the land surface in Yellowstone is rising or tilting a slight amount each year.

The Southern Rockies

The Southern Rockies include the Front Range and the Wet and Sangre de Cristo mountains along the eastern slope and the Park, Gore, and Sawatch ranges and the San Juan Mountains along the western slope. The eastern and western ranges are separated by a series of high basins: from north to south they are North Park, the Arkansas River valley, and the San Luis Valley. The Southern Rock-

Forested slopes of the Beartooth Mountains, Mont., in the northern Rocky Mountains.

ies extend northward into southern Wyoming in three prongs: the Laramie and Medicine Bow mountains and the Sierra Madre.

Only about 5,000 feet of sediment accumulated during middle Mesozoic times (about 200 to 150 million years ago) in the region now occupied by the Southern Rockies. Mountain building in these ranges resulted from compressional folding and high-angle faulting during the Laramide Orogeny, as the Mesozoic sedimentary rocks were arched upward over a massive batholith of crystalline rock. Some 10,000 vertical feet of the sedimentary rocks were then eroded; otherwise the Front Range would be approximately twice its present height.

The ranges of the Southern Rockies are higher than those of the Middle or Northern Rockies, with many peaks exceeding elevations of 14,000 feet. Colorado has 53 peaks over this elevation, the highest being Mount Elbert in the Sawatch Range, which at 14,433 feet (4,399 metres) is the highest point in the Rockies. These ranges were heavily eroded by several episodes of glaciation—the most recent ended about 7,500 years ago, and no active glaciers remain—resulting in spectacular alpine scenery. River valleys have been deepened in the past two million years, first from the direct action of glacier ice and subsequently by glacial meltwaters. Moraines occur in most valleys, marking the downslope extent of past glaciations.

The physiographic province called the Colorado Plateau in southeastern Utah, southwestern Colorado, northern Arizona, and northwestern New Mexico is another high-elevation region of the western United States, although it lacks the history of folding, faulting, and volcanic activity of adjacent regions. The uplifts in the Colorado Plateau are not as great as those elsewhere in the Rockies, and therefore less erosion has occurred; Precambrian rocks have been exposed only in the deepest canyons.

The plateau is actually a series of plateaus at different elevations arranged in a stairstep sequence through faulting. The horizontal sedimentary rocks have been dissected by the Green and Colorado rivers and their tributaries into a network of deep canyons. Some of these canyons are deeply entrenched meanders, such as the dramatic Goosenecks section of the San Juan River near Mexican Hat, Utah, where erosion through the canyon walls separating opposite sides of a meandering river loop has created a natural bridge.

The Grand Canyon

The Grand Canyon of the Colorado River cuts across the southern end of the Kaibab Upwarp in the southern plateau region. The canyon is up to 6,600 feet deep and exposes a remarkable sequence of sedimentary rocks. Weak rock types, such as shale and softer sandstone layers, form low-sloping benches, while more resistant rock types, such as limestone and harder sandstone layers, comprise cliff-forming units. Because of the alternating sequence of weak and resistant rocks in the canyon walls, a cliff-and-bench topography has formed that is typical of much of the Colorado Plateau region. The headward erosion of streams into the plateau surface eventually isolates sections of the plateau into mesas, buttes, monuments, and spires. Bedrock that has been fractured into series of parallel joints can weather into high rock walls known as fins. Subsequent weathering leads to the creation of natural arches. The same weathering processes on cliffs can create niches, which have been exploited by cliff-dwelling Indian cultures in the past.

Four mountain groups—the La Sal, Henry, Abajo, and Carrizo—are notable. From a central pipelike intrusion reaching deep into the Earth's crust, magma has been injected between layers of sedimentary rock, causing the overlying beds to bulge up in domes about one mile across. These domes are called laccoliths, and each of these mountain massifs is made up of a group of laccoliths.

Soils. Mountain soils in the Rockies are poorly developed, being extremely thin and young and too deficient in nutrients for most types of agriculture. High-valley soils are sometimes suitable for irrigation, depending on texture, steepness of slopes, length of snow cover, and the presence of trace elements (*e.g.*, selenium) that limit suitability for crop cultivation. Rangeland grazing is a more common pursuit. Soils of the Colorado Plateau also are generally shallow and stony, and they contain a high percentage of salts. In some locales, they can be made fertile if sufficient water is available to flush excess salts.

Climate. Along the great north-south extent of the mountains, the climate of the Rockies extends from the northern fringe of the subtropical zone in the far south to the Arctic in the far north. In the south, however, the continentality and high elevation of the mountains tend to reduce the advantages of latitude. Two vertical zones prevail throughout much of the range. The lower is characterized as cool temperate, with cold winters and relatively cool summers. This zone occurs between elevations of 7,000 and 10,000 feet in the south, with upper and lower limits decreasing proportionally with increasing latitude. The higher zone is alpine and tundralike in character, with severe winter conditions and short, cold summers; in the south the highest peaks may remain snow-covered until August, while in the north many of the high valleys sustain permanent glaciers.

Precipitation

Precipitation generally increases from south to north, with the north receiving about three times that of the south. In the south the climate tends to be dry. The San Luis Valley in Colorado, for example, has a mountain-desert climate and is one of the driest areas of the Rockies. Much of the total annual precipitation in the south falls as snow in winter, although characteristic of the summer are local, sometimes violent, afternoon thunderstorms. The Northern Rockies tend to receive precipitation more evenly throughout the year from Pacific cyclonic storms. Almost everywhere in the Rockies the growing season is short; some places are susceptible to frosts even in summer.

Plant life. The plant communities of the Rockies vary markedly according to elevation, latitude, and exposure. On the eastern slopes in Colorado and New Mexico, strong winter winds off the arid plains stunt and deform the scattered cedars and piñon pines. The lower elevations at this end of the system are predominantly treeless, except along watercourses, where cottonwoods and other broad-leaved, deciduous species cluster. Sagebrush occurs in valleys and basins as far north as southern Alberta.

Trees of the middle-elevation montane forest include aspen, yellow pine, and Douglas fir. The subalpine forests comprise western hemlock, lodgepole pine, western red cedar, white spruce, and Engelmann spruce. The tree-line elevation descends as latitude increases, and alpine tundra, characterized by low flowering plants, spans nearly the full length of the range. So-called elfin woodland, consisting primarily of dwarfed willows, occurs in the most northerly mountains. The myriad wildflowers of the forests and high meadows include columbine, bunchberry, larkspur, gentian, and Indian paintbrush.

Animal life. The fauna of the Rockies is varied and abundant. Among the large mammals emblematic of the rugged backcountry are the black bear, grizzly bear, mountain lion, and wolverine. Bighorn sheep and mountain goats inhabit the high crags in summer and migrate to the lower slopes for the winter months. Members of the deer family, such as the caribou, elk (wapiti), mule deer, and white-tailed deer, also migrate vertically between alpine meadows and subalpine forest cover; the solitary moose frequents northern lakes, streams, and marshy areas, feeding on willow foliage and aquatic plants. Yellowstone National Park in Wyoming is home to one of the largest herds of bison in North America. Wild horses and burros inhabit the surrounding plains, while coyotes roam the lower valleys and along roads and rail routes. Wolves, brought to near extinction by human predation, remain rare but have resurged since 1970 as their importance in the wilderness ecosystem has come to be appreciated. Smaller mammals of the lower elevations include the least chipmunk, red squirrel, Columbian ground squirrel, black-footed ferret, and marmot. The pika dwells on talus slopes, and the prairie dog inhabits the drier valleys and plateaus. Wildlife of the arid southern mountains comprises the pronghorn, jackrabbit, peccary, rattlesnake, and other desert species. Beavers and river otters can be found in watercourses throughout the region. Amphibians include several species of frogs, toads, and salamanders that are indigenous to the region.

Birds

Birdlife is comparably diverse. In summer such raptors as the bald eagle, golden eagle, osprey, peregrine falcon, and turkey vulture nest throughout the range. Several owl species are found, including the great horned owl. Woodland and meadow birds include species of grouse (ruffed, sage, spruce, and blue), ptarmigan, wild turkey, ring-necked pheasant, Clark's nutcracker, gray jay, and Steller's jay. Among wading birds are species of egret, crane, great blue heron, curlew, and avocet. An abundance of waterfowl—such as teal, snipe, numerous duck species, and the endangered trumpeter swan—spend the warm season on mountain lakes. Canada geese and white pelicans also spend a portion of the year in the region. The numerous hot springs of the Rockies provide a winter haven for many birds that would otherwise migrate southward.

The rainbow trout, while perhaps the most celebrated fish of the region, is largely introduced from California. The arctic grayling is a prominent denizen of high northern lakes.

The people. The human presence in the Rocky Mountains has been dated to between 10,000 and 8,000 BC. American Indian peoples inhabiting the northern mountains in modern times include the Shuswap and Kutenai of British Columbia, the Coeur d'Alene and Nez Percé of Idaho, and the Flathead of Montana. The traditional lands of the Shoshoni in Idaho and Wyoming and the Ute in Utah and Colorado extended into the west-central ranges. Southwestern groups include the Navajo, Hopi, and Pueblo. Nomadic Plains Indians who once ranged into the eastern Rockies included the Blackfoot, the Crow, and the Cheyenne.

Incursions by Europeans began in the Southwest in the 16th century. By the early 19th century, exploration and economic exploitation brought them into contact, and often conflict, with virtually all the indigenous mountain peoples. These encounters, along with shifting food supplies and intertribal territorial wars, generated extensive migration and attrition among some groups. Many Indians now live on the reservations established throughout the region. Although settlement is now widespread throughout most of the Rockies, population is concentrated in urban areas generally located at the base of mountains, along railways, or in river valleys.

The economy. *Water resources.* The Rocky Mountains in Canada and the United States are a region of water surplus, where precipitation exceeds losses from evaporation, runoff, and transpiration. The lands on either side of the mountain front, however, experience a water deficit. The people living in these areas have looked to water-storage projects in the Rockies for irrigation, domestic and industrial use, navigation, and hydroelectric power generation, as well as for flood control. Most of the potential sites for large dams already have been utilized, and smaller dams in the headwater regions are now being constructed.

The Colorado project

One of the most ambitious of these projects is in the Colorado Rockies, where a complex network of reservoirs, tunnels, and pipelines diverts water from the western slope of the Front Range to the large urban area centred on Denver along the eastern slope. This scheme, opposed by residents of the range's western slope, is the first in a series of projects extending downstream in the Colorado River system that may eventually utilize the entire flow of the river.

Mineral resources. Minerals have been of economic significance since the mid-19th century, although worldwide market fluctuations often have caused mine closures. Copper, easily the most valuable of the many metallic resources of the Rocky Mountains, has been extracted from large mines in British Columbia, Montana, Utah, and Arizona. The Rockies are more noted for their many underground mines for silver, gold, lead, and zinc, found in British Columbia, Colorado, Montana, Idaho, Utah, New Mexico, and Arizona. The Rockies also have produced large quantities of molybdenum, beryllium, and uranium.

Sapphires are mined in Montana, while great reserves of other nonmetallic minerals occur in various places in the mountains. These include phosphate rock, potash, trona, magnesium and lithium salts, Glauber's salt, gypsum, limestone, and dolomite. The large basins between the uplifts of the ranges contain many petroleum and natural gas fields. Alberta, Wyoming, New Mexico, Montana, Colorado, and Utah are all substantial producers, with the Powder River basin of Wyoming proving to be one of the leading regions.

The Rockies also hold extensive shale deposits containing a solid hydrocarbon material that can be driven off as crude oil by heat treatment. These oil shales occur principally around the Uinta Mountains in Wyoming, Colorado, and Utah. Immobile oil also is located in certain sandstones in various places. These deposits are called bituminous, oil, or tar sands. In both cases, the amounts of potential oil are vast, although the costs involved in extracting the oil have not made exploitation profitable.

The Rocky Mountains and the adjacent Great Plains to the east contain the Western Hemisphere's most abundant and accessible coal reserves. These consist largely of bituminous, subbituminous, and lignitic deposits and constitute a tremendous energy source. Most of this coal is mined using surface strip-mining techniques.

National parks, forests, and recreational areas. Many of North America's finest national parks, national monuments, and wilderness areas are in the ranges of the Rocky Mountains and in the Colorado Plateau. To these areas of natural beauty have been added such large recreation facilities as the Glen Canyon National Recreation Area, located on either side of Lake Powell in Utah and Arizona, and Flaming Gorge National Recreation Area, in Wyoming and Utah. The area in and around Yellowstone National Park represents one of the largest relatively intact temperate-zone ecosystems on the planet. More than 10,000 hot springs, along with the large populations of elk, bison, and moose and high-quality trout fisheries, draw large numbers of tourists.

Park accessibility

The construction of roads over high mountain passes have made recreational areas more accessible, especially Jasper and Banff national parks in Alberta and Glacier, Yellowstone, Grand Teton, and Rocky Mountain national parks in the United States. An increasing number of the high mountain roads, while closed to automobiles during winter, are used by snowmobile enthusiasts. High-speed highways facilitate long-range trips to the Rocky Mountain region from other sections of North America. Although transcontinental Canadian rail travel has been discontinued, Banff and Jasper national parks can still be reached by rail from the larger cities in Alberta and British Columbia. Small commuter airlines also have increased access to the parks.

Most of the land in the Rockies has been designated as national or provincial forests. In the United States the principle of multiple use governs management of these forests, with lumbering, mining, oil and gas drilling, and grazing permitted under federal regulation. The Canadian Rockies produce a large portion of that nation's timber, supporting numerous sawmills and pulp and paper mills. In the United States, by contrast, timber production from the Rockies is small compared with other forested regions, and recreation is the principal source of revenue in the national forests.

Environmental concerns. Serious problems have arisen as a result of timber harvesting, grazing, oil exploration, mining, and reservoir operations in the Rockies. Logging and oil exploration have been responsible for accelerated slope erosion, both from the operations themselves and from the access roads built to reach them. Erosion has stripped away the often thin soil cover and caused serious silting of streams. Trace quantities of harmful metals have been released into streams and groundwater from mining operations, particularly from the leaching of mill tailings. Reservoir operations have disrupted fisheries by altering the temperature and flow patterns of streams and by disrupting riparian (streamside) vegetation communities. Wildlife habitat has been lost through the development of lands for agriculture and livestock grazing.

Study and exploration. The Rocky Mountains were one of the last regions in North America to be explored by Europeans, because of the inaccessibility and ruggedness of the terrain. Roman Catholic missionaries worked their way northward from Mexico into New Mexico in the 17th and

18th centuries. In 1776–77 Silvestre Vélez de Escalante and his party explored and documented their travels into what is now Utah, reaching almost to the Great Salt Lake. The Scottish explorer Alexander Mackenzie, searching for a river course to the Pacific Ocean from the Canadian prairie, crossed the Rockies (1792–93) at a latitude higher than any other expedition until the early 19th century. The Lewis and Clark Expedition in 1804–06 explored and charted a route up the Missouri River into Montana and thence across Idaho and Oregon to the Pacific. The English explorer and fur trader David Thompson explored the headwaters of the Saskatchewan and Columbia rivers in the Canadian Rockies in 1807–11, setting up the first trading posts in that region and producing the first survey of the entire length of the Columbia River.

Possibly the most remarkable of all western explorations were those of Jedediah Smith in 1822–31. Following the Missouri River into east-central Montana, Smith first worked his way southward into the Bighorn Basin and thence into southeastern Idaho, northern and southwestern Utah, and southern Nevada, around the Sierra Nevada, and back to the Great Salt Lake across the Great Basin. Also important were the expeditions of John C. Frémont in the 1840s. Frémont followed the North Platte River into Wyoming, went up the Sweetwater River to the south end of the Wind River Range (South Pass), and thence traveled southwestward into Utah. This was an important scientific survey because he charted distances, determined latitudes, longitudes, and elevations, and recorded objectively in some detail what he saw.

The four western surveys

Four great western surveys were organized by the U.S. government following the American Civil War: the survey of the 40th parallel led by Clarence King (1867–78), the geologic survey of Nebraska and Wyoming led by Ferdinand Hayden (1867–78), the 100th-meridian survey led by George Wheeler (1872–79), and the expeditions to the Green and Colorado rivers in Wyoming, Utah, Arizona, and southern Nevada led by John Wesley Powell (1871–79). The maps and preliminary observations of these important surveys laid the groundwork for the great mass of scientific research that followed. The Rocky Mountains, with their abundant deposits of fossil fuels, uranium, and other minerals, continue to attract the attention of geologists. (A.J.E./R.A.Ma.)

SIERRA MADRE

The Sierra Madre is the principal mountain system of Mexico and includes the three ranges of the Sierra Madre Occidental (to the west), the Sierra Madre Oriental (to the east), and the Sierra Madre del Sur (to the south). These ranges enclose the great central Mexican Plateau, which itself is a part of the system—although the northern portion of the plateau also is considered to be part of the Basin and Range Province of the United States—and is broken by blocks of mountain ranges and large populated ephemeral drainage basins (*bolsones*). The greater part of Mexico comprises this comprehensive Sierra Madre.

Physical features. *Geology.* The Mexican Plateau is composed largely of folded strata of the Mesozoic Era (*i.e.,* between 245 and 66.4 million years old). Formations predominate from the second half of the Mesozoic among exposed rocks, but older sediments are widespread. The region's elevation, folding, and faulting were contemporaneous with the uplift of the Rocky Mountains. Early in the Tertiary Period (which began 66.4 million years ago and ended 1.6 million years ago), great outpourings of lava terminated a long interval of weathering and erosion. Subsequently, the large plateau block was uplifted, the displacement being greater to the south than to the north. Its margins have been dissected into the deeply gouged angular landscape of the Sierra Madre Occidental and the more rounded but rugged terrain of the Sierra Madre Oriental.

Although the western fringe of the plateau, the Sierra Madre Occidental, was long assumed to be a structurally simple feature consisting of nearly horizontal lavas manteling Mesozoic sediments and old crystalline rocks, a complex structural history has become apparent. The underlying strata were deformed by folding and faulting during several periods, and there are many intrusions of varying size. Strata mostly from the latter part of the Paleozoic Era (540 to 245 million years ago) overlie materials from the early part of the era in the Sierra Madre Occidental and to the west. Large amounts of lava and ash were deposited on earlier surfaces in the Tertiary Period.

The Sierra Madre Oriental, composed largely of folded sedimentary rocks of Cretaceous age (66.4 to 144 million years old), owes its present relief to uplift, faulting, and erosion since the mid-Tertiary. Igneous intrusion forms are numerous.

Volcanism

Marking the southern edge of the Mexican Plateau and spanning Mexico from coast to coast is a zone where volcanism developed during two episodes. The first episode occurred during the early and middle parts of the Tertiary, when immense quantities of lava were poured over the land. The second volcanic episode, which began in the Pliocene Epoch (5.3 to 1.6 million years ago) and has continued to the present, is associated with the development of such spectacular peaks as Citlaltépetl, or Orizaba (18,406 feet [5,610 metres]), Popocatépetl (17,930 feet), Iztaccíhuatl (17,159 feet), Toluca, or Zinantecatl (15,354 feet), and the Nevado de Colima (13,911 feet). In 1759 and 1943, respectively, the smaller volcanoes of El Jorullo and Paricutín burst into existence. Additional peaks, cinder cones, and other evidence of volcanism occur throughout the region.

To the west of the Isthmus of Tehuantepec in southern Mexico the great scarp of the Southern Highlands rises several thousand feet. This deeply dissected mountain mass reveals east-to-west folds in its base rocks of metamorphosed Cretaceous sediments and intrusives. The narrower western section of the highlands is known as the Sierra Madre del Sur. It is breached by the Balsas River.

Physiography. The Sierra Madre Occidental extends approximately 700 miles (1,100 kilometres) from northwest to southeast and is about 100 to 300 miles in width. Summits mostly exceed altitudes of 6,000 feet, and some peaks rise above 10,000 feet. From the east the mountains present relatively slight but broken relief; from the west they appear as formidable escarpments whose benched flanks drop into deep canyons called *barrancas.* The great mountain ranges and canyons trend northwest to southeast, which is generally the trend of the folds in the Mesozoic and older basement strata. The local relief may exceed 5,000 feet, and the majestic dimensions of some of these *barrancas*—notably Barranca del Cobre ("Copper Canyon")—compare with the Grand Canyon of the United States.

Extending southeastward from the Big Bend of the Rio Grande (called Río Bravo del Norte in Mexico) is a series of low mountains that are composed of folded sedimentary strata. South of Monterrey these mountains become a striking range, the Sierra Madre Oriental. Summit elevations are about 7,000 feet, but some peaks rise above 10,000 feet (Cerro Peña Nevada). Steep-walled, narrow valleys, a number of which are north to south in alignment, lie in the sierra; and there are several gateways from the Gulf of Mexico lowlands to the plateau.

The core of Sierra Madre del Sur is outlined by a narrow and discontinuous coastal plain to the southwest and by the structural depression of the Balsas River on the north. To the east of this depression is the Sierra Mixteca, which forms a highland bridge between the volcanic axis and the Southern Highlands. A labyrinth of narrow ridges and steep-flanked valleys forms the Southern Highlands. Much of this broken country crests at elevations of about 6,500 feet, and only a few peaks exceed 10,000 feet. Whereas the Mexican Plateau's volcanic mantle is relatively free of dissection, the Southern Highlands have been stripped of much of their volcanic cover. The older basement rocks are exposed in what are probably the most highly dissected landscapes of Mexico. There is very little flatland in the region. Abruptly terminating the region on the east is a magnificent scarp that overlooks the downfaulted block of the Isthmus of Tehuantepec.

Elevation as a factor of climate

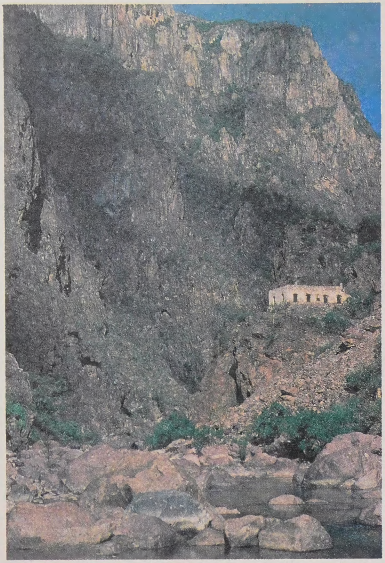
Climate. Elevation is more important in determining the thermal characteristics of Mexican climate than is latitude. The decrease in temperature that occurs with increasing elevation has made it possible to identify distinct

The Sierra Madre.

vertical temperature zones: *tierra caliente,* or "hot land", *tierra templada,* or "temperate land", and *tierra fria,* or "cold land". Unlike climatic areas farther from the Equator, there is little seasonal variation in temperature at any elevation in the tropics.

The *tierra templada,* which includes elevations from 3,000 to 6,000 feet, has mean temperatures of 65° to 75° F (18° to 24° C). Much of highland Mexico is in this thermal zone. It is the most pleasant of the zones for human habitation. During winter, frost may occur. In the cooler *tierra fria* the mean annual temperatures are between 55° and 65° F (13° and 18° C). Above 10,000 to 11,000 feet the mean annual temperature is less than 50° F (10° C), and above 14,000 to 15,000 feet it is less than 32° F (0° C).

Mountain masses, besides creating islands of cooler climate within the tropics, play a major role in the incidence of clouds and precipitation. The mountains form barriers over which air may be raised, cooled, and caused to condense. Within the mountains and in their lee there is a lower incidence of clouds and precipitation. Lee or descending air becomes warmer, and its capacity to retain moisture rises. Illustrating the effect of the mountains upon precipitation and cloudiness is the contrast between 80 inches (2,000 millimetres) of rain and 150 cloudy days per year for the eastern slopes of the Sierra Madre Oriental and the 40 inches of rain and 90 cloudy days per year that characterize much of the Pacific slope west of the Sierra Madre del Sur. The drier areas are in the rain shadow of the mountains.



Plant and animal life. The extent of the once-ubiquitous mountain forests has been greatly curtailed by centuries of human activity, owing not only to clearing of land for farming but also to the widespread use of wood in earlier times to make charcoal for metal smelting. Simultaneously, the distribution of animal life has been restricted. In the *tierra fria,* forests of conifers are found, followed in the *tierra templada* by mixed forests of oak and pine. At still lower elevations, and especially in the rain shadows, the Sierra Madre Occidental is characterized by a diverse, scrubby assemblage of xerophytic (drought-tolerant) plants. In contrast, the lower levels of the Sierra Madre Oriental display, especially in the southern part, a broad-leaved tropical luxuriance correlated with the reliable and adequate rainfall that they receive.

Deer and coyotes are widespread in the Sierra Madre. Gray wolves are still found in remote parts of the northern Sierra Madre Occidental. The grizzly bear probably became extinct in the wild after 1960, but the population of black bears has remained fairly stable. Large cats (jaguar and puma) are becoming scarce; but cottontail rabbits abound, and collared peccaries are fairly plentiful, as are wild turkeys and smaller game birds.

The people and economy. The remoteness, relative inaccessibility, and many habitable valleys of the Sierra Madre made it a refuge for a number of Indian peoples who succeeded in retaining much of their aboriginal culture for two or three centuries after their first contact with the Spaniards. Well known are the Huichol and the Cora in the southern states of Nayarit and Jalisco and the Tarahumara in the north (Chihuahua), as well as a number of other groups, especially in the Sierra Madre del Sur. The gradual acculturation of these peoples to the Mexican mestizo way of life was unavoidable, however, and in many areas the use of traditional languages, clothing patterns, and house types has been replaced; many young adults have abandoned the ways of their ancestral societies. Technological progress has furthered this process in the second half of the 20th century. Trucks and buses and even small airplanes capable of operating with short landing strips increasingly have been used to transport goods and people, replacing the traditional horses, mules, and burros.

Acculturation of mountain peoples

has been a serious barrier to east-west communications. Because of the mountains, Spanish exploration, regional commercial evolution, and the present road and railway systems developed independently on the Mexican Plateau and in the Pacific Coastal Lowlands of Sinaloa and Sonora states. No railroad crossed the mountain barrier until 1962, although construction was begun many years earlier on lines between Durango and Mazatlán and between Chihuahua and Topolobampo. The latter was finally completed. Only a few paved roads through the region link interior cities with Pacific coastal resorts and towns. The sparse settlement in this mountainous area is confined to mining centres or to farming and pastoral hamlets. Forest industries are most highly developed in the states of Chihuahua and Durango, but it may be that the long-term worth of the forest cover as watershed protection exceeds its value as timber. The Sierra Madre Occidental is the source of waters that support the oases of the plateau and of the lowlands adjoining the Gulf of California. Oases that have been formed by water from the mountains include those along the Carmen, Conchos, Nazas, and Aguanaval rivers in the plateau. The westward-flowing Yaqui, Mayo, Fuerte, Sinaloa, and Culiacán rivers water important farming districts in the coastal lowlands.

Among the substantial rivers that have watersheds that penetrate the Sierra Madre Oriental are the Moctezuma and Pánuco, the combined drainage system of which has captured a considerable area of the central plateau. The process of capture was aided by the opening of a drainage canal in 1607 (expanded in 1900) to tap the Basin of Mexico. Numerous harnessed and potential sources of hydroelectric development exist among the rivers that drain the eastern front of the mountains. Agricultural settlement is particularly dense in the state of Veracruz.

Study and exploration. The exploration and study of the Sierra Madre occurred in three main stages. The first, which lasted until the mid-16th century, consisted of Spanish reconnaissance and the subjugation of native peoples. The second, lasting until the late 19th century, was based on the mining of silver deposits—first in the south (Guanajuato, Zacatecas, and San Luis Potosí) and then progressively farther north and west (Fresnillo, Durango, Hidalgo del Parral, and Álamos). Along with the miners went Roman Catholic priests, and some Indian settlements received Jesuit missions. The more successful mining settlements later became cities and even state capitals. The third stage, that of scholarly inquiry, began with scattered Spanish studies in the 17th century. Modern scientific study of the mountains was initiated with the work of the Norwegian explorer and ethnologist Carl Lumholtz, who in 1890–98 did extensive fieldwork throughout the Sierra Madre Occidental. Lumholtz was followed by other scholars from Europe, Mexico, and the United States in such fields as archaeology, anthropology, art, history, geography, sociology, geology, botany, and zoology. The Sierra Madre and adjacent areas proved to be a source not only of mineral wealth but also of matters of scholarly and cultural import. (G.C.E./H.J.Bn.)

Work of Lumholtz

SIERRA NEVADA

The Sierra Nevada is a major mountain range of western North America, running along the eastern edge of the U.S. state of California. Its great mass lies between the large Central Valley depression to the west and the Basin and Range Province to the east. Extending more than 250 miles (400 kilometres) northward from the Mohave Desert to the Cascade Range of northern California and Oregon, the Sierra Nevada varies from about 80 miles wide at Lake Tahoe to about 50 miles wide in the south. Its magnificent skyline and spectacular landscapes make it one of the most beautiful physical features of the United States. As a recreation centre, its year-round facilities prove a magnet to the inhabitants of the huge urban areas of California, and it has considerable importance as a source of power and water. It was the focus of the celebrated California gold rush.

The Sierra Nevada range is an excellent example of how the human occupation and use of an area can modify its landscape. First mining and later logging and tourism have done more in 150 years to alter the flavour of the mountain scenery in many areas than the actions of ice and water over millennia.

For map coverage of the Sierra Nevada, see above *North American Desert*.

Physical features. *Physiography.* The Sierra Nevada is an asymmetrical range with its crest and high peaks decidedly toward the east. The peaks range from 11,000 to 14,000 feet (3,350 to 4,270 metres) above sea level, with Mount Whitney, at 14,494 feet (4,418 metres), the highest peak in the coterminous United States. Summits in the northern portion are much lower, those north of Lake Tahoe reaching altitudes of only 7,000 to 9,000 feet.

Much of the rock is granite or a near relative of granite. There are dividing bands of metamorphosed (heat- and pressure-altered) sedimentary rock—all that is left of a once extensive sedimentary basin—and some large areas of extrusive rock, especially from Lake Tahoe northward; at the northern limit of the Sierras, these rocks merge with the volcanic rocks of the Cascades.

Geology. It has long been recognized that the Sierra Nevada is a tilted block of the Earth's crust. A major fault zone bounds the block on the east, and it was along this that the great mass that became the Sierra Nevada was uplifted and tilted westward. This explains the asymmetry of the range. As the block was uplifted the abrupt, east-facing escarpment was cut into by the erosive action of wind, rain, temperature change, frost, and ice, and a series of steep-gradient canyons developed. Though the massive uplift began many millions of years ago, much of it occurred in the past two million years. The present-day relief of 10,000 to 11,000 feet along the eastern slopes in the southern Sierra Nevada attests to the tremendous uplift.

The basic tilted block

Drainage and glaciation. The more gentle west-facing slope has been dissected by a series of streams, much longer than those of the eastern slope. Such rivers as the

Yuba, American, Mokelumne, Stanislaus, Merced, and Kern have carved deep valleys into the predominant granite and some volcanics. All but the Kern drain either into the Sacramento River in the Central Valley on the north or into the San Joaquin on the south, their waters ultimately reaching the Pacific Ocean through the combined delta of these two rivers in San Francisco Bay. The Kern River has internal drainage into the Buena Vista Lake basin, south of the San Joaquin River.

During the Pleistocene glaciations, which started about 1,600,000 years ago and ended about 10,000 years ago, the river-eroded valleys were covered several times by great expanses of ice. Glacial climates developed and dissipated at least four times, and each time excessive snows built snow and ice fields and deep glaciers. The ice carved what had been V-shaped valleys into U-shaped ones down to an elevation of about 5,000 feet on the western slopes. So much ice existed on the mountaintops that an ice cap was formed as the glaciers coalesced. This cap extended almost 200 miles from Lake Tahoe in the north to the southern high sierra near Mount Whitney.

Extending from the cap were fingerlike valley glaciers, long on the more gentle western slopes but shorter on the sharply uplifted eastern face. The erosion caused by these glaciers is spectacular. It includes huge cirques (amphitheatre-shaped basins with precipitous walls), moraines (accumulations of rock debris), and thousands of glacial lakes dotting the Alpine and subalpine landscape. Such striking and beautiful landforms are the focus of Yosemite National Park and the Lake Tahoe basin. Lake Tahoe is the largest and deepest Alpine lake in the world; it has a surface area of nearly 200 square miles and reaches a maximum depth of about 1,640 feet in its northwestern portion.

Climate. The mid-latitude location of the range and its proximity to the moderating influence of the Pacific Ocean give the Sierra Nevada an unusually mild mountain climate. Although winter temperatures below 0° F (−18° C) are common in valley locations, they are rare on mountain slopes. The northwest-southeast orientation of the range, athwart the winter-storm tracks of central North America, produces copious precipitation during the wet season (November to April) on the windward (western) slopes, but a sharp rain-shadow effect occurs on the leeward (eastern) face. Precipitation averages from 30 inches (760 millimetres) in the western foothill zone to 70–80 inches between elevations of 4,500 to 6,500 feet in the northern half of the range. The leeward slopes receive substantially less—from 20 to 40 inches. Snowfall increases with elevation and latitude, the northern peaks of the range averaging 33 to 38 feet per year. As much as 5.5 feet has fallen in a single day at Echo Summit, and about 67 feet has been measured at the 7,085-foot Donner Pass. Snowpacks of 10 to 15 feet are not uncommon above altitudes of 7,000 feet. Snowfall

The Pacific High anticyclone, which dominates the wind pattern over the Sierra Nevada, is at its strongest in summer, when it draws dry air seaward across the mountains. Droughts of several years' duration—such as those of the mid-1930s, mid-1970s, and mid-1980s to early '90s—result when this high-pressure zone fails to loosen its grip during successive winters; when this occurs, the mid-latitude jet-stream storm track is weakened, split, or pushed to the north.

Plant life. Generally speaking, there are five fairly distinct vegetation zones on the western slopes. The lower foothills support mostly deciduous trees and shrubs, as well as the evergreen interior live oak (*Quercus wislizenii*). Black oak, Ponderosa pine, and incense cedar occur in the upper foothills. The montane forest, which constitutes the primary commercial timber zone, contains Douglas fir, red fir, Jeffrey pine, and the celebrated big tree, or giant sequoia, for which Sequoia National Park was designated a public preserve. Lodgepole pine, mountain hemlock, Sierra juniper, and western white pine are among the trees of the subalpine forest. Mosses, lichens, and low-flowering Alpine plants prevail above the tree line. The arid eastern slopes support sagebrush, bitterbrush, juniper, piñon pine, and aspen. Chaparral, a shrublike assemblage of broad-leaved evergreen shrubs dominated by chamiso, scrub oak, manzanita, and ceonothus, grows in all but the Alpine zones on both sides of the range.

Animal life. The large mammals most readily identified with mountainous regions have become less plentiful in the Sierra Nevada in the 20th century, in part because of increased human presence. Black bear inhabit a larger area than the more reclusive grizzly. Mountain sheep are now found only in the southern part of the range. The mule deer and its predator the mountain lion live in the foothills. Smaller mammals of the lower- and middle-

elevation forests include the American badger, striped skunk, bobcat, golden beaver, and northern flying squirrel. The fisher and wolverine have become rare. At the upper limit of woody vegetation live the cony, rock rabbit, and marmot.

The rich birdlife of the Sierra Nevada includes the Brewer blackbird, California horned lark, and pheasant of the lower valleys; the California quail, canyon wren, and roadrunner of the chaparral and foothills; mountain chickadee, spotted owl, and band-tailed pigeon in the timber zone; and goshawk and Hammond flycatcher in the upper forests. The pine grosbeak and white-toed woodpecker are among the birds of the subalpine zone.

Some trout species are native to the streams of the Sierra Nevada, but others have been introduced; fish stocking is now common in all areas because of damming and other disturbances to the natural habitat. Salmon and steelhead reach the mountain rivers during spawning season.

The people and economy. The American Indian inhabitants of the Sierra Nevada were divided into five main groups: the Yokut, Sierra Miwok, and Maidu on the western slopes and the Mono and Washo on the eastern. The hunting-and-gathering economy of these peoples had little permanent effect on the landscape other than locally through fires set to catch game. The first Europeans in the region were Spanish explorers and missionaries, who visited Alta (Upper) California beginning in the 1700s; their impact on the Sierra Nevada also was negligible. In the early 1800s Jedediah Smith, Joseph Walker, and other, less-celebrated American hunters and fur trappers passed through the region. In the mid-19th century the pristine serenity of the Sierra Nevada was ended as prospectors came, stayed, and stamped their mark on the region.

The California gold rush

The gold nuggets found in January 1848 on the American River (near present-day Placerville, Calif.) ushered in an international gold rush that was to have tremendous significance in the historical evolution not only of California but of the entire United States as well. Within two years of the initial discovery there were perhaps 50,000 working miners in the range. Banks, retail businesses, transportation facilities, timber operations, agriculture, and industry all arose and prospered in response to the needs of a burgeoning population. This economic boom hastened California's admission to the Union and fostered the region's first urban centres, notably San Francisco and Sacramento. By 1880 the gold era had peaked, though some mining activity has continued there since that time.

The first crude mine roads were followed by the regional and transcontinental railroads built in the 1860s and '70s. The first paved highways crossed the Sierra Nevada in the 1920s. The central portion of the range, however, still lacks a year-round road or rail crossing. Rapid economic development has brought environmental compromise. The Lake Tahoe basin, for example, one of the most beautiful settings in any mountain region and thus a tourist magnet, now incurs periodic air and water pollution, traffic congestion, and sewage-disposal problems, as well as aesthetic degradation.

The need for water and power (and, since World War II, recreation) also has changed the face of the Sierra Nevada. Three-fourths of the streams that drain the long western slopes are controlled. The first large water project in the early 1900s impounded the Hetch Hetchy Reservoir in Yosemite National Park for water use in San Francisco, inundating natural features that rivaled those of nearby Yosemite Valley. A more recent and extensive scheme is the California State Water Project, which was begun in the 1960s with the construction of the Oroville Dam on the Feather River in the northern Sierra Nevada.

Study and exploration. For many readers, the naturalist John Muir's *My First Summer in the Sierra,* a diary of camping and exploration in 1869, is one of the classics of American geographic writing. Muir, the founder of the Sierra Club (1892), a conservationist group concerned with the preservation of the scenic resources of the Sierra Nevada and like areas of the United States, dedicated his book to members of the club in 1911.

Geologists have studied the Sierra Nevada systematically since the late 19th century. Especially significant studies concern the Mother Lode system, Jurassic stratigraphy and its relation to intrusive granites, glacial erosion, placer gold, multiple intrusions, isotope ages, and chronology and nature of emplacement. (A.J.E./J.W.Ja.)

Drainage systems and waterways

COLORADO RIVER

Fed by thick blankets of melting snow where it rises in the high Rocky Mountains of north-central Colorado in the western United States, the Colorado River cuts a winding, southwesterly path for 1,450 miles (2,330 kilometres) to the Gulf of California. Its drainage basin covers 246,000 square miles (637,000 square kilometres) and includes parts of seven states—Wyoming, Colorado, Utah, New Mexico, Nevada, Arizona, and California. For 17 miles the river forms the international boundary between the U.S. state of Arizona and Mexico. The river drains a vast arid and semiarid sector of the North American continent, and because of its intensive development it is often referred to as the "Lifeline of the Southwest."

For map coverage of the Colorado river, see above *North American Desert.*

Physical features. *Physiography.* For more than a thousand miles of its course, the Colorado has cut a deep gorge. Where the river system is joined by lateral streams—the Virgin, Kanab, Paria, Escalante, Dirty Devil, and Green rivers from the west, and the Little Colorado, San Juan, Dolores, and Gunnison from the east—a transverse system of narrow, winding deep canyons has been cut. Each entering river and each lateral creek has cut another canyon, and thus the upper and middle parts of the Colorado basin are traversed by a labyrinth of deep gorges. The longest of these unbroken trunk canyons through which the Colorado flows is the spectacular Grand Canyon, extending from the mouth of the Paria to the Grand Wash Stream. Canyonlands National Park encompasses another of these regions at the juncture of the Green and Colorado rivers in southeastern Utah.

The Grand Canyon

Farther downstream the lower Colorado is flanked by two great deserts, the Mojave and the Sonoran. In a subsection of the Sonoran Desert comprising the Colorado and Yuma deserts lies the Salton Trough (Salton Basin), a large structural depression extending to the northwest from the head of the Gulf of California for a distance of 150 miles. At one time the gulf extended farther to the northwest, above the point at which the Colorado now enters. As the river brought its load of silt from the mountains and hills above to the gulf, however, it gradually erected a vast natural dam, and the waters on the north were separated from those on the south. The Colorado then cut a channel into the lower gulf. The upper waters, cut off from the sea, gradually evaporated, forming a large area of desert land extending to about 235 feet below sea level.

In 1905 floodwaters caused, about three miles south of the California-Mexico border, a break in diversion controls of the Imperial Canal. As a result, all the waters of the Colorado rushed into the Salton Sink, creating the Salton Sea, about 70 feet deep, 50 miles long, and 10 to 15 miles wide, with a total water area of some 300 square miles. The break threatened to inundate the agriculturally rich Imperial Valley and to block permanently a major railroad route. Because of the imminent danger, the railroad repaired the break and in 1907 completed a line of protective levees.

Plant and animal life. The Colorado River drainage area encompasses a wide range of natural environments—from Alpine tundra and coniferous forests in its headwaters and upper elevations; through semiarid plateaus and canyons supporting piñon pine, juniper, and sagebrush; to the truly arid landscapes dotted with creosote bush and other desert plants in the lower basin and delta. The distribution of animals varies with these habitats. Large mammals such as the elk, mountain sheep, pronghorn, mule deer, mountain lion, bobcat, and coyote (and formerly the grizzly bear and gray wolf) occupy the middle and upper elevations. Beavers, muskrat, and birds, including the great bald eagle, favour stream banks lined with willow, cottonwood, and tamarisk.

The Colorado River in Marble Canyon at the northeastern end of Grand Canyon National Park, northwestern Arizona.
© Gary Ladd

Modern river development has radically disrupted native species and habitats in the Colorado basin. Accidentally introduced in the mid-19th century, the tamarisk shrub has spread rapidly along the river, consuming large amounts of water. Large predators were systematically eliminated to support the ranching economy. River otters once flourished in the lower reaches. Four native fishes (the humpback chub, bonytail chub, Colorado squawfish, and razorback sucker), purposefully eradicated in the mid-20th century, subsequently have been protected at great expense under the Endangered Species Act.

History and economy. *Early inhabitants.* Ute and Southern Paiute Indian tribes, now living in reduced numbers on reservations, hunted and gathered in the plateaus and canyonlands of the upper Colorado basin for centuries. In the lower basin, the largest prehistoric canal irrigation system in the American West was built by the Hohokam Indians on the Gila and Salt rivers. Yuman tribes practiced more extensive patterns of floodplain farming and hunting on the Colorado, which was too large and variable for canal irrigation. In the face of economic exploitation of the region by whites, and the resultant ecological changes, Indian groups have struggled to maintain vestiges of traditional lifeways with respect to the river.

Study and exploration. The modern period began with Spanish exploration and settlement from the mid-16th century, which yielded brief descriptions of the Colorado but no permanent settlements such as those along the upper Rio Grande. Prior to the Civil War, American surveyors focused on routes, passes, and territorial boundaries. With the help of Indian scouts, they acquired enough information to map the river and its main tributaries. Mormons settled the Great Basin of Utah in 1847, moved quickly into tributary valleys of the Colorado in Utah and Arizona, and acquired knowledge that contributed to later scientific surveys.

Inland-shipping entrepreneurs such as Joseph Christmas Ives assessed the navigability of the river as early as 1858. The federal government sponsored major scientific surveys in the 1870s. John Wesley Powell's exploration of Colorado River canyons (1869 and 1871–72) was the most celebrated and the first to concentrate directly on the river. Powell's account combines vivid descriptions of geologic formations, rapids, and Indian cultures. George Wheeler's survey report of 1889 estimated the velocity and discharge of the river. After 1900, investigations would focus on issues of river development: flood control, irrigation, hydropower, and water supply.

The Powell expedition

Economic development. In 1922 the Colorado River Compact was concluded by the seven states that constitute its drainage area to facilitate federal investment in dams and reclamation. The river was divided at Lees Ferry, Ariz., into the lower compact states—Arizona, Nevada, and California—and the upper compact states—Wyoming, Utah, Colorado, and New Mexico; the total annual flow of the Colorado River was estimated to be 17 million acre-feet (the volume of area that would cover one acre to a depth of one foot) at Lees Ferry, of which 15 million acre-feet were equally, yet somewhat ambiguously, divided between the lower and the upper compact states. A treaty in 1944 allocated 1.5 million acre-feet of water per year to Mexico. It was later discovered that the initial estimate of Colorado River supplies was based upon an abnormally wet period and that substantially less water was available than the amounts specified in the agreements.

The first major development of the Colorado began in 1928, when Congress passed the Boulder Canyon Project Act. The act authorized the construction of Boulder (now Hoover) Dam, a multipurpose water-storage project that was a major engineering feat of its time; since its completion in 1936, the dam and Lake Mead, which it created with its impounded waters, have become major tourist attractions. The Colorado River system thus was the first drainage basin in which the concept of the multipurpose dam was employed—*e.g.,* for power development, irrigation, recreation, flood control, and navigation.

Many additional projects have since been undertaken. In the mid-1960s Glen Canyon Dam was completed, impounding Lake Powell. The dam was a controversial project: opposition to its construction helped shift policy from building large dams toward concepts of water management, environmental protection, and policy analysis. Three other large multiple-storage projects upstream have been completed on major tributaries. These are Flaming Gorge on the Green River in Wyoming and Utah, Aspinall (Curecanti) on the Gunnison River in Colorado, and the Navajo on the San Juan River in New Mexico and Colorado.

Shortly after the completion of Hoover Dam, planning and construction began downstream on the Parker Dam. From Havasu Lake, the reservoir impounded by the dam, water is transported some 250 miles across California to supply a portion of the water needs for Los Angeles and most of the water supply for San Diego. Davis, Imperial, Laguna, and Morelos dams further regulate flow and diversion in the lower basin.

Water diversion beneath the Rockies

The facilities described above do not serve all the demands for water from the Colorado. In 1945 the Colorado–Big Thompson Project, the first federal interbasin water-diversion project in the United States, was completed. Water was diverted by tunnel beneath the Continental Divide in Rocky Mountain National Park to help irrigate cropland in northern Colorado. Another large project, the Fryingpan-Arkansas, diverts water from Fryingpan River, a Colorado tributary, under the Sawatch Range of the Colorado Rockies and into the Arkansas River to supply water for the rapidly growing municipal areas of Pueblo and Colorado Springs. On the Blue River, another tributary, the city of Denver has built Dillon Reservoir, the water of which is piped beneath the Continental Divide to the large and growing Denver conurbation. Tunnel diversions also deliver water from the Colorado to the Rio Grande, Great Basin, and North Platte drainages.

In 1963 a decision of the U.S. Supreme Court made explicit the amount of water apportioned among the lower-basin states, as well as the amounts that had been implicitly "reserved" for Indian tribes and federal public lands. This decision paved the way for funding of the Central Arizona Project (completed in the 1980s), which transferred water to the cities of Phoenix and Tucson. The project consists of a mountain tunnel through which water from the southern end of Lake Havasu is pumped up and into an aqueduct that flows southward to the two cities.

Laced with innumerable dams, both large and small, that impound the total flow of the Colorado and by increasingly severe competition for whatever small quantities of water might remain, the basin remains fraught with litigation and controversy. Water projects must now undergo thorough environmental-impact studies in accordance with federal environmental protection legislation. Controversy between the United States and Mexico over the salinity of water delivered to Mexico was addressed in an international agreement in 1972, which led to desalinization experiments in the lower basin and irrigation management and projects for the disposal of saline water in the upper basin. Tensions continue to arise among the basin states over water allocation, interstate water marketing, drought management, potential effects of global climatic change, Indian water rights, and reservoir management. These issues have been watched closely not only in the affected region but also in other areas of the world, for which the Colorado River serves as a laboratory of water-resource experimentation and innovation. (M.J.Lo./J.L.W.)

COLUMBIA RIVER

The largest river flowing into the Pacific Ocean from North America, the Columbia River is exceeded in discharge on the continent only by the Mississippi, St. Lawrence, and Mackenzie rivers. The Columbia is one of the world's greatest sources of hydroelectric power and, with its tributaries, represents a third of the potential hydropower of the United States. In addition, its mouth provides the first deepwater harbour north of San Francisco. Two-fifths of the river's course, some 500 miles (800 kilometres) of its 1,240-mile (2,000-kilometre) length, lies in Canada, between its headwaters in British Columbia and the United States border.

For map coverage of the Columbia River, see above *North American Desert*.

Physical features. *Physiography and hydrology.* The Columbia drains some 258,000 square miles (668,000 square kilometres) of which about 85 percent of this basin is in the northwestern United States. Major tributaries are the Kootenay, Snake, Pend Oreille, Spokane, Okanogan, Yakima, Cowlitz, and Willamette rivers. High flows occur in late spring and early summer, when snow melts in the mountainous watershed. Low flows occur in autumn and winter, causing water shortages at the river's hydroelectric plants.

Major tributaries

The Columbia flows from its source in Columbia Lake, at an elevation of 2,700 feet (820 metres), in British Columbia near the crest of the Rocky Mountains, to the Pacific Ocean at Astoria, Ore. For the first 190 miles, its course is northwesterly; it then flows to the south for 270 miles to the border of Canada and the United States (elevation 1,290 feet), where it enters northeastern Washington. It traverses east-central Washington in a sweeping curve known as the Big Bend, its prehistoric course having been disarranged first by lava flows and later by ice sheets. The ice sheets were instrumental in creating the Channelled Scablands, a series of coulees (steep-walled ravines) trending northeast-southwest in the northern part of the Columbia Plateau; Grand Coulee is the largest of these. Shortly below the confluence with the Snake River, its largest tributary, the Columbia turns west and continues 300 miles to the ocean as the boundary between Oregon and Washington; in this last stretch the river has carved the spectacular Columbia Gorge through the Cascades Range.

Tides flow upriver for 140 miles. Portland, Ore. (about 110 miles from the mouth), and Vancouver, Wash. (100 miles), are the upper limit of oceangoing navigation, aided by a dredged channel; through the use of a series of locks, barge traffic is made possible to Lewiston, Idaho, more than 460 miles inland from the river's mouth at the junction of the Clearwater and Snake rivers.

Climate. The basin's climate, strongly affected by orographic influences, is partly continental and partly marine. The Rocky Mountains to the east block out most of the severe winter storms of the interior of the continent, and the Cascade Range to the west shields the basin from moist Pacific Ocean air. Summers are typically hot and dry with only occasional thundershowers; winters are moderately cold and dry with occasional snow or even rain. Temperature and precipitation vary greatly with elevation, but in the central basin January average daily temperatures are between about 25° and 30° F (−4° and −1° C), and July averages are mostly between 70° and 75° F (21° and 24° C). Average annual precipitation ranges from less than 8 inches (200 millimetres) at the lowest elevations to about 15 inches near the mountain foothills and 40 inches or more in the mountains. West of the Cascades the climate is marine-influenced, with long, rainy winters and cool, dry summers.

Plant and animal life. Native vegetation at lower elevations of the interior basin is mostly of the shrub-steppe variety, dominated by sagebrush and bunchgrasses. With increasing elevation, shrub-steppe gives way to ponderosa pine and then to fir, larch, and other pines. More than half of the original shrub-steppe vegetation has been eliminated by grazing and farming. Cheatgrass has become a troublesome invader. Greasewood and alkali salt grass dominate on poorly drained saline soils, while willow and black cottonwood dominate along watercourses. West of the Cascades, forests of Douglas fir with hemlock and western red cedar prevail.

Animal life was abundant and varied prior to white settlement. Notable were the great runs of salmon and steelhead trout; populations of beaver, deer, elk, bear, and bighorn sheep; flocks of waterfowl and upland birds, including eagles, ospreys, hawks, and falcons; and numbers of western rattlesnakes. The ability of the region to sustain large populations of wildlife has been drastically reduced, especially for salmon and beaver. The bald eagle and peregrine falcon have been listed as endangered, and such a designation has been considered for several salmon runs.

Reduction of wildlife

The economy. Many controversies have marked the economic development of the Columbia River. Notable among these have been the division of responsibility between public and private agencies, the effect on the fish life (particularly salmon) and loss of traditional Indian fishing sites, proposals for a Columbia Valley Authority, the proper rate of interest to be charged on the federal government's investment in hydroelectric power development, and arrangements for sharing power-generating revenues and costs with Canada for upstream storage reservoirs in British Columbia. Nonetheless, exploiting the river's hydroelectric and irrigation potentials has been instrumental in developing the region's economy.

This multipurpose development of the Columbia's main stem began in the 1930s with construction of Grand Coulee and Bonneville dams by the federal government. Nearly all of the river's 1,290-foot fall within the United States has been converted into a series of "stair steps" by 11 dams on the main river, augmented by dams on

Wells Dam on the Columbia River in central Washington, in the irrigated fruit-growing region of the state.
© Harald Sund

tributaries and three upstream storage reservoirs in British Columbia constructed in accordance with a treaty between the United States and Canada. The four lower dams on the Columbia, plus four more on the lower Snake, provide large navigation locks; and all are equipped with fish-passage facilities, the original assumption being that these fish ladders would make possible the continued annual upstream run of the salmon.

Grand Coulee Dam, the largest and most complex of the Columbia's dams, augments the low winter flows when power demand is greatest. A powerhouse completed in the 1970s makes use of the Canadian storage capacity, and the dam has remained one of the world's largest hydroelectric power plants. Water is also pumped from Franklin D. Roosevelt Lake, the reservoir behind Grand Coulee Dam, for the Columbia Basin Irrigation Project, the largest single project of its kind in the Northwest and the first large-scale use of the Columbia River itself for irrigation. The first water delivery was made in 1952 to the designated lands, which previously had been covered by sagebrush and other desert vegetation. Some three-fifths of the project's planned area is now being irrigated. A major share of the cost of this expensive project is being paid by the sale of the power generated at Grand Coulee Dam.

All power plants along the system are connected by high-voltage federally owned transmission lines, the backbone of a power network in which all utilities of the Pacific Northwest participate. This system is linked with the power grid in the state of California and with the American Southwest; surplus Columbia River power is sold to the Southwest during the summer (and Southwestern steam-generated power to the Northwest during the winter).

The treaty with Canada (1961), supplemented by a further pact in 1964, called for the United States to pay British Columbia sums representing that province's share of power- and flood-control benefits, for British Columbia to build three large dams (two of them on the Columbia), and for the United States to build a fourth dam on the Kootenay in Montana.

History. Numerous American Indian peoples inhabited the Columbia River basin for several thousand years.

Early explorers

Spanish explorers sailing up the Pacific coast in about 1775 probably were the first Europeans to sight the river's mouth. The Boston trader Robert Gray sailed up the Columbia in 1792 and named it for his ship. The American Lewis and Clark Expedition wintered at its mouth in 1805–06, and an English geographer, David Thompson, explored most of the river for the North West Company, reaching the mouth in 1811—only to find that Fort Astoria was already being built by the Americans. The upper basin was explored for the North West Company in 1807–11. Other early posts included Fort Vancouver (1825), of the Hudson's Bay Company, and Fort Walla Walla (1818), of the North West Company (after 1821 it merged with the Hudson's Bay Company).

Irrigation apparently was practiced at Fort Walla Walla (near present-day Wallula, Wash.) by the early 1830s and at the mission established in 1836 by Dr. Marcus Whitman at nearby Waiilatpu, and it was later extended to many tributary valleys east of the Cascade Range. The main stem of the Columbia was too deeply entrenched for early irrigation, but, as the only sea-level route to the interior, it served as the major transportation artery until the coming of the railroad. The canoes and barges of the fur traders and early immigrants had given way to river steamers by the 1850s. The many rapids—21 to the mouth of the Snake River—made navigation difficult; the worst point was circumvented by the first railroad in Washington, a 1.5-mile, wooden-railed, mule-drawn tram that later was replaced by a 6-mile rail line with steam locomotives. The heavy agricultural and mining trade of the Columbia River basin was dominated by Portland through a monopolistic combination of river steamers and connecting stages. A railroad was completed from Portland to Walla Walla, Wash., in 1882 and from St. Paul, Minn., to Portland and thence to Tacoma, Wash., on Puget Sound, the following year. In 1887 the Northern Pacific Railway reached Tacoma directly over the Cascade Range, and the monopoly of the Columbia River route was ended.

The abundance of salmon was noted by the early explorers. The first cannery on the Columbia opened in 1866, and by 1881 some 30 Columbia River canneries were supplying world markets, especially Great Britain, with salmon caught in nets, traps, and wheels. From a record of 21,500 tons in 1883, the annual Columbia River salmon catch has declined to about 10 percent of that quantity. Although such organizations as the Northwest Regional Power Council and the Bonneville Power Administration have made considerable effort to increase the size of the river's annual salmon run, much doubt remains as to whether fish populations can ever be restored to earlier levels or even maintained at their current size. Serious impediments have included the barriers to upstream migration presented by the dams and power-generating equipment, the loss of spawning grounds through inundation, the displacement of naturally spawned fish by those raised in hatcheries, the supersaturation of the water by nitrogen trapped as floodwaters plunge over spillways, and the loss of the river's natural current to guide spawning fish. (M.E.Ms.)

GREAT LAKES

The Great Lakes—Superior, Michigan, Huron, Erie, and Ontario—of east-central North America are one of the great natural features of that continent and of the Earth.

Relative size of the lakes

Although Lake Baikal in Russia has a larger volume of water, the combined area of the Great Lakes—some 94,850 square miles (245,660 square kilometres)—represents the largest surface of fresh water in the world, covering an area exceeding that of the United Kingdom. Their drainage basin of about 295,800 square miles (which includes the areas of the lakes themselves and their connecting waterways) extends approximately 690 miles from north to south and about 860 miles from Lake Superior in the west to Lake Ontario in the east. Except for Lake Michigan, the lakes provide a natural border between Canada and the United States, a frontier that was stabilized by a boundary-waters treaty of 1909. It is a source of pride for both countries that there are no fortifications or warships along the boundary.

Areas and Volumes of the Great Lakes

	surface area		world rank	volume		world rank
	sq mi	sq km		cu mi	cu km	
Superior	31,700	82,100	2nd	2,900	12,100	4th
Michigan	22,300	57,800	5th	1,180	4,920	6th
Huron	23,000	59,600	4th	850	3,540	7th
Erie	9,910	25,670	11th	116	484	15th
Ontario	7,340	19,010	14th	393	1,640	11th

Individually, the lakes rank among the 14 largest in the world (see Table). They played a central role in the European colonization and development of North America and for decades have attracted people and industry; Lakes Erie and Ontario and the southern portion of Lake Michigan are now ringed with large population concentrations. The lakes have not benefited from this development, however, and have been seriously affected by pollution. Concern over the fate of the lakes reached a high pitch in the late 20th century, with both the U.S. and the Canadian governments and individuals investigating methods for reversing the consequences of years of misuse of the lakes' waters.

The Great Lakes form the western portion of the larger St. Lawrence hydrographic system. This system extends generally eastward from the St. Louis River in Minnesota (which flows into Lake Superior), through the lakes and the St. Lawrence River, and empties into the Atlantic Ocean at the Gulf of St. Lawrence. For a discussion of the system east of Lake Ontario, see below *St. Lawrence River and Seaway.*

Physical features. *Geology.* The age of the Great Lakes is still not definitely determined. Estimates range from 7,000 to 32,000 years of age. It is generally accepted that Lake Erie reached its present level about 10,000 years ago, Lake Ontario about 7,000 years ago, and Lakes Huron, Michigan, and Superior some 3,000 years ago.

The present configuration of the Great Lakes basin is the result of the movement of massive glaciers through the mid-continent, a process that began about one million years ago during the Pleistocene Epoch. Studies of Lake Superior indicate that a river system and valleys formed by water erosion existed before the Ice Age. The glaciers undoubtedly scoured these valleys, widening and deepening them and changing the drainage of the area.

The last glacial stage in North America is called the Wisconsin Glaciation because it advanced southward to what is now the southern border of the state of Wisconsin. As the ice sheet melted and receded about 18,000 years ago, the first segments of the Great Lakes were created. Lake Chicago, in what is now the southern Lake Michigan basin, and Lake Maumee, in present-day western Lake Erie and its adjacent lowlands, originally drained southward into the Mississippi River. As the ice retreat continued, Lake Maumee was drained into Lake Chicago through a valley that now contains the Grand River in Michigan. Eventually, drainage to the east and into the Atlantic Ocean was established, at one time down the valleys of the Mohawk and Hudson rivers and then along the course of the upper St. Lawrence River. At one high-water stage, the waters of the Huron and Michigan basin formed the large Lake Algonquin. At the same time, Lake Duluth, in the western Lake Superior basin, also drained to the Mississippi.

Retreat of the ice

The weight of the ice sheet exerted enormous pressures on the landmass. As the ice sheet retreated, low-lying areas, such as the region to the east of Georgian Bay, were exposed. About 10,000 years ago, the upper lakes evidently discharged through this area via the Ottawa River valley, and their levels were substantially reduced. After the weight of the ice was removed, the land began to rise, closing off some outlets and changing the water levels of the lakes. The largest postglacial lake, Nipissing, occupied the basins of Huron, Michigan, and Superior. Drainage through the Ottawa River valley ceased, and outflow from the upper lakes was established by way of the St. Clair and Detroit rivers into Lake Erie. Uplift has continued at a rate of about 1 foot (30 centimetres) every 100 years; this is evidenced by the drowned river mouths of western Lake Erie.

A wide range of rock types and deposits are found in the Great Lakes because of their broad area and glacial origin. The ancient rocks of the Canadian Shield cover part of the Superior and Huron basins, while younger sedimentary rocks make up the remainder of the basins. There are limestone outcrops and large deposits of sand and gravel, usually near shore. Glacial clays and organic sediments occur in the deep areas.

Physiography. The lakes drain roughly from west to east, emptying into the Atlantic Ocean. Except for Lakes Michigan and Huron, their altitudes drop with each lake, usually causing a progressively increasing rate of flow.

Lake Superior, bordered by Ontario, the Upper Peninsula of Michigan, Wisconsin, and Minnesota, is the northernmost and westernmost lake and can be considered the headwater of the system. It is the deepest lake (mean depth 487 feet [148 metres]), lies at an altitude of 600 feet above sea level, and discharges into Lake Huron through the St. Marys River at an average rate of 75,600 cubic feet (2,141 cubic metres) per second.

Lake Michigan lies south of Lake Superior and is bordered by the Upper and Lower peninsulas of Michigan, Indiana, Illinois, and Wisconsin. It has a mean depth of 276 feet. The average water level is 579 feet above sea level, and its waters flow northward into Lake Huron through the Straits of Mackinac at 47,800 cubic feet per second.

Lake Huron lies at the same altitude as Lake Michigan and is slightly larger. Its mean depth, however, is only 195 feet. It is bounded by Ontario and Michigan. The average outflow is 183,000 cubic feet per second through the St. Clair River, the shallow basin of Lake St. Clair, and the Detroit River to Lake Erie.

Lake Erie is bordered by Ontario, New York, Pennsylvania, Ohio, and lower Michigan. It is the shallowest of the Great Lakes, with a mean depth of 62 feet. The basin slopes from west to east with depths of 24 feet and 210 feet, respectively. It lies at an altitude of 570 feet, and its waters discharge at an average flow of 202,000 cubic feet per second. The course of the outflow is along the Niagara River and includes a rapid plunge over Niagara Falls before the waters reach Lake Ontario.

Niagara Falls

Lake Ontario has the smallest surface area of the system. It has, however, the second greatest mean depth—283 feet. It lies between Ontario and New York, at an altitude of 245 feet, and discharges into the St. Lawrence River at an average rate of 242,000 cubic feet per second.

Hydrology and climate. The lakes ultimately receive their water supply from precipitation, which increases from west to east. The average annual precipitation in the Lake Superior basin is 30 inches (760 millimetres), in Lakes Huron and Michigan it is 31 inches, and in Lakes Erie and Ontario it is 34 and 36 inches, respectively. Between 65 and 85 percent of the annual precipitation is lost by evaporation, with the largest proportion occurring on Lake Erie (Erie receives most of its water from Lake Huron). Some water enters Lake Superior from the Hudson Bay drainage system via the Long Lake–Ogoki River diversion, while water drains out of Lake Michigan through the Chicago Sanitary and Ship Canal.

The Great Lakes and their drainage basin.

The lakes greatly modify the climate of the surrounding region. They absorb a large quantity of heat in the warmer months, which is then lost to the atmosphere during the colder months. This causes cooler summers and warmer winters. Precipitation is substantially higher along the eastern shores of the lakes, creating a snowbelt that afflicts Erie, Penn., Buffalo, N.Y., and similarly situated cities. Severe storms can occur over the lakes, particularly in late fall and early winter. Winds can reach gale force and generate waves 10 feet or more in height. Large areas of the surface waters freeze during winter, although open patches usually remain in the centres of the lakes.

Lake levels generally vary about one to two feet throughout the year, the highest levels occurring in summer and the lowest in late winter and early spring. There are small tides of about two inches, but they are relatively unimportant. Seiches—harmonic oscillations of the lakes—are caused by such atmospheric disturbances as winds or differences in barometric pressure. They have resulted in water piling up temporarily on one side, or end, of the lakes and have caused differences in the water level between Buffalo, N.Y., and Toledo, Ohio, on Lake Erie, as high as 13 feet or more. Currents are highly variable, they respond quickly to wind changes, and their direction is determined by the rotation of the Earth and the shape of the lake basins.

The Great Lakes have bicarbonate waters, the alkalinity of which ranges from 46 parts per million of carbonates in Lake Superior to 113 parts per million in Lake Michigan. Because Lake Huron is fed by both Superior and Michigan, its chemical content lies in the middle of the range. Alkalinity then increases slightly as the waters flow into and through Lakes Erie and Ontario.

The overall chemical composition of the lakes does not differ greatly from that of other large bodies of fresh water. Limestone in the Lake Michigan basin supplies large amounts of calcium and magnesium to the system, while sodium concentrations are greater than those of magnesium in Erie and Ontario. Although chemical distribution is relatively uniform in any one lake, concentrations of phosphorus and nitrogen are greatest along the shores, in bays and harbours, and especially near urban centres.

Chemical composition

During the 20th century, concentrations of most chemicals have increased significantly in all the lakes except Superior. Chloride, sodium, and sulfate have increased considerably in Lakes Erie, Michigan, and Ontario. Chloride concentrations have increased almost four times over levels reported in 1900, and limited data for Lake Erie indicate that nitrogen concentrations increased fivefold and phosphorus threefold in 30 years. Special importance is attached to these nutrients because they stimulate growth of algae, and their increased concentrations reflect the process of nutrient enrichment called eutrophication.

Plant and animal life. Diatoms—microscopic algae with glasslike shells of silica—are the major forms of algae, although green and blue-green algae are abundant during the summer in Lakes Erie, Ontario, and Michigan. Copepods and cladocerans, microscopic crustaceans, are important in the animal forms of plankton. Most abundant during the spring months in the upper lakes, plankton reaches two peaks of abundance—spring and fall—in the lower lakes and in the more productive waters of the upper lakes.

The organisms living on the bottom in shallow waters are the same kinds of snails, clams, worms, mayflies, and caddisflies found in most small lakes. The deep waters, however, are the realm of some organisms that are found only in the deep, cold lakes of the northern latitudes. These include the delicate opossum shrimp, the deepwater scud

(a crustacean), two types of copepods, and the deepwater sculpin (a spiny, large-headed fish). During the 1980s two nonindigenous creatures—the spiny water flea (a crustacean) and the zebra mussel (a mollusk)—gained access to the lakes and established large populations. Both have threatened the food web of native species, and the zebra mussel has become a nuisance by clogging water-intake pipes, covering spawning reefs, and fouling boat hulls.

The fish community of the lakes and tributaries includes representatives of most families of North American fishes. Lake trout, whitefish, and lake herring have always been important in the lakes, while perch, walleye, bass, and catfish are abundant in the shallow, warmer waters. The fish population has changed drastically over the past century. By 1880 the damming and pollution of tributaries had caused the elimination of Atlantic salmon and the restriction of whitefish. At the same time, lake sturgeon were purposely overfished, and carp were introduced. Smelt entered Lake Michigan in 1927 and in a short time had spread throughout the lakes. The predatory sea lamprey migrated into the upper lakes and established spawning populations in the 1930s, causing the collapse of the lake trout populations in Lakes Huron and Michigan by the early 1950s. Other large predators also were drastically reduced in numbers by the sea lamprey. Consequently, when the alewife migrated into the upper lakes between 1931 and 1954, it met little competition and predation and soon became the most abundant species. Alewives are of little commercial value, however, and have caused costly sanitary operations when, periodically, millions of them die and are washed up to rot on the beaches. A major international program to control the sea lamprey reduced its population substantially; and during the 1960s lake trout were reintroduced when it appeared that the sea lamprey was under control. Coho and chinook salmon were introduced both to provide a sports fishery and to control the alewife. Among the accidently introduced species, the small, perchlike ruffe preys on the eggs of native fishes, while the bottom-dwelling round goby competes for food and habitat with indigenous species.

The changing fish population

Herring and ring-billed gulls and terns are the most common birds; small islands are important nesting grounds for them. The lakes are important as wintering areas for ducks such as the scaup and the old-squaw duck, and a diversity of shorebirds and songbirds migrate through the region during the spring and fall. Various places along the shoreline, such as Point Pelée (Ontario) in Lake Erie, are favoured locations for bird-watching.

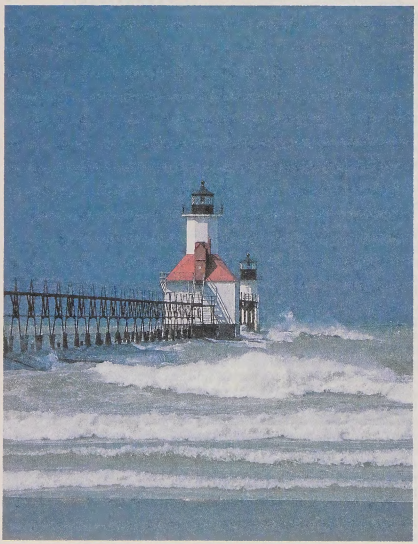
The economy. Early interest in the lakes was stimulated by the easy transportation route that they offered into the heartland of the continent. The value of the extensive forests and fertile land in the region was soon realized, and lumbering and agriculture became important. Large coalfields and deposits of iron, copper, limestone, and other minerals were found along or near the extensive shorelines. The combination of these vast resources with a plentiful water supply naturally favoured the development of huge industries and large metropolitan areas around the Great Lakes. Major urbanized areas include a band that extends from Milwaukee, Wis., through Chicago and around southern Lake Michigan; a band that stretches southward from Detroit, Mich., and then continues along the southern shore of Lake Erie; and the Toronto-Hamilton area on the northern shore of Lake Ontario.

Resources. Although most of the virgin pine forests were felled by 1910, the growing of timber is important and is supported by both federal and state governments. About half of the land in the counties bordering the lakes in the United States is devoted to farming, while nearly one-third of that in the bordering Canadian counties is under agriculture. The major crops raised are corn, soybeans, animal fodder, and fruits and vegetables; pork and dairy products are produced as well.

The ranges around Lake Superior—such as the Mesabi in Minnesota—were once a major source of iron ore for the United States. Peak production occurred in 1953, when almost 100 million net tons were produced. The large deposits of rich ores have since been depleted, but low-grade taconite ores can now be efficiently processed. Lake Superior's Keweenaw Peninsula is a major source of copper, although sources outside of the lakes are relatively more important.

Iron ore

Of major importance is the water supply that the lakes provide for bordering industries and municipalities. Hydroelectric generating stations exist on the St. Marys, Niagara, and St. Lawrence rivers. Numerous thermal- and nuclear-powered generating plants around the lakes utilize lake water for cooling.



Industry and transportation. The industry of the lakes region is highly diversified. The large steel mills in Illinois, Indiana, Ohio, and Ontario and the automobile industry centred in the Detroit area produce a large proportion of the continent's steel and motor vehicles. Nonetheless, many more workers are employed in the service industry.

Most of the total shipping tonnage includes iron ore, coal, and grain for lake ports, but some tonnage is shipped overseas through the St. Lawrence Seaway. The Welland Canal allows passage around Niagara Falls from Lake Ontario into Lake Erie, and the channels and locks in the St. Marys River have made Lake Superior accessible to ships up to 800 feet in length.

Fishing and recreation. Commercial fishing was once a primary industry on the lakes, but the decline of the more desirable species led to its collapse. A limited amount of commercial fishing is still carried on, however, for species such as whitefish. Emphasis has switched to sport fishing based on coho and chinook salmon, lake trout, walleye, and rainbow trout; this has grown into a major industry.

The value of the lakes for a broad spectrum of recreational activities is inestimable. Powerboating and sailing have become popular activities, and numerous marinas have been built. Many miles of sandy beaches stretch along the lake shores. State, provincial, federal, and county lands offer hundreds of camping, picnicking, and park areas for a thriving tourist industry.

Human impact on the lakes. The multiple uses of the

North Pier lighthouse on Lake Michigan at St. Joseph, Mich., as a storm approaches.

lakes are often conflicting. The shipping and hydroelectric-power industries favour higher water levels, for example, but property owners along the shoreline find that high levels increase erosion of the shoreline. Conservationists believe that the diversion of treated sewage away from the lakes, such as is being done at Chicago and various other cities, is the best solution for maintaining the quality of the lake waters. Regardless of the approach that is taken, it is clear that changes have occurred in the plant and animal life of the lakes and that these changes have been related to increases in the content of introduced chemicals, depletion of dissolved oxygen in some places, and the accumulation of sewage sludge on lake bottoms near urban areas.

Pollution of the lakes

Significant changes first became noticeable in about 1900 and paralleled the buildup of human population around the lakes. Misuse of the lakes became all too apparent and was perhaps most clearly dramatized by the growing number of beaches that were closed after 1950 because of pollution; but the less obvious accumulation of toxic substances in wildlife, especially fish and fish-eating birds, had much more serious implications. It came to be realized that pollution could affect either directly or indirectly all uses—raising the cost of water treatment, killing valuable fish species or rendering other species unfit to eat, and adversely affecting the tourist industry and the value of shoreline property. Since the 1970s a major cooperative effort at pollution control has been undertaken by authorities in Canada and the United States, and this has resulted in improved water quality and the resurgence of some fish populations.

Study and exploration. The Great Lakes region was inhabited for centuries by numerous American Indian peoples. With the colonization and expansion of European peoples in North America, the lakes became an integral part of the exploration and development of the continent. It was once speculated that Vikings explored the region in the 14th century—based on the discovery of a broken sword, an ax, and a shield boss near Nipigon Lake, Ont., and a rune stone at Kensington, Minn.—but it is much more likely that the first Europeans entered the region in 1535, when the French explorer Jacques Cartier traveled up the St. Lawrence River to the site of modern Montreal in his search for a route to the Orient. The Huron Indians told him of the great seas lying beyond, but the upper St. Lawrence and Lake Ontario were controlled by the Iroquois, who were unfriendly to the Europeans. Consequently, further exploration by another leading French explorer of North America, Samuel de Champlain, followed the course of the Ottawa River, Lake Nipissing, and the French River to Georgian Bay. He reached Lake Huron in 1615 and is credited with being the first European to see the Great Lakes. In 1634 Jean Nicolet—dispatched by Champlain to seek a route to China—led an expedition into Lake Michigan and down the length of Green Bay to the Fox River, where he encountered the Winnebago Indians. Other French explorers, including René-Robert Cavelier, Lord de La Salle, explored the lakes, made peace with the Indians, and established early settlements.

Three major conflicts affected the history and development of the Great Lakes. The French and Indian War (1754–63)—a struggle between the French and British to gain control of rich fur-producing lands—concluded with the cession of Canada to England. The main consequences of the American Revolution (1775–83) for the Great Lakes region were the migration of thousands of loyalists to New Brunswick, Nova Scotia, Quebec, and Ontario and the establishment of the international boundary between the United States and Canada. During the War of 1812, Lake Erie was the site of a major naval battle.

Modern research

Although several of the early explorers recorded observations of short-term fluctuations in water levels in early geographic writings, the first purely scientific expedition on the Great Lakes was not carried out until 1848. It was led by the Swiss naturalist Louis Agassiz and concentrated on studies of the north shore of Lake Superior. Water-level gauges were established in all the lakes by 1860, and all waters were charted by 1882. Studies of plant and animal life began in the 1870s, and the first study of lake currents was conducted in the early 1890s. Research on the lakes since 1900 largely has been in response to a sequence of crises. The collapse of the lake-herring fishing industry in the 1920s resulted in two major studies of Lake Erie. The invasion of the sea lamprey in the 1930s and concern over lake pollution and eutrophication since World War II has led to international research and cooperation for mitigative measures. Since 1980 additional research has been stimulated by concerns over shoreline erosion and the possible effects of global climatic change. (A.M.B.)

MACKENZIE RIVER

The Mackenzie River is one of the major river systems in the drainage pattern of North America: its basin is the largest in Canada, and it is exceeded on the continent only by the Mississippi-Missouri system. The Mackenzie system drains an area of some 697,000 square miles (1,805,200 square kilometres), which is almost as large as Mexico. From the headwaters of the Finlay River, which flows into Williston Lake (the impounded waters of the Peace River) west of the Rocky Mountains, the entire river system runs for 2,635 miles (4,241 kilometres) through the lake-strewn Canadian north to empty into the cold waters of the Beaufort Sea in the Arctic Ocean. The Mackenzie itself is 1,025 miles long, according to the conventional measurement from Great Slave Lake. The river is generally wide, mostly from 1 to 2 miles across, and in island-dotted sections, 3 to 4 miles wide. It has a strong flow. Its lake-covered triangular delta measures more than 120 miles from north to south and is about 50 miles wide along the Arctic shore.

The headwaters of the system include several large rivers, which themselves drain vast forested plains of northeastern British Columbia and northern Alberta. These drainage basins include the Liard River (about 107,000 square miles), the Peace River (116,800 square miles), and the Athabasca River (36,800 square miles). Much shorter rivers flow into the system from the east, draining the low rocky hills of the ancient structural mass known as the Canadian Shield. The system also includes the huge Great Slave Lake (11,030 square miles), Great Bear Lake (12,100 square miles), and the smaller Lake Athabasca (3,060 square miles).

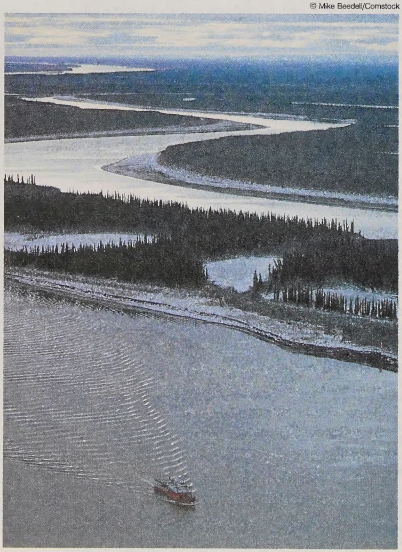
The whole region is subject to a harsh winter climate, and its resources are few and less accessible than those of southern Canada. Yet it is one of the few great unspoiled areas of the world, offering a varied wildlife and spectacular scenery.

For map coverage of the Mackenzie River, see above *Alaskan mountains.*

Physical features. The Mackenzie River itself begins at the western end of Great Slave Lake, at 512 feet (156 metres) above sea level. Deep (more than 2,000 feet in some places), clear water fills the lake's eastern arm, and shallow, murky water is found in the western part. Because of its large size and the extent of its winter ice cover, Great Slave Lake is the last part of the Mackenzie waterway to be free of ice in the spring, with some ice remaining until mid-June in the lake's centre.

Great Slave Lake

The ice on the Mackenzie River begins to break up in early to mid-May in its southern section, being preceded by breakup on the Liard River. Tributary rivers are free of ice before the Mackenzie itself, and high water and flooding are common during the breakup period, particularly when ice dams form. The ice across the lower Mackenzie River breaks up in late May; the channels in the Mackenzie River delta are usually free of floating river ice by the end of May or early June, with the western channels being influenced by the earlier breakup of the Peel River. Sea ice usually remains offshore from the delta in the Beaufort Sea during June, particularly if prevailing winds are onshore.



The upper course. The head of the Mackenzie River is about six miles wide where the western end of the Great Slave Lake narrows and is filled by one large island and several small ones. The river narrows to less than a half mile in width near Fort Providence, and it is there that ice bridges are built across the river in early winter to carry truck traffic along the branch of the Mackenzie

Highway that reaches Yellowknife on the northern arm of the Great Slave Lake. Ferries are used for this crossing in summer, but all road traffic ceases during the breakup period in May. Branch roads extend to Fort Simpson and Fort Liard; and, except for a winter trail that is used only occasionally, there are no through roads farther north along the Mackenzie River valley. Mills Lake is a shallow broadening of the Mackenzie River west of the village of Fort Providence. To the west the river again narrows to about a mile in width, and the current is fast at Green Island Rapids, about 12 miles east of Fort Simpson. There is, however, a channel among the boulders in these rapids that is deep enough for the flat-bottomed barges pushed by shallow-draft tugs that operate out of the southern Great Slave Lake terminal of the town of Hay River and along the Mackenzie.

At Fort Simpson the Liard River (693 miles long) joins the Mackenzie from the west from its source in the southeastern Yukon Territory. The contrast between the muddy, silt-laden water of the Liard and the clear water of the Mackenzie is sharply apparent in the river after the junction, as these "two rivers in one" remain separate in terms of certain physical properties for about 300 miles downstream. At Fort Simpson, as for much of its course, the Mackenzie flows between steep, gray gravel banks, 100 to 200 feet high, which obscure the view of the adjacent lowlands from the river.

Along most of its course, the Mackenzie flows through the Mackenzie Lowlands region, which is about 250 miles wide near Fort Simpson. Although it is classed as forested—mainly with a few species of coniferous trees, such as black and white spruce, and some balsam poplar—much of the region away from the tributary rivers is covered by swamps, muskegs (bogs), and lakes, as well as many open areas of grassy vegetation and low bushes. The Mackenzie Mountains rise steeply on the western side of the Mackenzie valley to altitudes of 5,000 to 6,000 feet; since the tree line is at about 3,000 feet, the upper slopes are barren. The eastern edge of the Mackenzie Lowlands is formed by ancient hills of the Canadian Shield, which slope up to altitudes of about 1,000 feet.

The Mackenzie Mountains

© Mike Beedell/Comstock

Tugboat on the Mackenzie River in the delta region near Inuvik, N.W.Terr.

The Mackenzie Lowlands are underlain by flat-lying sedimentary rock of the Cretaceous (*i.e.,* about 100 million years old) and Devonian (about 400 million years old) periods. Little of this rock is exposed at the surface, however, because it is mantled with glacial and alluvial deposition of clays, sands, and gravels.

North of Fort Simpson the Mackenzie River is a little less than 400 feet above sea level, is a mile wide, and flows between steep banks. The mean annual discharge is measured at 239,000 cubic feet (6,760 cubic metres) per second at Fort Simpson; the average monthly flow at high water during the summer (May to October) is more than 365,000 cubic feet per second, and this seems to derive equally from the Liard and upper Mackenzie. The latter supplies a larger share of the river's volume during winter.

The lower course. North of the trading post at Wrigley, the Redstone and Keele rivers enter from the west; they have deep canyons where they break out of the Mackenzie Mountains but flow across the lowland as shallow, braided streams. These rivers and the others that drain from the Mackenzie Mountains have their peak flows in June after the snow melts in the mountains and become shallow rivers in late summer. The Mackenzie River picks up relatively little volume within its valley lowland, as the average summer precipitation recorded at dispersed settlements is only about 7 or 8 inches (175 to 200 millimetres); total annual precipitation throughout the Mackenzie valley is 10 to 14 inches.

At the village of Fort Norman the cold, clear water of the Great Bear River enters from the east. This short river empties out of Great Bear Lake and is navigable for shallow-draft vessels, except for a short portage around rapids about 30 miles east of its mouth. Once more, there is a distinct summer demarcation for 50 miles northward in the Mackenzie River between its silt-laden water and the clear water from the Great Bear River on the eastern bank. At Norman Wells the Mackenzie River broadens to about 4 miles in width and is less than 175 feet above sea level. The mean annual discharge of the river there is 302,000 cubic feet per second, but flows during the summer months usually will average 460,000 cubic feet per second.

The Mackenzie Lowland is only about 30 miles wide in this section, being broken by the treeless summits of the Franklin Mountains, which rise to altitudes of little more than 3,000 feet on the east side of the river. Small lakes are not so common across the Mackenzie valley in this area as they are on the lowland west of Great Slave Lake. Forest vegetation is scanty except in the river valleys and in areas of better drainage; most of the trees are stunted spruce.

Where the Mountain River joins the Mackenzie from the west there is a fast-water section known as Sans Sault Rapids; the river drops about 20 feet within a few miles. There is ample depth of water for the shallow-draft barges during July, but, despite deepening of the channel by rock blasting, shallow water is sometimes a navigation problem in late summer. South of the Indian village of Fort Good Hope, the Mackenzie narrows as it flows between 100- to 150-foot perpendicular limestone cliffs known as The Ramparts. North of Fort Good Hope, the Mackenzie crosses the Arctic Circle. It is slightly entrenched and meanders across its flat valley floor, its banks being two to three miles apart; low islands are numerous, and shifting sandbars are a problem for the riverboats. Where the Arctic Red River enters from the south, the Mackenzie again flows between steep rock walls, which rise about 100 to 200 feet directly from the water.

The delta region. The Mackenzie River delta begins at Point Separation. The mean annual discharge of Mackenzie water into the delta, measured at the confluence of the Arctic Red River, is 340,000 cubic feet per second, increasing to an average of 540,000 cubic feet per second in summer. From the south the 425-mile Peel River is the last major tributary of the Mackenzie, although it actually flows into the Mackenzie delta to the west of Point Separation. The delta covers about 4,700 square miles and is a maze of branching, intertwining channels, numerous cut-

off lakes, and circular ponds. These lakes are an excellent habitat for muskrat, and the trapping of these animals became the main source of income for the Indian and Eskimo inhabitants of the delta in the period 1920–60.

The permafrost region

The perpetually frozen subsurface soil layer known as permafrost lies a few feet beneath the surface of the islands in the delta and exists in a discontinuous layer beneath the entire Mackenzie Lowlands north of Great Slave Lake. Depending on the type of vegetation cover, the top few inches to several feet of ground above the permafrost melts during the summer months. Northern construction of airfields, roads, and pipelines has to be adapted to these permafrost conditions; houses and other buildings are usually placed on wooden piles that are sunk and frozen into the permafrost to give stability. One of the distinctive features of the town of Inuvik is a utilidor, a linear boxlike metal container raised slightly above the surface of the ground, in which the separate sewer, water, and heating pipes are placed. Mackenzie River water-transport routes terminate at Tuktoyaktuk on the Arctic coast northeast of the delta; there cargo is transferred to other vessels of greater draft, which serve the small settlements, radar stations, and oil-exploration sites along the western Arctic coast.

The people and economy. The Mackenzie River basin is sparsely populated. Its natural resources are few, and they are less accessible than comparable resources in southern Canada. Fur-bearing animals were the resource attraction of the 19th century; although they are still trapped throughout the forests of the river basin, particularly by the Indian population, furs now constitute a minor element in the regional economy. Muskrat, marten, beaver, lynx, and fox are the main pelts sought. The forests in the southern part of the basin have been utilized locally for lumber and pulpwood in the Peace River area. The small conifer trees have future value as a source of pulpwood.

Agricultural land is developed only in the south, particularly in the Peace River area. Settlers moved into the Athabasca River, Lesser Slave Lake, and Peace River areas in large numbers after 1920, when the farmlands of the Canadian prairies were almost all occupied. When railroad connections were established southward to Edmonton, these farms were able to produce grain, livestock, and legume seed for external markets. A few farms and many gardens produced well along the Mackenzie River before 1940, but the improved transport since World War II has permitted most food to be imported. With July mean temperatures averaging about 60° F (16° C), and daily temperatures that reach into the 70s and sometimes 80s (*i.e.,* between about 21° and 29° C), climate does not prevent the growth of certain crops.

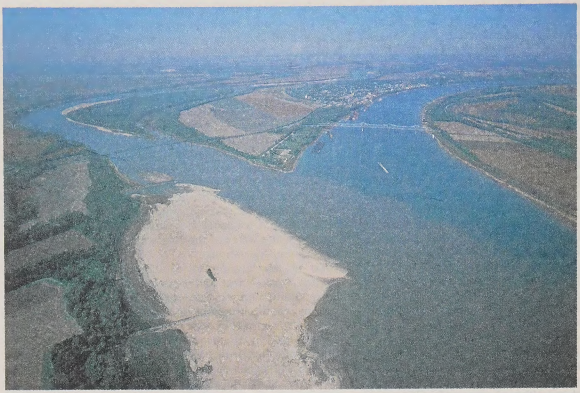
Minerals—particularly oil and natural gas—are the economic basis of some of the larger settlements in the basin. The first oil field was discovered at Norman Wells in 1921, but production did not begin until the 1930s. A small refinery at Norman Wells produces petroleum products for the industries, transport, and homes of the northern parts of the Mackenzie River valley, and the oil field there was enlarged in the 1980s and connected by a pipeline to Alberta. Other oil and natural gas fields have been discovered near the Mackenzie delta and offshore in the Beaufort Sea. The largest fields are in the southern parts of the river basin, in northwestern Alberta and northeastern British Columbia. The oil and gas from them also is carried southward by pipelines to be distributed from Edmonton, Alta., to refineries in southern Canada and the northern United States. An enormous reserve of petroleum lies in the Athabasca Tar Sands along the Athabasca River north of Fort McMurray; production there was initially limited by high development costs, but it increased in the 1980s as oil fields in Alberta were depleted.

The role of oil and minerals

Metallic minerals have been found along the eastern and southern edges of the basin. Valuable uranium ores were produced on the eastern shores of Great Bear Lake (1933–61) and on the northern side of Lake Athabasca (1950–80) in northwestern Saskatchewan; and the richest uranium mines yet discovered in Canada began operation in the 1980s on the southeastern side of Lake Athabasca. High-quality gold mines are the resource base of the city of Yellowknife, the capital of the Northwest Territories. Lead and zinc mines on the southern side of Great Slave Lake were depleted by 1990; the size of these deposits had been large enough, however, to bring the first railroad into the Northwest Territories, which was built in the 1960s from the Peace River area to the town of Hay River.

The water of the upper Mackenzie River system was too far from large industrial and urban markets to be used for hydroelectric power until the late 1960s. At that time the Peace River was dammed as it broke out of the Rocky Mountains and a large storage lake formed westward in the Rocky Mountain Trench. This electric power is transmitted south 600 miles to Vancouver, B.C. Otherwise, the only developed waterpower sites are on the Snare and Taltson rivers, which drop westward out of the Canadian Shield to the Mackenzie Lowlands and supply power to the mines and residents at Yellowknife. There is no utilization of the water of the Mackenzie River itself, except for river transportation.

Two of the large lakes of the Mackenzie basin are sources of lake trout and whitefish. Lake Athabasca was first exploited during the 1930s, and Great Slave Lake was opened to commercial fishing after 1945. In the latter lake, fish are caught in both summer and winter and transported south by truck or rail to urban markets in both Canada and the United States. The catch is controlled by seasonal quotas that prevent depletion of the species. The cold water of Great Bear Lake has some fish, but they grow too slowly to sustain anything but sport fishing. Fish of the Mackenzie River are netted by some local residents to supplement their imported food.



European exploration

History. Explorers and fur traders pushed westward across Canada in the late 18th century to the headwaters of rivers that flowed into Hudson Bay, seeking to tap the fur resources in the lands beyond. In 1778 one of them, Peter Pond, found Portage La Loche (Methy Portage) connecting the headwaters of Churchill River with the Clearwater River, itself one of the east-bank tributaries of the Athabasca River. In 1789 Alexander Mackenzie made his historic journey northward from the trading post of Fort Chipewyan on Lake Athabasca, exploring, with a crew of 12 in three canoes, the full length of the river that now bears his name.

Other fur traders of the North West Company followed early in the 19th century, establishing posts at several sites along the river and on its headwater tributaries. From the mid-1820s, supplies were carried in by the distinctive York boats, shallow-draft vessels with a sharply angled stern and bow. In 1884 the first steamer began to operate northward from Fort McMurray, at the junction of the Clearwater and Athabasca rivers, to Fitzgerald on the Slave River. At this point there are 16 miles of rapids in Slave River, the only break in 1,700 miles of shallow-draft river navigation from Fort McMurray to the Arctic Ocean. In 1886 the first steamer began operating north of Fort Smith—on the present border between the Northwest Territories and Alberta—taking supplies to the Mackenzie River trading posts and bringing out bales of fur. During the period 1920–1940, flat-bottomed stern-wheelers operated on the Mackenzie, but they were replaced after 1945 by small diesel tugs that could push several barges. (J.L.Ro.)

MISSISSIPPI RIVER

Paramount among North American rivers, the Mississippi combines with its major tributaries to form the world's third largest drainage system in area (approximately 1.2 million square miles, or 3.1 million square kilometres). As the central river artery of a highly industrialized nation, the Mississippi has become one of the busiest commercial waterways in the world; and, as the unruly neighbour of some of the continent's richest farmland, it has been subjected to a remarkable degree of human control. Furthermore, the river's unique contribution to the history and literature of the United States has woven it like a bright thread through the folklore and national consciousness of North America, linking the names of two U.S. presidents—Abraham Lincoln and Ulysses S. Grant—with that of the celebrated author Mark Twain. Draining all or part of 31 U.S. states and two Canadian provinces, the outline of the Mississippi system resembles a sturdy tree with two

Confluence of the (left) Mississippi and Ohio rivers at Cairo, Ill.
© Alex S. MacLean/Landslides

main lateral branches, the Ohio River to the east and the Missouri River to the west. Only a thin line carries the name of the parent trunk northward to the river's source at Lake Itasca, Minn.

Although the Mississippi can be ranked as the fourth longest river in the world by adding the length of the Missouri-Jefferson (Red Rock) system to the Mississippi downstream of the Missouri-Mississippi confluence—for a combined length of 3,710 miles (5,971 kilometres)—the 2,350-mile length of the Mississippi proper is comfortably exceeded by 19 other rivers. In volume of discharge, however, the Mississippi's rate of roughly 600,000 cubic feet (17,000 cubic metres) per second is the eighth greatest in the world.

Regional divisions

On the basis of physical characteristics, the Mississippi River can be divided into four distinct reaches. The headwaters reach, from the source to the head of navigation at St. Paul, Minn., is a clear, fresh stream winding its unassuming way through low countryside dotted with lakes and marshes. The upper Mississippi extends from St. Paul to the mouth of the Missouri River near St. Louis, Mo. Flowing past steep limestone bluffs and gathering in the streams and rivers of Minnesota, Wisconsin, Illinois, and Iowa, the river in this segment assumes the character that led Algonkian-speaking Indians to name it the "Father of Waters" (literally *Misi,* "Big"; *Sipi,* "Water"). Below the Missouri River junction, the middle Mississippi follows a 200-mile course to the mouth of the Ohio River. The turbulent, flotsam-laden Missouri, especially when in flood, adds impetus as well as enormous quantities of silt to the clearer Mississippi. Beyond the confluence with the Ohio at Cairo, Ill., the lower Mississippi swells to its full grandeur. Often a mile and a half from bank to bank, it becomes a brown flood, descending with deceptive quiet toward the Gulf of Mexico.

To geographers, the lower Mississippi has long been a classic example of a meandering alluvial river; that is, the channel loops and curls extravagantly along its floodplain, leaving behind meander scars, cutoffs, oxbow lakes, and swampy backwaters. More poetically, Mark Twain compared its shape to "a long, pliant apple-paring." Today the sunlight glittering on the twisted ribbon of water remains one of the most distinctive landmarks of a transcontinental flight. Now curbed largely by an elaborate system of embankments (levees) and spillways, this lower section of the Mississippi was the golden, sometimes treacherous, highway for the renowned Mississippi steamboats, those "palaces on paddle wheels" that so fired public imagination. From the explosive master pilot Horace Bixby, portrayed by Mark Twain, down to the nostalgic lyrics of Oscar Hammerstein's song "Ol' Man River," the creations of that era on the Mississippi have added colour to America's heritage.

Physical features. *Physiography.* The geology and physical geography of the Mississippi drainage area are essentially those of the Interior Lowlands and Great Plains of North America. Fringes also touch upon the Rocky and Appalachian mountains and upon the rim of the Canadian (Laurentian) Shield to the north. The focus of the system, the floodplain of the lower Mississippi, is of particular interest in that the geology and physical geography of the region are of the river's own making. Like a huge funnel, the river has taken sediment and debris from contributory areas near the lip of the funnel and deposited much of the product in the alluvial plain of the funnel's spout, illustrating the interdependence of the entire Mississippi system.

The most significant contributory area in recent times has been to the west of the river. Rising in western uplands, notably in the foothills of the Rockies, rivers such as the Red, Arkansas, Kansas, Platte, and Missouri remove considerable silt loads from the rolling expanses of the Great Plains. A wide, gently sloping mantle of unconsolidated materials, laid down over rock beds of the Cretaceous Period (*i.e.,* about 100 million years old), allows for each river to pick up an independent course toward the "Father of Waters." Precipitation in these western areas is light to moderate, usually less than 25 inches (635 millimetres) per year; but, because at least 70 percent of this precipitation falls as rain between April and September, the erosive capability of the rivers is enhanced (the runoff from winter snowmelt is more gradual than from rainstorms). The prairie soils, moreover, offer little resistance to erosion, so that the rivers are not only incised and braided in their courses but their silt load is high in relation to their volume.

Contributory areas

The Mississippi's eastern contributory rivers drain the well-watered Appalachian Mountain system. Most of this group, including the Kentucky, Green, Cumberland, and Tennessee rivers, flows via well-defined valleys into the Ohio and thence into the Mississippi. The erosive capacity of these rivers varies in relation to the geologic structure of their basins. These consist of harder rocks in the higher elevations and a softer sill of limestone of the Late Carboniferous Period (*i.e.,* about 300 million years of age), lying below the 1,000-foot elevation line between the Ohio and Tennessee rivers and in the glaciated area of the Ohio's right-bank tributaries.

The third contributory area of the Mississippi differs,

The Mississippi River basin and its drainage network.

once again, from the other two. The upper Mississippi gathers its strength in a region marked and scarred by glacial action. After the great ice sheets of the Wisconsin Glaciation had put down layers of debris across much of Minnesota, Wisconsin, northern Illinois, and northern Iowa, huge quantities of meltwater flowed south, washing channels through this debris. Today the upper Mississippi and its tributaries, the Wisconsin, St. Croix, Rock, and Illinois rivers, all trace the lines of these former sluiceways.

Pouring southward, the glacial meltwaters were joined by the proto-Missouri and Ohio rivers. The combined flood then gouged out the great north-south trough along which the lower Mississippi now flows. A thousand miles long, this trough is from 25 to 200 miles wide and bounded by escarpments rising up to 200 feet above the valley floor. Geologic studies have revealed that the floor of the glacial trough was later buried by a deep layer of material washed out from the ice sheet and dumped to a thickness of 100 to 300 feet in the central section.

The Mississippi's delta is an even more striking monument to the river's constructive work. There, at the tip of the drainage funnel, millions of years of sedimentation have spilled out across the floor of the Gulf of Mexico, forming a great cone of sediment 300 miles in radius and 30,000 square miles in area. The surface expression of this cone (just to the east of its apex) is the Mississippi's present delta, with an area exceeding 11,000 square miles. Stretching its distributaries into the gulf, the Mississippi delivers some 220 million tons of sediment there each year.

The delta

Climate. During winter, mean monthly temperatures in the Mississippi basin range from 55° F (13° C) in subtropical southern Louisiana to 10° F (−12° C) in subarctic northern Minnesota. Mean monthly temperatures in summer range from 82° F (28° C) in Louisiana to 70° F (21° C) in Minnesota.

Precipitation sources are low-level moisture from the Gulf of Mexico and some low-level and high-level moisture from the Pacific Ocean. Winter and spring precipitation occurs in the vicinity of fronts during passage of cyclonic storms that generally move from west to east. Average monthly precipitation in winter ranges from five inches or more in the south to more than three inches over much of the Ohio River basin to less than one inch over the western and northern Great Plains. Summer and early autumn rainfall occurs mostly as showers and thunderstorms and weaker frontal storms. Average monthly rainfall ranges from six inches in southern Louisiana and over the mountains of Tennessee and North Carolina to only two or three inches over the Great Plains.

Climates are humid over the eastern half of the basin,

with large quantities of winter and spring runoff generated over the Tennessee, Ohio, and southern Mississippi river basins. A north-south band of subhumid climates, neither fully humid nor semiarid, extends from central Texas northward to eastern North Dakota. To the west are the semiarid climates of the Great Plains, and along the Rocky Mountain crests an alpine climate prevails, in which winter snowfalls are released as spring and early summer meltwater runoff.

Hydrology. It is not surprising that the hydrology of so powerful a river as the Mississippi has been the subject of intense study. In the 19th century, Mark Twain described with considerable wit how the pilots of the Mississippi paddle wheelers banded together to run a common information service about changing conditions along the channel. Today the Mississippi River Commission is responsible for river work and considers it worthwhile to maintain a working scale model of the river so that its engineers can test new plans in miniature before embarking on expensive, full-scale projects. Indeed, by the 1920s it was generally believed that enough was known about the river's hydrology and enough control structures had been built to have tamed the river. Then in 1927 came the most disastrous flood in the recorded history of the lower Mississippi valley. More than 23,000 square miles of land were flooded. Communications, including roads and rail and telephone services, were cut in many places. Farms, factories, and whole towns went temporarily underwater. An immense amount of property was damaged, and at least 250 people lost their lives. The river engineers took another look at the hydrology of the Mississippi.

Mean water discharge data

Since the freak conditions of 1927, the mean discharge of water into the lower Mississippi by its major tributaries has been carefully monitored. The mean discharge of the main river past Vicksburg, Miss., is calculated at 570,000 cubic feet per second. About 135 miles downriver from Vicksburg, approximately 25 percent of the sediment and water discharge of the river is diverted into the Atchafalaya River through the Old River Complex (Old River Control Structures). These statistics, however, conceal all-important variations in river flow linked with the fluctuating state of the Mississippi's larger tributaries.

Broadly speaking, the western tributaries are the most irregular. They reach a spring or early summer peak that is up to three or four times as great as their winter contribution. The upper Mississippi and its tributaries reach their maximum flow about the same time (March–June), when melting snows are followed by early summer rains. The winter runoff from this area, however, is substantial. The crest of the Ohio's flow occurs slightly earlier. At Metropolis, Ill., just above the confluence with the Mississippi, the greatest monthly discharge is usually recorded in March, at which time the Ohio may be providing more than three-fifths of the water being monitored past Vicksburg in the lower river.

Thus, the Ohio is chiefly responsible for the lower Mississippi flood situations, which may be aggravated by such factors as early rains in the Great Plains, a sudden hot spell in early spring that melts the northern snows, and heavy downpours throughout the lower valley. Under such conditions the lower river will rise over its banks and put pressure against the levees. Tributaries will back up and form lakes on the far side of these same levees. The current, which normally runs no more than 2 to 3½ knots (2½ to 4 miles per hour), may then double at constricted points along the main channel. Thus, the monitoring station at Vicksburg, which at low water in 1936 recorded as little as 93,800 cubic feet per second, measured 2,060,000 cubic feet per second at high-water stage the following year.

Water quality

A variety of pollutants, derived from municipal, industrial, and agricultural sources, have been identified in the waters and sediments of the Mississippi River. Organic compounds and trace metals occur in relatively low concentrations; in addition to those naturally present in the water, they derive from industrial and municipal wastes and runoff from agricultural and urban areas. High concentrations of bacteria associated with human waste, however, have been found downstream from some cities and have been attributed to inadequately treated sewage flowing into the river; concentrations downstream from New Orleans, for example, have been found to be many times greater than concentrations above the city. Pollutants have had little widespread effect on the composition of benthic invertebrate populations, which are indicative of changes in water quality. Water samples taken at New Orleans have shown a relatively high dissolved-oxygen content and low biochemical oxygen demand. Thus, by this index, river pollution may be said to be low.

Plant and animal life. Although the natural vegetation of the Mississippi's immediate valley is the product of climate and soil rather than of the river, the Mississippi's swamps and backwaters are ecologically noteworthy. Threaded along the river, from the wild-rice marshes of Minnesota to the coastal wetlands of the delta, are pockets of thriving plant-animal associations. There, the abundance of natural cover, the comparative isolation, and the food provided by such plants as sedges, pondweeds, and millets encourages regular colonization by waterfowl. The path of these birds, as they move up and down the river with the seasons, has been called the Mississippi Flyway, an appropriate name for the vast aerial highway that reaches from the delta to the distant summer nesting grounds in northern Canada. An estimated eight million ducks, geese, and swans winter in the lower part of the flyway, and many more birds use it en route to Latin America. Typical flyway migrants are Canada geese and lesser snow geese, large numbers of mallard and teal, black ducks, widgeon, pintail and ring-necked ducks, and coots.

The most important varieties of fish found in the river include several types of catfish (some of which grow to considerable size and are fished commercially by local concerns along the middle and lower river); walleyes and suckers, which thrive in the upper river and provide the basis for a sport-fishing industry in Minnesota and Wisconsin; carp; and garfish. Alligators are now rare, being found only in the most isolated backwaters, while the shrimp and crab fisheries of the brackish waters are in decline.

History and economy. *Early settlement and exploration.* As its respectful Indian name indicates, the Mississippi played an important role in the lives of the aboriginal peoples settled on its banks. To the Indians of the river, the Mississippi was both highway and larder. On it they paddled their cottonwood dugouts and their bark canoes, and from it they took the fish that was a mainstay of their diet. Constant shifts of migration, local or large-scale, interwove tribal languages and cultures. By the time Europeans arrived, the Sioux, who originally had lived on the upper river, had withdrawn westward to give place to Ojibwa, Winnebago, Fox, and Sauk. Downriver the Illinois tribe had established prosperous agricultural communities. And in the lower valley itself lived clans of Choctaw, Koroa, Taensa, Chickasaw, Tunica, Yazoo, Pascagoula, Natchez, Biloxi, and Alibamu.

Early exploration

The Spanish explorer Hernando de Soto, commander of the first European expedition to penetrate to the river, had high hopes of plundering the southern tribes. In May 1541 his raiding force reached the river at a point south of what is now Memphis, Tenn. But the "Rio Grande," as the Spaniards called it, provided the newcomers with small profit and much grief. The river Indians launched repeated attacks; the Mississippi floods caught the Spanish unawares; and, ironically, de Soto, the European discoverer of the river, was buried in its waters, after which the rest of his disappointed expedition retreated to the sea, their homemade boats under a running fire from the Indians.

The next European explorers of the river appeared in 1673 out of French Canada—two canoeloads of voyageurs commanded by Louis Jolliet, a French government agent, and Jacques Marquette, a Jesuit priest. Portaging from the Fox River to the Wisconsin, they paddled down the Mississippi as far as the mouth of the Arkansas River. Nine years later the French explorer Renê-Robert Cavelier, Lord de La Salle, reached the delta itself, having opened the even easier portage from the Great Lakes via the Illinois River. He grasped at once the strategic significance

of the huge drainage system and promptly claimed the entire Mississippi basin for France. Within a generation, the Mississippi was a vital link between France's Gulf of Mexico settlements and Canada, and La Salle's claim was vaguely designated as "Louisiana."

But France's grasp on the Mississippi was never firm. French traders settled the upper river, establishing towns like St. Louis and Prairie du Chien (now in Wisconsin), whose names survive to this day. But the lower river passed into Spanish hands in 1769; the Treaty of Paris (1783) optimistically declared the river as the western boundary of the United States; and republican France reacquired the much-bartered stream only long enough to sell it to the United States as part of the Louisiana Purchase (1803). This last move recognized what had been obvious for a quarter of a century—the growing domination of the river by the Americans. They came by raft, flatboat, and ark (a "raft with a rim"), built and loaded on the left-bank tributaries that were in the forefront of the westward expansion of the United States. Unwieldy and expendable, these craft floated downstream to leave their cargoes and occupants as advance guards of American political and economic expansion. Only the long, slim keelboats made the return trip. They were worked upstream under pole, paddle, or sail or by the backbreaking "cordelle," a system under which the crew went ashore with a long bow hawser and pulled the vessel upstream by brute strength.

The torch of exploration also passed to the Americans after the Louisiana Purchase. In 1805–06 the pioneer expedition of the U.S. Army officer Zebulon M. Pike struggled to within 80 miles of the river's source, and in 1832 Henry Rowe Schoolcraft, an Indian agent for the U.S. government, identified and named Lake Itasca (from the Latin *veritas caput,* "true head") as the Mississippi's starting point.

The coming of the steamboats

Development of the river's commerce. Built in Pittsburgh, Pa., in 1811, the *New Orleans* was the first steamboat to appear on the river. Like some fearful omen, its maiden voyage coincided with the series of powerful earth tremors centred in Missouri just south of St. Louis (called the New Madrid earthquake) that caused much flooding and sudden relocation of sections of the main channel. But the *New Orleans* won through, and within a decade its successors had wrought a revolution on the Mississippi. In 1814 only 21 steamboats called at New Orleans, whereas 191 arrived during 1819, and 14 years later more than 1,200 cargoes were unloaded during the year. As the freight rates by steamer on the Ohio and Mississippi rivers plummeted, it became cheaper to send freight from Cincinnati, Ohio, to the U.S. east coast via the Mississippi and the long sea passage from New Orleans than to transport it over the Appalachians, a route that was 10 times shorter.

With the introduction of larger, high-pressure engines and more streamlined hulls, the steamboats extended their range, and the Mississippi became economic overlord to half the country. In 1820 the *Western Engineer* probed up the Missouri. In 1823 the *Virginia* churned its way up to Fort Snelling at the junction of the Mississippi with the Minnesota River. The steamboats brought an era of unprecedented prosperity to the river. Town after town sprang up, dependent on the regular arrival of packet boats bringing mail and passengers or freight boats that took on local produce and left off manufactured goods. Riverbank plantations maintained their own landings so they could ship crops direct, and riverside towns vied with each other to provide services such as fueling and warehousing. The waterfront at New Orleans, with its double line of twin-stacked steamers mingled with oceangoing ships, was among the busiest in the nation.

In 1861, however, came the Civil War; a sharp struggle for control of this vital waterway ensued immediately, which culminated in Ulysses S. Grant's siege of Vicksburg helped by the fortified gunboats and armoured steamers of the Union. When Vicksburg and the river fell into Union hands, the Confederacy was dealt a heavy commercial and strategic blow. President Abraham Lincoln, who himself had been a Mississippi flatboatman, could report that "the Father of Waters flows unvexed to the sea."

During the years immediately after the Civil War there was a brief but glorious revival in river traffic. New and faster steamboats were built and operated, often in rivalry to one another, a rivalry made famous by the three-day race, commencing June 30, 1870, between the *Natchez* and the *Robert E. Lee.* The latter won by dint of stripping out all unnecessary superstructure and taking on extra fuel supplies from tenders while steaming upriver at full speed. Yet even as the river was at its most flamboyant, the same westward expansion that had brought its development now passed it over. With the construction of east-west railroads and canals, the Mississippi's north-south alignment came to be regarded as a nuisance. Towns that had once sought to become staging posts up and down the river now competed to become crossing points. Commercial traffic dwindled, and the grand luxury paddle wheelers gave way to sombre, more prosaic towboats with blocks of barges.

Modern commercial activity. World War I produced a major resurgence in river trade. As other lines of transport became congested, the river was recognized as an increasingly valuable asset. With federal initiative, new barge lines were organized, and by 1931 the annual barge traffic moving along the river was twice the volume moved in any single year during the previous century. In 1907, for instance, the steamer *Sprague* established a new world record for size of tow. Its raft of 60 coal barges weighed 67,307 tons and covered an area of 6.5 acres (2.6 hectares).

Barge traffic

Sprague's record is unlikely to be matched by any other paddle wheeler, for the remaining steamboats are mostly showpieces, and the modern Mississippi towboat is of design radically different from its forebears. Screw-driven and diesel-engined, the modern towboat is made fast to the stern of its tow. Ahead stretches a rigid platform of barges as much as 1,500 feet long and with a designed draft of 9 feet. Most barges are built for specific cargoes. For dry cargo, they average 1,500 tons capacity and measure 195 feet long by 35 feet wide; for liquid cargo, the proportions are about 2,500 tons capacity and 295 feet by 50 feet. To aid navigation, towboat captains have at their disposal electronic depth finders, radar, contraguide rudders, a sophisticated system of riverbank lights and markers, and a radio telephone to warn other river users of their approach in narrow passages. Among the cargoes to be carried along the river in this fashion since about 1960 are the booster rockets for space research, which are so bulky as to be unsuitable for any other mode of transport.

Commercial use of the Mississippi waterway has shown sturdy growth. Leading cargoes, by bulk, were petroleum and derivative products, coal and coke, iron and steel, chemicals, sand and gravel, and sulfur. An increasing emphasis on bulk handling inevitably has meant the rapid growth of a few key port cities at the expense of their rivals.

Responsibility for overseeing the maintenance and improvement of the Mississippi as a commercial waterway, as well as the related tasks of flood control and bank protection (see below), falls upon the Mississippi River Commission. Created by act of Congress in 1879, the commission has supervised a massive program of river work that has profoundly reshaped the character of the Mississippi. The main stages of the navigation improvement program include a channel 9 feet deep and 250 feet wide at low water between Cairo, Ill., and Baton Rouge, La., authorized in 1896; a widening of this channel to 300 feet, approved in 1928; and its deepening to 12 feet, begun in 1944 and still under way. In addition, a ship channel 45 feet deep from Baton Rouge to the Gulf of Mexico has been under construction since its authorization by Congress in 1945. Farther upriver, the outstanding achievement has been the construction of 29 locks and dams on the upper river to take the 9-foot channel upstream to Minneapolis–St. Paul. Connecting into the Mississippi is a vast complex of related waterways—from the Intracoastal Waterway in the south, stretching between Florida and the Mexican border, to the channels that lead up the Ohio to its tributaries and through the Illinois waterway to the Great Lakes and St. Lawrence Seaway.

Flood control. Flood control along the river dates to the foundation of New Orleans in 1717 by the French, who built a small levee to shelter their infant city. Over

Levees

the next two centuries a complex array of riverbank structures was erected along the river to contain or divert floods. But it was not until after the catastrophic flood of 1927 that the federal government became committed to a definite program of flood control. The target has become an integrated flood-control system able to master a "project flood," the largest theoretical flood expected along the river. This program has altered the face of the river even more than the navigation program—with which it is linked—has altered its bed.

In principle, the Mississippi's floods are either constricted by levees, hastened out of danger zones by floodways and improved channels, dissipated down spillways and into reservoirs, or starved by the impounding of tributary floods. From Cape Girardeau, Mo., to the sea, the river is virtually "walled in" by a vast line of main-stem levees. This concrete barrier has, incidentally, isolated the river from much of the surrounding countryside, and many former riverbank towns are severed from their natural setting. In the event that the main levees are threatened, the excess floodwater drains away down spillways (*e.g.,* from north of New Orleans it is diverted past the city by spillways leading through Lake Pontchartrain to the Gulf of Mexico) or bursts "fuse plugs," the specially weakened sections of levee leading to harmless floodways or reservoirs. A major example of this type of floodway occurs at New Madrid, Mo., just south of the Ohio confluence.

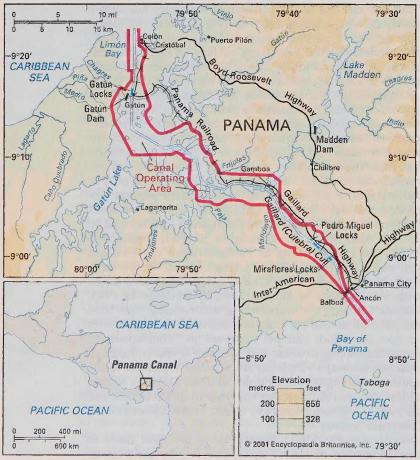
Elsewhere, a massive program of bank strengthening using mattresses of concrete slabs has reduced lateral erosion and increased channel stability. The careful positioning of underwater dikes to deflect the current, the cutting through of oxbow bends at their necks, and a continuous dredging schedule have all helped to reduce flood levels. Although the system operated successfully against the high-water levels of 1945 and 1950, it could not contain the flood of 1973 nor the record inundation of 1993 of the upper and middle Mississippi and lower Missouri.

Thus, the Mississippi flood-control program is not without its problems. It has been increasingly necessary, now that the river is caught behind the main-stem levees, to attend to the isolated tributaries. In some cases, costly pumping stations have been installed to lift the impounded water over the levees and into the main river. More dramatic has been the penalty for using the Atchafalaya River as a convenient spillway for floods on the lower river. The Mississippi threatened to divert permanently into this secondary channel, inundating the lower Atchafalaya, bypassing New Orleans, and rendering useless millions of dollars of flood-control works. Only at the cost of a vast and complex system of locks and barrages has the danger been averted. It has become increasingly clear that the river's delicate hydrology has been disturbed and that the program of river work must continue for many years.

(G.T.Se./R.A.Mu./R.H.K.)

PANAMA CANAL

The Panama Canal is a canal of the lake-and-lock type connecting the Atlantic and Pacific oceans through the narrow Isthmus of Panama, where the Continental Divide dips to one of its lowest points. The length of the Panama Canal from shoreline to shoreline is about 40 miles (65 kilometres) and from deep water in the Atlantic to deep water in the Pacific about 51 miles. The canal is one of the two most strategic artificial waterways in the world, the other being the Suez Canal. From its opening in 1914 until 1979, it was controlled solely by the United States, which built it. In 1979, however, control passed to a joint agency of the United States and the Republic of Panama, and Panama's participation gradually increased. By treaty, complete control of the canal passed to Panama at noon on Dec. 31, 1999, and administration of the canal became the responsibility of the Panama Canal Authority.



Length of the canal

Ships sailing between the east and west coasts of the United States, which otherwise would be obliged to round Cape Horn in South America, shorten their voyage by about 8,000 nautical miles by using the canal. Savings of up to 3,500 miles also are made on voyages between one coast of North America and ports on the other side of South America. Ships sailing between Europe and East Asia or Australia can save as much as 2,000 miles by using the canal.

Physical features. *The canal.* The Panama Canal lies at a latitude of 9° N. The canal does not, as is generally supposed, cross the isthmus from east to west. It runs due south from its entrance at Colón on the Atlantic side through the Gatún (Gatun) Locks to a point in the widest portion of Gatún Lake; it then turns sharply toward the east and follows a course generally to the southeast until it reaches the Bay of Panama, on the Pacific side. Its terminus near Balboa is some 25 miles east of its terminus near Colón. Parallel to the canal are the Panama Railroad and the Boyd-Roosevelt Highway.

In passing from the Atlantic to the Pacific, vessels enter the approach channel in Limón Bay, which extends a distance of about seven miles to the Gatún Locks. At Gatún a series of three locks lift vessels 85 feet (26 metres) to Gatún Lake. The lake—formed by Gatún Dam on the Chagres River and supplemented by waters from Lake Madden (called Lago Alajuela in Panama) formed by the Madden Dam—covers an area of 164 square miles (425 square kilometres). The channel through the lake varies in depth from 45 to 87 feet and extends for about 23 miles to Gamboa. At Gamboa the Gaillard (Culebra) Cut through the Continental Divide begins. The channel through the cut has an average depth of about 42 feet and extends some eight miles to the Pedro Miguel Locks. The locks lower vessels 31 feet to Lake Miraflores, at an elevation of 54 feet above sea level. Vessels then pass through a channel one mile long to the two-stepped locks at Miraflores, where they are lowered to sea level. The final segment of the canal is a dredged approach passage seven miles long through which ships pass into the Pacific. Throughout its length the canal has a minimum bottom width of 500 feet; in Gatún Lake the width of the channel varies between 500 and 1,000 feet, and in Lake Miraflores the width is 750 feet.

Locks. The canal locks operate by gravity flow of water from Gatún, Madden, and Miraflores lakes, which are fed by the Chagres and other rivers. The locks themselves are of uniform length, width, and depth. Each set of locks is built in tandem, to permit the simultaneous transit of vessels in either direction. Each lock gate has two leaves, 65 feet wide and 7 feet thick, set on hinges. The gates range in height from 47 to 82 feet; their movement is powered by motors recessed in the lock walls. They are operated from

The Panama Canal.

Ships traveling in opposite directions through the Miraflores Locks, Panama Canal. At centre on cog tracks on the lock wall are the electric locomotives used to tow the ships.
© Mario Alguze/The Image Works

a control tower, located on the wall that separates each pair of locks, and from which the flooding or emptying of the lock chambers is also controlled. The lock chambers are 1,000 feet long, 110 feet wide, and 41 feet deep.

Towing locomotives

Because of the delicate nature of the lock mechanisms, only small craft are allowed to pass through the locks under their own power. Larger craft are taken through by electric towing locomotives, which operate on cog tracks on the lock walls. Before a lock can be entered, a fender chain, stretched between the walls of the approach, must be passed. If all is proceeding properly, this chain is dropped into its groove at the bottom of the channel. If by any chance the ship is moving too rapidly for safety, the chain remains stretched and the vessel runs against it. The chain, which is operated by hydraulic machinery in the walls, then pays out slowly by automatic release until the vessel is brought to a stop. If the vessel should get away from the towing locomotive and, breaking through the chain, ram the first gate, there is a second gate 50 feet away that protects the lock and arrests further advance.

Breakwaters. Long breakwaters have been constructed near the approach channels in both oceans. Breakwaters extend from the west and east sides of Limón Bay; the west breakwater protects the harbour against severe gales, while the east one reduces silting in the canal channel. On the Pacific side a causeway extends from Balboa to three small islands (Naos, Perico, and Flamenco) and diverts crosscurrents that carry soft material from the shallow harbour of Panama City into the canal channel.

The economy. *Navigation.* Ships are taken through the canal by one or more pilots, who board each ship before it leaves the terminus. With waiting time, ships require about 15 to 20 hours to negotiate the canal. The average transit time, once a vessel has been authorized to proceed, is about 9 hours from deep water to deep water. When Gaillard Cut is not being dredged, canal traffic generally proceeds in both directions. The heavy rainfall of Panama makes operation feasible despite the irrevocable loss of large quantities of water with each transit. To conserve water, two or more vessels moving in the same direction are passed through together when their size permits.

Each ship is also boarded by measurers to verify its carrying capacity and to collect tolls. Manifests, ships' papers, and other documents are inspected and recorded. Transits are scheduled and monitored at points along the route by an automated marine-traffic control system.

Maintenance. Continual maintenance work on the canal and its associated facilities is needed to keep it in operation in a tropical climate. This includes dredging channels, scheduling overhauls of locks, and repairing and replacing machinery. Because of heavy rainfall and unstable soils, landslides in the hills adjoining Gaillard Cut have been an intermittent problem since the canal was built. Preventive and remedial measures frequently have been taken to keep the channel open, and a program to stabilize its banks was designed to draw away rainfall that might otherwise undercut its slopes. Two major slides have occurred since 1970, the first in 1974 and the second in 1986; in both cases one-way traffic had to be imposed for a time in the affected area.

Another serious problem threatening the canal has been the increased silting and sedimentation rate of the rivers and streams of the watershed and, ultimately, of the canal itself. This degradation has been caused by the slash-and-burn agricultural techniques practiced by local migratory farmers. The canal watershed was still completely forested in the early 1950s, but by the late 1970s it had been almost completely deforested, except for the area of the former Canal Zone. Measures to control soil erosion have been undertaken jointly by the governments of the United States and Panama.

Canal traffic. Traffic through the Panama Canal is a barometer of world trade, rising in times of world economic prosperity and declining in times of recession. From a low of 807 transits in 1916, traffic rose to a high point of 15,523 transits of all types in 1970. The cargo carried through the canal that year amounted to more than 132.5 million long tons. Although the total number of transits decreased thereafter, the canal carried more freight than ever because the average size of vessels had increased.

Principal trade routes

The principal trade routes served by the Panama Canal run between the following points: the east coast of the U.S. mainland and Hawaii and East Asia; the U.S. east coast and the west coast of South America; Europe and the west coast of North America; Europe and the west coast of South America; the east coast of North America and Oceania; the U.S. east and west coasts; and Europe and Australia.

Trade between the east coast of the United States and East Asia dominates international canal traffic. Among the principal commodity groups carried through the canal are crude oil and petroleum products, grains, and coal and coke. (N.J.P./W.D.B./B.L.G./W.W.)

Panama Canal Authority. The Panama Canal Authority was created by amendment of the Panamanian constitution. It is charged not only with administration, operation, conservation, maintenance, and modernization of the canal itself but also with maintenance and preservation of water resources in the entire Panama Canal watershed. The watershed is essential to the operation of the canal, and it also supplies water to cities at either end of the canal route.

The Authority is governed by a board of directors. The board consists of 11 members. The chairman, who has the rank of minister of state for canal affairs, is selected by the president of the republic. The legislative branch of the government designates one director, and the remaining nine members are appointed by the president with the concurrence of the Cabinet council. They must be ratified by an absolute majority of the legislative assembly.

Tolls. While under U.S. administration, tolls for use of the canal were set at rates calculated to cover costs of maintenance and operation, thereby making the canal self-financing. The charge for each transit was based upon the interior cargo or passenger-carrying capacity of a vessel. The rates established in 1914 remained virtually unchanged for 60 years. In 1973 the canal operated at a loss for the first time, and in 1974 the first of several rate increases went into effect.

In 1994 the Panama Canal Universal Measurement System (PC/UMS) went into effect. Traditionally, cargoes were carried below deck, and tolls were assessed on goods carried there. However, because of changes in marine de-

sign and the widespread use of containerized cargoes, a large portion of the burden is now carried on deck. These changes led to modifications in rules of admeasurement and to the assessment of tolls for on-deck container capacity. The Panama Canal Authority retained the toll rates in effect when the canal was transferred from U.S. control.

From the tolls collected, the Authority pays an annual fee to the Panamanian national treasury. Any surplus remaining after that and after the payment of canal operational and maintenance expenses also goes to the treasury.

History. *Construction.* As early as the 16th century, the Spanish recognized the advantages of a canal across the Central American isthmus. Eventually, two routes came to be considered, one through Panama and the other through Nicaragua. Impetus for selecting the route through Panama increased with the construction (by the United States) of the Panama Railroad in the mid-19th century, which closely followed the eventual route of the canal.

The first attempt to actually build a canal across Panama was undertaken in 1881 by the privately owned Compagnie Universelle du Canal Interocéanique (Universal Interocean Canal Company), which was financed by French capital and was under the leadership of Ferdinand de Lesseps, builder of the Suez Canal. The company collapsed in 1889, the victim of poor planning, terrible losses from disease among the workers, and bankruptcy. It was reorganized unsuccessfully in 1894 and had virtually ceased operation by 1898, after which its sole hope lay in holding together an enterprise that could be offered for sale.

The Spooner Act of 1902

Hope became reality with the passage of the Spooner Act of 1902 by the U.S. Congress, which authorized purchasing the assets of the French company and building a canal provided that a satisfactory treaty could be negotiated with Colombia (of which Panama was then an integral part). When treaty negotiations with Colombia broke down, Panama, with the implicit backing of the United States, declared its independence and was recognized by the United States in November 1903. The Hay–Bunau-Varilla Treaty was then negotiated between Panama and the United States. The treaty satisfied the Spooner Act and created the Panama Canal Zone; it was proclaimed in February 1904.

From the first Senate resolution in 1835 favouring Nicaragua until the dramatic change of location for the canal in the Spooner Act, the American public and government had consistently and overwhelmingly supported a canal through Nicaragua. That the canal was built in Panama is primarily attributable not to the intrinsic merits of the Panama route but to the ingenuity and zeal of two remarkable men who worked separately toward a common goal—the French engineer Phillipe-Jean Bunau-Varilla and the American lawyer William Nelson Cromwell. The political power that turned the U.S. government in favour of Panama was supplied by two people: President Theodore Roosevelt and Senator Mark Hanna. Roosevelt, once committed, supported the project enthusiastically and so is almost universally thought of as the "father" of the canal. Most of the actual work on the canal was done during the administration of William Howard Taft (1909–13), who had also been involved earlier in Roosevelt's administration.

When work on the canal began in the summer of 1904, the builders faced one crucial question, unsolved during the French era, of whether to build at sea level or at a high level with locks; and they had to deal with the great construction problem of how to control the Chagres River. The other major problem faced by the French—how to control tropical diseases like yellow fever and malaria—was largely solved during the canal's construction. In 1906 it was decided to build the locks according to a plan similar in all essential respects to one proposed in 1879 by Adolphe Godin de Lépinay de Brusly but rejected by Lesseps. The plan included the solution to the construction problem: the erection of an enormous earthen dam across the Chagres River, thereby creating what was then the largest artificial lake (Gatun Lake) in the world.

Work then began in earnest on what became the greatest engineering feat yet attempted. At times more than 40,000 people were employed on the project, which featured the use of massive steam shovels to dig Gaillard Cut (originally called Culebra Cut). The canal was opened to traffic on Aug. 15, 1914.

Opening of the canal

Capital improvements. The first major capital improvement on the canal was the construction of the Madden Dam and Power Project, which was completed in 1935. This not only stemmed and controlled the flow of water moving into Gatun Lake—to a rate of some 200 billion cubic feet (6 billion cubic metres) per year—but also created a large reservoir (Lake Madden) and increased the production of electric power in the region. The Boyd-Roosevelt Highway was then built across the isthmus, thereby adding a third means of transportation to the waterway and the railroad. In 1955 the Thatcher Ferry Bridge was built, which connected Panama City and Balboa to the west side of the canal. In 1970 Gaillard Cut was widened to 500 feet from its original 300 feet; and in 1974 the channel was deepened, permitting a constant allowable draft of 39.5 feet.

Many of the ships built since the 1970s—notably supertankers and large naval vessels—are too large to pass through the canal. Thus, there has been much study on the feasibility of either widening the existing canal and locks or building a larger sea-level canal at another location. Proponents of the sea-level canal contend that it would be less expensive to operate and—since it would have no locks—less vulnerable to military attack than the Panama Canal. Opponents to such a project cite its enormous expense and the possibility that it could create serious environmental problems by permitting the exchange between the two oceans of long-separated plant and animal species.

International status. The Hay–Bunau-Varilla Treaty was an irritant to Panamanian sensibilities from the moment it was signed. It had been written—and negotiated for the infant republic—by Bunau-Varilla, a French citizen who had not been in Panama for 18 years and who later openly admitted that he was willing for Panama to pay any price to ensure acceptance of the treaty by the U.S. Senate. The most onerous part of the treaty, in the Panamanian view, was the right granted to the United States to act in the entire 10-mile-wide, ocean-to-ocean Canal Zone as "if it were the sovereign." Thus, the Canal Zone became in effect a foreign colony that bisected Panama, despite Theodore Roosevelt's declaration in 1906 that no such result was intended. Some of the harsher effects of the treaty were ameliorated by subsequent treaties, principally those of 1936 and 1955, but the Panamanians continued to press for more drastic changes. After years of negotiation, agreement was reached between the two governments in 1977.

The Panama Canal Treaty

The Panama Canal Treaty of 1977 terminated all prior treaties between the United States and Panama concerning the canal; it also abolished the Canal Zone. The treaty recognized Panama as territorial sovereign in the former Canal Zone, but it gave the United States the right to continue managing, operating, and maintaining the canal and to use lands and waters necessary for those purposes during a transition period of 20 years. The treaty also provided for joint study of the feasibility of a sea-level canal and gave the United States the right to add a third lane of locks to the existing canal. The treaty went into effect on Oct. 1, 1979, and expired on Dec. 31, 1999.

The 1977 treaty was supplemented by a separate, but interrelated, Neutrality Treaty that also went into effect in 1979 but has no termination date. Under the Neutrality Treaty, the United States and Panama guarantee the permanent neutrality of the canal, with nondiscriminatory tolls and access for all nations; U.S. and Panamanian warships, however, are entitled to expeditious passage. After the termination of the Panama Canal Treaty in 1999, no nation other than Panama may operate the canal or maintain military installations within Panamanian territory. The United States, however, reserved the right to use military force, if necessary, to keep the canal open; this was, in part, the rationale behind the U.S. military intervention in Panama in 1989–90.

The U.S. Senate ratified the two treaties in 1978, after one of the lengthiest treaty debates in American history. The treaties were then implemented into U.S. domestic law by the Panama Canal Act of 1979. This act, among other things, established the Panama Canal Commission, which

replaced both the Panama Canal Company and the Canal Zone government. With the turnover of the canal in December 1999, the Panama Canal Authority assumed complete responsibility for the canal.

The international status of the canal also is affected by two older treaties. In the Hay-Pauncefote Treaty of 1901, the United Kingdom gave up its interest in an isthmian canal, and the United States agreed that there would be "entire equality" in the treatment of ships of all nations with respect to "conditions and charges of traffic." In the Thompson-Urrutia Treaty of 1914, the government-owned vessels of Colombia were exempted from paying tolls. (W.D.B./B.L.G./W.W.)

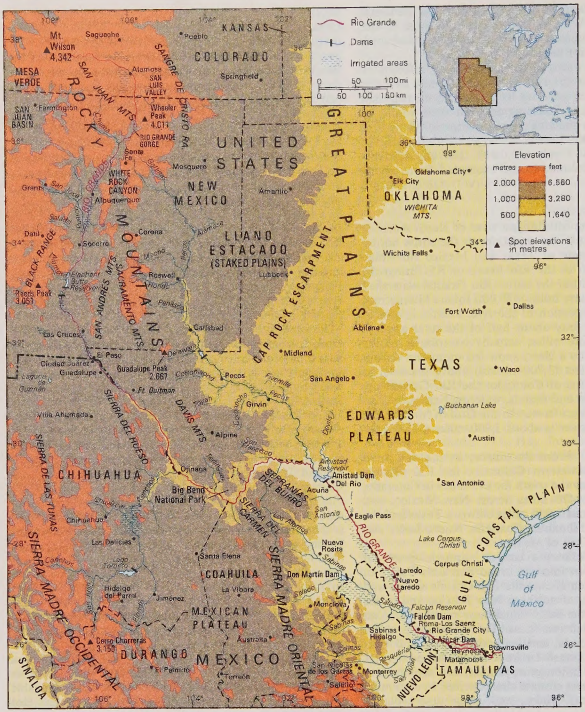
RIO GRANDE

The Rio Grande, the fifth longest river of North America and the 20th longest in the world, forms the entire border between the U.S. state of Texas and Mexico (in which country it is known as the Río Bravo or Río Bravo del Norte). The area within the entire Rio Grande watershed is some 336,000 square miles (870,000 square kilometres). Because a large proportion of the river's basin is arid or semiarid, however, only about half of the total area, or about 176,000 square miles, actually contributes to the river's flow. Rising as a clear, snow-fed mountain stream more than 12,000 feet (3,700 metres) above sea level in the Rocky Mountains of Colorado, the Rio Grande descends across steppes and deserts, watering rich agricultural regions as it flows on its way to the Gulf of Mexico; the total length of the river is about 1,900 miles (3,060 kilometres).

Physical features. From its sources in the San Juan Mountains of southwestern Colorado, the Rio Grande flows to the southeast and south for 175 miles in Colorado, southerly for about 470 miles across New Mexico, and southeasterly for about 1,240 miles between Texas and the Mexican states of Chihuahua, Coahuila, Nuevo León, and Tamaulipas to the Gulf of Mexico.

Diversity of landscapes and environments

Its early course follows a canyon through forests of spruce, fir, and aspen into the broad San Luis Valley in Colorado, after which it cuts the Rio Grande Gorge and White Rock Canyon of northern New Mexico and enters the open terrain of the Basin and Range and the Mexican Plateau physiographic provinces. There, declining elevation, decreasing latitude, and increasing aridity and temperature produce a transition from a cold steppe climate with a vegetation of piñon pine, juniper, and sagebrush to a hot steppe and desert climate characterized by mesquite, creosote bush, cactus, yucca, and other desert plants. Shortly before entering the Gulf Coastal Plain, the Rio Grande cuts three canyons between 1,500 and 1,700 feet in depth across the faulted area occupied by the "big bend," where the Texas side of the river comprises the Big Bend National Park. Along the remainder of its course the river wanders sluggishly across the Gulf Coastal Plain to end in a fertile delta where it joins the Gulf of Mexico.



The principal tributaries of the Rio Grande are the Pecos, Devils, Chama, and Puerco rivers in the United States and the Conchos, Salado, and San Juan in Mexico. The peak of flow may occur in any month from April to October. In the upper reaches of the Rio Grande it usually is in May or June because of melting snow and occasional thunderstorms, whereas the lower portion commonly experiences its highest water levels in June or September because of the occurrence of summer rainstorms. It has been estimated that the Rio Grande has an average annual yield of some 2.6 million acre-feet (3.2 billion cubic metres), of which about a third reached the gulf before the building of the Falcon Dam, upstream from Rio Grande City, in 1953; the river's average discharge rate is now about 3,000 cubic feet (85 cubic metres) per second.

The economy. Irrigation has been practiced in the Rio Grande basin since prehistoric times, notably among the ancestors of the Pueblo Indians of New Mexico. Increases in population and in the use of water made necessary the water treaties (1905–07 and 1944–45) between the United States and Mexico, as well as the Rio Grande Compact (1939) among Colorado, New Mexico, and Texas, concerning shared use of the waters of the upper Rio Grande subbasin (above the site of former Fort Quitman, Texas), and the Pecos River Compact (1948) between New Mexico and Texas, concerning the Pecos above Girvin, Texas. Essentially all of the average annual production of more than three million acre-feet in the upper Rio Grande (including the 60,000 acre-feet allotted to Mexico by treaty) is consumed within this subbasin. Not only below Fort Quitman but also in many stretches of the river from the New Mexico–Colorado border to below Brownsville, Texas, there has been no surface flow at various times. In some places the depth of the river has varied from nearly 60 feet to a bare trickle or nothing. Below Fort Quitman the Rio Grande is renewed by the Conchos and other Mexican rivers. The Conchos, which rises high in the Sierra Madre Occidental of Chihuahua, is the Rio Grande's most important tributary: it supplies more than one-sixth of the Rio Grande's total and, with the other Mexican rivers, produces about two-thirds of the available water. A number of large springs in the area between Hot

began in 1749 along the lower Rio Grande. With the Mexican explorations of Juan Bautista de Anza in the San Luis Valley of Colorado in 1779, the exploration of the entire Rio Grande basin was completed. Because most of the entire narratives of exploration and the resultant maps remained unpublished in the various archives of the Spanish government, American and European historians have tended to stress later non-Spanish explorations such as those by the Americans Zebulon M. Pike in 1807 and John C. Frémont in 1848–49 in the upper Rio Grande area. The careful scientific survey of the river, accompanied by good cartography, did not commence until the first of the international boundary commissions began its fieldwork in 1853, directed by a Mexican commissioner and surveyor and their equivalents representing the United States. From the 1850s to 1874—when the river was swept clean of all man-made structures by a great hurricane—small steamboats navigated the lower Rio Grande upstream to Rio Grande City and even to Roma when the river was high. Since then, accelerated erosion, silting, and sandbar formation have precluded navigation and have forced the United States and Mexico to spend much money and time in adjusting the international boundary to the numerous changes in the river channel. In October 1967 the United States formally returned to Mexico the El Chamizal area, between El Paso and Ciudad Juárez, which a shift of the river in 1864 had transferred to the left (north) bank.

Erosion, silting, and changes in course

(D.D.Br./R.H.Sc.)

ST. LAWRENCE RIVER AND SEAWAY

The St. Lawrence is the great hydrographic system of east-central North America. It connects the North River (source of the St. Louis River, in the U.S. state of Minnesota, which flows into Lake Superior) with Cabot Strait, leading into the Atlantic Ocean in the extreme east of Canada, crossing the interior of the North American continent for some 2,500 miles (4,000 kilometres). The St. Lawrence system is of vital geographic and economic importance to the United States and Canada. It can be divided into three broad sectors. Upstream lies the Great Lakes region, with narrow riverlike sections linking the broad expanses of the lakes themselves. In the centre, from the eastern outflow of Lake Ontario, near the Canadian town of Kingston, to the Île d'Orléans, just downstream from the city of Quebec, the system passes through a more normal watercourse. From the Île d'Orléans to the Cabot Strait, between Newfoundland and Nova Scotia, the system broadens out again, first as the St. Lawrence estuary, and then, passing Anticosti Island, as the oval-shaped marine region known as the Gulf of St. Lawrence. The discussion here is confined primarily to the latter two sectors; for a treatment of the first, see above *Great Lakes.*

The St. Lawrence is a mighty and unique hydrographic system. Bedded in an ancient geologic depression, it drains the heart of a continent. It is at once an international, an intra-Quebec, and a multiprovincial system. An axis of regional population, it is also a waterway linking Canada and the United States to western Europe and a large part of the rest of the world. The frontages of the several regions of the St. Lawrence River are not equally developed and do not maintain the same types of relationship with their hinterlands and with the outside world. Throughout its length, nevertheless, the St. Lawrence retains a great natural beauty, with landscapes beloved by all who live on its banks or make the long passage along its course.

The St. Lawrence Seaway, a massive navigational project undertaken jointly by Canada and the United States and completed in 1959, opened North America's industrial and agricultural heartlands to deep-draft ocean vessels. It forged the final link in a waterway some 2,340 miles long from Duluth, Minn. (at the westernmost point of Lake Superior), to the Atlantic by clearing a throughway in a 186-mile stretch of the St. Lawrence River between Montreal and Lake Ontario. Although the official seaway consists of only this stretch and the Welland Canal (connecting Lakes Ontario and Erie), the entire Great Lakes–St. Lawrence system, with 9,500 miles of navigable waterways, has come to be known as the St. Lawrence Seaway.

Physical features. *Geology.* The St. Lawrence River occupies a geologically old depression that involves three great geologic regions of North America: the Canadian Shield, the Appalachian Mountains, and the intervening sedimentary rock platform. This ancient setting has been broken up by movements of the Earth's crust along several zones of structural weakness and also has been worn down by a number of separate cycles of erosion. Toward the end of the Quaternary Period, the glaciers that had occupied the depression since the Pleistocene Ice Age were replaced by the Champlain Sea, which flooded the depression from about 13,000 to 9,500 years ago. A subsequent slight uplifting of the continent was enough to expel this arm of the ocean, and about 6,000 years ago a residual riverlike watercourse—the St. Lawrence—was established.

Physiography. The regional division of the St. Lawrence raises difficult problems, and, despite considerable scholarly work on the subject, the debate remains open. The following division has been based on such overall criteria as longitudinal gradient of the riverbed, tidal characteristics, salinity, the width of the river bottom, human geography, and animal life. Threshold zones, a dozen miles or so in length, mark the transition from one region to the next.

Regional divisions

The St. Lawrence of the International Rapids section forms a clearly defined region extending from Kingston to above Montreal, where the presence of sudden breaks of gradient in the riverbed, the necessity of a navigable route between Montreal and southern Ontario, and the regional needs for power have led to the creation of hydroelectric stations, canals, and a major part of the St. Lawrence Seaway. The flow volume of this section of the St. Lawrence, as measured at Cornwall, Ont., is about 218,000 cubic feet per second (6,100 cubic metres per second).

The region of the Quebec lowlands is made up of a short section with a calm and nonreversible flow. This portion of the river course is characterized by the inflow of the system's principal tributary, the Ottawa (Outaouais) River, by the presence of numerous islands, by the development of the greater Montreal conurbation, and also by a certain amount of water pollution. The development of the port of Montreal has depended on, among other factors, the deepening of the river channel—downstream through dredging and upstream through canalization—by means of engineering projects that were begun in the 18th century. During the winter months, a thick crust of ice connects the two banks of the river, and icebreakers maintain an open channel for shipping. In the past, the possibility of ice jams was great, with notable ice catastrophes occurring in 1642, 1838, and 1896. However, the port of Montreal has been kept open year-round since the mid-1960s.

The upper estuary extends from Lake Saint-Pierre to below the Île d'Orléans at Quebec. There, the current of a freshwater tide begins to be reversible. During the winter months, the ice covering recalls the conditions at Montreal, but it also anticipates those of the middle estuary (see below), where a distinction is necessary between banked (or reef) ice, which is solid and fissured, and conglomerate ice, which moves past offshore. High bluffs rising from the river littoral, which had great strategic value, led to the foundation of the city of Quebec in this region, in 1608. The immediately adjacent area became the historical cradle of the distinctive French-speaking population of Canada.

In the middle estuary, from the eastern end of the Île d'Orléans to the upstream side of the confluence with another major tributary, the Saguenay River, the St. Lawrence broadens but remains relatively shallow. Progressively, the water ceases to be fresh and becomes brackish, and with an east wind it may be possible, for the first time, to catch a whiff of seaweed. Tides, thrust into a narrowing channel, attain maximum height in this section. Breakaway reef ice from this area constitutes one of the major sources of ice in the downstream parts of the estuary.

The lower estuary, one of the greatest topographic alterations in the entire course of the St. Lawrence, is found near the Saguenay confluence, at right angles to a submarine furrow. In this region, the river bottom exhibits a significant break of gradient: within 10 miles of the confluence, the depth of the water increases from about 80 feet (25 metres) to 1,145 feet. It is by way of this drowned

valley that the cold, marine waters from downstream enter the region. In spite of the width of the watercourse, a number of ferries connect the two banks. In contrast to the thinly settled northern bank, behind which lie the inhospitable, rugged landscapes of the Canadian Shield, the southern frontage of the lower estuary is open largely toward its hinterland; and major roads, including the Trans-Canada Highway, lead away from the river toward New Brunswick and other Canadian maritime provinces.

The limits of the maritime estuary are, upstream, the promontory of the Pointe-des-Monts and, leading to the Gulf of St. Lawrence, Anticosti Island. (The latter, by reason of its size and its own circular currents, is an entity in its own right and cannot be considered as an element of the estuary.) Below the Pointe-des-Monts, the submarine valley mentioned above doubles in width, to more than 50 miles. A major arm of the counterclockwise current stemming from the Gulf of St. Lawrence, after entering the northern portion of this region, turns back to the east. The salinity found there discourages ice formation, and, on the northern shore, the port of Sept-Îles—although situated much farther north than Montreal—is in fact easier to keep open to navigation in winter. The north frontage, with a hinterland rich in iron ore and hydroelectric-generating potential and running at right angles to this portion of the estuary, offers great economic possibilities.

Climate and hydrology. In terms of both climate and hydrology, the St. Lawrence system as a whole covers several zones. First, in the movement downstream from the upper part of the system, some of the associated boreal character is lost; in its path from the northern streams tributary to Lake Superior down to Lake Erie, the system passes from a subarctic to a more temperate southern zone. This pattern is reversed in the eastern half of the system; thus, from the western end of Lake Erie to the northern coast of the St. Lawrence estuary, the climate again reverts progressively to a subarctic level. This basic division brings out the regional contrasts in the hydrology of the central section of the river. Lake Erie, for example, loses much water through summer evaporation, whereas the affluents feeding the estuary of the St. Lawrence are heavily influenced by snowfall characteristics. At Montreal a good portion of the river flow comes from the Great Lakes—hence its remarkable regularity. At the mouth of the estuary, on the other hand, the volume of ocean water coming in at high tide is considerably greater than the volume of river water flowing down at low tide; and there the St. Lawrence is profoundly marine, rather than lacustrine, in character. These basic regional hydrographic traits are also accentuated by a large seasonal variation in water temperature.

Plant and animal life. The biological world of the St. Lawrence region is relatively unchanged, although it has been influenced by humans for centuries. Some clear regional distinctions have been made between the upper and lower sections of the system and also between the depths and the surface of the water and between the banks and the centre of the river course.

Animal life comprises fish (including sturgeon, smelt, and herring), mammals (including the beluga [white whale] in the gulf), and mollusks (including the soft-shell clam [*Mya arenaria*]). A noted phenomenon, which is characteristic of all regions of the river, is the massive migration of ducks, bustards, and geese, which make use of the sandy shores or river reefs as seasonal food sources. The vegetation associated with the river undoubtedly reflects

Migration of waterfowl

the great shrubby zones that extend from Lake Erie to the northeast of the Gulf of St. Lawrence, made up of deciduous forest, mixed forest, coniferous forest, and open taiga. In addition, however, it exhibits such specifically river-linked characteristics as the sandbank grasses of the freshwater section and the halophytic (salt-tolerant) plants found from the middle estuary onward. (L.-E.H./P.C.)

The economy. The seaway has had a major economic impact on the United States and Canada. A principal reason for its construction was the discovery, in Quebec and Labrador, of vast deposits of iron ore needed by steel mills in the United States. Canada, an importer of American iron ore before the seaway opened, exported ore, the second largest commodity, to the United States thereafter. The largest commodity moved is grain, from farms on Canada's prairies and in the American Midwest, shipped through the seaway at considerable savings. Major users of the seaway are vessels known as lakers, which are designed to the maximum limits of the seaway locks in order to facilitate two-way trade. A laker can pick up grain in the western Great Lakes, destined for world markets, and return with Canadian iron ore, loaded in the lower St. Lawrence. The third-largest seaway commodity is coal, moved chiefly from U.S. mines via the Welland Canal to Canadian steel mills and power plants. Another commodity that is significant—because of its value rather than the amount moved—is imported iron and steel.

Bulk commodities make up about 90 percent of annual cargo tonnage, but vessels of many nations also use the seaway to deliver or pick up general cargoes.

The Great Lakes–St. Lawrence River system has become one of the world's most heavily used international trade routes. Some 35 to 40 million tons of cargo move annually through the Montreal–Lake Ontario section. Although the system often is characterized as a vast inland sea comparable to the Mediterranean, its use is restricted by limited access and by a severe winter climate that shortens the shipping season to about eight and a half months. In 1959 the seaway allowed passage of about 80 percent of the world's ships, a figure that has since decreased. The size of a vessel that uses it is limited to a draft of 26 feet, a length of 730 feet, and a beam of 76 feet. These dimensions have become relatively small by the standards of world cargo-ship construction.

History. *Early navigation.* Efforts to sail into the heart of the continent date from 1535, when the French explorer Jacques Cartier, seeking a northwest passage to the Orient, found his path blocked by the Lachine Rapids, southwest of what is now Montreal. The digging of shallow St. Lawrence canals for bateaux and Durham boats (long, tapering boats with flat bottoms and auxiliary sails) in the early 1780s; the construction of the Erie Canal from Buffalo, N.Y., to the Hudson River from 1817 to 1825; the opening of the first canal around Niagara Falls in 1829; and the completion of the first lock, at Sault Sainte Marie, Mich., in 1855, all fostered the dream of a navigable waterway into the continental interior. The United States, however, proved a reluctant partner in a venture, pursued by Canada from the beginning of the 20th century onward, to open the Great Lakes to sea traffic. The U.S. Senate rejected the Seaway Treaty of 1932 and allowed a second treaty, signed in 1941, to remain unratified for eight years. Faced with the likelihood that Canada would proceed alone, the U.S. Congress finally approved participation in the project in May 1954.

Interest in a navigable waterway

Construction of the seaway. The seaway project was one of the largest civil engineering feats ever undertaken. Construction began in the summer of 1954 and took nearly five years to complete. Over its course the project employed some 22,000 workers and utilized enough cement to build a highway 1,000 miles long and enough steel to girdle the Earth. About 6,500 people living in riverside communities had to be relocated, bridges were raised, and tunnels, dikes, and roads were constructed. Locks had to be constructed in the seaway and modernized in the Welland Canal to raise and lower large ships a total of 557 feet, making it the world's greatest waterway lifting operation. It takes about seven minutes for water to pour in or out of a seaway lock; the average locking takes about half an hour. To overcome the navigational hazard of the swift-flowing, 226-foot fall of the St. Lawrence River between Lake Ontario and Montreal and to develop its hydroelectric power potential required an investment of more than $1 billion.

For the navigation portion of the project, the Canadian government built two canals and five locks around the Cedar, Cascades, and Lachine rapids and three seaway dams; and the U.S. government built two locks, a 10-mile canal around the International Rapids, and two seaway dams and cleared shoals from the Thousand Islands section of the river. This series of operations created a waterway 27 feet deep, replacing six canals and 22 locks that had been limited to a depth of 14 feet.

In order to make the seaway operational, a number of other projects had to be undertaken as well. The U.S. Army Corps of Engineers deepened the Straits of Mackinac, between Lakes Michigan and Huron; the St. Marys River, between Lakes Superior and Huron; the Detroit River, Lake St. Clair, and the St. Clair River, between Lakes Erie and Huron; and many Great Lakes harbours. In addition, between 1913 and 1932 Canada had built seven lift locks of seaway dimensions in the Welland

Commodity-carrying laker in the St. Lawrence Seaway at Montreal.

Canal, which overcame the 326-foot plunge of the Niagara River and Falls, between Lakes Erie and Ontario. The seaway became operational in April 1959.

To tap the considerable energy of the river's tumbling waters, the seaway project included the construction in the International Rapids section of the Iroquois Control Dam near Iroquois, Ont., and the Moses-Saunders Power Dam near Cornwall. The project created the 30-mile-long Lake St. Lawrence. Generation of hydroelectric power began in July 1958. The generating capacity is shared equally by Ontario and New York state.

Financing the seaway. As the price of approving seaway legislation, the U.S. Congress required that the seaway project be self-liquidating; the Canadian government also adopted this as a national policy. Tolls were to be assessed at a rate sufficient to pay back the cost of the project in 50 years, to pay annual interest on the funds borrowed to build it, and to pay all operating costs. The two nations jointly established a system of tolls, with each nation collecting tolls in its own currency. This resulted in a split of about three-fourths of the revenue to Canada and one-fourth to the United States.

Tolls

Revenues from tolls in the early years of the seaway's operation consistently fell far short of annual operating costs and interest payments, putting the seaway deeper in debt. Neither the Saint Lawrence Seaway Authority, operating Canada's installations, nor the Saint Lawrence Seaway Development Corporation, running U.S. operations, was able to increase tolls to keep pace with higher operational costs until the late 1970s, when a new Joint Seaway Tariff of Tolls agreement was accepted by both countries. Tolls were again increased in the early 1980s. Annual shipping tonnage had reached its peak in 1977, however, after which a gradual decline ensued. Thus, despite the increase in tolls, revenues generally continued to fall short of expenses.

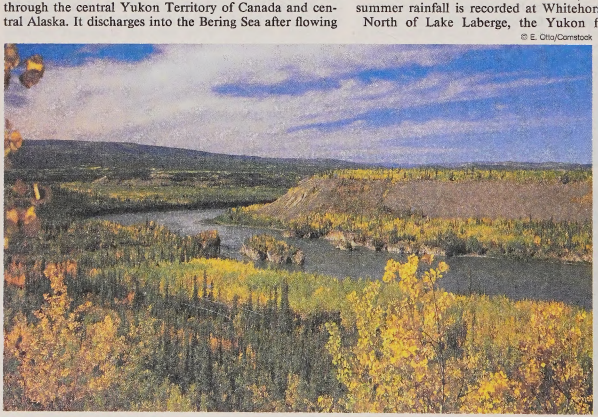
In the mid-1980s the U.S. government assumed the financial obligations of the American seaway corporation. The tolls that were collected (the American share by this time had been reduced to 15 percent of the total) were returned as rebates to the seaway's users, and the federal government provided direct subsidies to the American corporation. The Canadian authority, meanwhile, continued to operate as before and to charge tolls. The incentives to shippers offered by the rebates, however, helped stabilize seaway traffic by the end of the decade. (R.W.B./P.C.)

YUKON RIVER

One of the major North American rivers, the Yukon flows through the central Yukon Territory of Canada and central Alaska. It discharges into the Bering Sea after flowing northwestward and then generally southwestward through a low plateau that slopes down across Alaska. Its numerous headwater tributaries drain an area of about 328,000 square miles (850,000 square kilometres) out of a surrounding semicircle of high mountains. This huge area—larger than Turkey—was occupied solely by North American Indians until the mid-19th century, when peoples of European descent (including explorers from the eastward-expanding Russian Empire) began to move into the region, first as fur traders and then in search of mineral wealth. The discovery of gold on the Klondike River, a Yukon tributary, in 1896 precipitated an influx of settlement that created an international mythology of romantic frontier existence associated with the name Yukon.

The Yukon River measures 1,980 miles (3,190 kilometres) from the headwaters of the McNeil River (a tributary of the Nisutlin River). The main east- and north-bank tributaries are the Teslin, Big Salmon, Pelly, Stewart, Klondike, Porcupine, and Koyukuk; the west- and south-bank tributaries are the Takhini, White, and Tanana.

For map coverage of the Yukon River, see above *Alaskan mountains.*



Physical features. *Physiography and hydrology.* The McNeil headwaters rise in the Pelly Mountains of south-central Yukon Territory and flow south into Teslin Lake and thence into the Teslin River. The main headwaters of the Yukon River, however, flow from Atlin Lake and Tagish Lake in the vicinity of the border between British Columbia and Yukon Territory. About 50 miles downstream the Yukon once rushed through the rocky walls of narrow Miles Canyon and tumbled over rock ledges at Whitehorse Rapids. These obstacles to river travel during the gold rush era necessitated the construction of the short railroad from Skagway, Alaska, to Whitehorse in Yukon Territory, the latter becoming the southern terminal of water transport northward. The river has since been dammed south of Whitehorse for hydroelectric power; the rapids are buried under the reservoir lake, and deep water fills the former canyon.

The upper course

River ice begins to break up at Whitehorse, the territorial capital, in early May and loosens northward on Lake Laberge a few days later. The snow-fed tributaries from the Mackenzie Mountains to the east reach their flood peak in June, but glacier-fed streams such as the White, draining the north slopes of the St. Elias Mountains, do not have their greatest runoff until July. Once these peak runoff flows have passed, the Yukon River becomes a shallow, braided stream, as summer precipitation in the Yukon basin is low—about 6 inches (150 millimetres) of summer rainfall is recorded at Whitehorse and Dawson.

North of Lake Laberge, the Yukon flows through a

Five Finger Rapids on the upper Yukon River, Yukon Territory.

broad, generally flat-bottomed valley; riverbanks are not high, and the river meanders lazily across the valley floor, with numerous sandbars and small islands dotting the channel. About 25 miles north of the village of Carmacks, four small, rocky islands split the river into the Five Finger Rapids area, and the current flows swiftly past these islands. At the village of Selkirk, the junction of the Pelly River swells the Yukon's volume considerably, for the Pelly drains about 19,700 square miles of the generally uninhabited western slopes of the Mackenzie Mountains. North of Selkirk, the Yukon is a clear and gentle river, with numerous low islands breaking the channel. The White River, with a drainage area of about 19,500 square miles, adds silt from the glaciers and mountains to the southwest. The Stewart River, having about the same drainage area as the White River, flows out of the mining area of Mayo-Keno City to the east. At Dawson the Yukon has an average flow of 74,000 cubic feet (2,095 cubic metres) per second, but there is a wide difference between the high-water flows of June and the low water beneath the ice in March. There are no hydroelectric power developments on the Yukon, except for a small plant at Whitehorse. The river is thought to have considerable generating potential; but, because there has been no demand for power, no accurate evaluations have been made.

The Klondike is a small, east-bank tributary that joins the Yukon at the historic territorial town of Dawson. The Klondike valley floor is covered with sinuous, wormlike ridges of gravel deposited behind the gold dredges that have worked their way through the valley gravels over a period of nearly a century.

Downstream from Dawson the river valley narrows, and the low plateau is broken by mountains that rise to elevations of more than 4,000 feet, about 15 miles north of the Yukon River. The river itself is about 1,000 feet above sea level before it crosses the border into Alaska. The next large tributary, the Porcupine River, joins the Yukon at Fort Yukon, Alaska; the Porcupine drains the northern Yukon Territory and the southeastern slope of the high and rugged Brooks Range in Alaska, a land occupied by a small population of Indians. The Yukon then flows generally westward for about 150 miles across a broad, flat valley; the many channels of the braided river thread their way through numerous islands and sandbars. At the western end of the "flats" is a narrow gorge, where the river rushes through a low mountain barrier known as the ramparts.

The lower course

At the junction of the Tanana River, the main southern tributary in Alaska, the Yukon is less than 300 feet above sea level. Upstream on the Tanana lies Fairbanks, the largest city in the Yukon River basin. The snow- and glacier-fed waters of the Tanana drain the north slopes of the high Alaska Range, but, after the peak runoff in July, the Tanana becomes a shallow stream by late summer. West of the Yukon's confluence with the Tanana, the Yukon valley broadens south of the river; but within 5 miles of its northern banks rise the low Kokrines Hills, with peaks over 3,000 feet in altitude. About 175 miles downstream from the Tanana confluence, the last major tributary, the Koyukuk, drains southward from the south-central slopes of the Brooks Range. The Yukon there is only 117 feet above sea level and only about 100 miles due east of Norton Sound, but the river is forced to detour several hundred miles to the south and west around mountainous terrain.

As the Yukon nears the Bering Sea, it bends sharply northward to empty into Norton Sound. The river delta is about 40 miles across, swampy, and lake-covered. Many of the distributary channels are shallow, but the northeastern one, Apoon Pass, was once used by riverboats.

Climate. The valleys of the Yukon River basin, where nearly all of the population lives, have a subarctic climate with relatively warm, short summers; but the treeless upper mountain slopes, where there are no weather stations, are classified as having an Arctic climate. Bitterly cold air masses from Siberia or the Arctic Ocean cross Alaska and Yukon Territory throughout the long winter, but occasional warm air masses from the Pacific Ocean can penetrate over the high barrier of the St. Elias Mountains and bring warmer winter temperatures to the Whitehorse area. January mean temperatures are about −24° F (−31° C) at Dawson and about −6° F (−21° C) at Whitehorse. In 1947 the lowest temperature officially recorded in North America, −81° F (−63° C), was reported at Snag along the Alaska Highway in southwestern Yukon.

Average summer temperatures in the valleys of this high-latitude region, with its long hours of summer daylight, are moderately warm, with July mean temperatures of about 60° F (16° C) at Dawson and slightly lower at Whitehorse. Annual precipitation is low, as it is in most of northwestern Canada and central Alaska, with an average of about 10 inches (260 millimetres) recorded at Whitehorse and 12 inches at Dawson. Almost 50 percent of the precipitation falls as rain during the four summer months.

Plant and animal life. Coniferous forests grow to low height and low densities across the valley floors and lower mountain slopes of the Yukon River basin. The upper tree line is at an elevation of about 3,500 to 4,500 feet, depending on local exposure and drainage; thus, about two-thirds of mountainous Yukon Territory is treeless. The largest stands of potentially commercial forest are along the Alaska Highway in the Liard River valley in the southeastern Yukon, but this area is far from markets. White spruce is dominant on the valley floors, and black spruce grows in the poorly drained areas. In addition, Alpine fir and lodgepole pine are found in the lower areas along the Alaska Highway across the southern Yukon.

Mammals

A varied animal life inhabits the forested valleys. The larger mammals include black, brown, and grizzly bears; caribou, deer, and moose; and mountain goats and sheep at higher elevations. Timber wolves are common. Game birds such as grouse and ptarmigan are found, and waterfowl include many species of geese, swans, and ducks. The usual furbearers trapped by the Indian population include muskrat, mink, marten, lynx, weasel, fox, fisher, and squirrel. In the river itself are found species of such fish as Arctic grayling, burbot, pike, salmon, and whitefish.

The people and economy. The Yukon River basin has remained sparsely populated in the century and a half since it was first settled by Europeans. The lure of mineral wealth has been the main attraction of the region, and mining has maintained several of the settlements. Gold brought people to Fairbanks and Dawson; when the gold was depleted, Fairbanks continued to grow as it took on administrative and transportation functions for east-central Alaska, but the population of Dawson declined to only a tiny fraction of its size in the heyday of the gold rush. In the 1950s the Yukon territorial capital was moved from Dawson to the more accessible city of Whitehorse, on the Alaska Highway. Whitehorse then developed transportation and service functions for the other small settlements in the southern Yukon region and became the largest city in the territory.

Mines are marginal economic operations in the Yukon River basin because the area is far from world markets and has only a few land-transport routes. Lead, zinc, and silver have been produced at Keno City, near Mayo, since the 1920s, but the high-grade ore has to be transported southward to Trail, B.C., near the U.S.-Canadian border, for smelting. Since the early 1970s, copper and base metals have been mined at Faro, on the Pelly River west of the Mackenzie Mountains, and ore concentrates have been transported by truck to Whitehorse. Some gold is still extracted intermittently from alluvial deposits in several Yukon tributaries, and deposits of tungsten, iron, and coal are known.

Other economic activities are of minor importance in the Yukon basin. Fur trapping has been the traditional livelihood for the region's Indians, but low monetary returns plus the attraction of better pay from wage labour in the towns have taken many Indians away from their former migratory lives. Agriculture is a minor activity. Although vegetables, pasturage, and coarse grains can be grown during the long days of the short summer, only a small number of farms are operated; most of the food consumed in Whitehorse, for example, is shipped in from southern Canadian farms. Perhaps the main resource of the Yukon basin is its scenery, isolation, and sparse population, all of

which are attractive to tourists seeking to escape the more crowded and less scenically endowed areas of the continent. The many vistas of the winding river, its forested slopes supporting game and wildlife, and the game fish in the tributary lakes are all part of an attractive natural environment that has become more difficult to find in southern regions.

Era of the fur traders and the initial discoveries

History. The delta mouth of the Yukon River was known to the Russians when they occupied nearby St. Michael Island in 1831, but the headwaters in British North America remained unknown for another decade. By 1838 Russian fur traders had explored the river as far inland as Nulato (Alaska), where they established a post near the junction of Koyukuk River. By 1846 the Russians had mapped almost 600 miles of the lower river. The trader Robert Campbell, of the Hudson's Bay Company, explored Pelly River, one of the Yukon headwaters, in 1840. In 1848 he established a trading post at Fort Selkirk, at the junction of the Pelly and Yukon rivers, in order to trade with the local Indians. In 1851 Campbell explored the Yukon downstream to the junction of the Porcupine River, where Fort Yukon had been built in 1847. When the trading post at Fort Selkirk was burned by hostile Indians in 1852, however, Europeans withdrew from the upper Yukon basin for two decades.

Water transportation gradually extended upstream from the mouth of the Bering Sea. Shallow-draft steamers had been operating on the river in Alaska after 1866, and the first riverboat reached Yukon Territory a few years later. The Yukon River became known to the world following the rich gold strikes in 1896 on the Klondike River in Canada. In the summer of 1898 at least 20 vessels rounded the extremity of southwestern Alaska and navigated the lower Yukon River to reach the booming community of Dawson City (the name later was shortened to Dawson). Other gold seekers took a shorter route by penetrating north through the Coast Mountains from Skagway, Alaska; they made crude boats or rafts on Bennett Lake and floated downstream to the rapids near Whitehorse. From there riverboats took passengers and freight downstream to Dawson. When gold-mining activity declined during the years following World War I, the use of water transport on the Yukon River also decreased. The riverboats ceased to operate on the Canadian part of the river in the 1950s, being replaced by road and air transport to Dawson and other small towns. (J.L.Ro.)

BIBLIOGRAPHY

General works. FRED W. HEADON, *Continent of Contrast: A Study of North America* (1985), is a traditional geography text, treating the continent as divided into eight main regions and discussing the physical and human environment for each region. J.H. PATERSON, *North America: A Geography of the United States and Canada,* 8th ed. (1989), is similar, with more of the focus on human aspects. AMERICAN GEOGRAPHICAL SOCIETY OF NEW YORK, *Readings in the Geography of North America: A Selection of Articles from the Geographical Review* (1952), presents classic scholarly papers on a wide range of topics. J. WREFORD WATSON, *North America,* rev. ed. (1967); and TOM L. MCKNIGHT, *Regional Geography of the United States and Canada* (1992), are literate and comprehensive works. JOEL GARREAU, *The Nine Nations of North America* (1981), a highly readable journalistic work, explores the feasibility of rearranging the continent into regional political units.

NATIONAL GEOGRAPHIC SOCIETY (U.S.), *Atlas of North America* (1985), contains a variety of highly detailed maps and satellite-imagery photographs. Atlases of large portions of North America include GEOLOGICAL SURVEY (U.S.), *The National Atlas of the United States* (1970), still useful despite some gaps in coverage and the aging of much data; CANADA, ENERGY, MINES, AND RESOURCES CANADA, *The National Atlas of Canada,* 5th ed. (1985–); JAMES B. PICK, EDGAR W. BUTLER, and ELIZABETH L. LANZER, *Atlas of Mexico* (1989); and STANLEY A. ARBINGAST *et al., Atlas of Central America* (1979). (R.J.Sc./W.Ze.)

Geologic history. The Geological Society of America and the Geological Survey of Canada have undertaken the publication of a monumental, multivolume series, *The Geology of North America* (1986–), covering also the surrounding oceans. The series presents an up-to-date synthesis of research in the field, and, when completed, will provide the most comprehensive coverage of the subject. ALBERT W. BALLY and ALLISON R. PALMER (eds.), *The Geology of North America* (1989), is an overview volume in the series. Other useful texts include G. CHOUBERT and A. FAURE-MURET (eds.), *Geological World Atlas* (1976–), with a section illustrating North America; PHILIP B. KING, *The Tectonics of North America* (1969), written to accompany a map, and *The Evolution of North America,* rev. ed. (1977), both masterpieces whose scholarship predates the concept of plate tectonics; and ARTHUR ESCHER and W. STUART WATT (eds.), *Geology of Greenland* (1976), a comprehensive and well-illustrated study. (P.F.H.)

The land. CHARLES B. HUNT, *Natural Regions of the United States and Canada* (1974), offers comprehensive, if a bit dated, reference-quality coverage of soils, geology, climate, vegetation, and resources. WALLACE W. ATWOOD, *The Physiographic Provinces of North America* (1940), presents a classic geographic approach to the geologic and geomorphic regions and to the landforms and their formation. Studies with a more specific focus include WILLIAM WYCKOFF and LARRY M. DILSAVER (eds.), *The Mountainous West: Explorations in Historical Geography* (1995); RALPH C. HEATH, *Ground-Water Regions of the United States* (1984), an excellent brief summary; HOWARD B. SPRAGUE (ed.), *Grasslands of the United States: Their Economic and Ecologic Importance* (1974), a good review provided in a collection of symposium papers; UNITED STATES, SOIL CONSERVATION SERVICE, *Soil Taxonomy: A Basic System of Soil Classification for Making and Interpreting Soil Surveys* (1975, reprinted 1988), a definitive guide, according to the United States Department of Agriculture; and CANADIAN AGRICULTURAL SERVICES COORDINATING COMMITTEE, EXPERT COMMITTEE ON SOIL SURVEY, *The Canadian System of Soil Classification,* 2nd ed. (1987), a similar Canadian guide. Works on the climate include W.G. KENDREW and B.W. CURRIE, *The Climate of Central Canada: Manitoba, Saskatchewan, Alberta, and the Districts of Mackenzie and Keewatin* (1955); W.G. KENDREW and D. KERR, *The Climate of British Columbia and the Yukon Territory* (1955); STEPHEN S. VISHER, *Climatic Atlas of the United States* (1954, reprinted 1966); and UNITED STATES, ENVIRONMENTAL DATA SERVICE, *Climatic Atlas of the United States* (1968, reprinted 1983).

The flora and fauna are described in RICHARD J. PRESTON, JR., *North American Trees: Exclusive of Mexico and Tropical Florida,* 4th ed. (1989), a good reference text on habitats, taxonomy, and distribution of major forest trees and shrubs; H.A. FOWELLS (compiler and ed.), *Silvics of Forest Trees of the United States* (1965, reprinted 1975), a classic work on the ecology, distribution, and study of the environmental requirements and processes of tree growth of most, if not all, of the tree species found in the region; JOHN L. VANKAT, *The Natural Vegetation of North America* (1979), a survey of the geography and ecology of major plant communities; E. RAYMOND HALL, *The Mammals of North America,* 2nd ed., 2 vol. (1981), a comprehensive study; RALPH S. PALMER (ed.), *Handbook of North American Birds* (1962–88), the most thorough treatment of birdlife, although not all genera are included; and HOWARD P. BROKAW (ed.), *Wildlife and America: Contributions to an Understanding of American Wildlife and Its Conservation* (1978). GARY A. KLEE, *Conservation of Natural Resources* (1991), focuses mostly on the United States, but the concepts discussed are applicable to the whole of the continent. (R.J.Sc.)

The people. ROBERT D. MITCHELL and PAUL A. GROVES (eds.), *North America: The Historical Geography of a Changing Continent* (1987), collects 18 chronologically arranged essays treating the development of the United States and Canada over time and space from the days of early European exploration to the late 20th century. D.W. MEINIG, *The Shaping of America: A Geographical Perspective on 500 Years of History* (1986–), explores geographic influences on continental history in eloquent prose and with imaginative graphics. The demographic, economic, and political history of the continent is well illustrated in CHARLES O. PAULLIN and JOHN K. WRIGHT (eds.), *Atlas of the Historical Geography of the United States* (1932, reprinted 1975), a monument of historical and geographic scholarship; NATIONAL GEOGRAPHIC SOCIETY (U.S.), *Historical Atlas of the United States* (1988), a visually appealing volume with informative bibliographic references; EDWIN SCOTT GAUSTAD, *Historical Atlas of Religion in America,* rev. ed. (1976), an expert analysis of the principal U.S. denominations and some general aspects of religion in the United States; and JAMES PAUL ALLEN and EUGENE JAMES TURNER, *We the People: An Atlas of America's Ethnic Diversity* (1988), a superlative work which offers scores of full-colour county- and state-level maps, along with text, covering a multitude of ethnic groups. Other works of interest are STEPHAN THERNSTROM (ed.), *Harvard Encyclopedia of American Ethnic Groups* (1980), which presents detailed reference essays by authoritative scholars; WILLIAM C. STURTEVANT *et al.* (eds.), *Handbook of North American Indians* (1978–), encyclopaedic coverage using both the topical and "tribal" approach; and JOSEPH J. SPENGLER, *Population and America's Future* (1975), a thoughtful evaluation of U.S. demographic patterns and trends and their implications for the national welfare.

Broad looks at the culture of the continent include WILBUR ZELINSKY, *The Cultural Geography of the United States,* rev. ed. (1992), exploring the historical and spatial development of the American cultural system and its special characteristics, while also offering bibliographic guidance to the literature; MICHAEL A. GOLDBERG and JOHN MERCER, *The Myth of the North American City* (1986), a superb comparative study that describes and attempts to explain the obvious sharp differences in the ways Canadian and U.S. cities look and function; JOEL GARREAU, *Edge City: Life on the New Frontier* (1991), a penetrating look at the changing U.S. metropolis, with the unprecedented mushrooming of virtually autonomous cities along the rims of metropolitan areas; and JOHN HERBERS, *The New Heartland: America's Flight Beyond the Suburbs and How It Is Changing Our Future* (1986), a thoughtful treatment of the exurbanization of the U.S. population and its implications. JOHN R. STILGOE, *Common Landscape of America, 1580–1845* (1982), is an ambitious attempt to describe and explain the full range of the built-up landscape in its historical and regional dimensions; while MICHAEL P. CONZEN, *The Making of the American Landscape* (1990), collects 18 original essays on the creation of North American built-up landscapes, past and present. Specific features of culture are explored in CRAIG M. CARVER, *American Regional Dialects: A Word Geography* (1987), which interprets the findings of a massive lexicographic project and discusses language development over the vast territory; CHARLES REAGAN WILSON and WILLIAM FERRIS (eds.), *Encyclopedia of Southern Culture* (1989), a monumental compendium of engrossing information; and ALAN GOWANS, *Images of American Living: Four Centuries of Architecture and Furniture as Cultural Expression* (1964, reissued 1976), a profound treatment of the meaning of these aspects of material culture.

The economy. BRIAN J.L. BERRY, EDGAR C. CONKLING, and D. MICHAEL RAY, *The Geography of Economic Systems* (1976), is a general theoretical text, with detailed case studies including a survey of North America's industrial heartland. Another broad study is ANN MARKUSEN, *Regions: The Economics and Politics of Territory* (1987), an enterprising economist's effort to come to grips with the stubborn reality of regional differences and their economic and political implications. The relationship between the main sectors of economy and their locations is explored in HOWARD F. GREGOR, *Geography of Agriculture* (1970), an informative introduction, with most examples focusing on North America; E. WILLARD MILLER, *Manufacturing: A Study of Industrial Location* (1977), a standard text with special emphasis on the U.S. scene; ANN MARKUSEN, PETER HALL, and AMY GLASMEIER, *High Tech America: The What, How, Where, and Why of the Sunrise Industries* (1986), an excellent economic geography; SUSAN HANSON (ed.), *The Geography of Urban Transportation* (1986), a collection of original essays focusing on the U.S. situation; and JAMES E. VANCE, JR., *Capturing the Horizon: The Historical Geography of Transportation Since the Transportation Revolution of the Sixteenth Century* (1986), a comprehensive study of the topic, with ample attention to North America, and *The Merchant's World: The Geography of Wholesaling* (1970), a provocative theoretical and historical treatment with special reference to the United States.

Discussions of resources and their exploitation are found in LEONARD L. FISCHMAN (ed.), *World Mineral Trends and U.S. Supply Problems* (1980), a consideration of long-term potential supply and price problems for seven major nonfuel minerals; *Minerals Yearbook,* offering detailed annual surveys of the mineral industries of the United States and the world; MICHAEL WILLIAMS, *Americans and Their Forests: A Historical Geography* (1989), a definitive monograph on all aspects of U.S. forests and their exploitation, past and present; GORDON G. WHITNEY, *From Coastal Wilderness to Fruited Plain: A History of Environmental Change in Temperate North America, 1500 to the Present* (1994), also focusing on the forests; REXFORD DAUBENMIRE, *Plant Geography: With Special Reference to North America* (1978), a standard text on the subject; JOHN W. BARRETT (ed.), *Regional Silviculture of the United States,* 2nd ed. (1980), an assessment of the biological, physical, and economic qualities of the forested regions of the country; JAMES J. GERAGHTY *et al., Water Atlas of the United States,* new ed. (1973), a compendium of atmospheric, hydrologic, and water-use data; and WATER RESOURCES COUNCIL (U.S.), *The Nation's Water Resources, 1975–2000: Second National Water Assessment,* 4 vol. in 29 (1978), a comprehensive appraisal.

EARL COOK, *Man, Energy, Society* (1976), presents a broad review of the role of energy in modern society, with an emphasis on the fossil fuels and energy policy questions that face the United States. DAVID J. CUFF and WILLIAM J. YOUNG, *The United States Energy Atlas,* 2nd ed. (1986), offers comprehensive coverage of energy resources, production, transport, consumption, and other relevant topics using maps, graphs, and text. PHILIP R. PRYDE, *Nonconventional Energy Resources* (1983), is a broad survey of solar, wind, geothermal, hydroelectric, biomass, nuclear, electrochemical, and oceanic energy resources. (W.Ze.)

North American geographic features of special interest. *Landforms:* Information on the geology and physiography of the Alaskan mountains is found in HOWEL WILLIAMS (ed.), *Landscapes of Alaska: Their Geologic Evolution* (1958), a well-written description of all parts of the peninsula; CLYDE WAHRHAFTIG, *Physiographic Divisions of Alaska* (1966), a detailed summary survey with good maps and illustrations; and GEORGE PLAFKER and HENRY C. BERG, *The Geology of Alaska* (1994), a comprehensive work. MAYNARD M. MILLER, "Alaska's Mighty Rivers of Ice," *National Geographic Magazine,* 131(2):194–217 (February 1967), surveys the glacial character of Alaska's mountainous coast. Plant and animal life is outlined in LESLIE A. VIERECK and ELBERT L. LITTLE, JR., *Alaska Trees and Shrubs* (1972, reprinted 1986), a good field guide for identification; JACOB PETER ANDERSON, *Anderson's Flora of Alaska and Adjacent Parts of Canada,* new ed. edited by STANLEY L. WELSH (1974); and CLARENCE J. RHODE and WILL BARKER, *Alaska's Fish and Wildlife* (1953), a brief nontechnical summary. ROBERT MARSHALL, *Alaska Wilderness: Exploring the Central Brooks Range,* 2nd ed. (1970), describes the physiography, flora, and fauna of this region. NATIONAL GEOGRAPHIC SOCIETY (U.S.), SPECIAL PUBLICATIONS DIVISION, *Alaska's Magnificent Parklands* (1984), provides general descriptions of the state's main parks. (M.M.M.)

MAURICE BROOKS, *The Appalachians* (1965, reissued 1975), is an accurate and comprehensive geography. NEVIN M. FENNEMAN, *Physiography of Eastern United States* (1938), includes a survey of Appalachia's natural resources. CLYDE H. SMITH, WILMA DYKEMAN, and DYKEMAN STOKELY, *Appalachian Mountains* (1980), is a volume of photographs capturing the natural beauty and variety of the extended mountain chain, with the accompanying text developing historical and cultural themes. THOMAS L. CONNELLY, *Discovering the Appalachians* (1968), describes the natural setting, with simple maps. STEPHEN KULIK *et al., The Audubon Society Field Guide to the Natural Places of the Northeast,* vol. 2, *Inland* (1984), includes excellent descriptions of and detailed guides to the Appalachian areas of the Northeast. MICHAEL FROME, *Strangers in High Places: The Story of the Great Smoky Mountains,* rev. ed. (1980), offers a detailed survey of natural and human history. JOHN ANTHONY CARUSO, *The Appalachian Frontier: America's First Surge Westward* (1959), is a scholarly study of the barrier presented by the mountain chain. ALLAN W. ECKERT, *The Frontiersmen* (1967), presents a documented exploration of the frontier and pioneer life in the area. ANN SUTTON and MYRON SUTTON, *The Appalachian Trail: Wilderness on the Doorstep* (1967), discusses the history and natural surroundings of major portions of the trail; while STEVE SHERMAN and JULIA OLDER, *Appalachian Odyssey* (1977), chronicles the authors' hike along its entire length. HARLEY E. HOLLEY, *Blue Ridge Parkway* (1969), describes the history of the establishment of the parkway. (W.D.)

The physical environment of the Great Plains is described in TIM FITZHARRIS, *The Wild Prairie: A Natural History of the Western Plains* (1983); and CLAUDE A. BARR, *Jewels of the Plains: Wild Flowers of the Great Plains Grasslands and Hills* (1983). IAN FRAZIER, *Great Plains* (1989), combines a discussion of the landscape with a survey of social life and customs. The first important historical account of the Great Plains was WALTER PRESCOTT WEBB, *The Great Plains* (1931, reprinted 1981). Webb's brilliant interpretation of cultural adaptation is extended in CARL FREDERICK KRAENZEL, *The Great Plains in Transition* (1955). The past and present of North American Indian culture are explored in ROBERT H. LOWIE, *Indians of the Plains* (1954, reprinted 1982); PRESTON HOLDER, *The Hoe and the Horse on the Plains: A Study of Cultural Development Among North American Indians* (1970, reprinted 1991); and PETER IVERSON (ed.), *The Plains Indians of the Twentieth Century* (1985). MARI SANDOZ, *Old Jules* (1935, reprinted 1985), is a classic novel on the frontier and pioneer life of European settlers. JOHN W. BENNETT, *Northern Plainsmen: Adaptive Strategy and Agrarian Life* (1969, reissued 1976), is an anthropologist's analysis of modern trends for the Canadian plains. (J.L.Di.)

On the natural setting of the North American Desert, historical works include DANIEL TREMBLY MACDOUGAL, *Botanical Features of North American Deserts* (1908, reprinted 1971), early investigations in the southwestern United States and in Mexico; DANIEL TREMBLY MACDOUGAL *et al., The Salton Sea: A Study of the Geography, the Geology, the Floristics, and the Ecology of a Desert Basin* (1914); and JOHN WESLEY POWELL, *Report on the Lands of the Arid Region of the United States,* new ed., edited by WALLACE STEGNER (1962). A massive survey of geographic research on deserts is presented in WILLIAM G. MCGINNIES, BRAM J. GOLDMAN, and PATRICIA PAYLORE (eds.), *Deserts of the World: An Appraisal of Research into Their Physical and Biological Environments* (1968). Other relevant works are SLATER BROWN,

"The Great American Desert," in his *World of the Desert* (1963); EDMUND C. JAEGER, *The North American Deserts* (1957); and ANN SUTTON and MYRON SUTTON, *The Life of the Desert* (1966), an abundantly illustrated volume focusing on desert biology. Other special studies include WILLIAM A. BURNS (ed.), *The Natural History of the Southwest* (1960); and CARLE HODGE and PETER C. DUISBERG (eds.), *Aridity and Man: The Challenge of the Arid Lands in the United States* (1963). GORDON L. BENDER (ed.), *Reference Handbook on the Deserts of North America* (1982), is an informative source. (R.E.C.)

The geography and geology of the Pacific mountain system are treated in JAMES G. ASHBAUGH (ed.), *The Pacific Northwest: Geographical Perspectives* (1994), covering climate, vegetation, agriculture, and the economy. STEWART T. SCHULTZ, *The Northwest Coast* (1990), a popular, comprehensive view of the people, economy, and landforms of the region; PAUL E. HAMMOND, *Guide to Geology of the Cascade Range* (1988), a well-written work; JOHN ELIOT ALLEN, MARJORIE BURNS, and SAM C. SARGENT, *Cataclysms on the Columbia* (1986), a fine overall exploration of the Missoula floods; and A. JON KIMMERLING and PHILIP L. JACKSON, *Atlas of the Pacific Northwest,* 7th ed. (1985). A good explanation of how the ocean has shaped the Oregon coast, producing different landforms between California and Washington, may be found in PAUL D. KOMAR, "Ocean Processes and Hazards Along the Oregon Coast," *Oregon Geology,* 54(1):3–19 (January 1992). (J.G.A.)

Two nontechnical, abundantly illustrated descriptions of the Rocky Mountains are WILLIAM S. ELLIS and DICK DURRANCE II, *The Majestic Rocky Mountains* (1976); and BRYCE S. WALKER *et al., The Great Divide* (1973, reissued 1985), covering the landforms, plant life, and early exploration of the American Rockies. The mountains are also treated in MEL GRIFFITHS and LYNNELL RUBRIGHT, *Colorado: A Geography* (1983); and AMERICAN WEST, *The Magnificent Rockies: Crest of a Continent* (1973). DENNIS GLICK, MARY CARR, and BERT HARTING, *An Environmental Profile of the Greater Yellowstone Ecosystem* (1991), compiles baseline information on the ecological processes and components of the greater Yellowstone ecosystem and discusses how the ecosystem's future is affected by current and proposed resource development plans. DAVID V. HARRIS and EUGENE P. KIVER, *The Geologic Story of the National Parks and Monuments,* 4th ed. (1985), chapters 8–11, covers the geologic history and special features of U.S. parks and monuments in the northern, middle, and southern Rockies and on the Colorado Plateau. LAWRENCE M. OSTRESH, JR., RICHARD A. MARSTON, and WALTER M. HUDSON, *Wyoming Water Atlas* (1990), although specifically about Wyoming water resources, treats issues that are typical throughout the Rocky Mountain region. (R.A.Ma.)

The geology of the Sierra Madre is described in LEE A. WOODWARD and STUART A. NORTHROP (eds.), *Tectonics and Mineral Resources of Southwestern North America* (1976). Large-scale maps of Mexico, made with the help of satellite photography, are found in MEXICO, INSTITUTO NACIONAL DE ESTADÍSTICA, GEOGRAFÍA E INFORMÁTICA, *Atlas nacional del medio físico,* rev. ed. (1988). CARL LUMHOLTZ, *Unknown Mexico: A Record of Five Years' Exploration of the Western Sierra Madre; In the Tierra Caliente of Tepic and Jalisco; And Among the Tarascos of Michoacan,* 2 vol. (1902, reissued as *Unknown Mexico: Explorations in the Sierra Madre and Other Regions, 1890–1898,* 1987), offers an account of the author's pioneering geographic and anthropological research in the Sierra Madre Occidental. T. PHILIP TERRY, *Terry's Guide to Mexico,* rev. ed., edited by JAMES NORMAN (1972), is a classic descriptive guide. On animal life in the Sierra Madre, two books are especially useful: A. STARKER LEOPOLD, *Wildlife of Mexico: The Game Birds and Mammals* (1959, reprinted 1972), contains excellent illustrations and maps, including a good map of vegetation; while A. STARKER LEOPOLD, RALPH J. GUTIÉRREZ, and MICHAEL T. BRONSON, *North American Game Birds and Mammals* (1981), a similar later work, covers a larger area but less intensively. The people of the mountains are discussed in ROBERT C. WEST and JOHN P. AUGELLI, *Middle America: Its Lands and Peoples,* 3rd ed. (1989), a broad systematic geography covering Mexico, Central America, and the West Indies; and ROBERT WAUCHOPE (ed.), *Handbook of Middle American Indians,* 16 vol. (1964–76), especially vol. 1, *Natural Environment and Early Cultures,* and vol. 7–8, *Ethnology.* (H.J.Bn.)

On the natural history of the Sierra Nevada, classic accounts of explorations are found in RODERICK PEATTIE (ed.), *The Sierra Nevada* (1947); JOHN MUIR, *My First Summer in the Sierra* (1911, reissued 1990), a classic of geographic writing, and *The Wilderness World of John Muir,* compiled by EDWIN WAY TEALE (1954, reissued 1982); and TRACY I. STORER and ROBERT L. USINGER, *Sierra Nevada Natural History: An Illustrated Handbook* (1963). Analyses of the geology of the mountains are found in JOHN L. BURNETT, "Geology of the Lake Tahoe Basin," *California Geology,* 24(7):119–127 (1971); EDWARD B. SCOTT, *The Saga of Lake Tahoe: A Complete Documentation of Lake Tahoe's Development over the Last One Hundred Years* (1957); and MARY HILL, *Geology of the Sierra Nevada* (1975). The climate is detailed in JOHN W. JAMES, "A Record-Breaking Sierra Nevada Snowfall: Its Meteorologic and Topographic Causes," in AMERICAN METEOROLOGICAL SOCIETY, *Third Conference on Mountain Meteorology* (1984), pp. 144–146; and DAVID H. MILLER, *Snow Cover and Climate in the Sierra Nevada* (1955). (J.W.Ja.)

Drainage systems and waterways: PHILIP L. FRADKIN, *A River No More: The Colorado River and the West* (1981), is a lucid introduction describing the river from the headwaters to the delta. JOHN WESLEY POWELL, *Canyons of the Colorado* (1895, reissued as *The Exploration of the Colorado River and Its Canyons,* 1987), is an exciting account of an early scientific exploration with a wealth of geologic and ethnographic detail. A broader context of exploration and settlement is provided in RICHARD A. BARTLETT, *Great Surveys of the American West* (1962, reprinted with expanded bibliography, 1980); and WILLIAM H. GOETZMANN, *Exploration and Empire: The Explorer and the Scientist in the Winning of the American West* (1966, reissued 1978). WILLIAM L. GRAF, *The Colorado River: Instability and Basin Management* (1985), examines the physical geography of the basin, with emphasis on natural processes and the impact of human activity. NATIONAL RESEARCH COUNCIL (U.S.), COMMITTEE ON WATER, *Water and Choice in the Colorado Basin: An Example of Alternatives in Water Management* (1968), remains a landmark study of river-basin management and policy. JAMES L. WESCOAT, JR., *Integrated Water Development: Water Use and Conservation Practice in Western Colorado* (1984), describes how basinwide policies influence every aspect of water use in local areas. GARY D. WEATHERFORD and F. LEE BROWN (eds.), *New Courses for the Colorado River* (1986), combines a balanced review of historical controversies with creative approaches for addressing them in the future. (J.L.W.)

Studies of the physical environment of the Columbia River include NATES MCKEE, *Cascadia: The Geologic Evolution of the Pacific Northwest* (1972), a classic, well-illustrated survey; JERRY F. FRANKLIN and C.T. DYRNESS, *Natural Vegetation of Oregon and Washington,* new ed. (1988), which examines the complex vegetation patterns of the region; and JOHN A. ALWIN, *Between the Mountains: A Portrait of Eastern Washington* (1984), a descriptive work. GEORGE SUNDBORG, *Hail Columbia: The Thirty-Year Struggle for Grand Coulee Dam* (1954), offers a fascinating account of the long controversy that led to the decision to construct the dam. ANTHONY NETBOY, *Salmon of the Pacific Northwest* (1958), was the first work to predict the consequences of dams on the salmon population. GENE TOLFERSON, *BPA and the Struggle for Power at Cost* (1987), provides a more recent description of developments in the region's economy that are directly influenced by the river. WILLIAM DIETRICH, *Northwest Passage: The Great Columbia River* (1995), chronicles the history of various environmental and social issues connected with the river. A wealth of information is provided in the reports of special agencies, such as NORTHWEST POWER PLANNING COUNCIL (U.S.), *Columbia River Basin Fish and Wildlife Program* (1982), with later irregular updates. DOROTHY O. JOHANSEN and CHARLES M. GATES, *Empire of the Columbia: A History of the Pacific Northwest,* 2nd ed. (1967), is a standard history of the area, with a comprehensive bibliography. D.W. MEINIG, *The Great Columbia Plain: A Historical Geography, 1805–1910* (1968), is the classic work on the settlement history of eastern Washington. Two other readable accounts of history and folklore are MURRAY C. MORGAN, *The Columbia: Powerhouse of the West* (1949); and STEWART H. HOLBROOK, *The Columbia* (1956, reprinted 1974). (M.E.Ms.)

JACK L. HOUGH, *Geology of the Great Lakes* (1958), provides information on the lakes' geologic origin. A summary of the physical, chemical, and biological characteristics of the Great Lakes, with an account of early research in the field, is offered in ALFRED M. BEETON and DAVID C. CHANDLER, "The St. Lawrence Great Lakes," in DAVID G. FREY (ed.), *Limnology in North America* (1963), pp. 535–558. HARLAN HATCHER and ERICH A. WALTER, *A Pictorial History of the Great Lakes* (1963), surveys early exploration, shipping, and settlement in the region. Useful background information on the region is found in LEE BOTTS *et al., The Great Lakes: An Environmental Atlas and Resource Book* (1987); and R.A. ASSEL *et al., Great Lakes Ice Atlas* (1983). A history of ecological changes in the basin and their effect on the lakes is presented in WILLIAM ASHWORTH, *The Late, Great Lakes* (1986). THEODORA E. COLBORN *et al., Great Lakes, Great Legacy?* (1990), discusses the Great Lakes as an ecosystem, changes in the lakes' environment, and institutional arrangements for dealing with these problems. The region's economic situation is assessed in FEDERAL RESERVE BANK OF CHICAGO and GREAT LAKES COMMISSION, *The Great Lakes Economy* (1985), a compendium of data on resources and industry, and *The Great Lakes Economy: Looking North*

and South (1991), an interpretive analysis. NOEL M. BURNS, *Erie: The Lake That Survived* (1985), discusses the environmental and economic degradation of the lake and its environs and the signs of rehabilitation. Also useful is GREAT LAKES SCIENCE ADVISORY BOARD, *Report* (biennial), which includes summaries of health, societal, and education issues related to pollution and toxic chemicals. (A.M.B.)

MACKENZIE RIVER BASIN COMMITTEE (CANADA), *Mackenzie River Basin Study Report* (1981), examines the development of water and related resources. Environmental aspects are treated in THOMAS R. BERGER, *Northern Frontier, Northern Homeland: The Report of the Mackenzie Valley Pipeline Inquiry,* rev. ed. (1988), which also includes a survey of the Native American population of the area. JAMES K. SMITH, *The Mackenzie River: Yesterday's Fur Frontier, Tomorrow's Energy Battleground* (1977), surveys the economic history of the Mackenzie River valley. ROBIN MINION (compiler), *Communities and Towns of the Northwest Territories* (1985), looks at the modern situation. T. FENGE *et al., Land Use Programs in Canada: Northwest Territories* (1979), is also worth consulting. (J.L.Ro.)

Two early reports prepared for the Mississippi River Commission are of interest: HAROLD N. FISK, *Geological Investigation of the Alluvial Valley of the Lower Mississippi River* (1945), a classic work, with an accompanying atlas of the geologic history; and D.O. ELLIOTT, *The Improvement of the Lower Mississippi River for Flood Control and Navigation,* 3 vol. (1932), a detailed survey of history, physical characteristics, flood-control measures, and navigation improvements prior to 1930. Later developments are chronicled in ROBERT W. HARRISON, *Alluvial Empire: A Study of State and Local Efforts Toward Land Development in the Alluvial Valley of the Lower Mississippi River, Including Flood Control, Land Drainage, Land Clearing, Land Forming* (1961), a nontechnical work; and JOHN MCPHEE, "Atchafalaya," in his *The Control of Nature* (1989), pp. 3–92, a fascinating description of attempts to manage and control the lower Mississippi in Louisiana. MARK TWAIN, *Life on the Mississippi* (1883, available also in later editions), is a classic humorous account of river conditions and of the life of a river pilot in the mid-19th century; it remains invaluable for background detail on the river's history. GERALD M. CAPERS, *The Mississippi River Before and After Mark Twain* (1977), is a popular history. (R.A.Mu./R.H.K.)

A concise physical description of the Panama Canal is found in SANDRA W. MEDITZ and DENNIS M. HANRATTY (eds.), *Panama: A Country Study,* 4th ed. (1989). PAUL J. SCHEIPS (ed.), *The Panama Canal: Readings on Its History* (1979); and DAVID MCCULLOUGH, *The Path Between the Seas: The Creation of the Panama Canal, 1870–1914* (1977), detail the history of the canal's construction. The decision to build the canal in Panama as opposed to other locations is discussed in such historical works as MILES P. DUVAL, JR., *Cadiz to Cathay: The Story of the Long Diplomatic Struggle for the Panama Canal,* 2nd ed. (1947, reissued 1968); and GERSTLE MACK, *The Land Divided: A History of the Panama Canal and Other Isthmian Canal Projects* (1944, reprinted 1974). NORMAN J. PADELFORD, *The Panama Canal in Peace and War* (1942), focuses on the strategic significance of the waterway. Later works treat the canal mostly from the point of view of international law and foreign relations, including G.A. MELLANDER, *The United States in Panamanian Politics* (1971); PAUL B. RYAN, *The Panama Canal Controversy: U.S. Diplomacy and Defense Interests* (1977); J. MICHAEL HOGAN, *The Panama Canal in American Politics* (1986); and WALTER LAFEBER, *The Panama Canal: The Crisis in Historical Perspective,* updated ed. (1989). (B.L.G.)

Flow of the Rio Grande and Related Data from Elephant Butte Dam, New Mexico, to the Gulf of Mexico (annual), published by the International Boundary and Water Commission (United States and Mexico), is an excellent source of information on the hydrology, climatology, drainage basins, and irrigated areas of the Rio Grande region. UNIVERSITY OF TEXAS AT EL PASO, CIVIL ENGINEERING DEPARTMENT, *Water Resources of the Upper Rio Grande Basin,* 2 vol. (1970), contains detailed climatic, hydrologic, and reservoir data and includes information on irrigation and political and legal aspects. A wide variety of articles from numerous disciplines pertaining to the Rio Grande are found in the *Natural Resources Journal* (quarterly); and *Journal of Borderlands Studies* (semiannual). JERRY E. MUELLER, *Restless River: International Law and the Behavior of the Rio Grande* (1975), is an informative blend of geomorphology and political geography. JOHN W. HOUSE, *Frontier on the Rio Grande* (1982), focuses on the river as an international boundary and emphasizes regional political and social aspects. SAN DIEGO STATE UNIVERSITY, INSTITUTE OF PUBLIC AND URBAN AFFAIRS, *Environmental Problems Along the Border* (1979), contains several pertinent articles concerning the Rio Grande. Historical works on the river include PAUL HORGAN, *Great River: The Rio Grande in North American History* (1954, reprinted 1991); LAURA GILPIN, *The Rio Grande, River of Destiny* (1949); and NORRIS HUNDLEY, *Dividing the Waters: A Century of Controversy Between the United States and Mexico* (1966). (R.H.Sc.)

The geography, hydrology, and physical features of the St. Lawrence River and Seaway are detailed in CANADIAN HYDROGRAPHIC SERVICE, *Sailing Directions, Gulf and River St. Lawrence,* 6th ed. (1985). RONALD I. HEILMANN, HAROLD M. MAYER, and ERIC SCHENKER, *Great Lakes Transportation in the Eighties* (1986), reports shipping and economic conditions in the area. Relevant information is found in *Seaway Review* (quarterly). A short study, *The Great Lakes St. Lawrence System: The World's Richest Economic Region, Served by the World's Most Efficient Trade Route* (1984), offers a pertinent overview. Historical surveys are provided in GENNIFER SUSSMAN, *The St. Lawrence Seaway* (1978); and JEAN-CLAUDE LASSERRE, *Le Saint-Laurent* (1980). (P.C.)

RICHARD K. MATHEWS, *The Yukon* (1968), is an informative geography from the series *Rivers of America.* A brief study of hydrology is found in UNITED STATES, ARMY, CORP OF ENGINEERS, ALASKA DISTRICT, *Yukon and Kuskokwim River Basins, Alaska* (1987). *Yukon Data Book* (biennial) is a reference periodical published by the Yukon Territory government. Informative illustrated descriptions of travel along the river include KEITH TRYCK, *Yukon Passage: Rafting 2000 Miles to the Bering Sea* (1980); and STAN COHEN, *Yukon River Steamboats* (1982). ALLEN A. WRIGHT, *Prelude to Bonanza* (1976), describes the discovery and exploration of the territory. Other histories of the territory and the people include R.C. COUTTS, *Yukon: Places & Names* (1980); MELODY WEBB, *The Last Frontier* (1985, reissued as *Yukon: The Last Frontier,* 1993); and CATHARINE MCCLELLAN, *Part of the Land, Part of the Water: A History of the Yukon Indians* (1987). Surveys of present-day conditions can be found in D.K. REDPATH, *Land Use Programs in Canada, Yukon Territory* (1979). (J.L.Ro.)

Norway

Norway, the "northern way," occupies the western half of the Scandinavian peninsula of northern Europe. The country, called Norge in traditional Norwegian and Noreg in New Norwegian, has an area of 125,050 square miles (323,878 square kilometres), excluding the dependencies of Svalbard and Jan Mayen, Bouvet Island, and Peter I Island. With the Barents Sea to the north, the Norwegian Sea and the North Sea to the west, and Skagerrak (Skager Strait) to the south, Norway has land borders only to the east—with Sweden, Finland, and Russia. Nearly half of the inhabitants of the country live in the far south, in the region around Oslo, the capital. About two-thirds of Norway is mountainous, and off its much-indented coastline lie some 50,000 islands.

Norway has always depended heavily on its economic relations with foreign countries; this has been the case during both its periods of independence and those times when it has been politically united with its fellow Scandinavian nations, Sweden and Denmark. These foreign links are illustrated by the heritage of the Vikings, who plundered the coasts from the British Isles into the Mediterranean Sea and sailed the Atlantic Ocean to North America. Later the Norwegians turned to trading in fish and lumber, and the modern nation emerged as a major maritime transporter of the world's goods as well as a world leader in specialized shipbuilding. In the 1970s the exploitation of offshore oil and natural gas became the major maritime industry; shipbuilding declined substantially during the 1980s.

Lying on the northern outskirts of the European continent and thus avoiding the characteristics of a geographic crossroads, Norway has maintained a great homogeneity among its peoples and their way of life. Its projections for life expectancy are among the highest of any in the world. The main political division reflects differing views on the importance of free market forces. But the Socialists long ago stopped insisting on nationalization of the nation's industry, and the non-Socialists have accepted extensive governmental control of the country's economy. Such evidence of national consensus, along with abundant waterpower, offshore oil, and peaceful labour relations, have been a major factor in the rapid growth of Norway as an industrial nation in the 20th century and in the creation of one of the highest standards of living in the world.

Physical and human geography

THE LAND

Norway occupies part of northern Europe's Fennoscandian Shield. The extremely hard bedrock, which consists mostly of granite and other heat- and pressure-formed materials, ranges from 1,000,000,000 to 2,000,000,000 years in age.

Glaciation

Relief. Glaciation and other forces wore down the surface and created thick sandstone, conglomerate, and limestone deposits known as sparagmite, as well as numerous extensive areas, called peneplains, whose relief has been largely eroded away. Remains of the latter include the Hardanger Plateau, 3,000 feet (900 metres) above sea level, Europe's largest mountain plateau, covering about 4,600 square miles (11,900 square kilometres) in southern Norway; and the Finnmark Plateau, 1,000 feet (300 metres) above sea level, occupying most of the northernmost and largest county of Norway.

From the Cambrian through the Silurian geologic periods, from about 570,000,000 to 395,000,000 years ago, most of the area was below sea level and acquired a layer of limestone, shale, slate, and conglomerate from 330 to 525 feet thick. Folding processes in the Earth then gave rise to a mountain system that is a continuation of the Caledonian System of the British Isles. Norway has an average elevation of 1,600 feet, compared to 1,000 feet for Europe as a whole.

Rivers running westward acquired tremendous erosive power. Following fracture lines marking weaknesses in the Earth's crust, they dug out gorges and canyons that knifed deep into the jagged coast. To the east the land sloped more gently, and broader valleys were formed. During repeated periods of glaciation in the Great Ice Age of the Quaternary Period, less than 2,500,000 years ago, the scouring action of glaciers tonguing down the V-shaped valleys that were then part of the landscape created the magnificent U-shaped drowned fjords that now grace the western coast of Norway. Enormous masses of earth, gravel, and stone were also carried down by glacial action as far south as present-day Denmark and northern Germany. The bedrock, exposed in about 40 percent of the area, was scoured and polished by the movements of these materials.

Soils. In the melting periods between ice ages, large areas were flooded by the sea because the enormous weight

of the ice had depressed the land. Thick layers of clay, silt, and sand were deposited along the present coast and in large areas in the Oslo and Trondheim regions, which rise as high as 650 feet above sea level today. Some very rich soils are found below these old marine coastal regions. In the large areas covered by forests, the main soil has been stripped of much of its mineral content, creating poor agricultural land.

Drainage. The Glåma (Glomma) River, running south almost the entire length of eastern Norway, is 372 miles long—close to twice the length of the two other large drainage systems in southern Norway, which meet the sea at the cities of Drammen and Skien. The only other long river is the 224-mile-long Tana-Anarjåkka, which runs northeast along part of the border with Finland. Among Norway's more than 160,000 lakes, by far the largest is Mjøsa, which is 50 miles north of Oslo on the Lågen River, a tributary of the Glåma.

Climate. Although it occupies almost the same degrees of northern latitudes as Alaska, Norway owes its warmer climate to the Gulf Stream, which carries 4,000,000 to 5,000,000 tons of tropical water per second into the surrounding seas. The Gulf Stream usually keeps the fjords from freezing, even in the Arctic Finnmark region. Even more important are the southerly air currents brought in above these warm waters, especially during the winter.

Effect of the Gulf Stream

The annual mean temperature on the west coast is 45° F (7° C), or 54° F (30° C) above average for the latitude. In the Lofoten Islands, north of the Arctic Circle, the January mean is 43° F (24° C) above the world average for this latitude, one of the greatest thermal anomalies known. Norway lies directly in the path of the North Atlantic cyclones, which bring frequent gales and changes in weather. Western Norway has a marine climate, with comparatively cool summers, mild winters, and up to 80 inches (2,030 millimetres) of mean annual precipitation. Eastern Norway, sheltered by the mountains, has an inland climate with warm summers, cold winters, and less than 30 inches mean annual precipitation.

Plant and animal life. Norway has about 2,000 species of plants, but only a few, mainly mountain plants, are endemic to Norway. Thick forests of spruce and pine predominate in the broad glacial valleys up to 2,800 feet above sea level in eastern Norway and 2,300 feet in the Trondheim region. Even in the thickest spruce woods, the ground is carpeted with leafy mosses and heather, and a rich variety of deciduous trees—notably birch, ash, rowan, and aspen—grow even on the steepest hillsides. The birch zone extends from 3,000 to 3,900 feet above sea level, after which there is a willow belt that includes dwarf birch.

In western Norway conifers and broad-leaved trees abound in approximately equal numbers. North of the Arctic Circle there is little spruce, and pine grows mainly in the inland valleys amid their surprisingly rich vegetation. Wild berries grow abundantly in all regions: they include blueberries and cranberries of small size and yellow cloudberries, a fruit-bearing plant of the rose family that is little known outside Scandinavia and Great Britain.

Reindeer, wolverines, lemmings, and other Arctic animals are found throughout Norway, although in the south only in the mountain areas. Elk are common in the large coniferous forests and red deer on the west coast. Only 100 years ago large animals of prey were common in Norway, but now the bear, wolf, and lynx are found only in a few areas, mainly in the north. Foxes, otters, and many species of marten, however, are common, and in many areas badgers and beavers thrive.

Mammals

Most of the rivers and lakes have a variety of fish, notably

The Seven Sisters Falls, Geiranger Fjord, with sod roof houses on the hillside, western Norway.
Kirkendall—Spring Photographers

trout and salmon. The latter are found in at least 160 rivers, often in an abundance that attracts anglers from all over the world.

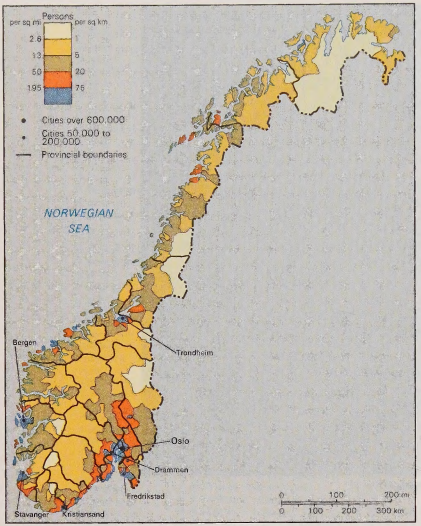
Of the large variety of birds, many migrate as far south as southern Africa for the winter. In the north people collect eggs and down from millions of seabirds, and, as far south as Ålesund, small cliff islands often are nearly covered by several hundred thousands of nesting birds. Partridges and several kinds of grouse are common in the mountains and in the forests and are popular game birds.

Traditional regions. There are four traditional regions of Norway, three in the south and one in the Arctic north. The three main regions of the south are defined by wide mountain barriers. From the southernmost point a swelling complex of ranges, jointly called Langfjellet (Long Mountains), runs northward to divide eastern Norway, or Østlandet, from western Norway, or Vestlandet. An eastward sweep of the mountains separates Østlandet in the north from the Trondheim region, or Trøndelag. Almost exactly at the midpoint of the country, northern Norway, or Nord-Norge, begins.

Eastern Norway. Østlandet has more than half of Norway's population, most of whom live in the metropolitan area of the national capital, Oslo, and in the many industrial cities and urban agglomerations on both sides of Oslofjorden.

The agricultural core of the Østlandet lies in the lowlands extending eastward and southward to the Swedish border. With suitable precipitation during the growing season, the highest July temperatures in Norway, a soil consisting of relatively rich marine deposits, and large nearby markets, the land is intensively cultivated. There are even a number of large, heavily mechanized farms producing cereal grains, which generally do not grow well in such latitudes. Most of the farms, however, are small. To supplement their income from domestic animals, vegetables, and fruits, a great number of farmers pursue forestry as a secondary occupation, since most of the forests are a part of farm acreages.

Norway has never had the agricultural villages that are common elsewhere in Europe. The more densely populated areas of the country have grown up around crossroads of transportation, from which people have moved to the cities and suburbs. Thus, there is actually little borderline between the rural and urban populations. For many years Oslo has attracted settlers from all over the country, becoming a national melting pot surrounded by the most important agricultural and industrial districts of Norway.



Urban and rural populations

In the interior of Østlandet, farms are located along the sides of the broad valleys, the bottoms of which contain only washed-out deposits of soil. Frost is more frequent in spring and fall than it is in the coastal areas. The largest forests in Norway are to be found between the Swedish border and the Glåma River, east of Oslo. The coastline facing Denmark across the Skagerrak passage, stretching from Oslofjorden to the southern tip of Norway, is densely populated and contains many small towns, coastal villages, and small farms. Centred on the city of Kristiansand, this southern area is sometimes set apart as a fifth region, Sørlandet. The coastline has developed into Norway's foremost summer vacation area. The land is hilly, but the growing season is slightly longer than around Oslo. The interior of this area, with narrow valleys running up into the beginnings of Langfjellet, is very sparsely populated, and the people of the scattered settlements depend more on dairy farming, sheep raising, and forestry. Economically and in view of other practical aspects, however, Sørlandet is usually included as part of Østlandet.

In all, about half of Østlandet is forested. The region has slightly more than half of Norway's total forest resources and an equivalent share of Norway's total area of fully cultivated land. In mining and manufacturing Østlandet also has more than half of the nation's total production value and of its total trade. These lions' shares of the national wealth, combined with the concentration of economic activity around Oslofjorden, secure for Østlandet the highest average income per household of the four regions.

Western Norway. The narrow coastal zone of Vestlandet has many islands and steep-walled, narrow fjords cutting deep into the interior mountain region. The major exception is the wide Jæren Plain, south of Stavanger. With rich glacier-formed soils, exceptionally mild winters, long growing seasons, and plentiful precipitation, Jæren boasts the highest yields of any agricultural area in Nor-

Agriculture in Jæren

Population density of Norway.

way, and those who farm this rich land are not distracted by the necessity of forestry or fishing.

Stavanger is an expanding industrial centre, particularly in canning and engineering. It is also the main base for the petroleum and natural gas activities in the North Sea. To the north, Haugesund thrives on fishing and other industries. The island of Karm comprises a rich agricultural area. The fjord areas of Hardanger are more sheltered, with rich fruit districts specializing in apples and cherries.

Bergen is the natural centre of Vestlandet. Since the late Middle Ages, when it was an active trading centre for northern Europe, the city has had a more international character than any other in Norway. The Sunnmøre district, farther north on the coast, has the important fishing port of Ålesund as its local centre; it contains many engineering firms, and the bulk of Norway's furniture industry is gathered on its rocky coast. Fishing, which predominates farther to the north, around the cities of Molde and Kristiansund, is a main second occupation, as forestry is in Østlandet. Deep in the Vestlandet fjords lie many of Norway's largest smelting plants.

Central Norway. Trøndelag is Norway's most typical agricultural region, with flat, fertile land around the wide Trondheim Fjord and the city of Trondheim. Nearly one-third of its area is forested, and fishing is important. It once had a large proportion of Norway's mining industry. Trondheim, the third largest city in Norway and for long periods the national capital, dominates the economic life of Trøndelag and is a centre for education and research.

Northern Norway. Nord-Norge, most of which is above the Arctic Circle, is truly the "land of the midnight sun" in the summer, whereas during December and most of January the sun does not rise. Most of the region is filled with mountains with jagged peaks and ridges, even on the islands. A long string of large islands jutting into the North Atlantic west of Vest Fjord forms the Lofoten Wall. Numerous fjords scissor into this narrow strip of Norway's northern tail. As many roads are closed during winter, sea and air transportation are vital.

Isolation of the north

Some of the inland valleys have dense forests. The short summers and poor soil limit agriculture to a largely subsidiary activity, though the production of milk, meat, and potatoes is surprisingly high in many districts. Fishing, mining, and manufacturing dominate the economy.

THE PEOPLE

In most parts of Norway the nucleus of the population is Nordic in heritage and appearance. Between 60 and 70 percent have blue eyes. An influx of people from southern Europe has been strong in southwestern Norway. Nord-Norge has about nine-tenths of the 20,000 to 30,000 Sami (Lapps, or Laplanders) living in Norway. Only about 2,800 of them still live on the Finnmark Plateau and move their reindeer herds down to the coast for summer grazing. The Sami were Norway's first inhabitants; they arrived at least 10,000 years ago, probably from Central Asia.

The Norwegian language belongs to the North Germanic branch of the Germanic language group. The alphabet has three more letters than the Latin alphabet—æ, ø, and å. Modern Norwegian has many dialects, but all of them, as well as the Swedish and Danish languages, are understood throughout Scandinavia. Until about 1850 there was only one written language, called Riksmål, or "Official Language," which was strongly influenced by Danish during the 434-year union of the two nations. Landsmål, or "Country Language," was then created out of the rural dialects. After a long feud, the forms received equal status under the terms Dano-Norwegian (Bokmål, or "Book Language") and New Norwegian (Nynorsk), respectively. Dano-Norwegian is the main language in local schools.

Dialect status

About nine-tenths of all Norwegians belong to the Evangelical Lutheran national church, the Church of Norway. In addition to other Christian denominations, there are small groups of Muslims and Buddhists.

With a significant increase in the proportion of the population over age 80, the population of Norway grew slowly but steadily at the end of the 20th century. The birth rate fell slightly during the 1990s—but so did the death rate, as life expectancy (about 75 years for men and about 81 years for women) was among the highest in Europe.

THE ECONOMY

The economy is dependent largely on the fortunes of Norway's important petroleum industry. Thus, it experienced a decline in the late 1980s as oil prices fell but by the late 1990s had rebounded strongly, benefiting from increased production and higher prices. Norway reversed its negative balance of payments, and the growth of its gross national product (GNP)—which had slowed during the 1980s—accelerated. By the late 1990s Norway's per capita GNP was the highest in Scandinavia and among the highest in the world. To reduce economic downturns caused by drops in oil prices, the government in 1990 established the Government Petroleum Fund, into which budget surpluses were deposited for investment overseas.

Fewer than 5 percent of the industrial companies in Norway have more than 100 employees. Nonetheless, they account for half of the industrial labour force and for more than half of production. The smaller companies are usually family-owned, whereas most of the larger ones are joint-stock companies. Foreign interests control companies accounting for about 10 percent of total production. Only a few larger concerns are state-owned, and even these are usually run with almost complete independence.

Industrial ownership

Agriculture and fishing are highly organized, and they are subsidized by the state. In remote districts private industry may receive special incentives in the form of loans and grants or tax relief. Taxes are high, with sharply progressive income taxes and a value-added (or consumption) tax of 23 percent on all economic activity. Total tax revenues are equivalent to about half of the GNP, but much of this represents transfers of income; *i.e.*, it is returned to the private sector in the form of price subsidies, social insurance benefits, and the like. All this has added to economic problems of inflation, but increases in productivity have made possible a high rate of growth in real income.

Resources and industry. By the mid-1990s Norway had become the world's second largest oil exporter (behind Saudi Arabia). About half of export earnings and nearly one-tenth of government revenues came from offshore oil and

gas. It was estimated that high oil production levels could last at least into the second decade of the 21st century.

More than one-fourth of the huge investment made in Norwegian offshore operations by the mid-1990s went toward the development of the Troll field just west of Bergen, one of the largest offshore gas fields ever found. Its development ranked as one of the world's largest energy projects. With a water displacement of one million tons and a height of nearly 1,550 feet (470 metres), the Troll A production platform was the tallest concrete structure ever moved when it was towed into place in 1995. Gas deliveries from the Troll field made Norway a leading supplier of natural gas to continental Europe.

About half of Norway's 65,000 largest lakes are situated at elevations of at least 1,650 feet (500 metres), about one-fifth of the country lies 2,950 feet (900 metres) or more above sea level, and predominantly westerly winds create abundant precipitation. As a result, Norway has tremendous hydroelectric potential. It is estimated that almost one-third of that potential is economically exploitable, of which more than three-fifths had been developed by the mid-1990s. Some 850 hydropower stations meet virtually all Norway's electrical consumption needs. Norway's per capita production of electricity is the world's highest, twice that of the United States.

Hydroelectric power

About one-third of the country's electricity production is utilized by the electrometallurgical industry. In addition to being among the world's leading exporters of metals, Norway is a significant producer of iron-based alloys. Europe's largest deposit of ilmenite (titanium ore) is located in southwestern Norway. The country also is the world's principal producer of olivine and an important supplier of nepheline syenite and dimension stone (particularly larvikite). Pyrites and small amounts of copper and zinc also are mined, and coal is mined on Svalbard. In all, mining and manufacturing (excluding petroleum activities) account for more than one-third of Norway's export earnings.

Agriculture, forestry, and fishing. By the 1990s the number of farms of at least 1.25 acres (0.5 hectare) had decreased by more than half of its 1950 total of more than 200,000. Much of the abandoned acreage was absorbed into the remaining farms. Nevertheless, many farms remain small; about half have more than 25 acres (10 hectares) of farmland, while about 1 percent have more than 125 acres (50 hectares). Labour for hire is scarce, and most of the work must be done by farmer-owners themselves. Extensive mechanization and fertilization, however, have kept total farm output on the increase. Livestock is the major agricultural product, and, though the country is more than self-sufficient in animal products, it remains dependent on imports for cereal crops.

Although less than one-twentieth of Norway's total area is agricultural land, productive forests comprise more than one-third of the total area. Along the coast fishing plays an important role. It forms the basis of a large and growing fish-processing industry and offers seasonal employment for many farmers. Most fishing vessels are owned by the fishermen themselves, the necessary crew members being paid by shares of gross income in a continuation of a centuries-old tradition of the sea. A critical problem is how to avoid depleting the fish resources while maintaining the volume. About half the catch, most of it near the coast, goes into fish meal and oil, but some is processed for human consumption in freezing plants.

Employment in fisheries

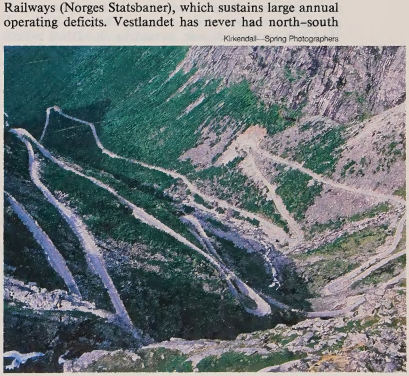
By the mid-1990s fish farming had developed into the cornerstone of the coastal economy. The total number of fishermen decreased from about 100,000 in 1950 to fewer than 25,000 by the mid-1990s, and the number of vessels decreased by more than three-fifths over the same period. Once a world leader in Antarctic whaling, Norway has since 1968 hunted only smaller species of toothed whales. In the late 1980s and early 1990s Norway complied with the International Whaling Commission's total ban on commercial whaling. By the mid-1990s, however, the government gradually allowed limited catches on some species, arguing that they were not endangered any longer and that they posed a serious threat to fish populations. The latter argument is also used in defense of sealing, though both whaling and sealing have declined sharply.

Finance and trade. The Bank of Norway has all the usual functions of a central bank, and it also advises the government on the practical implementation of credit policy. In 1984 foreign banks were allowed to establish branches in Norway. The country has an active stock market.

As a result of the downturn in the Norwegian economy in the late 1980s, commercial banks experienced a crisis in 1991. Many of the largest became primarily government-owned as new capital was invested by the Government Bank Security Fund; the old shares were declared worthless. Critics argued that the crisis was worsened by new rules requiring that the depreciation of property be counted as a loss, even when the property was not sold. By the mid-1990s, however, the government-rescued banks had returned to profitability.

Norway's petroleum industry has ensured a strong positive balance of payments for the national economy, despite some declines in the manufacturing and agricultural sectors. The great majority of Norway's petroleum exports go to the nations of the European Union. Other important exports are machinery and transport equipment, metals and metal products, and fish. Norway's principal trading partners are the United Kingdom, Germany, and Sweden. Principal imports include machinery, motor vehicles, ships, iron and steel, and food products, especially fruits and vegetables.

Oil and natural gas



Transportation. The elongated shape of Norway and its many mountains, large areas of sparse population, and severe climate make special demands on transportation services. Only the Oslo region has sufficient traffic density to make public surface transportation profitable. A large fleet of vessels links the many fine ports along the sheltered coast. Norway's largest and busiest ports include those in Bergen, Oslo, Stavanger, Kristiansund, and Trondheim. Norwegian shipowners run one of the world's largest merchant fleets, carrying about one-tenth of the world's total tonnage. Shipping accounts for more than half of Norway's foreign-currency earnings.

Bus transport plays a key role in public transportation, aided by some 215 scheduled ferry routes. The number of private automobiles has increased rapidly, creating parking problems and traffic jams in the major cities. Of the more than 50,000 miles (80,000 km) of public roads in Norway, about two-thirds are hard-surfaced. In 2000 the Lærdal-Aurland tunnel (15.2 miles [24.5 km]) was opened along the route linking Oslo and Bergen. The world's longest road tunnel, it provides a reliable connection between the two cities, replacing mountain highways that were impassable during the winter months.

The 2,500 miles of railway, more than half of which has been electrified, are operated by the Norwegian State Railways (Norges Statsbaner), which sustains large annual operating deficits. Vestlandet has never had north–south

Railways

Kirkendall—Spring Photographers

Switchback road of Trollstigheim Pass, Møre og Romsdal *fylke* (county), western Norway.

railway connections, only routes running east from Stavanger and Bergen to Oslo and from Åndalsnes to Dombås on the line linking Oslo and Trondheim. The connection from Bodø to Trondheim was completed in 1962. Farther north, the only railway is the extension of the Swedish railway system to Narvik, which is used mainly to carry iron ore for export. Of the three other links with Swedish railways, one runs from Trondheim and two from Oslo—the southernmost connecting Norway to the Continent via the Swedish and Danish railways.

Norway is a partner in the Scandinavian Airlines System (SAS), which pioneered commercial flights across the Arctic. Two private airline companies add to the increasing domestic service among Norway's more than 40 airfields with scheduled civilian traffic. The major airports for international flights are located near Oslo, Stavanger, and Bergen.

ADMINISTRATION AND SOCIAL CONDITIONS

Norway is a constitutional hereditary monarchy. The legislative body is the 157-member Storting, elected by vote of all persons over 18 years of age. The monarch nominally selects the prime minister and State Council with the agreement of the Storting.

Government. The constitution of Norway, drafted in 1814 when Norway left the 434-year union with Denmark, was influenced by British political traditions, by the constitution of the United States, and by French revolutionary ideas. Amendments can be made by a two-thirds majority in the Storting. Unlike many parliamentary forms of legislature, the Storting cannot be dissolved during its four-year term of office. If a majority in the Storting votes against an important Cabinet issue, the minister responsible or even the whole Cabinet resigns. In legislative matters the monarch has a suspending right of veto, but this has never been exercised since the 91-year union with Sweden was dissolved in 1905.

Multi-party system

Norway's political life functions through a multiparty system. Before national elections, held every four years, political parties nominate their candidates at membership meetings in each of Norway's *fylker* (counties). According to its population, each *fylke* elects a number of representatives to the Storting, with party representation allotted on the basis of the percentage of the vote received.

The Norwegian Labour Party (Det Norske Arbeiderpartiet; DNA), the dominant party from before World War II until the mid-1960s, advocates a moderate form of socialism. In its many years of governing Norway, however, it nationalized only a few large industrial companies. The Conservative Party, which traditionally has been the major alternative to the DNA, accepts the welfare state and approves of the extensive transfers of income and of government control of the economy. Between 1945 and 1965 the government was formed by the DNA, which won clear majorities in the Storting.

After 1965, however, no single party was able to obtain a majority in the legislature, and Norway was governed by a succession of non-Socialist coalitions and minority governments. Political parties that have played important roles during this period include the Christian People's (Democratic) Party, Centre Party (called the Agrarian Party until 1958), Socialist Left Party, Progress Party, and Liberal Party.

Local administration

The city of Oslo constitutes one of the country's 19 *fylker*. The other *fylker* are divided into rural and urban municipalities, with councils elected every fourth year, two years after the Storting elections. For the country as a whole, the municipal elections tend to mirror the party division of the Storting. The municipal councils elect a board of aldermen and a mayor. Many municipalities also employ councillors for such governmental affairs as finance, schools, social affairs, and housing. Norwegians pay direct taxes to both federal and municipal governments.

The *fylker* can levy taxes on the municipalities for purposes such as roads, hospitals, secondary schools, and other joint projects. The *fylke* councils comprise delegates from the municipalities, while the *fylke* governors are appointed by the Cabinet.

Justice. Before civil cases can ordinarily be taken to court, they first must be submitted to conciliation councils, which settle many issues without recourse to more formal legal action. Decisions of the conciliation councils can be appealed to the courts, and Norway also has a formal system of courts of appeal. The Supreme Court is the final arbiter of legal decisions. The rights of the citizen are guarded also by an ombudsman, who acts on their behalf as an intermediary in matters with public administrators.

Armed forces. Military service of 12 to 15 months, plus refresher training, is compulsory for all fit Norwegian men between 22 and 44 years of age. Nonetheless, Norway's defense force is far too small to protect all of its territory against a major aggressor. Its strategy is designed to defend key areas, especially in the north, until forces from other members of the North Atlantic Treaty Organization (NATO) could be moved in. The Norwegian units have great mobility, and, with its important strategic location as NATO's northern flank and its myriad of fjords to serve as naval bases for fleets in the North Atlantic, Norway has sophisticated early-warning systems.

International military alliances

The NATO headquarters for northern Europe is located at Kolsås, near Oslo. Foreign troops and nuclear weapons, however, are excluded from Norway by law except in cases of war or immediate threat of war. The Norwegian Air Force has a number of ground-to-air missiles and various aircraft from other Western nations. The navy consists of heavy coastal artillery and such light vessels as gunboats, torpedo boats, submarines, and corvettes up to 1,800 tons. The total active military personnel number fewer than 40,000—of which nearly two-thirds are conscripts—but an additional 280,000 are members of first-line reserves and can be mobilized quickly in cases of emergency.

Education. All of Norway's municipalities require nine years of basic schooling, with an optional 10th year. Mandatory subjects include Norwegian, religion, mathematics, music, physical education, science, and English. Optional courses in the arts and in other foreign languages and vocational training in such areas as office skills, agriculture, and seamanship are available in the upper grades. With three years of additional high school, students may take the examinations leading to university study. A small percentage of college and university students study abroad. Institutions of higher education in Norway have been expanded to accommodate the doubling of the student group by the end of the 20th century. The country's four universities are located in Oslo (established 1811), Bergen (1946), Trondheim (1968), and Tromsø (1968).

As many students attend vocational schools as attend colleges and universities, and a few thousand students attend folk high schools, boarding schools offering a one-year course designed for 17-year-old students from rural areas. Only a few of Norway's schools charge tuition, and all students are eligible for government loans.

National programs in medicine and welfare

Health and welfare. Compulsory membership in a national health-insurance system secures for all Norwegians free medical care in hospitals, compensations for doctors' fees, and free medicine, as well as an allowance to compensate for lost wages. Membership fees securing cash benefits during illness or pregnancy, covered by another insurance fund, are compulsory for salaried employees and optional for the self-employed. Most Norwegian doctors work in hospitals, the majority of which are owned by the state, counties, and municipalities. Extensive programs of preventive medicine have conquered Norway's ancient nemesis, tuberculosis. There is also a well-developed system of maternal and child health care, as well as compulsory school health services and free family counseling by professionals. A public dental service provides care for 90 percent of the children between seven and 15 years of age. In some municipalities dental care has been extended downward to three years of age and upward to 20 years.

A "people's pension" was established in Norway in 1967 to ensure for the entire population a standard of living reasonably close to the level that the individual had achieved during his working life. The pension covers old age as well as cases of disability or loss of support. The premiums are paid by the individual members, employers, municipalities, and the state. The basic pension is adjusted every year, regardless of the plan's income. Supplementary

pensions vary according to income and pension-earning time. The state pays a family allowance for all children up to 16 years of age.

Housing and living standards. Until the 1970s Norway felt the housing shortage created by World War II; the shortage was aggravated by high costs in the densely populated urban areas. But housing standards have improved tremendously, and most families live in houses built since the war, a majority of them financed by state loans on favourable terms.

Norway ranks among the top 10 nations of the world in gross national product per capita. From 1945 to 1970 individual income per capita tripled in real terms. Tax rates that progress upward with income and the greatly increased social-security benefits, allocated mainly according to need, contributed to a leveling of incomes. The perennial shortage of labour, especially of skilled workers, had a parallel effect.

Norwegians spend a smaller share of their income than formerly on food, beverages, and tobacco. Travel and leisure activities have increased their share rapidly, however, as have such household goods as electrical appliances. During the 1960s the number of automobiles per inhabitant increased dramatically, from one in 21 to one in three. A four-week vacation every year with somewhat more than full wages was established by law in 1964. Working hours may not exceed nine hours a day or 40 hours per week. A five-day workweek had become the rule by the late 1960s.

CULTURAL LIFE

Located on the outskirts of Europe, and with much of its inland population almost completely isolated until the 20th century, Norway has been able to preserve much of its old folk culture. On the other hand, as seafarers and traders the Norwegians have always received fresh cultural stimuli from abroad. A number of Norwegians have made important contributions in return, notably the playwright Henrik Ibsen and the composer Edvard Grieg. The Norwegian recipients of the Nobel Prize for Literature are Bjørnstjerne Bjørnson, Knut Hamsun, and Sigrid Undset.

Literature and performing arts

Although Norway comprises one of the world's smallest language communities, the country is among the leaders in books published per capita. The annual number of new titles is about 5,000, of which two-thirds are of Norwegian origin. Literature is subsidized through a variety of means, including tax exemption, grants to writers, and government purchasing for libraries. In all, there are about 5,000 public or school libraries, which annually lend some 24,000,000 books.

Permanent theatres have been established in several cities, and the state traveling theatre, the Riksteatret, organizes tours throughout the country, giving as many as 1,200 performances annually. The Norwegian Opera, opened in 1959, requires state subsidies, as do most other theatres. Films in Norway are subject to censorship, primarily on grounds of violence and, to a lesser extent, for erotic content. The production of Norwegian-made feature films is subsidized, but they usually number about 10 each year.

Visual arts

In addition to its National Art Gallery, Oslo opened a special museum in 1963 to honour Edvard Munch, probably Norway's most famous painter. The Sonja Henie–Niels Onstad Art Centre, opened in 1968 near Oslo, contains modern art from all over the world.

Norwegian painters of the 20th century have excelled in murals to such an extent that they are rivaled only by Mexican painters. Other artists are world renowned for their multimedia assemblages, pictorial weaving, and nonfigurative art in sculpture as well as painting. The works of Gustav Vigeland have been assembled in Oslo's Vigeland sculpture park in a spectacular display centred around a 60-foot granite monolith containing 121 struggling figures.

Medieval stave churches of upright logs and houses of horizontal logs notched at the corners have inspired the architecture. Private houses, almost all of wood, are made to fit snugly into the terrain. For larger buildings, steel and glass are supplemented by concrete that often is shaped and textured with considerable imagination.

Arts and crafts and industrial design flourish side by side, often inspired by archaeological finds from the Viking Age, by the culture of the northern Lapps, and by advanced schools of design. Norway has markedly increased its exports of furniture, enamelware, textiles, tableware, and jewelry, much of which incorporates design motifs reflecting these cultural heritages as well as avant-garde styles.

Recreation. Norwegians have the special advantages of abundant space and a traditionally close contact with nature. Cross-country skiing is a national pastime in the long winter season. In the Olympic Winter Games, the tiny nation has won more medals than any country except the Soviet Union. The Norwegians have more than 200,000 second homes, mainly located along the sheltered coastline and in the mountains. Even from downtown Oslo it takes only a 20-minute drive to get into deep forests, and on a pleasant Sunday in the winter the hills surrounding the city abound with skiers.

Scientific research. Science and research have limited means in a small country. In the natural sciences, however, reflecting the country's intimacy with an overpowering physical environment, individual efforts of Norwegians have won particular acclaim. Norwegian explorers, beginning with Erik the Red and his son Leif Eriksson and continuing in modern times with such men as Fridtjof Nansen, Roald Amundsen, and Thor Heyerdahl, have been world famous.

The communications media. Some 165 newspapers are published in Norway, about half of them daily, except for Sundays and holidays. Although most of the newspapers are small, average circulations have increased. Most newspapers have affiliations with political parties, but these affiliations are reflected very little in readership. The labour press, for example, has less than a quarter of the total circulation, even though the Labour Party is supported by approximately 40 percent of the voters. Press ethics are on a high level, and the independence of the editors is universally recognized.

Broadcasting is operated by an independent government organization, with no commercial sponsors or advertising over the two radio networks and one television network. Educational and informational programs are given priority over entertainment. Every home with radio and television pays an annual fee. Regular colour-television broadcasts began in 1973. In 1982 several private radio stations began trial operations.

For statistical data on the land and people of Norway, see the *Britannica World Data* section in the BRITANNICA BOOK OF THE YEAR. (Ja.C.)

History

The earliest traces of human occupation in what is now Norway are found along the coast, where the huge ice shelf of the last ice age melted first, between 11,000 and 8000 BC. The earliest finds are stone tools of the Komsa type north of the Arctic Circle and the Fosna type from Trøndelag to the Oslo Fjord, all dating from 7000 to 6000 BC. Coastal fauna provided a means of livelihood for Arctic fishermen and hunters, who may have made their way south along the Norwegian coast about 10,000 BC, when the interior was still covered with ice. The theory has also been advanced that these peoples came from the south and followed the coast northward considerably later.

Early settlements

In the south of the country are dwelling sites dating from about 5000 BC. Finds from these sites, which include bone and stone tools from the entire coast, give a clearer idea of the life of the hunters and fishermen. The implements vary in shape and are made of different kinds of stone; those of later periods are more skillfully made. Rock carvings have been found, usually near hunting and fishing grounds. They represent game such as deer, reindeer, elk, bears, birds, seals, whales, and fish, vital for the survival of the coastal peoples. Enormous rock carvings at Alta in Finnmark were made at sea level continuously from 6200 to 2500 BC as land rose from the sea after the last ice age.

EARLIEST PEOPLES

Between 3000 and 2500 BC, new migrants settled in eastern Norway. They were farmers who grew barley and kept

cows and sheep. The hunting-fishing population of the west coast was also gradually replaced by farmers, though hunting and fishing remained useful secondary means of livelihood.

From about 1500 BC bronze was gradually introduced, but the use of stone implements continued; Norway had few riches to barter for bronze goods, and the few finds consist mostly of elaborate weapons and brooches that only chieftains could afford. Huge burial cairns built close to the sea are characteristic of this period. The motifs of the rock carvings differ from those typical of the Stone Age. Representations of the Sun, animals, trees, weapons, ships, and men were all strongly stylized, probably as fertility symbols connected with the religious ideas of the period.

Little has been found dating from the early Iron Age (the last 500 years BC). The dead were cremated, and their graves contain few burial goods. During the first four centuries AD, the people in Norway were in contact with Roman-occupied Gaul. About 70 Roman bronze caldrons, often used as burial urns, have been found. Contact with the civilized countries farther south brought a knowledge of runes; the oldest known Norwegian runic inscription dates from the 3rd century. At this time the settled areas in the country increased, a development that can be traced by coordinated studies of topography, archaeology, and place-names. The oldest root names, such as *nes, vik,* and *bø* (cape, bay, and farm), are of great antiquity, dating perhaps from the Bronze Age, while the earliest of the groups of compound names with the suffixes *vin* (meadow) or *heim* (settlement), as in Bjørgvin (Bergen) or Sæheim (Seim), usually date from the first centuries AD.

Settlements. The period of the collapse of the Roman Empire in the west (400–600) is characterized by rich finds, including chieftains' graves containing magnificent weapons and gold objects. Hill forts were built on precipitous rocks for defense. Excavation has revealed stone foundations of farmhouses 60 to 90 feet long (one even 150 feet long), the roofs of which were supported on wooden posts. These houses were family homesteads where several generations lived together, people and cattle under one roof. From this period and later (600–800), nascent communities can be traced. Defense works require cooperation and leadership, so that petty states of some kind with a defense and administrative organization must have existed.

Clan and tribal states

These states were based either on clans or tribes (*e.g.,* the Horder of Hordaland in western Norway). By the 9th century each of these small states had *thing*s, or *ting*s (local or regional assemblies), for negotiating and settling disputes. The *thing* meeting places, each eventually with a *horg* (open-air sanctuary) or a *hov* (temple), were usually situated on the oldest and best farms, belonging to the chieftains and wealthiest farmers. The regional *thing*s united to form even larger units, assemblies of deputy yeomen from several regions. In this way, the *lagting* (assemblies for negotiations and law-making) developed. The Gulating had its meeting place by the Sogne Fjord and may have been the centre of an aristocratic confederation along the western fjords and islands called the Gulatingslag. The Frostating was the meeting place for the leaders in the Trondheim Fjord area; the earls (*jarl*) of Lade near Trondheim seem to have added the coastland from the Romsdals Fjord to the Lofoten Islands to the Frostatingslag. A *lagting* developed around Lake Mjøsa in the east and eventually established its meeting place at Eidsvoll, becoming known as the Eidsvating. The area around the Oslo Fjord, although at times closely tied to Denmark, developed a *lagting,* with its meeting place at Sarpsborg, that was called the Borgarting.

The Vikings. The name Viking at first (*c.* 800) meant a man from the Vik, the huge "bay" that lies between Cape Lindesnes in Norway and the mouth of the Göta River in Sweden and that has been called Skagerrak since 1500. The term Viking Age has come to denote those years from about 800 to 1050 when Scandinavians set out on innumerable plundering expeditions abroad. Surplus population, superior ships and weapons, well-developed military organization, and a spirit of adventure seem to have combined to cause this great movement. The Norwegians mostly sailed westward, raiding and settling in Ireland, Scotland, England, France, the Shetlands, Orkneys, and Hebrides, the Isle of Man, and in the unpopulated Faeroe Islands and Iceland. Men of Norwegian descent settled in Greenland and undertook expeditions to Vinland (somewhere on the northeast coast of America). Many Vikings returned home, and this meeting with western Europe was decisive for the unification and Christianization of Norway. (C.Jo./G.Sa.)

In the second half of the 9th century, the Viking chief Harald I Fairhair from the Oslo Fjord area managed, in alliance with chiefs of the Frostatingslag and parts of the Gulatingslag, to pacify the western coast. The final battle took place in Hafrs Fjord near Stavanger sometime between 872 and 900, whereafter Harald proclaimed himself king of the Norwegians. His son and successor, Erik I Bloodax (so called because he murdered seven of his eight brothers), ruled about 930–935. He was replaced by his only surviving brother, Haakon I, who had been reared in England. Haakon was Norway's first missionary king, but his efforts failed; he died in battle in 960.

Christianization. The Viking chiefs established relations with Christian monarchies and the church, especially in Normandy and England. Thus Olaf I Tryggvason, a descendant of Harald Fairhair, led a Viking expedition to England in 991. He was baptized and returned to Norway in 995, claiming to be king and recognized as such along the coast, where Christianity was already known. These areas were Christianized by Olaf, by peaceful means if possible and by force if necessary; he also sent missionaries to Iceland, where the new religion was adopted by the parliament (Althingi) in 1000. In the same year Olaf was killed in the Battle of Svolder. Fifteen years later, another descendant of Harald Fairhair, Olaf II Haraldsson, who had returned from England, was acknowledged as king throughout Norway, including the inland areas. Olaf worked to increase royal power and to complete the Christianization of the country. In so doing, he alienated the former chieftains, who called on Canute of Denmark, now ruler of England, for help. Olaf was killed in battle with the Danes and peasant leaders at Stiklestad in 1030.

Olaf Tryggvason

Canute's rule in Norway soon proved unpopular with the chieftains, and, with support from the bishops, the deceased king Olaf became St. Olaf, the patron saint of Norway. With the death of Canute in 1035, Olaf's young son, Magnus, was elected king. He was succeeded in 1047 by his uncle, Harald III Hardraade, a former commander of Vikings in the imperial guard in Constantinople. Harald was killed during a vain attempt to conquer England in 1066.

The patron saint of Norway

The Olaf kings firmly established the Norwegian monarchy with the help of English bishops. In return, sees and abbeys received the larger part of the estates that the Fairhair "dynasty" had confiscated from the Viking chieftains during the unification of Norway.

THE 12TH, 13TH, AND 14TH CENTURIES

At the end of the Viking Age, all royal sons, legitimate or illegitimate, were considered to have equal claims on the crown if they were accepted by a *lagting.* During the 11th and early 12th centuries it was not unusual for Norway to have two or more joint kings ruling without conflict. Thus Harald Hardraade's son Olaf III reigned together with his brother Magnus II until the latter died in 1069. Olaf ruled from 1066 to 1093 without being involved in a war; by giving the dioceses (Nidaros, Bergen, Stavanger, and Oslo) permanent areas, he inspired the first Norwegian towns. Olaf's son, Magnus III Barefoot, ruled for 10 years, during which he undertook three expeditions to Scotland to establish Norwegian sovereignty over the Orkneys and the Hebrides. He was succeeded by his three sons Olaf IV (1103–15), Eystein I (1103–22), and Sigurd I Magnusson (1103–30), who ruled jointly and imposed tithes, founded the first Norwegian monasteries, built cathedrals, and incorporated the clergy of the Scottish isles into the church of Norway.

Conflict of church and state. Following the rule of Magnus III's sons, the increasing power of the church and the

Civil war

monarch contributed to the century of civil war. During the early 12th century the kings expanded their direct rule over the various provinces, and the family aristocracy in Norway grew discontented. After 1130 interest groups within Norwegian society supported pretenders, and the church was successful in exploiting civil unrest to win independence.

In 1152–53 the English cardinal Nicholas Breakspear (later Pope Adrian IV) visited Norway, resulting in the establishment of an archbishopric in Nidaros (Trondheim). In 1163 the church supported the claims of a pretender, Magnus V Erlingsson, in return for his obedience to the pope, guarantees for the reforms of 1152, and the issuance of a letter of privileges for the church. Magnus' coronation was the first at which the archbishop presided. The first written law of succession, dating from this coronation, established primogeniture in principle and the prior right of legitimate royal sons to the crown. Instead of election by the *things*, a representation, dominated by the church, served as the electoral body. The law was never applied, and Magnus was succeeded by Sverrir Sigurdsson, a priest from the Faeroe Islands, who represented himself as a grandson of the first pretender king. After seven years of fighting, Sverrir was acknowledged in 1184 as king of all Norway and set out to bring the church under royal control. He refused to recognize the reforms and privileges made since 1152, and the archbishop and most of the bishops went into exile; Sverrir was excommunicated. The exiles in Denmark established a rebellious party and allied themselves with the secular enemies of the King, who were opposed to the King's administrative reforms, which included the establishment of the *hird* as a new aristocracy composed of court officials and the heads of estates. This opposition party won control of the Oslo area and the inland areas and threatened Sverrir's rule until his death in 1202.

The "Golden Age" of Norway

Civil war continued until 1217, when Sverrir's grandson Haakon IV became king, beginning the "Golden Age" of Norway. Haakon modernized the administration by creating the chancellor's office and the royal council. He prohibited blood feuds, and a new law of succession was passed by a national assembly (1260) that established the indivisibility of the kingdom, primogeniture, the prior claim of the legitimate royal sons, and, most importantly, the hereditary right of the king's eldest legitimate son to the crown. During Haakon's reign, relations in the northern area were first regulated by a treaty with Russia (Novgorod; a similar treaty went into effect in 1326). Greenland and Iceland agreed voluntarily to personal unions with the Norwegian king in 1261 and 1262, marking the greatest extent of the Norwegian empire, which included the Faeroes and the Scottish isles. Haakon died during an unsuccessful expedition to the Hebrides in 1263, and in 1266 his successor ceded the Hebrides and the Isle of Man to Scotland in return for recognition of the Norwegian claim to the Orkney and Shetland islands.

Haakon's son and successor, Magnus VI, earned the epithet Lawmender for his work on Norway's legislation. During his reign (1263–80), a common national law code, with special chapters for the towns, replaced the earlier provincial laws in 1274–76. Haakon's law of succession was confirmed; and a hereditary nobility, exempted from taxes in return for military service, was established. The king thus took over the legislative functions, and the *thing* became courts presided over by royal judges (*lagmenn*). Such a systematic national code, prepared in the king's chancery, was unique in 13th-century Europe. It remained in force in Norway until the Norske Lov of 1687, while the version of the code for Iceland is still partly in force. In a concordat of 1277, some of the privileges of the church of Norway were curtailed, but those that were confirmed left the church essentially independent.

Magnus was succeeded by his young son Erik II (1280–99). Erik's regency was led by secular magnates who controlled central power throughout his reign. The church tried to win privileges that had been denied by Magnus, but the regency proved stronger. The magnates also tried to limit the rights of the German merchants in Norway but were answered by a blockade from the Hanse cities and were forced to agree to the German demands. Erik was succeeded by his brother Haakon V (1299–1319), who determined to renew the royal power. He built a series of fortresses, including Akershus in Oslo, marking the shift of political power from the west coast to the Oslo area. Haakon was unable to restore royal power to the extent he wished, however.

Union with Sweden. Haakon's successor was Magnus VII Eriksson, the young son of his daughter Ingeborg and Duke Erik, son of Magnus I of Sweden. The child was also elected to the Swedish crown in 1319, creating a personal union between the two countries that lasted until 1355. The countries were to be governed during the King's minority by the two national councils with the King's mother as a member of both regencies. The regency in Norway failed to prevent the increasing power of the magnates, and after the King came of age (1332), he was forced to recognize his younger son Haakon as king of Norway (1343) and to abdicate in his favour when he reached his majority (1355). Magnus' elder son Erik was designated king of Sweden. The Black Death struck Norway in 1349–50 and probably killed two-thirds of the population. The upper classes were particularly hard hit: only one of the bishops survived, and many noble families were reduced to the peasantry by the death of their workers and the decrease of their incomes.

The impact of the Black Death

The power of Haakon VI (1355–80) was also limited. The casualties of the Black Death among the high civil servants and clergy were replaced by Danes and Swedes. The central government as a whole lost control over the kingdom, and the local areas began to conduct their own affairs. Haakon VI married Margaret, the daughter of Valdemar Atterdag of Denmark, and their son, Olaf, was elected king of Denmark in 1375. Olaf also became king of Norway at his father's death (1380), but he died in 1387 at the age of 17, and his mother, who had served as regent in both kingdoms for him, now became the ruler.

Greenland. The first Nordic settlers on Greenland reached the island in 985 under the leadership of Erik the Red. Two colonies were established on the western coast, one near Godthåb and one near Julianehåb, where a few thousand Norsemen engaged in cattle breeding, fishing, and sealing. The most important export was walrus tusks. A bishopric and two cloisters were organized on Greenland. The Greenlanders lacked wood and iron for shipbuilding and could not support communications with Europe; in 1261 they submitted to the Norwegian king, to whom they would pay taxes in return for his acceptance of responsibility for the island's provision through a yearly voyage. A worsening of the climate may have occurred early in the 14th century, resulting in a decline in agriculture and livestock breeding. Plagues ravaged the populace: the Black Death alone is estimated to have halved the population. When Norway, with Greenland and Iceland, became subject to the Danish king, conditions worsened; the only ships that then sailed to Greenland belonged to pirates. Around 1350 the Godthåb settlement was apparently deserted and then occupied by Eskimo (Inuit), and in 1379 the Julianehåb area was attacked. The last certain notice of Norsemen on Greenland came in 1410: sometime during the following 150 years they disappeared from Greenland. It was not until the beginning of the 18th century that Greenland again came into the Danish sphere.

THE KALMAR UNION

With the accession of Margaret I of Denmark to power in 1387, the foundation was laid for political union with Denmark. She adopted her nephew Erik of Pomerania, then six years old, as her heir, and in 1388 she was acclaimed queen of Sweden as well. The next year Erik was proclaimed heir apparent in Norway, and in June 1397 he was crowned king of all three Scandinavian nations in a ceremony at Kalmar, Swed.

Under the Kalmar Union, Norway became an increasingly unimportant part of Scandinavia politically, and it remained in a union with Denmark until 1814. Margaret and Erik left vacant the highest Norwegian administrative position and governed Norway from Copenhagen. Most appointments made in Norway were given to Danes and

Germans. Whereas in Denmark and Sweden national councils took over the government, in Norway the council was unable to assert itself. After the accession of Christian I, Norwegian government was again centred in Copenhagen. The lower estates were also essentially powerless against the Danes, and isolated peasant uprisings had neither good leadership nor clear political goals. In 1448 Norway accepted the Swedish candidate for king, Karl Knutsson, but was forced to acknowledge Christian I of Oldenburg and to remain in the union with Denmark. In 1468 Christian pawned the Orkney and Shetland islands to the Scottish king to provide a dowry for his daughter, and the islands were never reclaimed.

Loss of the Orkney and Shetland islands

The cause of this political impotence in Norway has been a subject of considerable debate. According to one theory, the conscious policy of the kings since the 12th century of crushing the local family aristocracy to strengthen royal power deprived the country of a counterpart to the strong and often rebellious Danish and Swedish aristocracies. A second theory holds that geography was responsible for the absence of a strong aristocracy: the poorness of the soil prevented economic expansion through the creation of large estates. This geographic factor, together with the loss of population during the Black Death and subsequent epidemics, may explain why Norway's aristocracy was more affected by the plague than were the nobles in the rest of Scandinavia. The huge loss in population deprived the aristocracy of much of its labour force, which led to the abandonment of farms and the decline of many nobles into the peasant class. (H.En./G.Sa.)

THE 16TH AND 17TH CENTURIES

After 1523 the Norwegian council tried to obtain some independence for Norway within the union. But because the bishops dominated the council, they became the losers in the Norwegian parallel to the 1533–36 civil war in Denmark. As a result, the council was abolished, and the bishops lost all hope for help from Sweden, which did not want to provoke Denmark and whose king was himself leaning toward Lutheranism. Olaf Engelbrektsson, the last Norwegian archbishop and head of the council, left Norway in early 1537 for the Netherlands, taking with him the shrine of St. Olaf.

In Norwegian political history, the year 1536 is a nadir—in Copenhagen, Norway was proclaimed a Danish province forever. Norwegian topography and society, however, were very different from those of Denmark, and the hereditary Norwegian crown was viewed as a distinct monarchy. Thus, Norway was allowed to keep most of its ancient institutions and laws, and new institutions and laws had to be given in a special Norwegian version (for example, the Norske Lov of 1687). From 1550 Norway's natural resources, including fish, timber, iron ore, and copper—commodities from outside the Baltic area and most useful to all western Europe—were increasingly exploited. Consequently, a Norwegian bourgeoisie became a political factor. After 1560 Denmark had a constant fear of Swedish plans to occupy Norway. Therefore it was important that the Norwegians should not feel oppressed by rule from the political centre in Copenhagen. All this may explain the special attention the Danish government gave to Norway.

Rise of the Norwegian bourgeoisie

Most representative of this attitude was Christian IV, who visited Norway often and founded several towns (*e.g.,* Kristiansand, with the plan to control the Skagerrak; Kongsberg, with its silver mines; and Christiania, after a destructive fire in Oslo, 1624). He even went on an Arctic tour to Vardø in 1599, proclaiming the Arctic waters to be the "king's streams." This was part of his reaction to Swedish pretensions toward the Arctic Ocean.

A certain separatist policy has been attributed to Hannibal Sehested, the King's son-in-law and in the 1640s governor of Norway. He actually created an army (by conscription of peasants) and a separate financial administration, but he may have wanted a platform against the Danish nobility to work for absolutism. There were no signs of secession in the Norwegian population. When he was deposed in 1651, the financial administration was ruled from Copenhagen.

For almost a generation after 1664, Ulrik Frederick Gyldenløve, the illegitimate son of Frederick III, was governor of Norway. He courted the Norwegian peasants and at the same time gave monopolies on trade and on timber exports to restricted numbers of merchants. By applying such principles the government in Copenhagen and the Danish public servants managed to rule Norway after the Swedish annexations of Skåne, Halland, and Bohuslän. Norway's modern frontiers were established in 1660 and confirmed by treaty with Sweden in 1751, when Norway received the interior of Finnmark.

THE 18TH CENTURY

Romanticists of the later 18th century idealized Norwegian rural society, with its free peasants in a wild landscape. Certainly, their situation contrasted favourably with that of the Danish tenants; the landowning farmers in eastern Norway, especially, earned sizable incomes from their timber forests. In the east, therefore, and in the region of Trøndelag, the countryside was characterized by a class of wealthy timber merchants and farmers and a large rural proletariat. Elsewhere in the countryside, social conditions were more nearly equal. The Norwegian population consisted almost exclusively of peasants and fishermen; no city or urban agglomeration exceeded 15,000 inhabitants.

Thomas Malthus was the first demographer to see the exceptional possibilities for population studies in the Scandinavian countries, where civic registers were kept by parsons. In 1799, the year following his publication of *An Essay on the Principle of Population,* Malthus went to Norway to confirm his theories about checks on population growth. He found a late marital age, which he ascribed incorrectly to military service and a large servant class. In fact, early marriages were hindered by poverty and lack of land. Moreover, Norwegian population statistics of the 18th century indicate years of famine and epidemics, as do Swedish and Danish statistics. Malthus was correct, however, in discerning that demographic evolution in nonindustrialized countries could be studied better in Scandinavia than anywhere else in the world.

How and why the Norse community in Greenland perished at the end of the Middle Ages is an unsolved and fascinating problem. In the beginning of the 18th century there still was hope of finding Norse descendants among the Eskimo in Greenland. A Norwegian clergyman, Hans Egede, having managed to persuade the authorities that such people should be converted to the Lutheran faith, arrived in the Godthåb Fjord (in the southwest), finding only Eskimo, to begin a new European settlement in Greenland. Later in the century another colony was founded at Julianehåb (almost at the southern tip of the island).

Revival of settlement in Greenland

Two factors are visible in this activity. First, the Pietist movement, which had a considerable influence in Denmark, demanded religious conversion and stressed an obligation to bring the gospel to the heathens. A Ministry of Missions, founded in 1714, supported Egede in Greenland as it supported missionary activity among the *samer* (Lapps) in northern Norway and among Indians at Tranquebar on the Coromandel Coast. Second, missionary activity became possible because of a close alliance with commercial interests. Egede himself founded a company in Bergen for trade with Greenland. The trade later passed to the Royal Greenland Trading Company of Copenhagen. The trade with Finnmark (now the northernmost part of Norway) was reserved, in principle, for merchants of Copenhagen as well.

THE NAPOLEONIC WARS AND THE 19TH CENTURY

Denmark–Norway's attempt to remain neutral in the struggle between France and England and their respective allies early in the 19th century came to an end after England's preemptive naval actions of 1807, in which the entire Danish fleet was taken. The continental blockade of England that followed, which was against Danish interests, was a catastrophe to Norway. Fish and timber exports were stopped, as well as grain imports from Denmark. The consequences were isolation, economic crisis, and hunger. In 1810–13 England consented to some relaxation of its counterblockade against Norway. As a whole, however,

the years 1807–14 convinced leading groups in Norway that they needed a political representation of their own.

The Treaty of Kiel. Swedish foreign policy was erratic during those years, but Denmark–Norway remained an ally of Napoleon until 1814. After Napoleon's defeat at the Battle of Leipzig (1813), Sweden repeated its 17th-century strategy by attacking Denmark from the south. At the Treaty of Kiel (Jan. 14, 1814), Denmark gave up all its rights to Norway (but not to the old Norwegian dependencies of Iceland, the Faeroes, and Greenland) to Sweden.

The Danes did not intend this agreement to end the union with Norway. Officially loyal to the Treaty of Kiel, the Danish government worked for the eventual return of Norway. This probably is why the crown prince Christian Frederick, governor of Norway, in collusion with the Danish king, organized a rising against the Treaty of Kiel. In doing so he needed support in Norway, and he thus came to rely on two political forces, each with regionalist aims. The larger faction consisted of civil servants and peasants, who were loyal to Copenhagen but traditionally in opposition to its centralizing policy. The other was the small but important group of timber merchants in eastern Norway, who wanted independence from Copenhagen for their trade with western Europe. Since 1809 they had conspired for a union between Sweden and Norway.

Constitution of May 17, 1814

This was the main background of a constituent assembly, called by Christian Frederick to meet at Eidsvoll, 40 miles north of Christiania. It drew up the constitution of May 17, 1814 (which still exists), and elected Christian Frederick to the throne of Norway.

Union with Sweden. Norwegian independence got no support from the great powers, and Sweden attacked Norway in July 1814. After a fake war of 14 days, Christian Frederick resigned. Jean Bernadotte (later known as Charles XIV John; called Karl Johan in Sweden and Norway), the Swedish crown prince, accepted the Norwegian constitution, and in so doing could no longer argue on the basis of the Treaty of Kiel. This was of the greatest political importance to the Norwegians. As a constitutional monarchy, Norway entered the union with Sweden in November 1814; only minor modifications were made in its constitution—the king and foreign policy would be common; the king would be commander in chief of Norway's armed forces, which could not be used outside Norway without Norwegian consent; a government in Christiania (with a section in Stockholm) and the Storting (Norwegian parliament) would take care of national affairs. (G.Sa.)

For Norway the Treaty of Kiel meant secession from Denmark, the forming of its own separate state with complete internal self-government, and a political centre in Christiania. The history of Norway during the 19th century is marked by the struggle to assert its independence of Sweden within the union and its attempts to develop a modern Norwegian culture.

Population, trade, and industry. *Population.* Norway's population grew more rapidly during the 19th century than in any other period of its history. The population rose from 883,000 in 1801 to 2,240,000 in 1900. Whereas the urban population was only 8.8 percent in 1800, it had reached 28 percent by 1900. After Ireland, Norway had the highest relative emigration of all European countries in the 19th century. From 1840 to 1914 about 750,000 people emigrated, especially to the American Middle West.

Economic conditions. Norway was also severely hit by the economic crisis that followed the Napoleonic Wars. Norway's exports consisted mainly of wooden goods to Great Britain and, to a certain extent, of glass and iron products. After the war, when the British introduced preferential tariffs on articles of wood from Canada, Norwegian forest owners, sawmills, and export firms were badly hit. Iron and glass exports also met with marketing difficulties. Fish, which after timber was the country's most important export commodity, was only lightly hit by the slump; and by the 1820s the herring fisheries on the west coast enjoyed a period of vigorous expansion. From the 1850s on, agriculture developed rapidly. Modern methods were adopted, and an emphasis was laid on cattle breeding. Simultaneously, the building of railroads began ending the isolation of the small communities and opening the way for the sale of agricultural products. It was, however, the great expansion of merchant shipping (especially between 1850 and 1880) that gave the most powerful boost to the country's economy. Norway's percentage of world tonnage rose from 3.6 percent to 6.1 percent; and at the end of the century Norway possessed, after the United Kingdom and the United States, the largest merchant navy in the world. The economic resources that merchant shipping brought to the country laid the basis for industrialization. From 1860 Norway's industry expanded rapidly, especially in the timber and wood-pulp trade and in engineering. Socially and economically this expansion was a springboard for shipowners, manufacturers, and businessmen, all of whom began to play a much greater role in politics toward the end of the 19th century.

Merchant shipping

The age of bureaucracy (1814–84). The economic development in the decades immediately after the Napoleonic Wars meant a reduction in the power of the big business concerns and great estates. The decision to abolish the nobility in 1821 was indicative of the greatly reduced social and economic circumstances of the upper classes. At the same time, the position of the civil servants was strengthened, and from then until the latter part of the 19th century they controlled the political power of the country. Apart from the civil servants, there were only two other political factors of any importance in Norway at this time: the farmers and the monarch.

Parliamentary authority. The Eidsvoll constitution of 1814 gave the Storting greater authority than parliamentary bodies had in any other country except the United States. The king retained executive power and chose his own ministers, but legislation, the imposition of taxes, and the budget were within the authority of the Storting. The Storting had the power to initiate legislation, and the king had only a suspension veto. When the union's monarch Charles XIV John (ruled 1818–44) demanded the right of absolute veto, the Storting categorically refused, despite the King's attempt to intimidate them with shows of military strength. Faced with this unanimous resistance, the King was forced to abandon his struggle, and the Storting's dominant position became the firm defense against Swedish attempts to unite the two countries. As a national demonstration, Norway began in the 1820s to celebrate May 17, the date of the Eidsvoll constitution, as a national day. The King's attempt to outlaw the celebration resulted in violent demonstrations, and during the 1830s he conceded this point also.

Monetary problems. Norway had at the same time many major problems to resolve on the domestic front. The war, which had been to a great extent financed by an increased issue of bank notes, had brought about a reduction of the riksdaler to one-fifteenth of its original value. To ward off inflation, a severe sterling tax was imposed, and in 1816 a new bank of Norway was established that had the monopoly of issuing bank notes. In spite of strong precautionary measures, however, it was not until the currency reform of 1842 that finances were stabilized. From an economic point of view, the civil service was decidedly liberal, and the guild system and old trade regulations were abolished during the 1840s and 1850s. By 1842 it was decided to reduce tariffs, a decision that gradually made Norway a free-trade country.

Political change. The influence that the vote gave to the farmers was not exploited at first, and they continued to elect civil servants as their parliamentary representatives. About 1830, however, a demand was raised for a decrease in expenditure, and, under the leadership of Ole Gabriel Ueland, a more deliberate "class" policy began to be conducted in the Storting. In 1837 a statute regarding local self-government was enacted that offered training for grass-roots politicians. The farmers' policy led to sharp conflicts with influential groups of bureaucrats and finally became a struggle for political power on the national level. Under pressure from a radical labour movement, which arose after 1848 under the leadership of Marcus Thrane, and from the later mounting tension in the relationship with Sweden, many farmers turned to the middle classes and the minor civil servants. The intensely nationalistic attitude of this leftist coalition was expressed in its at-

tempts to strengthen national culture and language. The struggle for the introduction of the vernacular as the official language instead of the bureaucrats' Danish-influenced tongue became an important item of the coalition's policy. The coalition was organized as the Venstre (Left) political party in 1884.

The union conflict (1859–1905). Because the union's king usually resided in Sweden, he was represented in Norway by a governor general. This gave rise to the governor-general conflict, which was not resolved until 1873, when Sweden yielded to Norway's main demands. The result was that in Norway the king was regarded as Swedish, and his right to nominate the government in Norway was considered a danger to the country's autonomy. The conflict revolved around the question of the Storting's confidence in the government. During the reign of Oscar II (ruled in Norway 1872–1905), matters came to a head when a Conservative government refused to pass an amendment to the constitution that the Storting had three times accepted.

Resignation of the government

After a trial before the court of impeachment (Riksretten) the government was forced to resign in 1884. The Storting and not the king had thus acquired the decisive influence on the government, and Norway became the first country in Scandinavia to be governed by parliamentary means.

Although Norway had won full self-government on the domestic front, the union was still represented externally by the Swedish-Norwegian king, and the country's foreign policy was conducted by the Swedish foreign minister. From the 1880s, therefore, there was an increasing demand for an independent Norwegian foreign minister. In 1891, Venstre won an impressive majority at the polls with this question, among other things, on its program. In spite of this, the Venstre government headed by Johannes Steen, which the King had appointed after the election, did not take up the question of the foreign minister but raised instead a more limited demand for a Norwegian consular service. Even this was flatly refused by Sweden in 1892. When the Storting attempted to carry out this reform independently, it was forced under threat of military action to negotiate with Sweden on a revision of the whole question of the union. Though Sweden soon showed its readiness to be most compliant, the incompatibilities had become so marked that there was no real chance of a compromise.

The negotiations collapsed in 1898, and Norway at the same time demonstrated its independence by abolishing the union emblem on its merchant flag despite the King's veto. New negotiations were opened in an attempt to solve the more limited demand for an independent consular service, but when these negotiations also failed Norway took the matter into its own hands, and the Storting passed a bill establishing Norway's own consular service. When the King refused to sanction the bill, the coalition government, under the leadership of Christian Michelsen, resigned. As, under the circumstances, it was impossible for the King to form a new Norwegian government, the Storting declared "the Union with Sweden dissolved as a result of the King ceasing to function as Norwegian King," on June 7, 1905. The Swedish Parliament refused, however, to accept this unilateral Norwegian decision. Under threat of military action and partial mobilization in both countries, Norway entered into negotiations on the conditions for the dissolution of the union. A settlement was reached in Karlstad in September 1905, which embodied concessions from both sides. The Swedish-Norwegian union was thus legally dissolved, and shortly afterward Prince Charles of Denmark was elected in a referendum as Norway's king and came to the throne under the name of Haakon VII.

Dissolution of the union

THE 20TH CENTURY

Economic and industrial growth. The period 1905 to 1914 was characterized by rapid economic expansion in Norway. The development of the merchant fleet, which had begun during the second half of the 19th century, continued, and at the outbreak of World War I Norway's merchant navy was the fourth largest in the world.

From about the turn of the century, Norway's immense resources of waterpower provided a base for great industrial expansion. The large number of waterfalls bought by Norwegian and foreign companies gave rise to grave concern that the country's natural resources were falling into foreign hands or were becoming monopolized by a small number of capitalists. In 1906 three-quarters of all developed waterpower in Norway was owned by foreign concerns. Venstre and the growing Norwegian Labour Party pressed for legislation to protect the natural resources of the country. The proposed bill on concessions (later known as the Concession Laws) played a dominating role in Norwegian politics from 1905 to 1914. It led to a split in Venstre, but the majority of Venstre supported the bill, which was passed by the Storting in 1909 and remained in force despite continued criticism.

Concession Laws

The Norwegian Labour Party (DNA) had been founded in 1887, and universal suffrage was one of the principal points in the party program. In the 1890s Venstre likewise adopted this policy, and in 1898 universal male suffrage was introduced. By reforms in 1907 and 1913 the vote was extended to women. One consequence of industrialization and the introduction of universal suffrage was the growing influence of the DNA. A number of social reforms were enacted: a factory act, which included protection for women and children, accident insurance for seafaring men, health insurance, a 10-hour working day (in 1915), and a 48-hour workweek (1919); a 40-hour workweek was introduced in 1977.

World War I and the interwar years. *World War I.* With the outbreak of war in 1914, Norway, like Sweden and Denmark, issued a declaration of neutrality. Norway was badly hurt by the war at sea, about half of Norwegian merchant shipping being lost. As the Allied powers could almost totally control Norway's foreign trade, they forced it to break off exports of fish to Germany and, at the same time, forbade exports of iron pyrites and copper, which were important commodities for the German war industry. Because of the many casualties caused by submarine warfare, public feeling in Norway was strongly anti-German. The government, however, under the leadership of Venstre politician Gunnar Knudsen, insisted upon maintaining the appearance of neutrality. The war brought a distinct boom to Norway, although the prosperity was unevenly distributed. Within the DNA, the left wing formed the majority in 1918, and in 1919 the DNA, unlike the other Social Democratic parties in western and central Europe, joined the Comintern (Third Communist International). The DNA, however, was unwilling to submit to the centralization that Moscow demanded, and in 1923 it withdrew.

Dependence on foreign trade

The Great Depression. In the years up to 1935 the various governments—formed alternatively by the Conservatives, the Liberals (Venstre), and the Farmers' Party—pursued, by and large, a liberal economic policy. After the inflation caused by World War I and the postwar years, the main aim during the 1920s was to guide the currency (the krone) back to its former value. Norway received only an insignificant share in improved world market conditions, and by 1927 the unemployment figures were as high as 20 percent of the organized labour force. The Depression in the early 1930s increased unemployment still further, and by 1933 at least 33 percent of the work force, including many civil servants, was unemployed.

The government, led by the Farmers' Party (1931–33) and Venstre (1933–35), tried to combat the crisis with extensive reductions in governmental expenditure but refused to consider an expansionist financial policy or the emergency relief measures that the DNA demanded. The DNA thus enjoyed great success in the elections of 1933, although failing to gain a majority in the Storting. When the DNA formed the government in 1935, with Johan Nygaardsvold as prime minister, it needed the support of at least one other party. By a compromise with the Farmers' Party, the DNA received support for a social program that included old-age pension reform, revision of the factory act, statutory holidays, and unemployment insurance financed by increased taxation. State investments were also greatly increased. Although the situation was improved, unemployment in Norway was still as high as 20 percent of the organized labour force in 1938.

Social reforms

Despite economic difficulties, the high rate of unemploy-

ment, and the many labour conflicts, the interwar years were a period of vigorous expansion, and the country's industrial production was increased by 75 percent during the years 1913 to 1938.

Foreign policy. During the 1920s Norway acquired Svalbard and Jan Mayen, and Norwegian hunters and fishermen occupied an area on the east coast of Greenland. Denmark's demand for sovereignty of the area led to a conflict that was settled in the Permanent Court of International Justice in The Hague in 1933 in Denmark's favour. In 1939 the government proclaimed that Queen Maud Land in Antarctica was under Norwegian sovereignty. Because the League of Nations in 1936 had proved ineffective at keeping the peace, Norway's foreign minister, Halvdan Koht, attempted within the framework of the league to coordinate the policy of the smaller states in an effort to preserve peace. Norway continued to pursue a strictly neutral policy and declined Germany's invitation to join in a nonaggression pact in 1939.

World War II. With the outbreak of hostilities in 1939, Norway declared itself neutral. On April 9, 1940, German troops invaded the country and quickly occupied Oslo, Bergen, Trondheim, and Narvik. The Norwegian government rejected the German ultimatum regarding immediate capitulation. The Norwegian Army, which received help from an Allied expeditionary force, was unable to resist the superior German troops, however. After three weeks the war was abandoned in southern Norway. The Norwegian and Allied forces succeeded in recapturing Narvik but withdrew again on June 7, when the Allied troops were needed in France. The same day, the King, the Crown Prince, and the government left for London, and on June 10 the Norwegian troops in northern Norway capitulated. The government, through the Norwegian Shipping and Trade Mission (Nortraship), directed the merchant fleet, which made an important contribution to the Allied cause. The war, however, caused the loss of half of the fleet.

The German invasion

In Norway, Vidkun Quisling, leader of the small Norwegian National Socialist party (Nasjonal Samling, or National Union), which had never obtained a seat in the Storting, proclaimed on April 9 a "national government." This aroused such strong resistance, however, that the Germans thrust him aside on April 15, and an administrative council, consisting of high civil servants, was organized for the occupied territories. Political power was wielded by the German commissioner, Josef Terboven. In September 1940 the administrative council was replaced by a number of "commissarial counselors" who in 1942 formed a Nazi government under the leadership of Quisling. The "Nazification" attempt aroused strong resistance, however. Initially, this took the form of passive resistance and general strikes, which the Germans countered with martial law and death sentences. Once the resistance movement became more firmly organized, its members undertook large-scale industrial sabotage, of which the most important was that against the production of heavy water in Rjukan in southern Norway.

At the end of the war, the German troops in Norway capitulated without offering resistance. On their retreat from Finland in the winter of 1944–45, however, the Germans burned and ravaged Finnmark and northern Troms. The Soviet troops who liberated eastern Finnmark in November 1944 withdrew during the summer of 1945.

The postwar period. The liberation was followed by trials of collaborators; 24 Norwegians, including Quisling (whose name has gone down in history as a byword for a traitor), were sentenced to death and executed, and 19,000 received prison sentences. By a strict policy that gave priority to the reconstruction of productive capacity in preference to consumer goods, Norway quickly succeeded in repairing the ravages left by the war. By 1949 the merchant fleet had attained its prewar size, and the figures for both industrial production and housing were greater than in the 1930s. Until the 1980s, Norway had full or nearly full employment and a swiftly rising standard of living.

Political and social change. After the liberation in 1945, a coalition government was formed under the leadership of Einar Gerhardsen. The general election in the autumn of 1945 gave the DNA a decisive majority, and a purely Labour government was formed with Gerhardsen as prime minister. The DNA governed almost continuously from 1945 to 1965. King Haakon VII died in 1957 and was succeeded by his son, Olaf V. The Labour governments continued the social policies initiated in the 1930s. A general retirement pension law was passed in 1956, and a law on social welfare replaced the former "poor law" in 1964. The election of 1965 resulted in a clear majority for the four centre and right-wing parties, which formed a coalition government under the leadership of Per Borten. In 1971 the coalition government split, and the DNA again came to power, headed by Trygve Bratteli.

As a consequence of the referendum on the European Economic Community (EEC, or Common Market; see below), the Labour government resigned and was followed by a non-Socialist coalition government under the leadership of Lars Korvald. The DNA returned to power in 1973 with Bratteli again as prime minister. When he resigned as leader of the party and prime minister in 1976, he was succeeded by Odvar Nordli. Gro Harlem Brundtland, Norway's first woman prime minister, took over the government and party leadership from Nordli in February 1981. Her government was defeated at the polls in September of that year, and a Conservative, Kåre Willoch, became prime minister. Brundtland returned as prime minister in May 1986 but was again defeated three years later. The Conservatives formed a three-party coalition government under Jan Peder Syse but resigned after one year over the issue of Norway's future relationship with the EEC. Brundtland again formed a minority Labour government. King Olaf V died in 1991 and was succeeded by his son, Harald V.

Since the 1970s a central issue in Norwegian politics has been the exploitation of the rich natural gas and petroleum deposits in the Norwegian part of the North Sea. The petroleum industry made possible continued high employment until the 1980s, but it also caused a sharp rise in domestic prices. In addition, the industry has become so dominant in Norway that fluctuations in the world petroleum market have profound effects on the Norwegian economy.

North Sea petroleum

Postwar foreign policy. When the antagonisms between the great powers came to a head in 1948, Norway took part in the negotiations set in motion by Sweden on a Nordic defense union. The negotiations produced a tacit Cold War "Nordic balance." For instance, in 1949 Norway, followed by Denmark, joined the newly formed North Atlantic Treaty Organization (NATO), but NATO was not allowed to establish military bases or stockpile nuclear weapons on their territories; Sweden remained neutral. The compensation for these self-imposed restrictions was a gradual improvement in relations between the Soviet Union and the Nordic countries.

The dissolution of the Soviet Union in the early 1990s revived an old problem concerning the boundary between Norway and Russia in the Barents Sea of the Arctic Ocean. Once merely an esoteric legal issue, the boundary took on great importance because of its strategic naval relevance to Russia and because extensive deposits of petroleum and natural gas may lie beneath the shallow waters.

(Jö.We./G.Sa.)

Since the 1960s the question of Norway's relations with the EEC (from 1993 the European Community within the European Union [EU]) has split the country's citizenry across traditional party lines and even within families. A member of the European Free Trade Association (EFTA) from its formal inception in 1960, Norway decided to follow the lead of fellow EFTA member Great Britain from 1961 by entering into negotiations for membership in the EEC. These initiatives were thwarted in 1963 and 1967 by the strong opposition of French president Charles de Gaulle. Norwegian orientation toward the EEC was suspended until 1969, when the country again followed Britain's lead (along with Ireland and EFTA member Denmark) in applying for EEC membership. All four were accepted, but in 1972 Norwegian voters defeated the referendum on membership by more than 53 percent; the other three nations joined the organization in 1973.

For some 10 years thereafter Norway joined the remaining EFTA countries in signing a variety of free-trade agree-

ments with members of the EEC that, though they were bilateral, incorporated the economic liberalism of the EEC. Negotiations begun in 1989 between the two organizations culminated in 1991 in an agreement to form a free-trade zone called the European Economic Area (EEA). Norway became a member of the EEA when it came into effect in 1994.

Meanwhile, the dissolution of the communist governments of the Soviet bloc countries of central and eastern Europe and the breakup of the Soviet Union itself in 1989–91 changed the European political scene as well as the plans inherent in the inauguration of the EEA. EFTA members Austria, Finland, and Sweden suddenly felt politically free to apply for full membership in what soon would become the EU. Norway followed suit, applying for membership in November 1992. In a national referendum in November 1994, however, the Norwegian electorate again rejected the treaty negotiated by the government, albeit by a slightly smaller margin than in 1972.

It may seem contradictory that Norway has continued to reject EU membership. Norway, as a founding member of NATO, has been solidly integrated into Western security politics since 1949. The export of petroleum and natural gas from the North Sea has greatly strengthened Norway's economy and has more fully integrated it into the global economy. Nonetheless, the movement toward European political, monetary, and military unity that found expression in the Maastricht Treaty and establishment of the EU reminded too many Norwegians of the unions in their past that had subjugated Norway for more than half a millennium. The proponents of EU membership could not convince the opponents that Norway had obtained favourable concessions in its negotiations with the EU regarding fisheries, agriculture, and the exploitation of petroleum and natural gas. Moreover, the opponents were fearful that Norway would once more lose its national independence. Thus, at the beginning of the 21st century Norway found itself in a much-diminished EFTA (with Iceland, Liechtenstein, and Switzerland) but, through its affiliation with the EEA, strongly tied economically to the EU. (G.Sa.)

For later developments in the history of Norway, see the BRITANNICA BOOK OF THE YEAR.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 921, 923, 961, 963, and 972.

BIBLIOGRAPHY

General works: MAGNE HELVIG and VIGGO JOHANNESSEN, *Norway: Land, People, Industries,* 4th ed. (1974), provides a concise but informative introduction. A more comprehensive survey is found in RONALD G. POPPERWELL, *Norway* (1972). The Norwegian newspaper *Aftenposten* publishes a guidebook, *Facts About Norway,* 23rd ed. (1993). Other guides include ERLING WELLE-STRAND, *Tourist in Norway,* 6th ed. (1980); GUNNAR JERMAN, *New Norway 8,* trans. from Norwegian by ROLF GODDERHAM (1993); and ARVID BRYNE and JOAN HENRIKSEN, *Norway, Behind the Scenery* (1986).

Current writings on the country's development, history, economics, and culture are found in the periodicals *Norwegian Archaeological Review* (semiannual); *Scandinavian Journal of History* (quarterly); *Acta Borealia* (semiannual); and *The Scandinavian Economic History Review* (3/yr.). LELAND B. SATHER (compiler), *Norway,* ed. by HANS H. WELLISCH (1986), is an annotated bibliography of works in English.

The economy, administration, and social condition: ARNE SELBY, *Norway Today* (1986), presents a brief overview of Norwegian society; whereas NATALIE ROGOFF RAMSOY (ed.), *Norwegian Society* (1973; originally published in Norwegian, 1968), is a comprehensive survey. Specific studies include IAN WHITAKER, *Social Relations in a Nomadic Lappish Community* (1955); ROBERT PAINE, *Coast Lapp Society,* 2 vol. (1957–65); JON LEIRFALL, *Old Times in Norway,* trans. from Norwegian (1986); and TOVE STANG DAHL, *Child Welfare and Social Defence* (1985; originally published in Norwegian, 1978). Political developments are surveyed in HENRY VALEN and DANIEL KATZ, *Political Parties in Norway* (1964); WILLIAM M. LAFFERTY, *Participation and Democracy in Norway* (1981); and JOHAN JØRGEN HOLST (ed.), *Norwegian Foreign Policy in the 1980s* (1985). Economic history is traced in THORVALD MOE, *Demographic Developments and Economic Growth in Norway, 1740–1940* (1977); ALAN S. MILWARD, *The Fascist Economy in Norway* (1972); and FRITZ HODNE, *An Economic History of Norway, 1815–1970* (1975). Modern economic conditions are examined in FRITZ HODNE, *The Norwegian Economy, 1920–1980* (1983); JOHN C. AUSLAND, *Norway, Oil, and Foreign Policy* (1979); and WALTER GALENSON, *A Welfare State Strikes Oil: The Norwegian Experience* (1986).

Culture: GABRIEL TURVILLE-PETRE, *Myth and Religion of the North: The Religion of Ancient Scandinavia* (1964, reprinted 1975), deals with pre-Christian religious beliefs. Translations of the original sagas and of Old Norse poetry include *The Poetic Edda,* ed. and trans. by URSULA DRONKE, 2 vol. (1969–97); and SNORRI STURLUSON, *The Prose Edda,* trans. from Icelandic by ARTHUR GILCHRIST BRODEUR (1916, reissued 1967), and *The Heimskringla. A History of the Norse Kings,* 3 vol., trans. from Icelandic by SAMUEL LAING, ed. by RASMUS B. ANDERSON (1964–68). The historical development of the Norwegian language is explored in EINAR HAUGEN, *Language Conflict and Language Planning: The Case of Modern Norwegian* (1966); and KAREN A. LARSON, *Learning Without Lessons: Socialization and Language Change in Norway* (1985). The arts are discussed in JANICE S. STEWART, *The Folk Arts of Norway,* 2nd enlarged ed. (1972); KRISTIAN LANGE, *Norwegian Music,* 2nd rev. ed. (1982); JAN ASKELAND, *Norwegian Painting* (1971), and *Norwegian Printmakers: A Hundred Years of Graphic Arts,* trans. from Norwegian (1978); EIVSTEIN PARMANN, *Norwegian Sculpture* (1969); CHRISTIAN NORBERG-SCHULZ, *Modern Norwegian Architecture* (1986); and HARALD BEYER, *A History of Norwegian Literature,* trans. and ed. by EINAR HAUGEN (1956, reissued 1979; originally published in Norwegian, 1952). SVERRE MORTENSEN and PER VOGT (eds.), *One Hundred Norwegians: An Introduction to Norwegian Culture and Achievement* (1955), is a collection of biographies. A main biographical source for history and culture is EDVARD BULL *et al.* (eds.), *Norsk biografisk leksikon,* 19 vol. (1923–83). (Ja.C.)

History: Broad surveys of the country's history include T.K. DERRY, *A Short History of Norway,* 2nd ed. (1968, reprinted 1979), and *A History of Scandinavia* (1979), both good introductions; and ROLF DANIELSEN *et al., Grunnrekk i norsk historie: fra vikingtid til våre dager* (1991). Two monumental standard works are KNUT MYKLAND (ed.), *Norges historie,* 15 vol. (1976–80); and *Aschehougs Norgeshistorie* (1994–), lavishly illustrated. Highly recommended is the work by PHILLIP PULSIANO *et al.* (eds.), *Medieval Scandinavia: An Encyclopedia* (1993). A study based on excavations of a Norse settlement in Newfoundland is presented in ANNE STINE INGSTAD, *The Norse Discovery of America,* 2 vol. (1985). PIERRE JEANNIN, *L'Europe du Nord-Ouest et du Nord aux XVII^e et XVIII^e siècles,* 2nd ed. updated (1987), is a comprehensive history of the area and the period. Social conditions are explored in MICHAEL DRAKE, *Population and Society in Norway, 1735–1865* (1969). Recommended volumes from the series *Handbok i Norges historie* are PER SVEAAS ANDERSEN, *Samlingen av Norge og kristningen av landet 800–1130* (1977); KNUT HELLE, *Norge blir en stat 1130–1319,* 2nd ed. (1974); ROLF FLADBY, *Samfunn i vekst: under fremmed styre, 1536–1660* (1986); KNUT MYKLAND *et al., Norge under eneveldet, 1660–1720* (1975); and STÅLE DYRVIK *et al., Norge under eneveldet, 1720–1800* (1976).

The 19th and 20th centuries are covered in TORE PRYSER, *Norsk historie 1800–1870: frå standssamfunn mot klassesamfunn* (1985); SVERRE STEEN, *Det frie Norge,* 5 vol. (1951–62), continued in *På egen hånd: Norge etter 1905* (1976), and *Frihet og liv er ett: Norge fra 1920-årene til 1950* (1977); JENS ARUP SEIP, *Utsikt over Norges historie,* 2 vol. (1974–81), covering the years 1814–84; and three related works: ARNE BERGSGÅRD, *Norsk historie, 1814–1880* (1964); JOSTEIN NERBØVIK, *Norsk historie, 1870–1905,* new ed. (1993); and BERGE FURRE, *Norsk historie, 1905–1990: våre hundreår* (1992). RAYMOND E. LINDGREN, *Norway-Sweden: Union, Disunion, and Scandinavian Integration* (1959, reprinted 1979), examines cooperation among Scandinavian countries in the first half of the 20th century. The war years are studied in OLAV RISTE, *The Neutral Ally: Norway's Relations with Belligerent Powers in the First World War* (1965), and *"London-regjeringa": Norge i krigsalliansen, 1940–1945,* 2nd ed. (1995), on the Norwegian exile government in London. TIM GREVE, *Haakon VII of Norway,* trans. and ed. by T.K. DERRY (1983; originally published in Norwegian, 1980), is especially useful for the analysis of Norway's independence and its role in World War II. A survey of the postwar period is found in FRANKLIN D. SCOTT, *Scandinavia,* rev. and enlarged ed. (1975); and T.K. DERRY, *A History of Modern Norway, 1814–1972* (1973), which focuses on 20th-century industrialization and economy. Comprehensive and excellent is THOMAS PEDERSEN, *European Union and the EFTA Countries: Enlargement and Integration* (1994). FREDRIK SEJERSTED *et al., EØS-rett* (1995), is recommended as a central work on the legal situation in Norway after the implementation of the EEA rules. (G.Sa.)
